A linguistic area is a geographical area in which, due to language contact and borrowing, languages of a region come to share certain structural features—not only borrowed words, but also shared elements of sound and grammar. Other names sometimes used to refer to linguistic areas are Sprachbund, diffusion area, adstratum, and convergence area. Areal linguistics is concerned with linguistic areas, with the diffusion of structural traits across language boundaries.

2. *Defining Linguistic Areas*

Central to a linguistic area is the experience of structural similarities shared among languages of a geographical area (where usually some of the languages are unrelated or at least are not all close relatives). It is assumed that the reason the languages of the area share these traits is because they have borrowed from one another.

Areal linguistics is important in historical linguistics, whose goal is to find the full history of languages. A full history includes understanding of both inherited traits (shared in related languages because they come from a common parent language, for example features shared by English and German because both inherited

traits from Proto-Germanic, their parent) and diffused features (shared through borrowing and convergence among neighboring languages; examples below).

While some linguistic areas are reasonably well established, based on a number of shared areal traits, all linguistic areas could benefit from additional investigation.

Some proposed linguistic areas amount to barely more than preliminary hypotheses, while in general linguistic areas have been defined, surprisingly, on the basis of a rather small number of shared traits.

3. *Examples of Linguistic Areas*

For understanding of areal linguistics, it will be helpful to consider the better known linguistic areas together with some of the traits shared by the languages in each area (for more details, see Campbell 1998, pp. 299–310).

3.1 *The Balkans*

The Balkans is the best known linguistic area. The languages of this area are: Greek, Albanian, Serbo-Croatian, Bulgarian, Macedonian, and Rumanian; some scholars also add Romani (the language of the Gypsies) and Turkish. Some salient traits of the Balkans linguistic area are: (a) A central vowel (somewhat like the vowel in English 'but') (not in Greek or Macedonian). (b) Syncretism of the dative and genitive cases (merged in form and function); this is illustrated by Rumanian *fetei* 'to the girl' or 'girl's' (compare *fată* '*girl*'), as in *am dat o carte fetei* 'I gave a letter to the girl' and *frate fetei* 'the girl's brother.' (c) Postposed articles (not in Greek), e.g., Bulgarian *mâž-ât* 'the man'/*mâž* 'man,'-*ât* 'the.' (d) Futures signalled by an auxiliary verb corresponding to 'want' or 'have' (not in Bulgarian or Macedonian), e.g., Rumania *voi fuma* 'I will smoke' (literally, 'I want to smoke') and *am să cânt* 'I will sing' (literally 'I have sing'). (e) Perfect with an auxiliary verb corresponding to 'have.' (f) Absence of infinitives (instead, the languages have constructions such as 'I want that I go' for 'I want to go'); for example, 'give me something to drink' has the form corresponding to 'give me that I drink,' e.g., Rumanian *dă -mi să beau*, Bulgarian *daj mi da pija*, and Greek *dós mu na pjó*. (g) Double marking of objects which refer to humans or animals by use of a personal pronoun together with the object, e.g., Rumanian *i-am scris lui Ion* 'I wrote to John,' literally 'to.him-I wrote him John,' and Greek *ton vlépo ton jáni* 'I see John,' literally 'him.Acc I see the/him.Acc John' (see Joseph 1992).

3.2 *South Asia* (*Indian Subcontinent*)

This area is also well known. It is composed of languages belong to the Indo-Aryan, Dravidian, Munda, and Tibeto-Burman families. A few traits from the list of several shared among languages of the area are: (a) retroflex consonants (pronounced with the tip of the tongue pulled back towards the hard palate); (b) absence of prefixes (except in Munda); (c) Subject–Object–Verb (SOV) basic word order, including postpositions rather than prepositions (i.e., the equivalent of 'people with' instead of, as in English, 'with people'), (d) absence of a verb 'to have'; and (e) the 'conjunctive or absolutive participle' (meaning that subordinates clauses tend to have particles, rather than fully conjugated verbs, which are placed before the thing they modify, for example, the equivalent of 'the having eaten jackal ran away' where English has 'the jackal which had eaten ran way').

Some of the proposed areal features are not limited to the Indian subcontinent (e.g., SOV basic word order, found throughout much of Eurasia, and in other parts of the world). Some traits are not necessarily independent of one another (for example, languages with SOV basic word order tend also to have subordinate clauses with participles, not fully conjugated verbs, and tend not to have prefixes) (see Emeneau 1980).

3.3 *Mesoamerica*

The language families and isolates (languages with no known relatives) which make up the Mesoamerican linguistic area are: Nahua (branch of UtoAztecan), Mayan, MixeZoquean, Otomanguean, Totonacan, Xincan, Tarascan, Cuitlatec, Tequistlatecan, and Huave. Five diagnostic areal traits are shared by nearly all Mesoamerican languages, but not by neighboring languages outside this area. They are: (a) Possessive construction of the type *his-dog the man* 'the man's dog,' as in Pipil (UtoAztecan): *ipe:lu ne ta:kat*, literally 'hisdog the man.' (b) Relational nouns (locational expressions composed of noun and possessive pronominal prefixes, which function as prepositions in English), of the form, for example, *my-head* for 'on me,' as in Tz'utujil (Mayan): (*č*)*ri:x* 'behind it, in back of it,' composed of *č* 'at, in,' *r* 'his/her/its' and *i:x* 'back,' contrasted with *čwi:x* 'behind me,' literally 'atmyback.' (c) Vigesimal numeral systems based on twenty, such as that of Chol (Mayan): *hun-k'al* '20' (1×20), *ča?-k'al* '40' (2×20), *uS-k'al* '60' (3×20), *ho? k'al* '100' (5×20), *hun-bahk'* '400' (1-*bahk'*), *ča?-bahk*' '800' (2×400). (d) Non-verbfinal basic word order (no SOV languages) although Mesoamerica is surrounded by languages both to the north and south which have SOV word order, all languages within the linguistic area have VOS, VSO, or SVO basic order, not SOV. (e) Many loan translation compounds (calques) are shared by Mesoamerican languages, e.g., 'boa' = 'deersnake,' 'egg' = 'birdstone/bone,' 'lime' = 'stone(ash),' 'knee' = 'leghead,' and 'wrist' = 'hand-neck.' Since these five traits are shared almost unan-

imously throughout the languages of Mesoamerica but are found extremely rarely in languages outside Mesoamerica, they are considered strong evidence of the validity of Mesoamerica as a linguistic area. Additionally, a large number of other features are shared among several Mesoamerican languages, but are not found in all of the languages of the area, while some other traits shared among the Mesoamerican languages are found also in languages beyond the borders of the area. To cite just one example found in several but not all Mesoamerican languages, sentences which in English have a pronoun subject such as 'you are carpenter,' are formed in several Mesoamerican languages with a prefix or suffix for the pronoun attached directly to the noun, as in Q' eqchi' (Mayan) *iSq-at* (women-you) 'you are a women,' *kwinq-in* (man-I) 'I am a man': Pipil *ni-siwa:t* (you-woman) 'I am a woman,' *ti-ta:kat* 'you are a man' (see Campbell et al. 1986).

3.4 The Northwest Coast of North America

The best known linguistic area in North America is the Northwest Coast. It includes Tlingit, Eyak, the Athapaskan languages of the region, Haida, Tsimshian, Wakashan, Chimakuan, Salishan, Alsea, Coosan, Kalapuyan, Takelma, and Lower Chinook. The languages of this area are characterized by elaborate systems of consonants, which include series of phonetically very complex sounds. In contrast, the labial consonant series (which includes in English, for example, *p*, *b*, and *m*) is typically either lacking or contains few consonants: labials are completely lacking in Tlingit and Tillamook, and are quite limited in Eyak and most Athabaskan languages. The vowel systems are limited, with only three vowels (*i*, *a*, *o* or *i*, *a*, *u*) in several of the languages. Some shared grammatical and word-formation traits, from a list of many, include: extensive use of suffixes; nearly complete absence of prefixes; reduplication processes (where the first part of the word is repeated) of several sorts, signaling various grammatical functions, e.g., iteration, continuative, progressive, plural, collective, etc.; evidential markers in the verb (a suffix indicating, for example, whether the speaker has first-hand knowledge of the event, has only hearsay knowledge, or doubts it); and directional suffixes in the verb (telling whether the action is towards the speaker, away from the speaker, and so on); a masculine/feminine gender distinction in demonstratives and articles; a visibility/invisibility opposition in demonstratives (that is, for example, one word corresponding to English 'that' used for things the speaker can see, 'that boy' (visible), and an entirely different word for 'that' for things not visible to the speaker, 'that boy' (not visible, known about, but not present). Northwest Coast languages have distinct verb words for singular and plural (that is, an entirely different root may be required with a plural subject, for example, 'the children sat on the ground,' different from the root used with a singular subject, such as 'the child sat on the ground'—where the word for 'sat' would be distinct in the two instances).

Some other traits are shared by a smaller number of Northwest Coast languages, not by all. One example is the so-called 'lexical suffixes,' found in a number of the languages (Wakashan and Salishan). Lexical suffixes are grammatical endings which designate familiar objects (which are ordinarily signaled with full independent words in most other languages) such as body parts, geographical features, cultural artifacts, and some abstract notions. Wakashan, for example, has 300 of these. Another example is the very limited role for a contrast between nouns and verbs as distinct categories in several of the languages (see Campbell 1997, pp. 330–4).

3.5 The Baltic

The Baltic area is defined somewhat differently by different scholars, but includes at least Balto-Finnic languages (especially Estonian and Livonian), Latvian, Latgalian, Lithuanian, and Baltic German. Some would include Swedish, Danish, and dialects of Russian, as well. Some of the shared features which define the Baltic area are: (a) first-syllable stress, palatalization of consonants (a'y'-like release of these consonant sounds, as in Russian $p^{y}at^{y}$ 'five'), (b) a tonal contrast; (c) partitive case (to signal partially affected objects, equivalent to, for example, 'I ate (some) apple' found in Balto-Finnic, Lithuanian, Latvian, some dialects of Russian); (d) evidential voice ('John works hard (it is said)'; Estonian, Livonian, Latvian, Lithuanian); (e) prepositional verbs (German *ausgehen* (out-to-go) 'to go out'; Livonian, German, Karelian dialects); (f) SVO basic word order; and (g) adjectives agree in case and number with the Nouns they modify) (see Zeps 1962).

3.6 Ethiopia

Languages of the Ethiopian linguistic area include: Cushitic, Ethiopian Semitic, Omotic, Anyuak, Gumuz, and others. Among the traits they share are: (a) SOV basic word order, including postpositions; (b) subordinate clause preceding main clause; (c) gerund (non-conjugated verbs in subordinate clauses, often marked for person and gender); (d) a 'quoting' construction (a direct quotation followed by some form of 'to say'); (e) compound verbs (consisting of a noun-like 'preverb' and a semantically empty auxiliary verb); (f) negative verb 'to be'; (g) plurals of nouns are not used after numbers (equivalent to 'three apple' for

'three apples'); (h) gender distinction in second and third person pronouns (English has the 'he'/'she' gender distinction for third person, but nothing like 'you' (masculine)/'you' (feminine), found here); and (i) the form equivalent to the feminine singular used for plural agreement (feminine singular adjective, verb, or pronoun is used to agree with a plural noun) (see Ferguson 1976).

4. *How are Linguistic Areas Determined?*

On what basis is it decided that some region constitutes a linguistic area? Scholars have at times utilized the following considerations as criteria: (a) the number of traits shared by languages in a geographical area, (b) bundling of the traits in some significant way (for example, clustering at roughly the same geographical boundaries), and (c) the weight of different areal traits (some are counted differently from others on the assumption that some provide stronger evidence than others of areal affiliation) (see Campbell et al. 1986).

With respect to the number of areal traits necessary to justify a linguistic area, in general, the linguistic areas in which many diffused traits are shared among the languages are considered more strongly established; however, some argue that even one shared trait is enough to define a weak linguistic area. Without worries over some arbitrary minimum number of defining traits, it is safe to say that some areas are more securely established because they contain many shared traits, whereas other areas may be more weakly defined because their languages share fewer areal traits. In the linguistic areas mentioned above, there is considerable variation in the number and kind of traits they share which define them.

With respect to the relatively greater weight or importance attributed to some traits than to others for defining linguistic areas, the borrowed word-order patterns in the Ethiopian linguistic area provide an instructive example. Ethiopian Semitic languages exhibit a number of areal traits diffused from neighboring Cushitic languages. Several of these individual traits, however, are interconnected due to the borrowing of the SOV basic word order patterns of Cushitic languages into the formerly VSO Ethiopian Semitic languages. The orders Noun–Postposition, Verb–Auxiliary, Relative Clause–Head Noun, and Adjective–Noun are all correlated and thus they tend to co-occur with SOV order cross-linguistically (see *Word Order*). If the expected correlations among these constructions are not taken into account, one might be tempted to count each one of these word orders in different constructions as a separate shared areal trait and their presence in Ethiopian Semitic languages might seem to reflect several different diffused traits (SOV counted as one, Noun–Postposition as another, and so on), and they could be taken as several independent pieces of evidence defining a linguistic area. However, from the perspective of expected word-order co-occurrences, these word-order arrangements may not be independent traits, but may be viewed as the result of the diffusion of a single complex feature, the overall SOV word-order type with its various correlated orderings in interrelated constructions. However, even though the borrowing of SOV basic word order type may count only as a single diffused areal trait, many scholars would still rank it as counting for far more than some other individual traits based on the knowledge of how difficult it is for a language to change so much of its basic word order by diffusion.

With respect to the criterion of the bundling of areal traits, some scholars had thought that such clustering at the boundaries of a linguistic area might be necessary or at least helpful for defining linguistic areas properly. However, this is not so. Often one trait may spread out and extend across a greater territory than another trait, whose territory may be more limited, so that their boundaries do not coincide ('bundle'). This is the most typical pattern, where languages within the core of an area may share many features, but the geographical extent of the individual traits may vary considerably one from another. However, in a situation where the traits do coincide at a clear boundary, rare though this may be, the definition of a linguistic area to match their boundaries is relatively secure. As seen earlier, several of the traits in the Mesoamerican linguistic area do have the same boundary, but in many other areas, the core areal traits do not have the same boundaries, offering no bundling and no clearly identifiable outer border of the linguistic area in question.

5. *Areal Linguistics and Language Classification*

Unfortunately, it is not uncommon to find cases of similarities among languages which are in reality due to areal diffusion but which are mistakenly taken to be evidence of a possible remote family relationship among the languages in question. One example will be sufficient to illustrate this: the 'Altaic' hypothesis.

The core Altaic hypothesis holds that Turkic, Mongolian, and Manchu-Tungusic are related in a larger language family, though versions of the hypothesis have been proposed which would include also Korean, Japanese, and sometimes also Ainu. While Altaic is repeated in encyclopedias, most specialists find that the evidence at hand does not support the conclusion of a family relationship among these language groups. The most serious problems for the hypothesis has to do with the fact that much of the original motivation for joining these languages seems to have been based on traits which are shared areally, for example, vowel harmony (where within a word there is a restriction on which vowels can cococur with each other, for example, only combinations of back

vowels (*a*, *o*, *u*) or only vowels from the front vowel set (*i*, *e*, *æ*) but not some from one set and others from the other set in the same word), relatively simple inventories of sounds, agglutination, suffixing, SOV word order, and subordinate clauses whose verbs are participles, not fully conjugated verbs. These are also areal traits, shared by a number of languages in surrounding regions whose structural properties were not well known when the hypothesis was first framed. Because these traits may be shared among these languages due to areal linguistic contact and borrowing, such traits are not compelling evidence of a family relationship (with its assumption that the traits were inherited from an earlier common ancestor).

From this example, it is easy to see one reason why the identification of areal traits is so important in historical linguistics. In this case, failure to recognize the areal traits led to a questionable proposal of genetic relationship among neighboring language families.

L. Campbell

Arendt, Hannah (1906–75)

Born on October 14, 1906 in Hannover, Arendt grew up in a liberal Jewish family in Koenigsberg. Later, she studied philosophy, protestant theology, and Greek philology in Marburg, Heidelberg, and Freiburg. During this time, she got to know and was greatly influenced by two philosophers: Martin Heidegger and Karl Jaspers. In 1928 she received her Ph.D. in Heidelberg for her thesis on 'The concept of love in the work of St. Augustin.' Understanding the implications of Hitler's accession to power, she left Germany in 1933. She temporarily settled in Paris where she volunteered for a Jewish refugee organization. In 1941 she emigrated to the USA, and became an American citizen 10 years later. She worked as a lecturer at various American universities and colleges, and was a well-known freelance writer who contributed to the American intellectual culture as well as to the postwar European political discourse. Arendt died on December 4, 1975 in New York.

1. Arendt's Methodological Approach to Theory and Thinking

One cannot comprehend Arendt's thought without taking into account her personal experience of National Socialism and the genocide of the European Jewry. Throughout her life, Arendt always pointed to the existence of National Socialist and Stalinist terror and to concentration camps, which she considered the utmost challenges to political thinking.

It appears that she interlinked all her concepts and categories as well as the history of thought on which she based her notions with the experience of totalitarianism. She considered totalitarianism not only to be a breach in modern civilization but was even convinced that totalitarian rule challenges modern political thinking. This view gave rise to her seemingly unscientific methodological approach to thinking: How to create a world to which mankind feels attached and in which the individual does not lose their ability to judge? How to protect the 'body politic' from self-destruction? In this context, the concept of 'understanding the world' seems to become the overarching hermeneutic idea which interrelates all other categories: judging, acting, being in the public, etc.

Arendt focuses on reconsidering the instruments applied in social sciences. She believes that these were reduced to an absurdity by totalitarianism (see also Lefort 1988, p. 48). Her considerations encompass a wide range of historical, philosophical, and political references. Her concept of 'the world,' and her radicalization of hermeneutics by questioning the self as a subject have political and philosophical connotations.

There are some specific methodological aspects that need to be considered to understand Arendt's way of thinking:

(a) Historically Arendt focuses on the disintegration of the public sphere in the European societies (e.g., France and Germany but also Russia) at the end of the nineteenth century. Her point of reference is the emergence of a new form of total domination in the 1930s, which basically differs from former types of

tyranny or dictatorship but refers to the concept of natural law and/or of dialectical law. For Arendt, the need to understand totalitarianism epistemologically arises from the fact that totalitarianism cannot be sufficiently explained by historical and social sciences (Arendt 1994, p. 317). She argues that totalitarian rule has had a major impact on the categories applied in social sciences (Arendt 1994, p. 318). She criticizes social sciences for assuming that political action is basically a rational process (in the sense of Max Weber, see *Weber, Max (1864–1920)*). But totalitarian terror is, in Arendt's view, not at all rational but meaningless and contingent. Therefore, it is not possible to grasp the absolute meaninglessness of destruction, evil, and mass murder by adopting social-science approaches. This is the reason why Arendt's hermeneutic concept is closely interlinked with her criticism of social sciences.

(b) Arendt aims to 're-open' the political dimension of modern political thinking by applying her concept of understanding. In this context, 'reopening' means that a dimension, which has been lost, has to be rediscovered: the public sphere as a sphere of human interaction. It is the public sphere that keeps the body politic (the political system) alive. In Arendt's view, the removal of institutions and legal systems as well as the abolition of political freedom under totalitarian rule are direct consequences of the dissolution of the public sphere in modern times.

(c) In terms of philosophical categories, understanding is taken to be different from cognition. Understanding is not simply an intellectual concept of the world but is a hermeneutic process, and thus also a philosophical and emotional approach to the world. Understanding is interlinked with experience and judgement.

(d) Understanding is also supposed to be different from having 'correct information and knowledge,' although the two are interrelated. Understanding also differs from scientific knowledge. In Arendt's critical view knowledge is meaningless without preliminary understanding. Here, she breaks with the tradition of natural and social sciences according to which the knowledge about facts and details of a phenomenon and putting these pieces together in systematical order means to recognize these facts and details or to realize their truth.

Furthermore, 'understanding' does not mean 'causal and historicist explanation': 'The necessity which all causal historiography consciously or unconsciously presupposes does not exist in history. What really exists is the irrevocability of the events themselves, whose poignant effectiveness in the field of political action does not mean that certain elements of the past have received their final, definite form, but that something inescapably new was born' (Arendt 1994, p. 326).

In this way, Arendt again draws a line between political thinking and the world of scientific analysis. Her approach denies all teleological and deterministic as well as deductive thinking. However, it includes a fundamental criticism of the concept of progress and rationality in modern history.

Methodologically, her work is challenging insofar as she opposes the traditional (usual) meaning of concepts. In all of her greater works she critically reviews concepts and conceptions as facets of the history of thinking; she eventually tries to re-establish an authentic relation between a given concept, reality and the acting individual; furthermore she seeks to reveal what is new about the object of recognition. Thus, her work is also a major contribution to hermeneutics in social sciences.

2. *Basic Concepts in Arendt's Thinking*

Arendt did not evolve a systematic political theory nor did she elaborate a philosophical system. However, her approach to political thinking remains a challenge for both political theory and philosophy. It is based on a different understanding of the major concepts of political theory. Her critical view of the techniques applied in social sciences induced Arendt not only to do research on etymological changes in social science concepts (e.g., freedom, morality) but also to relate her own concept to the overarching idea how to reveal the political dimension in the community of citizens.

2.1 *The Concept of Society*

Society is considered a never-ending process in which citizens act and judge towards an open future within a public sphere; it is not perceived as a set of institutions and ways of living. Arendt opposes traditional views of theory on society by denying that society is to be seen as a (national) entity.

In her view institutions have a protective function. However, they can also pose a threat to the 'humanness of the world.' In this respect, Arendt follows Max Weber in his criticism of bureaucracy. She agrees that the public realm cannot do without institutions, but here again her concept of institution is different, for example, the act of setting up a 'political body' during a revolution is taken to be an institution by itself.

The 'humanness' is supposed to be maintained only by the citizens. Thus, it may not be surprising that Arendt relates her basic concepts to certain abilities of citizens: thinking, judging, and acting in the public realm.

2.2 *The Political*

Arendt's concept of 'the political,' which is basically different from 'politics,' is based on her distinction

between the public sphere and the needs and desires dominating the private sphere.

The political is not a substance of humankind but arises in the midst of citizens in the public realm. This is another example of the way in which Arendt relates her concepts to the sphere of interaction. In her view, the political gives rise to a new beginning in the sphere of interaction.

Arendt's way of thinking can be closely related to the tradition of political thinking which emerged in Greek and Roman antiquity. She acknowledged the Greek 'polis' and the Roman republic as historical forms of political sphere, to which die American founding fathers referred to perceiving the republic as a permanent founding of itself (self-instituting) within a system of checks and balances.

2.3 Political Freedom

The term 'freedom' (like 'society') refers to a process of interaction in the political sphere and not primarily to institutions. Freedom is not restricted to the individual or to the private sphere. Moreover, 'political freedom is distinct from philosophic freedom in being clearly a quality of the I-can and not of the I-will. Since it is possessed by the citizen rather than by man in general, it can manifest itself only in communities, where the many who live together have their intercourse both in word and in deed regulated by a great number of *rapports*—laws, customs, habits, and the like. In other words, political freedom is possible only in the sphere of human plurality, and on the premise that this sphere is not simply an extension of the dual I-and-myself to a plural We' (Arendt 1981, p. 200).

Basically, political freedom appears to have a double meaning: on the one hand there is the act of setting up a 'political body' (e.g., by means of a constitution) and on the other hand there are the *rapports* of citizens in favor of their political body.

2.4 Power

As with the concept of freedom to which it is linked, power is interrelated to the public realm. Arendt does not interlink power with domination, and violence. She disagrees with the definition of power given by major social scientists and especially by Max Weber (Weber 1978, p. 53).

In Arendt's thinking power, that is, political power, cannot be 'possessed' by individuals nor—as this was assumed during the French Revolution—by 'the people.' On this point Arendt differs from the liberal as well as from the revolutionary concept of power. 'Power corresponds to the human ability, not just to act in concert. Power is never the property of an individual; it belongs to a group and remains in existence only so long as the group keeps together' (Arendt 1972, p. 143).

This means that power belongs to the public sphere. It can be incorporated by means of a revolution, a political uprising or an act of founding. However, if power is institutionalized it tends to become bureaucratic. In this respect Arendt agrees with the skepticism of Max Weber about modern bureaucracy.

Thus, power comes up and disappears again depending on the contingency of history.

2.5 'Alienation from the World' and 'Being in the World'

Arendt experienced emigration, exile and the deplorable status of a stateless person over many years. It is no accident that the issue of alienation plays a major role in her works. But again, alienation is not related to the private realm but to the public sphere. Alienation refers to the estrangement of individuals from their political community. According to Arendt's theory of humanness, individuals have to 'appear' in the world, join their fellow men and commit themselves to the preservation of the world they live in through their actions. This is what 'citizen' means.

In this context, 'world' (and opposed to 'being without a world'/worldlessness) refers to the fundamental fact of being born into an already existing world.

However, Arendt's concept of alienation differs from the one of Marx or other philosophical authors insofar as it focuses not on the individual but on the relationship between the citizens and the world which they have created (see *Marx, Karl (1818–89)*).

This is the starting point from which Arendt pursues two objectives: to reflect upon how to make the world worldly and to humanize thinking. This is a constant theme throughout her work.

2.6 Totalitarianism

All of Arendt's works on political thinking refer to the political events of the time. Her research on totalitarianism during the 1940s focuses on various aspects.

(a) She identifies totalitarianism as a new type of total domination. It bases on violent antidemocratic movements which later become part of a political system which engages in the control of institutions and the personal lives of the people, sets up a specific ideology, and establishes systematic terror.

(b) She focuses on the 'The origins of totalitarianism,' that is, imperialism and anti-Semitism as the major sources of destroying the political body of the European democracies since the nineteenth century.

(c) She considers totalitarianism as representing a breach in modern civilization which began a long time ago. Here again she argues that the categories of thinking are deeply affected by this process.

Arendt considers totalitarian rule as a possible outcome of the weaknesses of modern age. It is bewildering that modern democracies themselves may generate totalitarian elements. Hence, in Arendt's view totalitarian rule cannot be dismissed as an 'accident in history'; there is always the possibility that this form of rule emerges.

This is why it is problematic to discuss moral behavior in a traditional sense after the emergence of totalitarian rule has occurred. Wherever human nature was reduced to the level of 'material' it seems inappropriate to simply re-establish rules that were violated or manipulated. For Arendt, it is important to reflect on the dimensions of a world which gave rise to such a development and which continues to exist after the break-down of totalitarianism.

2.6.1 Radical and Banal Evil. One word within Arendt's concept of totalitarianism generated major criticism: 'evil.' Arendt distinguishes between radical and banal evil. 'Radical evil' makes human beings superfluous. Arendt uses this concept to find an explanation for Nazi death camps. 'Radical evil' stands for both an absolute and a contingent negation of humanness. The other side of evil is its banality. Arendt takes the Nazi functionary Adolf Eichmann as an example. Her characterization of Eichmann as 'banal' has been widely misinterpreted as a diminution of his personal responsibility (Arendt 1963). But what Arendt really meant has more to do with another dimension of evil: the absence of thinking (that means, of self-reflection and of conscience). Thus, Arendt presents Eichmann as a specific type of modern person who has lost their relationship to the world as a 'common good.'

3. *Arendt as a Political Thinker of Morality*

At first sight it appears strange to describe Arendt's way of thinking as moral (ethical) because Arendt does not evolve a theory of 'acting correctly.' Neither does she construct a system of values. She does not apply moral standards to judge political thinking and acting. Moreover, she deconstructs the popular meaning of morality by uncovering its etymological roots. It turns out that 'morality' has more to do with being committed to the world than with internalizing values.

Seen from her perspective, acting within the political sphere means to establish civil (civic) manners; this can only be achieved if political action is related to 'home' which may also be called 'the world people share.'

Arendt's principal work 'The origins of totalitarianism' concludes by referring to Heidegger's philosophy. There is a quasi-existential fixed point which is inaccessible to totalitarian rule: the fact of natality. The simple fact that people are born cannot be removed; the birth of a child will continue to represent a new beginning for the world. 'Beginning, before it becomes a historical event, is the supreme capacity of man; politically it is identical with man's freedom… This beginning is guaranteed by each new birth; it is indeed every man' (Arendt 1981, p. 479).

Hence the basic prerequisite for human action is there; it is one of the fundamentals of human existence. The question that arises is: How can this existential potentiality of political action be given shape?

Acting politically is only possible in a public sphere. This sphere provides the common world people share in which thinking in public and acting take place. Citizens have to see to it that this public sphere can be renewed. At this point Arendt differs from Kant's theory of morally acting. Unlike Kant, Arendt does not perceive 'polical community' as a limited place, that is, a city (polis) but as a never-ending process of taking action in a sphere that can only be protected by the citizens themselves. The citizens' concerns arise from a joint interest in the world they live in, a world, which keeps on giving new beginning to them.

Arendt considers a renewal of the public sphere to be the only possibility to counteract the (self-)destructive potential of modern times. The conclusion that can be drawn after experiencing totalitarian rule is that evil in the world can only be faced if people commit themselves to making the world they share fit to live in for their fellow citizens and if they permanently renew this 'habitability.'

The difficulty which has arisen is that the distinction between public and private sphere becomes increasingly blurred: it was intentionally destroyed by totalitarian rule, and similarly, it is jeopardized by the increasing importance of social interests and needs in modern society. Nevertheless Arendt argues, a world that is shared by people can only emerge by creating a public sphere. However, this can only be achieved to the extent to which citizens succeed in agreeing on making freedom the overall objective of their actions.

Aristocracy/Nobility/Gentry, History of

1. Troublesome Terminology

This article concentrates on Europe. No room can be spared for explicative forays to other parts of the world but one should mention the striking similarities between medieval nobility in Europe and the Japanese *samurai*, as well as in modern times export of European aristocratic structures to other parts of the world.

Even within the European core, diverse terminologies reflected different social structures of particular countries. In the British usage, 'nobility' equals 'aristocracy,' the term 'gentry' being used for the landowners without hereditary titles. English terms do not necessarily fit the Continent. In *The New Cambridge Modern History* (1970) J. P. Cooper wrote: 'Though the word noble was usually reserved for the peerage in England, … in France, Poland and other countries it included those without titles who in England were called the gentry.' In this article the term 'nobility' will be used in this comprehensive meaning, corresponding with the German *Adel*, Italian *nobiltà*, or French *noblesse*, all terms originally connected with land ownership. In particular languages there were parallel terms that laid stress on the origins of the nobility. In German *Ritter*, as well as in Swedish *riddare* and French '*chevalier*' or Spanish '*caballero*,' originally signified 'horseman.' In Poland the word *szlachta* stressed upon its hereditary character (from German *Geschlecht* over Czech *šlechta*), while in Sweden medieval *frälse* underlined their freedom from taxes. All these terms have been value-charged. They gave birth to various modern descriptive terms like 'workers' aristocracy' or 'trade-unions' aristocracy. The derivatives of 'gentry' have in English a particular value: e.g., this quotation from a London real estate newsletter: 'Cleared sites (in Battersea) ready for development ... herald for the next area to be *gentrified*.'

2. Ancient-world Origins

The word 'aristocracy' is of ancient Greek origin and signifies the 'rule of the best.' In Homeric times 'the best' signified chiefs of the noble families who pretended to share with the king a descent from the gods, and were also prominent by their wealth and personal prowess. They formed a class of 'horsemen' or 'knights' (*hippeis*) connected by blood and by various community institutions. They governed the state by means of the council of the *gerontes* (the elder). In the eighth and early seventh century BC, social position of the aristocrats was based on their land ownership but also upon commerce, robbery, and piracy. They dominated the communities (*poleis*) and organized colonization. Many factors contributed to destruction of aristocratic rule, like change of military tactics (riders in single combat were replaced by *phalanx* of heavily armed foot soldiers) and ascent of nonagrarian social groups striving for power.

The fate of the aristocracy in ancient Greece had shown the track that many other ruling groups would follow: from undisputed moral and political domination to the rise of rival groups, to loss of oligopoly of power. However, prestige related to ancient roots (real or fictitious) survived and would become a constituent of all aristocracies. Aristocracy as the 'rule of the best' was a moral ideal; if birth was replaced by wealth as the decisive qualification it became oligarchy.

In republican Rome several groups consecutively enjoyed oligopoly of prestige and power. The earliest hereditary estate was the patricians (the *patriciate*) who in the late fifth century BC reached almost complete oligopoly of offices. In the later fourth century, their competitors, the plebeians (*plebs*), also got access to power. The outcome was a sort of convergence of top strata of both estates through matches and family alliances. In the late fourth and the third centuries a new aristocracy was emerging, the *nobilitas*. Its base were great landed estates run by the slaves and by the peasants, more and more dependent as clients. About 30 houses had access to power both

civil and military. Electoral system and honorary unpaid offices secured their domination. Territorial expansion offered them benefits (fruits of power in the provinces) and created new dangers. 'The mighty few' (*pauci potentes*, so wrote Cicero) were being pressed by the *equites*, originally a moneyed group which in stormy times of civil wars strove for power and virtually assimilated to the *nobiles*.

Augustus and his imperial successors changed the role of *nobilitas* by the very introduction of the Imperial Court. Later on, along with spatial expansion of the Roman Empire emerged provincial aristocracies whose role increased when the center was losing its grip on more distant provinces invaded by the 'Barbarians.' Roman traditions influenced medieval and modern vocabularies of elites.

3. *The Early Middle Ages and la Féodalité*

The dissolution of the Roman Empire in the West (fifth century AD) brought about new nobilities from among the retinues of Germanic chieftains and local Roman governors. Their structures became somehow stabilized with emergence of new states. The milieu of princely (royal) households offered opportunities of advancement for diverse social types like the prince's companions, allied tribal chiefs, valiant warriors, and also bondsmen or slaves who had a chance to serve the prince's person directly. A parallel but closely interwoven network was created by the Church. The bishops exercised secular control over large territories, and the Church offered a convenient upward path to able and ambitious persons of modest origin. This is true for later periods as well. When after the twelfth century nunneries multiplied, they constituted cache for daughters of good stock who easily became abbesses or prioresses of great prestige and considerable power. Individual success signified family advancement as well. Close relation to the Church has been for many centuries an important factor of aristocratic way of life. In Germany, even Protestant noble families claimed right to particular benefices of the Catholic Church they had traditionally enjoyed before the Reformation.

Medieval and modern aristocracies with their hereditary titles of honor had their roots in the royal household and in the administration of the early state. Office holders strove at permanent and hereditary positions. Instability of the early medieval states helped them. So in Carolingian times 'count' (Latin: *comes*) was a judge who accompanied the Emperor. In the twelfth century emerged other *comites*, provincial governors, and 'viscounts' as their representatives. Border provinces of the Empire were governed by the 'marquesses' (German *Markgraf*), 'Duke,' or (German) *Herzog* which meant 'leader of hosts.' 'Baron' (German *Freiherr*) was either a great landowner or just a substantial 'free man,' i.e., primarily the prince's companion, not his simple subject; it was also an equivalent of 'nobleman.' So the recipients of the *Magna Carta* (1215) were *barones*.

More rigid rules of interpersonal relationships were conceived originally in France in the twelfth, and developed into sophisticated structures in the subsequent centuries. In that system, now often called 'feudal,' whoever counted was somebody's vassal and had his own vassals as well. Everybody knew his specific rung on a long ladder on top of which was the ruler who had a special relationship with God. This formed a power system based on personal relationships, a skeleton of the medieval 'state,' called by the German constitutional historians *Personenverbandstaat*. Diverse alterations and finesses of these rules cannot be analyzed here albeit they determined the vicissitudes of particular aristocracies. Enough to mention the notion of 'pairs' (the king's direct vassals equal to each other and also his companions like the legendary 'Knights of the Round Table') making the council of prince's advisors with juridical privileges, and a pressure group conscious of their common interests. In Norman-dominated countries (most important were England and the Kingdom of Naples) the ruler was recognized as direct *seigneur* of all vassals; in other countries the principle reigned that 'the vassal of my vassal is not my vassal.' The Norman principle became a legal tool whenever the king wished to curb his vassals. In the thirteenth century it helped to create in Naples a state of rather bureaucratic character. The other system tended to become a complicated mixture of conflicting loyalties. It troubled France and Germany.

From the late Middle Ages the nobilities in particular countries were being shaped by factors as different as intensity of money economy and customs or laws of inheritance. Money had a destructive influence upon feudal relationships: debts and mortgage haunted landed estates. A system, later called 'bastard feudalism,' replaced the fiefs by money payments. In the Hundred Years War feudal hosts of France proved helpless time and again against English foot militia and the longbows. Eventually mercenary troops raised by entrepreneur-commanders replaced them. Most successful commanders aspired to aristocratic titles. In Italy, mercenary commanders (*condottieri*) were nobles, even sovereign princes, and they often recruited their workforce among lesser nobles from Romagna, Friuli, or Marche. The nobles were looking for their place in constantly growing state machine.

4. *Early Modern State: Crisis and Adjustment*

Not everybody was, however. The fifteenth and early sixteenth centuries witnessed multiform critical phenomena: rents were falling, so robber knights emerged in Bohemia (they were active among the Hussites) and in East Germany. A revolt of lesser nobles broke out in

many parts of the Empire: princes and bishops eventually won and razed many knights' castles. In the Renaissance, assemblies of estates became all over Latin Europe a power factor parallel to the monarch. The nobles participated in them chiefly through their elected members (along with the clergy and the burghers) but the pairs and titled nobles usually had their personal seats secured. The Assemblies became the forum of open competition between the nobility and the burghers. The nobles of a given province usually aimed at an oligopoly of posts and offices, against the burghers and any outsiders.

Recent research has concentrated attention on the 'crises' of nobility and its particular strata. Precious little remained of the original theses. In most countries the nobles (in the broadest sense) rather successfully adapted themselves to new economic and political conditions but this created major shifts within the estate; thence the 'crisis.' The ideal of an unspoiled and bucolic noble life competed with that of a life of public service. A precondition for state service was legal training, and the gentry largely disdained from formal education. Therefore some rulers encouraged foreign travel or founded special lay colleges (like the Knights' Academy in Siegen or nobles' colleges in Denmark and Sweden). In Elizabethan and Stuart England, young gentlemen crowded Inns of Court, and in Scotland the legal training of young noblemen was encouraged by law. In the seventeenth century German nobles became more prone to acquiring legal training as they needed it to service their princes. Not so for the French *noblesse*.

Internal stratification of the estate was of utmost importance. It differed according to size. Here are some estimates: in Denmark, around 1600, the nobles made 0.25 percent of population; in Bavaria, Saxony, and Holland slightly more of the population were nobles; in Bohemia and in Prussia, in 1700, 1 percent; in Poland 7 percent, and in Castile about 10 percent (see Labatut 1978, Meyer 1973). In some regions (Vizcaya in Spain, Masovia in Poland) membership of the noble estate was massive.

In the sixteenth century, ideas of unspoiled bucolic life competed with that of public service. However, if economic and social differentiation of the estate was great enough, the more mighty organized their lesser neighbors into clienteles. 'Liveries' and noble retinues were forbidden in Tudor England and virtually suppressed in Spain in the mid-sixteenth century. In France, a century later, they failed as a weapon of the princes during the *Fronde*.

The seventeenth century may be regarded as a century of opposition between the 'Court' and the 'Country.' The former became a principal source of prestige and privilege, a center of culture and power. It was never that important in England as it was in France, Spain, and Austria.

In the East, where demesne farming prevailed, the state was 'coercion-intensive' (as Charles Tilly 1990 defines it). In Prussia and Livonia the landed gentry (*Junker*) identified with state and its army. In Russia they were the Tsar's dependent servants and did not become an estate before the mid-eighteenth century. In Poland a sequence of fifteenth-century statutes secured independence from the royal administration. The structure of politics in Poland-Lithuania was shaped by the relationship between the gentry and the magnates. Neither of them were interested in a strong executive, after an elective monarchy was introduced, and the political patronage of the magnates became the dominant factor.

In Sweden, nobility, having virtually no medieval traditions, developed into an estate of civil and military officers through ennoblement of commoners. Absolutist reforms of 1680 got their full support against the aristocracy. The system of rangs (known also in Denmark and later introduced in Russia) served their interests.

In France the *noblesse d'epée* felt endangered by the robins (*noblesse de robe*), or commoners, who were massively buying land and titles of nobility on a large scale. Strict *dérogeance* (ban on improper, disqualifying, sources of income) created economic problems. The high aristocracy had enjoyed military command and governorships of provinces as their *chasse gardée*. But their influence was rather restricted to the Court intrigues, masterfully described in the memoirs of Duke de Saint-Simon (1699–1752).

5. *Pride and Prejudice*

One may argue that noble culture has been based on these two vices. The whole idea of nobility drew from tradition, and much imagination was employed to deepen the roots of each family tree. The Renaissance discovery of Roman literature enriched noble imagination with hosts of ancient heroes. Most seminal were the escapees from burning Troy. When in 1624 a scion of the distinguished Lithuanian family Pac visited Florence, both he and his hosts, the Pazzi, were happy to get 'proof' of their common heroic, Homeric origins. The nobilities favored imagined glorious ancestry: the Germanic Francs (as opposed to the commoners descending from the Celtic Gauls) in France, and in England the Norman knights of William the Conqueror. The Lithuanian gentry descended from a Palemon (of Troy, for that matter) and the Polish one from Japhet son of Noah (as contrasted with Cham for the peasantry and Sem for the Jews). In Italy, France, and Spain noblemen and scholars discussed the relative importance of long, impeccable pedigree, lifestyle, and personal valor.

Of more practical importance were property rights and the rules of inheritance. They determined the economic continuity of families. Chiefly in the south (Naples, the islands, Spain) feudal property was dominant, which in cases of conflict, became a tool of

the monarch. In the England of the early Stuarts, the Court of Wards was an instrument of fiscal oppression of the nobles and the Long Parliament (1640) abolished it instantly. In Naples and Sicily the nobles continuously pressed their Spanish sovereigns for more liberal rules of feudal inheritance.

The preferred rule of inheritance was the entail which treated landed estates as family property and neutralized the tendency to division. However, it limited opportunities to mortgage the real estate and left open the fate of younger sons and daughters. In the English case, entail served landed property well: it kept property intact and the younger sons easily found jobs in business, professions, royal service, and eventually in the colonies. On the Continent, ambitious, less substantial nobles as 'noblemen-errant' searched for service abroad. Count Achatius zu Dohna (from Prussia) and Prince Eugene (of Savoy) were among the best known. In Poland, shared inheritance contributed to the impoverishment of the gentry and the growth of the magnate. The latter secured entail, for themselves, as a legal exemption.

6. *Urban Aristocracies*

The cities had aristocracies of their own. North of the Alps, they were usually called 'patriciate' and in Italy simply *nobiltà*. In the High Middle Ages, before town guilds took over the government, most cities were run by royal officers of noble extraction. The most impressive relics of that early stage and its lifestyle are thirteen towers that dominate the cityscape of San Gimignano and the incredible two constructions still towering over Bologna. In most cities, however (Florence, Basle for example) victorious town guilds destroyed these bastions of noble power, only to create the elites of their own. The large, wealthy town offered great benefits to the people of influence, and led to strong oligarchic trends in urban 'communes.' The top families were often more aristocratic than the aristocrats *sensu strictiori*. In Italy and later also in south Germany, ruling elites introduced the *serrata*, or closed lists of families with exclusive right to city offices in a given city. The most famous was the Golden Book of Venice (1297) but it was by no means unique. The patricians cultivated their special ways and observed *dérogeance* taboos. In Germany, the symbol of urban independence was 'Roland,' the legendary companion of Charlemagne and personification of knightly valor. King Arthur too became the eponym of exclusive clubs (*Artushöfe*). The patricians built country residences and acquired landed property chiefly as a status symbol. It was often apparent that they treated this as a collective enterprise. In the fifteenth and sixteenth centuries, in the Swiss city of Luzern, a small cluster of patrician families raised urban troops and leased them to neighboring powers. The patricians commanded them and collected most of the money paid for their services. Profits from power and politics were closely interwoven.

The *connubium* or marriage market strictly limited to elite families created problems, and between the sixteenth and eighteenth centuries many urban aristocracies from Venice to Lübeck experienced a shortage of skilled candidates for urban offices. The medieval register of noble families centuries later did not secure wealth compatible with their social standing. Therefore the Venetian *nobiltà* created, at the city's expense, a system of social welfare for the noble poor.

In general, the urban patriciate in many respects was similar to the aristocracy. They were closely related, too, because landed aristocrats did not scorn urban money. In Germany, patricians from many cities of the Empire (*Reichsstädte*) enjoyed the status of the *Reichsadel*. The Habsburgs granted aristocratic titles to wealthy burghers who supported them with loans and banking services. Names like Fugger (Augsburg), Doria, and Spinola (Genoa) are only the most famous among many. In some cases the patrician was automatically regarded as a noble: in the tiny imperial city (*Reichsstadt*) of Wels, owners of important local salt (brine) wells were, by imperial patent, regarded as nobles (incidentally, this status was enjoyed by Franz von Papen, who preceded Hitler as German Chancellor). In France some city posts were ennobled almost automatically. Even the most exclusive Maltese Order excepted candidates from Florence, Genoa, Lucca, and Pisa from its very strict *dérogeance* rules.

Members of the urban elite merged with the nobility *tout court* in many ways. They met at Royal Councils, acquired landed estates and prestigious titles, and profited from the inflation of honors in the sixteenth and seventeenth centuries. They defended their exclusive status against bureaucratic encroachments of enlightened absolutism. The elites of some larger cities made a particularly closed, self-conscious caste. The twilight of the patrician civilization was best described by Thomas Mann in *The Buddenbrooks* (1901).

7. *Triumph and Twilight of Aristocracy*

The French Revolution closed a chapter, but not the whole story, of European aristocracy. Although aristocrats were given preference onto the scaffold (even a heiress of Tchernobyl, who visited Paris at a wrong time, lost her head), the First Consul and later Emperor created his own Court and constituted a new stratum of *notables* based on loyalty to the ruler and on merit. Political changes largely destroyed the prestige of French élites whose membership reflected, in the nineteenth century, the vicissitudes of the nation. But still, in 1839, the Marquess Astolphe de Custine argued that the true nobility cannot be bestowed on or purchased. The ruler, he continued, can appoint dukes; education, opportunity, and genius or virtue

can create heroes; but nobody and nothing can make a noble. We had been twelve ducs and pairs, he quoted a Napoleon's appointee, but I was the only nobleman among them. However, in Custine's opinion, such restrictive concept of nobility became a mirage and possibly has never been anything more. Everywhere commoners were being ennobled: bankers, industrial entrepreneurs, statesmen and politicians, army and navy officers. Monarchies, even restricted by the constitutions of the second half of the nineteenth century, needed traditional elites as political support and as an ornament. In Berlin, the last emperor Wilhelm II recreated a very formal and lavish court ceremonial. In Britain, in 1876 Queen Victoria became Empress of India and made Benjamin Disraeli, a statesman of Jewish extraction, Earl of Beaconsfield. Immemorial traditions were being cheerfully invented. In the 'first industrial state' the high nobility had a greater than ever share of land and substantial political influence.

For a contrast, in the East, after the dissolution of the Polish Republic (1795) the three partitioning powers inherited numerous lesser nobles but almost no titled ones. This unusual gap had to be filled and eventually anybody who was able to prove members of the Senate among his ancestors who pursued a noble lifestyle, could become baron or count. 'Austrian Count' became, in Poland, an ironic comment. In general, however, in the monarchies, ennoblement and aristocratic titles were becoming a mere ornament and final prize for distinguished service and/or business performance.

Constitutional and political changes in Europe in 1917–18 and after were destructive for the nobility, and not only those in Europe. For instance, neither republican nor Frankist Spain were solving the problems that were vital for the nobles in former Spanish colonies in Latin America. There was great demand for a sovereign overlord.

After 1918 radical projects of agrarian reforms threatened the foundation of noble interest in many countries but it was destroyed only in the Soviet Russia. The former Russian aristocrat becoming taxi driver in Paris became a literary *topos*. Another totalitarian system, Nazi Germany, finally won support of the Prussian Junkers. In the beginning, Adolf Hitler's party seemed to them too radical, too plebeian, but the preceding Weimar Republic had also been disappointing for them. Nevertheless the Junkers shared nationalistic commitments and a fear of the left, and loyalty to the sovereign persisted as the foundation of their ethos. But in later years, when Germany was losing the war, many of them had to reconsider their attitudes vis-à-vis Hitler's régime.

Perhaps the *Credo* of the late aristocrats eventually challenging the Nazi dictator could have been outlined that way: the aristocracy never collaborates with the tyrant in defense of order; its tradition is on the one hand defense of the people against despotism, on the other defense of civilization against the revolution, that most dreadful of tyrants (or so Astolphe de Custine had had it). The failed coup against Hitler on 20 July, 1944 brought them to a bloody end, and the postwar loss to Poland of the territories beyond Oder-Neisse frontier cut off their economic base.

The conspiracy against Hitler was perhaps the last conscious political action of an aristocracy. The political influence of that class seems lost for good, notwithstanding the distinguished intellectual, scientific, or political performance of their individual members. What remains is the value of their collective tradition and the sentiment or flavor so well presented to the modern world by a *Principe* Giuseppe Tomaso di Lampedusa or a Jean Marquis d'Ormesson.

Aristotelian Social Thought

Aristotelian social thought refers both to Aristotle's own thinking about society and politics, and to the body of ideas inspired by his works. Since the latter has taken many different forms and often departs significantly from the former, this article will devote a separate section to each.

1. *Aristotle's Social and Political Thought*

There are good reasons for accepting the common characterization of Aristotle as the first social or political scientist. Certainly, none of his predecessors engaged in anything like his systematic study of political life as it is actually lived. Nevertheless, in order to appreciate both Aristotle's own ideas as well as their appeal to later students of society and politics, it is important to recognize the ways in which his understanding of social science differs from its contemporary counterparts.

First, Aristotle integrates rather than separates empirical and normative analysis. As a result, the contemporary distinction between political science and political philosophy would have made little sense to him. Aristotle distinguishes, instead, between what he calls practical and theoretical knowledge. The former, which includes both the study of politics and the study of ethics, takes its bearing from human purpose and choice. It therefore can never reach anything like the precision and certainty that the theoretical sciences, which begin with necessary causes and certain first principles, seek to attain.

Aristotelian social science also diverges from its contemporary counterparts in its reliance on teleological principles. In particular, Aristotle believes that the natural needs and ends of human beings draw them into political life. It is this belief that allows Aristotle to integrate the empirical and normative analysis of social relations, for it leads him to argue that we cannot understand the good life that human beings seek without understanding the dynamics of the ordinary political interactions which make it possible, and that we cannot understand the dynamics of ordinary political life without understanding the good life of virtuous activity that makes political life desirable.

Aristotle develops these ideas in a number of texts, the most important of which are the *Politics* (Aristotle 1956b) and the *Nicomachean Ethics* (Aristotle 1956a). Aristotle and his students also assembled a collection of accounts of the constitutions of hundreds of Greek city-states; but only one of these accounts, *The Constitution of Athens* (Aristotle 1950), has survived.

The key concepts in Aristotle's social thought are community, friendship, justice, and regime (or constitution). Community (*koinonia*) is the term that Aristotle uses to characterize the whole range of human association, from business partnerships and groups of travelers, to families and polities. Wherever people share something, be it interest, pleasure, a sense of the good, or common origins, there is community, according to Aristotle. And wherever community develops, there also develop distinctive forms of friendship and justice, the bonds of mutual concern and mutual obligation that, Aristotle argues, we find in even in the most ephemeral or self-serving forms of human association.

The form of sharing that distinguishes political community, according to Aristotle, is taking turns in the process of ruling and being ruled. When Aristotle argues that human beings are by nature political animals, he is arguing that fully mature individuals will eventually form such communities in their pursuit of the good, unless prevented by external coercion or unfortunate circumstances. The fact that most human beings, apart from the Greeks and a few other Mediterranean peoples, do not organize their lives in this way poses a problem that Aristotle deals with only in a very cursory way; for example, by suggesting that although Asians are intelligent enough to form political communities, they lack the spiritedness or self-assertion needed to replace the despotic empires in which they live.

Aristotle distinguishes among the different forms of political community with reference to two things: the number of people who actually share in the process of ruling, and the claims to rule that they make. His famous sixfold classification of regimes—three correct regimes: monarchy, aristocracy, and polity; and three deviations from the correct regimes: tyranny, oligarchy, and democracy—reflects these principles of differentiation. Behind this relatively simplistic system of classification, however, there lies a much richer and more insightful political sociology. In almost all actual cases that Aristotle discusses, political community takes the form of oligarchy, democracy or some mixture of the two. Democracy, as Aristotle understands it, is not just the regime in which the majority rule; it is the regime in which the egalitarian principles and shared freedom on which the many base their claim to rule shapes everyday social life. Similarly, oligarchy is not just the regime in which the few distinguished people rule; it is the regime in which the inegalitarian principles, and especially the unequal wealth, on which the few base their claim to rule,

shapes social relations. As a result, the regime (*politeia*) represents for Aristotle both an ordering of offices or constitution and the particular way of life promoted by the principles of justice that support this ordering of offices. (The closest modern parallel is probably the way in which Alexis de Toqueville 1988 characterizes democracy and aristocracy in *Democracy in America*.)

Thus when Aristotle argues that a mixed regime, a blending of oligarchic, aristocratic, and democratic political institutions, offers the greatest hope for improving ordinary political life, he is not just seeking to lessen political conflict by giving competing groups a stake in the regime. He is also seeking to improve the standards of political morality within communities by mixing the egalitarian and inegalitarian principles of justice that sustain each group's claims to power. Furthermore, Aristotle suggests that the middle class, where it exists, has an interest in supporting these improved standards of justice associated with the mixed regime. Overall, the mix of class, regime, and moral analysis in the middle books of the *Politics* contain a variety of insights that deserve greater attention from contemporary social and political scientists.

2. *Aristotelian Social Thought After Aristotle*

Although Aristotle founded one of the leading ancient schools of philosophy, known as the Lyceum or the Peripatetics, his social and political ideas were not very influential in the ancient world. His analysis of communal life was so single-mindedly focused on the Greek city-state (*polis*) that it must have seemed irrelevant in a world increasingly dominated by the vast empires created by the Macedonians and the Romans. The afterlife of Aristotelian social thought thus takes the form of a series of revivals and rediscoveries, rather than a continuous tradition of commentary and interpretation.

These revivals and rediscoveries of Aristotelian social thought have played an important role in the intellectual life in at least three periods: the high Middle Ages, the years immediately following the French Revolution, and the decades since World War II. In each of these periods students of contemporary society and politics came to believe that Aristotle's texts preserved fundamental insights that had been lost or obscured by their contemporaries.

2.1 *The High Middle Ages*

Among the Muslim, Jewish, and Christian philosophers of the high Middle Ages, Aristotle's name was accorded a degree of authority that few, if any, secular thinkers have ever received. To most of them Aristotle was 'the Philosopher', and his texts were a compendium of the knowledge of the natural and social world that Holy Scripture could not provide.directly As a result, the most famous thinkers of the Middle Ages, such as al-Farabi, Maimonides, and Thomas Aquinas, all looked at the social world from the perspective of Aristotelian concepts and categories, even when that perspective seemed out of line with the world of feudal privilege, sanctified monarchy, and universal scripture-based religions in which they lived.

There was, however, at least one important political problem facing medieval philosophers that Aristotle had not addressed: the tension between secular and religious authority or, put more broadly, between reason and revelation. Some of the most important and interesting transformations of Aristotelian social thought developed out of the need to address this problem. Thomas Aquinas (1959), for example, used Aristotle's brief and cryptic remarks about the difference between natural and conventional right (in Book 5 of the *Nicomachean Ethics* 1956a) to reconcile reason and revelation. He argued that natural right was that part of the eternal law by which God governs the universe that human beings can know without the aid of scriptural guidance. In doing so, he founded the tradition of natural law thinking that continues to shape Catholic social doctrines, a tradition that is often, rather misleadingly, identified with Aristotle's own thinking about natural right. (When, for example, sixteenth-century Catholic thinkers debated whether slavery violated natural law or not, it was Aristotle's arguments in favor of slavery that proved decisive for many of them.) Marsilius of Padua (1956), in contrast, used Aristotle's theory of political community to justify the independence of politics from religious authority. He argued that it was consent of those who take turns in ruling, rather than any superior knowledge of God's will or the natural world, that sustains political authority. In doing so, he recruited Aristotle as an ally in the struggle for republican government and political autonomy.

2.2 *After the Revolution*

Aristotle's extraordinary authority for medieval philosophers made him a conspicuous target for many Renaissance and early modern critics of scholasticism, an approach to philosophy that Thomas Hobbes often ridiculed as 'Aristotelity.' Although his works continued to be read during these periods, it was not until the end of the eighteenth century and the reaction to the French Revolution that his social thought again played a prominent role in Western intellectual life, at least outside of the tradition of Catholic natural doctrines.

In the wake of the social upheavals of the French Revolution, many social critics came to view Aristotle's claims about the priority of the community to the individual as a healthy corrective to the

individualism and social contract thinking that had been popular among the Revolution's supporters. Echoes of Aristotle's claim that human beings are by nature political animals can be heard repeatedly in the writings of the Revolution's critics—even if they were at the same time careful to keep his defense of republican forms of government at arm's length. For them, Aristotelian social thought served as an alternative starting point for reflection on society and politics, rather than as, for medieval philosophers, an exemplary system of analysis.

2.3 After World War II

The postwar period has seen a variety of attempts to revive Aristotelian approaches to social and political analysis. All of these efforts present themselves as alternatives to what is perceived as the mainstream academic approach to the study of politics, society, and morality. Many are inspired by a sense that modern social science cannot explain—and may have even contributed to—the catastrophes of twentieth-century totalitarianism. For these latter-day Aristotelians, Aristotle's emphasis on the integration of normative and empirical analysis provides a better way of both explaining and resisting the seductions of nihilism and totalitarianism. For some, like Leo Strauss (1953), the key to this alternative social science is Aristotle's understanding of natural right, his sense that there is ultimately a natural basis for our judgments about political morality. For others, like Hannah Arendt (1958), it is Aristotle's understanding of citizenship as direct political engagement that is inspiring. Aristotelian social thought has, accordingly, been very influential among both conservative moralists and radical democrats in the postwar intellectual world.

In more recent years, it has been Aristotle's emphasis on community and the moral virtues that has drawn the most attention from students of social and political life. Aristotelian social thought, in this instance, provides a corrective to the limitations of liberalism rather than to the menace of totalitarianism. The most influential example of this contemporary reinterpretation of Aristotle is Alisadair MacIntyre's *After Virtue* (1984).

Any return to something like the authoritative status that Aristotelian social thought had in the Middle Ages seems extremely unlikely. But as a rallying point for critics of both liberal political philosophies and purely empirical forms of social science, the Aristotelian approach to the study of politics and society is likely to maintain its vitality for some considerable time.

Aristotle (384–322 BC)

1. Life

Aristotle remains the most influential philosopher of antiquity apart from Plato. Reactions against his philosophy marked the rise of modern science and political theory; some contemporary developments in the social and political sciences now involve a revival of aspects central to his thought.

Aristotle was born in Stagira (Chalcidice), the son of Nicomachus, physician to the Macedonian king, in

384 BC. At the age of 17 he moved to Athens and, for 20 years, studied and taught in Plato's Academy, the international centre of science and philosophy at the time. On the basis of his encyclopedic knowledge, Aristotle discussed problems posed by Plato, raising objections against his teacher's theory of Forms. At this stage, Aristotle developed his own positions in areas of the philosophy of nature, of ethics, metaphysics and rhetoric. He also developed the first known system of formal logic (syllogistics) and collected rules of dialectical and rhetorical argumentation (*topoi*).

After Plato's death, Aristotle left Athens for the first time, travelling for 12 years in the eastern Aegean. He stayed briefly (343–2 BC) at the Macedonian court of Philip II as tutor to his son Alexander (the Great).

Political changes allowed Aristotle to return to Athens, where he set up his own school in the Lyceum. Probably all his major treatises were written or finished during this period (335–4 to 323–2 BC), but of Aristotle's extensive oeuvre only a fraction survives. After Alexander's death and surges in political opinion against Macedonia, Aristotle was accused of impiety. To save the Athenians from committing a second crime against philosophy (referring to the death of Socrates), Aristotle left Athens for Chalcis where he died (322) at the age of 63.

2. *General Contribution to Knowledge*

Aristotle's philosophy represents a unity between systematically assembled and compared arguments, empirical data concerning language, nature and society, and a search for causes and first principles in terms of which these data can be understood. This effort is guided by an unprecedented quest for conceptual precision without loss of systematic and terminological flexibility. He establishes criteria and methods of inquiry that for centuries defined scientific knowledge and procedure. Aristotle's inquiries are the first to compartmentalise knowledge into separate theoretical, practical, and productive disciplines such as mathematics, the philosophy of nature, metaphysics, ethics, and politics, rhetoric and poetics. Aristotle is also the first to lay the foundations for psychology, biology, botany, anatomy, zoology, and geology.

Aristotle's ethical and political investigations and methods of inquiry in the area of human action have now become disputed paradigms of practical philosophy, but are of particular relevance for the social sciences. In contrast to an understanding of social/political sciences as independent of ethics, Aristotle argues for their mutual interdependence. He also elucidates the sense in which they deal with areas of knowledge that make specific claims to conceptual and methodological precision and truth. Theoretical accounts in these areas tend not to be exact in the same sense in which a science can be understood as 'perfect knowledge,' but nor are they imprecise. This special mode of reasoning does not render them inherently deficient as forms of knowledge. On the contrary, it makes them particularly suited for completing their proper task, for their goal is not theory pursued for its own sake but, as Aristotle argues, the alteration of praxis.

2.1 *Theory of Scientific Knowledge*

Aristotle regards it as a fact that 'all human beings naturally desire to know.' The resulting types of knowledge attain their ultimate end in an understanding of truth which implies universality and necessity, since it is based on knowledge of first principles. Although these are evident *per se*, they are frequently not well known to us. Scientific procedure, as described in the *Analytica*, involves two intrinsically related activities: the inductive-abstractive process (*epagoge*) leading from data commonly known to first principles which are frequently unknown, and the deductive process (*apodeixis*) of inference from self-evident first principles to subsequent statements. The first procedure originates in perception, imagination, memory, and experience, when the active intellect grasps the universal by collecting, comparing, and abstracting it from the manifold data presented to it by the passive intellect. Conversely, the deductive procedure of science that, for the most part, follows rules of formal logic, begins with first principles grasped by the intellect and deduces further sets of valid statements from them.

Although the program of presenting areas of scientific knowledge as deductive systems gave rise to the notion of science as knowledge *more geometrico*, only small portions of Aristotle's own scientific and ethicopolitical writings fit this pattern.

For Aristotle, the search for first principles, the clarification of difficulties involved in problem-solving, the elimination of unacceptable premises, and consensus are achieved most efficiently by disciplined discourse between researchers. Aristotle's method of dialectics, designed specifically to serve this purpose, involves continuous training in the use of *topoi*, mainly listed his *Topica*. They are especially suited for logically coherent reasoning based on reputable opinions, which may form the starting points of scientific inquiry or may represent essential elements of analysis within disciplines related to social sciences, such as ethics, politics, or rhetoric.

2.2 *Theoretical Sciences: Physics and Metaphysics*

Aristotle's treatise *Physics* attempts to explicate causes and principles of nature (*physis*). This involves the analysis of essential features of the process of natural change and of its sources which include teleology. In

the Aristotelian tradition, distinctions made in this context were also used for describing sociopolitical change. Whatever is in motion, changes from an actual state in which it is not yet whatever it is potentially, to another actual state in which it has become what it was potentially, provided that no obstacle occurs. In this context, 'matter' is the reality underlying all physical change, although matter is never actually found unformed. Whenever a new form is acquired, this also means the privation of the previous form. Matter (such as the bronze of a statue: material cause) and form (its shape: formal cause) are sources of change, just like that which initiates it (the artist's action: efficient cause) and the end for the sake of which the forming of the item was begun (final cause). Finally, Aristotle discusses the notion of an ultimate source of motion in the universe, which leads him to a concept of a prime unmoved mover different from nature.

The treatises collected as *Metaphysics* describe differing but related approaches to a 'first science' which underlies any particular area of knowledge: a science of principles and causes attributable to every being qua being (ontology), of basic constituents of reality (theory of substance), and of its prime constituent (theology). Elements of metaphysics comprise a theory of principles considered to be universal in thought and reality, such as the principle of non-contradiction. Aristotle's theory of substance distinguishes between substance as primary reality and its properties (accidents). 'Substance' denotes a concrete individual of a natural kind or the species that it exemplifies. Real in the strict sense are individual substances which exist actually and not only potentially. The highest rank among them is taken up by an entity characterized by immaterial, immutable, separate, and intelligent actual existence, called God.

Although Aristotle's theory of substance was replaced by later ontologies, his theoretical terminology of matter, form, potentiality, actuality, and causality had a lasting impact on the language of science and philosophy. The substantialist notion of individuals of a natural kind persists until today, and is implied by aspects of contemporary debates on the respective roles of social structure and human agency.

2.3 Practical Sciences: Ethics and Politics

The science presented in the *Politics* is based on a study of the history and development of 158 constitutions of Greek states, the *Constitution of the Athenians* being the only one that survived. It deals with the city-state (*polis*) which exists for the sake of the good life of its citizens, the culmination of a natural process of congregating. People can only flourish as human beings within this context, Aristotle considers. Flourishing as a human being (*eudaimonia*) is the ultimate end of human action. It is the primary concern of a type of ethical reflection that finds its most celebrated form in Aristotle's *Nicomachean Ethics*. Flourishing is based on intellectual and moral virtues. They are neither innate—as if teleology involved deterministic development—nor against nature. They must be acquired by instruction, by deliberate choice, and practice within a given ethos of a community. They include bravery, magnanimity, justice, or friendship. For the most part, Aristotle understands moral virtues as habits of manifesting, relative to our own capabilities, the optimum of a mean between too much and too little in any situation involving action or emotional response (this does not imply a quantifiable average, valid for everyone).

Whereas ethics studies forms of excellence as a human being, excellences of character and related intellectual habits such as practical wisdom (phronesis), political science examines societal institutions, constitutions, forms of government, and virtues as a citizen which are necessary for the good life and for the well-being of the whole community. Both disciplines attempt to explain how under ideal and less than ideal conditions these ends may or may not be achieved. They are intrinsically connected. Insofar as constitutions and legislation are committed to envisaging the city-state as 'a community in a good life in houses and villages with the aim of a life perfected in itself,' ethics is the discipline which also provides norms of human excellence for the household (economics) and for politics. Insofar as the notion of political science frequently takes on the wider meaning of practical philosophy it covers not only strategy, economics, and rhetoric but also ethics.

Since it is a characteristic feature of a human being not only to be a living being capable of reason (*zoon logon echon*) but also a being which dwells in city-states (*zoon politikon*), Aristotle distinguishes between two basic forms of life through which a person's ultimate end may be achieved: the theoretical life of contemplating unchangeable truth and the political life. Although the theoretical life promotes the highest form of activity, each form has a specific dignity of its own.

Not all forms of state, distinguished by differences between types of constitution or their distribution of offices, are equally conducive to a good life. A city-state may be governed by a single ruler, by small, or by large groups. These may govern in the interest of all or in their own interest. Consequently, Aristotle distinguishes between three basic features of correct government existing for the common good: kingship, aristocracy, polity, and three of deviant, self-interested character: tyranny, oligarchy, and democracy. His analysis of subtypes reveals their differing socio-economic bases and inherent tensions between rich and poor. Because of their effects on the polis, he pays special attention to sources of revolution and socio-political stability. These inquiries lead him to favor a 'mixed' constitution (polity) providing for peace.

Those who are neither rich nor poor should hold the balance of power, which is based on collective decision-making and the public promotion of human excellence. Since it is in conditions of peace that men live well, any city-state should provide for self-sufficiency and self-defence and hence avoid both economic or cultural dependence, as well as expansionist policies which risk enlarging the state, thus destroying it.

2.4 Productive Sciences or Arts: Rhetoric and Poetics

For Aristotle, rhetoric is the medium of political reasoning and hence a necessary element of political life, which depends on joint deliberations and decisions on the basis of public speeches for and against what should be done or avoided, praised or blamed, accused or defended. Consequently, the art of public discourse described in his *Rhetoric* is rooted in political science and ethics and the art of dialectical argumentation. Rhetoric consists in a method of discovering and convincingly presenting deliberations or presenting a case in the Assembly, on festive occasions of the state or at Court, and these concern matters that were, are or will be conducive or inimical, to the good life in a city-state. Knowledge of the rhetorical method also lays bare the structure of discourse that leads to error. This art is necessary for a culture of political oratory, in turn necessary for optimising decision-making, particularly in areas of human action where undisputed certainties are unavailable and reasonable arguments based on reputable opinions or probability are as much required as character and emotional commitment. Thus, Aristotle's paradigmatic type of rhetoric is the deliberative genus of the Assembly, rather than doctrinal teaching or forensic oratory.

The art described in the *Poetics*, dealing centrally with a theory of tragedy, has an equally practical and political function. Poets, in Aristotle's view (in opposition to Plato's), count among the best educators of a people. The specific task of a tragedy consists in leading members of the audience—while they empathize with the rise and fall of the hero of the drama—through woeful compassion and fearful alarm to a cleansing of their own most profound emotive dispositions to the way they live their lives as human beings in their polis and their cosmos. The dispositional balance reached by this process helps to reorganize citizens' relations to human flourishing. It also creates a bond of unanimity, necessary for the good life of a community.

Although rhetoric and poetics are arts (*technai*), they are not like mechanical arts for producing objects for use or consumption. their products are characteristic of human beings *qua* human: they are speeches or actions which relate to human praxis either thematically or representationally (*mimesis*), by revealing basic tensions and truths related to living a life as a human being. They are indispensable aids for the sociopolitical invention of a good life in finite time and the formation of cultural identity. Social science disregards their constitutive function for sociability only at the risk of substantial theoretical loss.

3. Aristotle and the Contemporary Social Sciences

No one denies the historically contingent character of Aristotle's theories or his practical concern with analyzing conditions of living well in a polis-community rather than in a modern nation-state. Yet neither are his thoughts entirely moulded by his historical situation, nor does the qualitative difference between the polis and modern society render them obsolete. Aristotle's descriptive and analytical work, particularly in connection with his theory of human action and his typology of aspects of constitutions, made the *Nicomachean Ethics* and the *Politics* classics of ethics and political theory. Basic concepts of Aristotle's practical philosophy are discussed in contemporary philosophy and political science.

Analytical as well as narrative theories of action, of human agency and the self (Ricoeur 1992) are based on Aristotle's ethics and poetics, which highlight the fact that a discussion of narrative and of its constituent structures not only concerns the nature and scope of social and political theory but also raises crucial questions about personal and cultural identity. Moreover, the focus on the practical impact of the relation between thought, emotions and character apparent in the *Rhetoric* is now reappearing in feminist and other contemporary approaches to sociology.

Insofar as a hermeneutical consciousness of human interaction is a necessary element of discovery and explanation in the social and historical sciences, they share family resemblances with practical rationality (*phronesis*) as described by Aristotle (Gadamer 1975). They involve research that strictly cannot be separated from the persons who possess and share this knowledge. Consequently, scientific reasoning about social interaction and institutions involves rhetorical forms of argument or reasoning with a practical purpose (Edmondson 1984).

The fundamental distinction introduced in the *Nicomachean Ethics* between praxis and productive activity, besides supplying reasons for esteeming praxis highly, functions as a critical tool for understanding the genesis of contemporary Western societies and their potential of providing a good life under conditions of labor (Arendt 1958).

Reference to an Aristotelian concept of praxis is also prominent in reconceptions of the political in communitarianism (MacIntyre 1985). They highlight the constitutive role of practices for a community, insofar as they are shared activities that are undertaken

not as means to an end but as choice-worthy in themselves. Their perceived importance for human well-being involves a reconsideration of central issues of Aristotelian virtue ethics and its guiding concept of the good life, as well as an analysis of features essential for functioning as a human being. For the most part, such reconceptions attempt to integrate sociocultural pluralism, involving a multiplicity of competing ideas of the good life. Such pluralism requires a conception of politics as basically deliberative, since reasoned social and political decision-making depends on creating joint convictions in areas of the contingent. This process depends on a rhetorical culture as a constitutive element of political culture. Since Aristotle's *Rhetoric* represents a synthesis of conceptual frameworks necessary for understanding the functioning of rhetorical culture, he provides a paradigm for developing a theory of political deliberative argumentation under pluralist sociopolitical conditions. Under the title of '*topoi*,' Aristotle's heuristic for systematically exploring and presenting whatever is potentially convincing has entered theories of (legal) argumentation (Perelman 1969) and social science/political science research (Hennis 1977). Even authors with a critical distance from neo Aristotelianism nonetheless adopt Aristotle's rhetorical heritage by discussing notions of deliberative democracy or politics. The scope and rigor of Aristotle's thought will no doubt continue to inspire generations of social scientists.

Arms Control

Arms control, a term popularized in the early 1960s, may be defined as the effort, between and among countries, to negotiate binding limitations on the number and types of armaments or armed forces, on their deployment and disposition, or on the use of particular types of armaments. It also includes measures designed to reduce the danger of accidental nuclear war and to alleviate concerns about surprise attack. Although the two terms are often used interchangeably, it is distinct from disarmament, which has the more ambitious objective of seeking to eliminate, also by international agreement, the means by which countries wage war (Blacker and Duffy 1984). The goal of eliminating war extends far back in history, but in modern times disarmament came into focus with the Hague Peace Conferences in 1899 and 1907. These and subsequent efforts met with what can only be termed limited success.

Schelling and Halperin, in their seminal work, *Strategy and Arms Control*, first published in 1961, listed three objectives for arms control: to reduce the likelihood of war; to limit the extent of damage should war occur; and to reduce expenditures on military forces. As US and Soviet weapons arsenals mushroomed during the Cold War and each country spent liberally to keep pace with the other militarily, later analysts tended to offer less sweeping goals. These

included reducing the number of nuclear weapons and redirecting the arms race into areas less likely to threaten the stability of the international system.

The end of the Cold War and the collapse of the Soviet Union gave rise to expectations, both at the expert level and among publics more broadly, that the sudden cessation of the superpower arms race would create opportunities for radical reductions in the nuclear and conventional weapons arsenals of the major powers.

Although the leading industrialized countries have taken some steps in that direction—US armed forces, measured in terms of total numbers, have declined by one-third since 1990—progress in eliminating the nuclear-weapons stockpiles of the US and Russia has proven to be an elusive goal. To compound the problem, the number of nuclear-armed states has actually grown in recent years as India and Pakistan, in a series of highly publicized weapons tests in 1998, announced their arrival as full-fledged nuclear powers. The means to deliver these weapons, as well as chemical and biological agents, across hundreds (and even thousands) of miles has also spread as countries such as North Korea, Iraq, and Iran continue to invest heavily in programs to develop and deploy long-range ballistic missiles.

Arms control, particularly between the US and the Soviet Union, aroused controversy from the outset. The Limited Test Ban Treaty, signed by representatives of the US, the United Kingdom, and the Soviet Union in 1963, provoked sharp debate when US president John F. Kennedy submitted this arms control 'first' for Senate approval. Some critics saw the treaty, which prohibits the testing of nuclear weapons above ground, under water, and in space, as unenforceable. These and other concerns notwithstanding, the treaty eventually was ratified and fears of Soviet noncompliance proved to be unfounded.

More favorably received in the US was the United Nations-sponsored Nuclear Non-Proliferation Treaty (NPT), which sought to restrict the size of the 'nuclear club' by inducing non-nuclear weapons states to renounce the acquisition of such weapons in exchange for a commitment (among other pledges) on the part of the nuclear-weapons countries to reduce their own arsenals. The NPT, which entered into force in 1970, was renegotiated in 1995, at which time the signatory states agreed to extend the treaty's provisions for an unlimited period of time. Conspicuous by their absence as states-parties to the NPT are the two newest declared nuclear powers, India and Pakistan, as well as Israel, which is believed to possess a small but sophisticated arsenal of nuclear weapons.

The NPT was critically important in facilitating the start of bilateral US–Soviet negotiations in 1969 to limit central strategic forces. Known by the acronym SALT, for Strategic Arms Limitation Talks, the negotiations resulted in two arms-control agreements in 1972. The first and more important was the Antiballistic Missile (ABM) Treaty, by which the two countries agreed to limit the number of ABM sites and thus not deploy nationwide defensive systems to protect their homelands against nuclear-missile attack. The second accord was a 5-year freeze on the construction of long-range land- and sea-based ballistic missile 'launchers' (underground silos and submarine missile tubes, respectively). The so-called Interim Agreement on Offensive Weapons was a temporary measure to slow the competition in offensive weaponry, pending negotiation of a more permanent and restrictive treaty (Newhouse 1973).

The second phase of the negotiations, lasting from 1972 to 1979, led to the signing of several agreements, including an accord further limiting US and Soviet ABM deployments and the 1974 Threshold Test Ban Treaty, which restricts the yields of underground nuclear weapons tests. The most important agreement concluded during this period was the 1979 SALT II treaty, a lengthy and complex document that attempted to extend and refine many of the provisions of the 1972 Interim Agreement (Talbott 1979). The US Senate never ratified the treaty, however, largely because of the dramatic deterioration in superpower relations that began during the abbreviated administration of President Gerald Ford and accelerated during the term of his White House successor, Jimmy Carter. Despite the ambiguous legal status of the treaty following the failure to obtain its ratification, both the US and the Soviet Union abided by most of its provisions well into the 1980s.

Negotiations on US and Soviet strategic nuclear forces, renamed the Strategic Arms Reduction Talks (START) by President Ronald Reagan, resumed in the summer of 1982. Through the remainder of Reagan's presidency, the two sides reached consensus on many key points, including the desirability of 50 percent reductions in long-range nuclear forces and the need for intrusive, on-site inspections to prevent cheating.

Among the issues not resolved was how to construct the preferred relationship between strategic offensive and defensive forces. In a dramatic reversal of its earlier negotiating position, the US now favored the rapid development and deployment of nationwide defensive systems, as shown by its sponsorship of the Strategic Defense Initiative (SDI), first outlined by Reagan in March 1983 in a nationally televised address (Fitzgerald 2000, Nolan 1989). The Soviet Union was sharply critical of SDI and resisted the conclusion of any new agreement to reduce strategic offensive weapons, pending a commitment by the US to abide by the terms of the ABM treaty, narrowly interpreted, through at least the end of the century.

The rise to power of the Soviet leader Mikhail Gorbachev in 1985 signaled a fundamentally new phase in arms control. One of Gorbachev's most important foreign policy objectives was to curtail sharply the political rivalry between the USSR and the

West by, among other steps, delimiting their military competition. The first major result of this policy was the Intermediate-Range Nuclear Forces (INF) Treaty, concluded in 1987, which eliminated all US and Soviet land-based nuclear missiles with ranges between 500 and 5,500 kilometers. This was followed in 1990 by a treaty to reduce conventional forces in Europe (CFE), signed by 22 member-states of the North Atlantic Treaty Organization (NATO) and the now-defunct Warsaw Pact. At about the same time, US and Soviet negotiators completed work on the long-awaited START treaty, and in July 1991, President George Bush traveled to Moscow to join Gorbachev in signing the accord. Less than 6 months later, Gorbachev—the architect of the most ambitious reform program in the 74 year history of the Soviet Union—resigned as president and the USSR ceased to exist.

At a hastily called summit meeting in June 1992, Bush and Russian Federation president Boris Yeltsin agreed to press for early ratification of the START treaty. They also pledged to conclude a second and more ambitious agreement to reduce US and Russian strategic nuclear arsenals by up to two-thirds within a decade and to eliminate all multiple-warhead land-based missiles. Some 2 weeks before the inauguration of Bill Clinton as US president in January 1993, the two sides made good on their promise and concluded the START II treaty. As relations between the US and Russia deteriorated during the second half of the 1990s, the treaty itself languished; although finally ratified by both sides, nearly a decade after its signing most of the agreement's provisions still had not been implemented.

The US–Russian arms-control agenda has also been complicated by the confused, and confusing, nuclear legacy of the Soviet Union. In the wake of the Soviet collapse, four of the country's now independent republics, including Russia, found themselves in possession of thousands of nuclear weapons and hundreds of long-range delivery systems. Under pressure from Russia and the West, in May 1992 the governments of Belarus, Kazakhstan, and Ukraine promised to abide by the terms of the 1991 START I agreement and to join the NPT as non-nuclear weapons states. With financial and technical assistance from the US, all nuclear warheads and their associated missile systems deployed on Belarusian, Kazakh, and Ukrainian territory eventually were disarmed and dismantled. The denuclearization of the three former Soviet republics constitutes the most important—and perhaps the only unambiguous—arms control success story of the 1990s.

The abrupt end of Soviet rule gave rise to a second kind of security problem for which policymakers everywhere were ill prepared. The frequency and intensity of ethnically and religiously inspired conflicts in such heretofore remote parts of the former USSR as Tajikistan and the southern Caucasus increased dramatically following the collapse of central authority in Moscow. The breakdown of political control in these and proximate regions, coupled with the extreme poverty that afflicted many of the people caught in the fighting, served both to prolong these struggles and to frustrate diplomatic efforts to contain them.

In addition, the unraveling of the Soviet Union's alliance relationships left a number of countries politically orphaned and therefore less secure. This too served to increase regional instability. It also encouraged some states—North Korea being a case in point—to seek to develop nuclear weapons of their own despite the determined opposition of the major powers, especially the US.

At the start of the twenty-first century the most important challenge to arms control, however, is the prospective change in the relationship between long-range, offensive nuclear forces and weapons designed to defend against them. For the last 40 years, what Philip Green characterized in the mid-1960s as the deadly logic of nuclear deterrence helped preserve the uneasy truce between Washington and Moscow. In its simplest form, deterrence held that no rational leadership in possession of nuclear weapons would ever intentionally authorize their use against a nuclear-armed adversary because of the near-certain knowledge that the victim of such an attack would retaliate in kind. With effectively no ability to ward off or deflect such a retaliatory strike, the would-be aggressor would thus be deterred from initiating a nuclear exchange in the first place (Brodie 1965, Schelling 1960).

As the capacity to build nuclear weapons spreads to countries other than the so-called great powers, interest in acquiring the means to defend against their possible use has grown, particularly in the US. Even a comparatively modest system of active defenses—one designed to defeat a handful of incoming ballistic missile warheads launched from whatever quarter—arouses concern, however, because of the latent ability of such a system to expand and improve over time. The larger and more robust a system of national missile defense becomes, the better it will be at defending against more complex threats. The more able it becomes, in other words, the more threatening it will seem to the more established nuclear powers, including Russia and China, for whom the unchallenged ability to retaliate with overwhelming force constitutes the bedrock of their security (Wilkening 2000). According to the classic tenets of arms control, the large-scale deployment of strategic defensive systems could therefore erode stability and increase the likelihood of war.

It is probably not beyond human ingenuity to design and construct a 'mixed' strategic environment that allows for a modicum of defense while preserving nuclear deterrence in its essentials. Given the understandable urge to escape the persistent threat of nuclear annihilation, it seems safe to assume that governments will persist in their efforts to square this

strategic circle. Policymakers everywhere would do well to remember, however, that nuclear deterrence, for all its flaws, has kept the peace for half a century, and that any attempt to replace it with something else is likely to entail serious risks and potentially enormous costs.

Aron, Raymond (1905–83)

The life and works of Raymond Aron coincide with the period of conflicts generated by ideologies. Born in 1905, twelve years before the Bolshevik Revolution, he died in 1983, in the middle of the European missile crisis, the last event of the Cold War before the fall of the Berlin Wall in 1989.

1. Chronology

Raymond Aron was born on March 14, 1905 in Paris into a family of Jewish origin, completely integrated into patriotic and republican society. A brilliant student, he went to the Ecole Normale Supérieure, where he became friends with Sartre and Nizan, and then went on to the *Agrégation de Philosophie*. Germany in the 1930s revealed to him the violence of history, and drew him into a critical attitude and a personal approach which made him unique among the French intellectuals of the twentieth century. In the tradition of Montesquieu, Constant, Tocqueville, and Elie Halévy, he is the most eminent representative of liberal thinkers in France in the twentieth century.

From 1930 to 1933, Aron stayed in Cologne and in Berlin. The rise of Nazism led him to break with the socialism and pacifism of his youth. Reading Max Weber and the phenomenologists—particularly Husserl and Heidegger whom he introduced in France—took him away from the idealism and positivism which at that time dominated the French academic philosophy. The doctoral thesis he defended in 1938 dealt with the philosophy of history; it created a scandal in the French university by using epistemological doubt to criticise positivism in the field of social sciences. Called up in 1939, Aron answered General de Gaulle's call in June 1940 and reached London, where he edited the review *La France Libre* until the Liberation. The Second World War represented a major upheaval, with the quadruple shock of defeat, exile, dismissal from the university following the status of Jews as applied by Vichy, and finally of genocide. During the Cold War, Aron identified himself, with André Malraux as one of the few well known intellectuals to oppose the attraction of communism in France and to participate in the Congress for Cultural Freedom, created to contain Soviet influence throughout the world. As a result this isolated him completely. He pursued a double career up to his death in 1983, first as a university professor, at the Sorbonne and later at the Collège de France, after an interim period at the Ecole des Hautes Études, and second as a journalist, at *Combat*, then at *Figaro* (1947–77) and finally at *L'Express* (1977–83). He was faithful to the choice of vocation he had made in the 1930s, to be a committed witness trying to reflect on history and politics as they happened. He was fully recognized outside France where he was held by academics and politicians to be an interlocutor of the first order. At the end of his life, Aron became reconciled with French intellectuals, at the same time as they were converted to the fight against totalitarianism following the disclosures on the Gulag by Solzhenitsyn as well as with the general public which welcomed enthusiastically his *Mémoires* (Aron 1983). He died on October 17, 1983 in Paris.

2. Works and Beliefs

Aron defines his works as:

> a thought on the twentieth century, in the light of Marxism, and an attempt to throw light on all areas of modern society: economics, social relations, class relationships, political systems, relationships between nations, and ideological discussions.

Freeing himself from the traditional separations between disciplines, his thoughts have covered many

areas of knowledge, mainly philosophy, sociology, international relations, ideological controversy, and commentaries on current events. They find their unity, however, in the idea of the condition of man as presented in his thesis, *Introduction à la Philosophie de l'Histoire* (1938), whose meaning can be summarized in the formula. 'Man is in history; man is historical; man is a history.' Human existence is tragic, as each of us is forced to make decisions about one's destiny from partial knowledge and with limited powers of reasoning. For all that, it is not condemned to nihilism and despair, as one's commitment allows one to overcome the relativism of history and knowledge to reach a portion of freedom and truth. According to Aron, freedom is first, this primacy being historical and not metaphysical. The idea of modern freedom became clear in Europe in the Age of Enlightenment, then gained strength in the presence of the industrial society of the nineteenth century, and later with the resistance against totalitarianism.

Aron stands out by his early understanding of ideologies whose hostility to democracy give structure to the twentieth century. From the end of the 1930s, he showed, with Elie Halévy, the novelty and the common features which united Fascism, Nazism, and Communism, while proving that before all they were fighting democracies. Contrary to Hannah Arendt, Aron does not think of either democracy or totalitarianism in terms of essence, but as historical constructions mixing a general design, institutions, and the action of men such as Lenin and Stalin, Mussolini and Hitler, Churchill and de Gaulle. After the war, he was also the first French intellectual to give a correct interpretation of Cold War—which he defined with the formula 'Peace impossible, war unlikely'—and of nuclear deterrence. Through his critical commentary of Marx—where he separates the sociologist of the industrial civilization from the prophet of the revolution—and of the French Marxists—primarily among them Sartre, Merleau-Ponty, and Althusser,—Aron proved the impossibility of reconciling historical determinism with human freedom, and contrasted the development of Western economies with the prediction of an unavoidable crisis of Capitalism.

The comparison between liberal and socialist systems also nourished the sociology of industrial societies—*Dix-huit Leçons sur la Société Industrielle* (Aron 1962a), *La Lutte de Classes* (Aron 1964), *Démocratie et Totalitarisme* (Aron 1965a). For Aron, 'an industrial society is one in which big companies constitute the typical form of the organization of labor,' which accompanies the accumulation of capital and the generalization of economic calculus. The common features of the capitalist and communist systems do not mean their convergence, as their political structures remain completely opposed. Pluralism is in conflict with the one-party system, fundamental liberties with a state truth, the autonomy of organized forces in society with their control, the constitutional state with an oversized machinery of repression, market economy with centralized planning. The primacy of political variables excludes any symmetry between the two blocks. Aron is against pluralism or market economy being made into values. They are of means and not ends. Political liberalism separates itself from the utilitarian tradition, of which the most complete version in the twentieth century is to be found in Hayek's *The Constitution of Liberty*. He assigns a most important role to the state, whose task is to establish civil rights within a society and to defend the sovereignty of a country in the field of international relationships.

The study of international relations is indispensable to counterbalance the analysis of industrial society: on the one hand, the rise of violence with the alternation of war and peace, and the fighting of nations and empires; on the other hand, the working of commercial society, based on peaceful competition, and conveying an individualism which attempts to free itself from state tutelage. He was introduced to strategy, while staying in London, through the analysis of the theater of operations in World War II, and he participated in the thinking on the use of nuclear weapons very early on and was a regular commentator on international events. Aron put forward in *Paix et Guerre* (Aron 1962b) a theoretical interpretation of the world diplomatic and strategic system, based on the key role of the states, the only arbitrators in case of armed conflicts. Recognizing the pre-eminence of sovereign states led Aron to be seen outside France as the thinker behind the foreign policy of General de Gaulle, while he was considered in France the most severe critic of de Gaulle's grand design. *Penser la Guerre*, *Clausewitz* (Aron 1976) continues the exploration of conflicting relationships between violence and reason, sovereignty and empires. From the ambivalence of Clausewitz, who was the theoretician of total war and limited conflicts, the rise to extremes and the control of force, Aron shows how the different patterns of international relations in the twentieth century, a European inheritance from the nineteenth century, the interwar period, and the Cold War, combine the passions of peoples and the interest of states, a strategic global view, and an unstable balance between rival powers.

At the same time as his university work, Aron exercised an increasing intellectual and moral authority on French opinion through his columns in *Figaro* and *L'Express* as well as through his papers which threw light on the political crises of the country. From 1957, he pronounced himself in favor of Algerian independence, explaining its inevitable nature. Even a military victory could not prevent a political defeat, as France was fighting in Algeria the ideals which she had claimed for herself from the Revolution, primarily the right of nations to self-determination. In 1968, he analyzed the events of May as a pseudo-revolution in which the extravagance of ideological speeches con-

cealed the lack of a political plan, leading to a nihilism destroying the Republic as well as the University *La Révolution Introuvable* (Aron 1968b). *Les Désillusions du Progrès* (Aron 1969a) develops a meditation on the disenchantment of democratic societies, while the *Plaidoyer Pour l'Europe Décadente* urges rich and vulnerable Europe to find again a major role in politics avoiding the alternatives of integration within the US sphere of influence or subservience to the Soviet empire.

Aron's thought combines a philosophy of history and a moral doctrine in action which rests on the wisdom of statesmen and the commitment of citizens. He rejects the traditional separation between liberalism, which underestimates the weight of history, the strength of violent passions, and the clash of ambitions, and politics, ready to be exonerated from any link with truth and reason. The structure of the multiple aspects of modern societies thus allows one to find out the complex interactions between the organizational transformations, the play of political forces and rival interests, and the ultimate freedom of people to finally '…create their own history, even if they do not know the history they are creating.' Hence, a method at the same time realistic, probabilistic, and dialectical. Realistic, because it refuses any transcendental principle and continuously claims for itself a moral doctrine of responsibility; probabilistic, because it tries to throw light on the complexity of decisions in history by studying the range of possibilities; dialectical because it refuses any determinism and any Manichaeism to take on the complexity and uncertainty which only can allow the resolution of the conflict between the unpredictable side of history with the search for knowledge and the hope of a common vocation for humanity.

This approach breaks with that of most twentieth century French intellectuals who have tried to think about power, whether Alain, Malraux, or Sartre. Alain's ambition was to draw up permanent rules which should govern the relationships between citizens and the governments, from an equilibrium between the liberating principle of universal suffrage and the resistance to alienation. Hence there was a disregard for history and a pacifist commitment which tragically ignored the menace of totalitarianism. Malraux meant to give sense and dignity to man by his revolt against destiny, by a commitment to a cause, and by his participation in an epic, in this case that of General de Gaulle from 1945. Between indifference and adhesion, Sartre, as Aron, claims to represent critical commitment, but this remains abstract, in a state of weightlessness in relation to history. Sartre postulates a radical freedom of conscience, liberated from time and space, composed by the exaltation of violence. Conscience finds itself enslaved and solitary and frees itself through collective revolt, confirmed by terror. This individualistic ontology which attributes an almost mystical function to violence espouses closely the prophetic dimension of Marxism, and is the starting point for Sartre's long association with communism. Aron opposes him by asserting the reinstatement of history in the field of politics and the role of institutions, which open up a possibility for men to act on their future as well as a field for reform of free societies. In the face of these pacifist, epic, or revolutionary visions, Aron defends relentlessly the existence and the rights of a government both fully liberal and fully responsible.

Raymond Aron's liberal political science finds its ultimate horizon in the wager laid on the idea of reason, in the meaning of Kant. At the point of maximum tension between the universal and the particular, it gives its meaning to the commitment of man in history. Aron respected religious faith for which he reserved a space to which he did not enter, the idea of a revelation or of a sacred history remaining fundamentally foreign to him. He considered, however, reason as a 'hidden universal,' which, by freeing man from natural condition and historicity, opens the possibility of a reconciliation between power and liberty. After the death of God and the end of ideologies, in the midst of the fight against the barbarity of genocide and the mass terror of totalitarian regimes, Aron elaborates and sketches the outline of moderate and intelligent policies which mobilize the forces of freedom and man's reasoning to contain the explosion of passions and violence. He reminds statesmen that there is something above politics, Truth. He reminds men of science and of faith, that there is only incomplete knowledge and there is no true commitment if not free. Between the reasoning of power and the power of reason, Aron's moderate realism bases democracy on the fragile equilibrium of tensions which it generates and from which freedom is nourished, on the appreciation of compromise which allows liberty to take roots for a long period. He was a patriot and a cosmopolitan, a relentless adversary of totalitarianism and spokesman of universal history, and he is one of the modern thinkers of freedom and its contradictions in the twentieth century. His views on the power of the citizen are still current, in a world where the disillusionment of free nations is in contrast with the aggressive renewal of feelings of national identity, in a postwar period which must reconcile at the same time the utopia of a world based on the coming of market democracy and the warlike fatalism of a clash of civilizations which would place the twenty-first century in a confrontation of cultures, following those of nationalisms in the nineteenth century and of ideologies in the twentieth century.

3. *Summary*

Raymond Aron, as with other great liberal thinkers, was too respectful of each person's freedom and too

influenced by the principles governing methodological individualism to found a school of thought. But his mark in French political history and thinking was just as profound due to the fact that, far from relying on a network of disciples and institutions, it was anchored in an intellectual heritage which transcends partisan differences or academic studies. Aron succeeded in continuing and revitalizing, in the midst of the century of ideologies, the tradition of French political liberalism, in particular through the creation and development of the reviews *Preuves*, *Contrepoint*, and *Commentaire*. In France, his attitude and his writings—particularly the publication of *L'Opium des Intellectuels* Aron (1955)—contributed decisively in progressively detaching the intellectuals from Communism and, from there, to the resistance of French society to Communism. At the same time, Aron's action and thinking were of tremendous importance in the conversion of a large part of governmental and administrative elite to the Atlantic Alliance and the building of the European Community. Abroad, he acquired a huge moral notoriety and had a privileged relationship with numerous scholars, philosophers, and statesmen, such as Henry Kissinger with whom he maintained a frequent dialogue. Aron thus was a unique example of a twentieth-century French intellectual who was both patriot and European, republican and liberal, antitotalitarian and cosmopolitan. In the face of collective passions and demagogy which overtake regularly democracies in general and French political life in particular, Aron played the major part, according to Claude Lévi-Strauss of a 'teacher of intellectual hygiene.'

Arousal, Neural Basis of

One of the most important discoveries in the early years of brain research was that by Moruzzi and Magoun (1949). They reported that electrical stimulation of the brainstem of the anesthetized cat produced a pattern of electrical activity recorded from the cerebral hemispheres that was identical to that observed in an awake, alert cat. This pattern was elicited by stimulation of the reticular formation, a diffuse area of neurons and axons, and was characterized by low voltage fast activity, or LVFA, in the electroencephalogram (EEG), which is the record of the electrical activity of the outermost region, or neocortex, of the cerebral hemispheres. LVFA is commonly referred to as neocortical arousal or EEG desynchronization. It replaced the high amplitude slow wave activity pattern that characterized the anesthetized or sleeping cat, and it is considered to be the most prominent index of arousal, alertness or vigilance. With this discovery, the concept of the ascending reticular activating system (ARAS) was established, a system that was believed to maintain the neocortex in an energized, alert state required for the most efficient processing of incoming

information. Soon thereafter the search began for the exact brain substrates in terms of the neurochemistry and brain pathways that contributed to maintaining the neocortex in this energized state, as described below.

1. Forebrain Contributions to Arousal: The Nucleus Basalis of Meynert

Research following the discovery of the ARAS suggested that brainstem neurons within this system contained the neurotransmitter, acetylcholine (ACh), and that they sent projections to widespread neocortical areas where they released ACh to maintain neocortical arousal. Support for this hypothesis was based on several observations. First, greater amounts of ACh were released in the neocortex during LVFA than during high amplitude slow activity. Second, electrical stimulation of the reticular formation elicited ACh release in neocortex. Third, pharmacological agents that blocked the receptors for ACh reduced LVFA in the awake, behaving animal (see Steriade and Biesold 1990 and Dringenberg and Vanderwolf 1998 for reviews of this early research).

As research on the ARAS progressed, several important observations suggested that this early hypothesis needed modification. First, complete transection of the presumed connections from the reticular formation ARAS to the neocortex did not result in a permanent loss of LVFA. Second, ACh containing neurons of the traditionally defined brainstem ARAS were not found to project directly to the neocortex, suggesting the existence of structures located more rostrally in the brain that were capable of sustaining neocortical arousal via the release of ACh. With the development of more sophisticated neuroanatomical techniques, it became clear that major groups of ACh-containing neurons exist in the forebrain and that one group, the nucleus basalis of Meynert (NB), sent widespread projections to the neocortex (Wainer and Mesulam 1990).

More recent research has demonstrated that the NB projection to the neocortex is a major contributor to neocortical arousal. Several lines of evidence support this conclusion (see Steriade and Buzsaki 1990). First, stimulation of the NB elicits LVFA and results in an increase in the extracellular concentration of ACh that depolarizes neocortical sensory neurons, thereby enhancing their response to sensory stimuli. This depolarization is the basis for the observed LVFA and creates a stand-by mode for the most efficient processing of incoming information by neocortical neurons. Second, lesions of the NB that markedly decrease neocortical ACh result in an increase of high-amplitude slow wave activity in the EEG similar to that observed following administration of drugs that block ACh receptors and that are commonly referred to as cholinergic receptor antagonists. Third, the activity of neurons in the NB that project to the neocortex demonstrate significant, positive correlations with the amount of neocortical arousal; that is, the greater their activity, the greater the amount of LVFA. Fourth, stimulation of the NB enhances the response of sensory cortex neurons to sensory stimuli. These accumulated results strongly suggest that NB cholinergic neurons function in neocortical arousal and create a neocortical state for the optimal processing of information; in essence, a physiological correlate of arousal.

2. Brainstem Contributions to Arousal: Cholinergic, Noradrenergic, Serotonergic, and Histaminergic Neuronal Groups

2.1 The Ch-5 Cholinergic Contribution to Arousal

Recall that Moruzzi and Magoun (1949) reported that electrical stimulation of the reticular formation elicited neocortical arousal in the cat. Recent research has demonstrated that ACh containing neurons are located in this region. This group of neurons has been designated as the Ch-5 cholinergic cell group (Wainer and Mesulam 1990). Neurons within the region where the Ch-5 group is located project to the region of the NB, and electrical stimulation of the Ch-5 region activates neurons in the NB that demonstrate positive correlations with neocortical arousal (Detari et al. 1997). This projection, therefore, offers a pathway by which stimulation within the traditionally defined ARAS elicits neocortical arousal via an influence on the NB. Importantly, however, the majority of the neurons that project from the Ch-5 cell group to the NB are not acetylcholine containing (Jones and Cuello 1989). This suggests that the stimulation-induced neocortical activation from the Ch-5 region is not due to activation of Ch-5 cholinergic neurons but perhaps to activation of neurons containing the excitatory neurotransmitter, glutamate.

While the cholinergic neurons of the Ch-5 group do not appear to contribute to neocortical arousal via an influence on the NB, they nevertheless make a significant contribution to arousal via their release of ACh on neurons of the thalamus that receive sensory information directly from the sense organs. For example, Ch-5 neurons project directly onto neurons of the dorsal lateral geniculate nucleus (dLGN) (Wainer and Mesulam 1990). The latter receive information directly from the retina and transmit that information to the visual neocortex for further processing. When active, Ch-5 neurons release ACh on to dLGN neurons which influences these neurons in a manner identical to the influence of ACh on neocortical sensory neurons. It depolarizes them, making them more sensitive to incoming sensory information (Steriade and Busaki 1990, McCormick and Bal 1997).

Thus, Ch-5 ACh neurons, similar to the influence of NB ACh neurons on the neocortex, enhance the processing of incoming information in the sensory thalamus.

2.2 The Serotonergic Contributions to Arousal

While antagonists of ACh receptors have been demonstrated to block neocortical arousal, these antagonists do not block neocortical arousal under all conditions. It has been convincingly demonstrated in the rat that the neocortical arousal that accompanies certain types of behaviors such as walking, stepping, head movements, rearing, postural adjustments or spontaneous limb movements occurs in the presence of cholinergic receptor antagonists. However, neocortical arousal that occurs during grooming, licking, chewing and immobility behaviors is lost (Dringenberg and Vanderwolf 1998). Additional research has demonstrated that antagonists of the neurotransmitter, serotonin (5-HT), block neocortical arousal accompanying the former group of behaviors (Dringenberg and Vanderwolf 1998). The raphe nuclei, a series of serotonin containing cell groups within the midbrain, provide a rich serotonergic projection to the neocortex. Electrical stimulation of the raphe nuclei produces neocortical arousal that is blocked by serotonergic receptor antagonists, whereas selective destruction of serotonergic cells in the raphe nuclei abolishes the neocortical arousal that is resistant to cholinergic receptor antagonists. Additional research has demonstrated that injections of serotonergic antagonists directly into the neocortex can block neocortical arousal produced by noxious stimulation, thereby suggesting that 5-HT, similar to the actions of ACh, works directly at the level of the neocortex to elicit neocortical arousal (Dringenberg and Vanderwolf 1998).

The fact that 5-HT has been reported to depolarize neocortical cells and enhance their excitability is consistent with its ability to produce neocortical arousal (McCormick 1992). It, therefore, appears that both the serotonergic and cholinergic systems contribute to neocortical arousal by direct actions on the neocortex. Indeed, it has been demonstrated that the combined application of cholinergic and serotonergic receptor antagonists completely blocks neocortical arousal accompanying all behaviors, suggesting that other areas which contribute to neocortical arousal may exert their effects via an action on either the serotonergic and/or cholinergic systems (Dringenberg and Vanderwolf 1998). One such area that appears to exert such an indirect effect is the locus coeruleus (LC), as described below.

2.3 The LC Noradrenergic Contribution to Arousal

The LC, more than any other brain structure, possesses the most extensive connections with other brain areas. It comprises a small group of neurons in the dorsal brainstem that contain the neurotransmitter, norepinephrine (NE). The widespread projections of the LC to the neocortex makes it a prime candidate for a function in arousal. Indeed, much research over the years has strongly implicated the LC in neocortical arousal. Perhaps the most compelling evidence for this function derives from the demonstration in rats that infusions into the LC of a small volume of an agent that excites LC neurons elicit a shift from neocortical high amplitude slow wave activity to LVFA (Berridge and Foote 1994). There also appeared a shift in the EEG recorded from the hippocampus to one of intense theta wave activity, an activity pattern that is observed in concert with neocortical arousal. These effects were blocked by intraperitoneal injections of a NE receptor antagonist. Contrariwise, infusions into the LC of a small volume of an agent that inhibits the activity of LC neurons produced a shift in the neocortical EEG from LVFA to high amplitude slow wave activity and abolished hippocampal theta wave activity. Infusion sites within 0.5mm of the LC were without effect. Additional research is consistent with these observations. For example, recordings taken from LC neurons in the monkey demonstrated that their activity correlated positively with neocortical arousal; that is, they showed increased activity during LVFA during waking and decreased activity during high amplitude slow wave activity during drowsiness (Aston-Jones et al. 1996). Finally, the LC is the sole source of NE in the neocortex, and NE applied to neocortical sensory neurons decreases their spontaneous firing rate while enhancing their response to sensory input; in essence, increasing the signal-to-noise-ratio of the neuron. A similar action for NE on thalamic sensory neurons has been observed (McCormick 1992).

The accumulated results suggest that the LC, when active, releases NE in the neocortex which in turn elicits neocortical arousal. Recent research, however, suggests that the LC exerts its effect indirectly since antagonists of cholinergic receptors block the effects of LC electrical stimulation on neocortical arousal (Dringenberg and Vanderwolf 1998). Consistent with these findings is recent research demonstrating that the effects of NE on the neocortical EEG are exerted by an excitatory action on the cholinergic cells of the medial septum which influences neocortical arousal in as yet an unknown manner (Berridge et al. 1996). Nevertheless, the noradrenergic neurons of the LC appear to play an important role in neocortical arousal, although an indirect one.

2.4 Histaminergic Contributions to Arousal

It has long been recognized that antihistamines produce drowsiness accompanied by high amplitude slow wave activity in the EEG. Research has demonstrated that the sole source of histamine-containing neurons in the brain originates in a structure called the

tuberomamillary nucleus (TM) located in the basal hypothalamus and that these neurons send widespread projections to many brain areas including the neocortex (Inagaki et al. 1988). Antihistamines are antagonists of histamine receptors, and their effects on behavioral state and the EEG strongly implicate the histamine-containing neurons of the TM in neocortical arousal. Numerous observations support this hypothesis. For example, selective activation of histaminergic receptors by intracranial injections of histamine elicits neocortical arousal whereas chemically induced inactivation of TM neurons produces high amplitude slow wave activity in the EEG and sleep (Lin et al. 1989, Tasaka et al. 1989). Finally, TM neurons in the cat have been observed to be most active in the aroused, awake, state but demonstrate decreased activity during high amplitude slow wave activity indicative of slow wave sleep (Vanni-Mercier et al. 1984).

Histamine has been shown to depolarize neurons, rendering them more likely to fire in response to incoming information (McCormick 1992). This action is similar to that observed for ACh and 5-HT and could result in neocortical arousal. Some recent evidence, however, suggests that histamine's effect on neocortical arousal, like the effect of NE, may be indirect. For example, neocortical arousal is still present after large depletions of brain histamine, suggesting that histamine is not essential for neocortical arousal (Dringenberg and Vanderwolf 1998). This observation has led to the suggestion that histamine may exert its effects on neocortical arousal via modulation of the cholinergic or seronergic arousal systems (Dringenberg and Vanderwolf 1998).

3. *Modulation of Neocortical Arousal Systems*

The research described above suggests that the cholinergic, serotonergic, noradrenergic, and histaminergic systems contribute either directly or indirectly to neocortical arousal. Given these contributions, an important question arises concerning the environmental stimuli that activate these different systems and that would, in turn, enhance neocortical arousal. Insight into the answer to this question derives from research describing the neuronal responses of these systems to environmental stimuli. Recall from the previous discussion that the spontaneous activity of NB, LC, and TM neurons correlates with the state of neocortical arousal. They demonstrate increased frequency during LVFA during waking, and decreased frequency during high amplitude slow wave activity indicative of drowsiness and sleep. It is important to emphasize, however, that the spontaneous activity of NB and LC neurons is markedly increased by the presentation of stimuli that elicit neocortical arousal and that are relevant to the survival of the organism. For example, novel stimuli that signal a change in the environment, or conditioned, emotionally-arousing stimuli that predict the imminent occurrence of either an important pleasant or unpleasant event, elicit significant increases in activity in NB and LC neurons (Aston-Jones et al. 1996, Richardson and DeLong 1991, Whalen et al. 1994). Presumably, these increases in activity would serve to create a brain state for the most efficient processing of environmental information. This would contribute to the organism's welfare in the face of a changing environment or in the presence of stimuli which are predictive of events of import to the organism's welfare. Research is now underway to determine the brain pathways and structures that serve to convey these stimuli to these arousal systems. For example, neurons located in the amygdala project to the NB and respond to novel as well as conditioned, emotionally arousing stimuli (Kapp et al. 1992).

Furthermore, electrical stimulation of the amygdala has been reported to elicit neocortical arousal and to excite neurons in the NB region that project to neocortex (Dringenberg and Vanderwolf 1998). These observations suggest that stimuli relevant to the organism's welfare may be conveyed to the NB arousal system from the amygdala.

An important focus for future research will be to determine if the amygdala has a similar influence on the brain's other arousal systems. An equally important focus will be to determine the extent to which these systems play redundant and/or uniquely different roles in modulating the level of neocortical arousal. Finally, it is important to note that brain areas that promote sleep actively inhibit many of these arousal systems. An important current research focus is on the delineation of the exact mechanisms by which these arousal systems become inhibited during sleep, a focus described in more detail in the article describing the neural systems contributing to sleep (see *Autonomic Classical and Operant Conditioning*).

Art and Culture, Economics of

1. Introduction

Though Adam Smith, William Jevons, Alfred Marshall, David Ricardo, and John Maynard Keynes (who also collected paintings) were intrigued and had some views on the issues which will be discussed, research on the economics of art and culture is said really to have started after the essay by Baumol and Bowen (1966) on why, unless they receive financial support, the performing arts may disappear. The field is now relatively well established, has an association, the Association of Cultural Economics International, which publishes a quarterly journal, the *Journal of Cultural Economics*, organizes, every two years, a conference that is attended by 200 to 300 scholars, and has been able to generate teaching positions in a few economics departments in Europe and in the United States. The field is, nevertheless, still in its infancy

The topic is not well-defined, since it is located at the crossroads of several disciplines: art history, art philosophy, sociology, law, management, and economics, and tries (or should try) to tackle questions such as why Van Gogh's paintings are expensive, and why copies of his works are cheap; why pre-Raphaelite painters came back into vogue in the 1960s, after having been completely forgotten during almost a century (with an obvious effect on their prices); why European public or national museums are not allowed to sell parts of their collections; how the performance of museums should be evaluated; which (and given the budget constraint, how many) buildings should be saved from demolition, and kept for future generations; why the arts should be supported by the state; why there are superstars who make so much money; and whether works that have been sold should nevertheless be subject to copyright laws. From this enumeration, it should appear that all the fields are interacting, but that this does not often make an art historian understand mathematical economics, nor an economist show interest in pre-Raphaelite painters.

The list also raises the issue of whether economists interested in cultural economics should simply apply their usual tools to questions related to and data coming from the arts, or whether they should take culture as an opportunity to add new issues to the existing economic literature. Should economists take as granted that prices and consumers' incomes are the main determinants of the demand for theater plays, or should they also understand what quality means in such heterogeneous markets, define it, measure and enter it as a variable in their regressions?

To describe the main problems which arise in cultural economics, it is useful to make the distinction between the performing arts (music, theatre, opera, dance), the visual arts (paintings, sculpture, art objects), and cultural heritage (museums, historical buildings, monuments and sites), though there are some unavoidable intersections (museums accumulate paintings, some artists in the visual arts produce unique performances in galleries). There is a tendency, nowadays, to add what came to be called the cultural industries, which cover books, movies, popular music, records, and the media (radio, television, newspapers

and, of course, the ever present and invasive Internet). The discussion will be devoted mainly to the first three groups, which are often referred to as 'high culture,' and will try to point out what cultural economists have found interesting, discuss the tools which they have imported from economics to analyze culture, which new insights the analysis of art markets has added to economics, and what the questions are that have been left open or untouched. However, to start with: a topic that applies to all groups, has kept many cultural economists busy, and has led to a large literature in the field. Should the state support the arts and, if so, how?

2. *Public Support of the Arts. Why?*

Many arguments have been invoked to justify public support, and to correct for assumed market failures. Some apply to all forms of artistic activities (including the cultural industries), and some are more specific. Here is a nonexhaustive list of the most important economic rationalizations for such support.

(a) The oldest and most often invoked argument is that art, whatever its form, is a public good. It benefits not only those who attend or see it, and who pay for it, but also all other consumers, who do not necessarily wish to contribute voluntarily to its production (performing or visual arts) or to its preservation (museums) and free ride, or who cannot contribute, since they are not yet born (heritage). If the arts are left to the market they will not be priced correctly, and will thus be underproduced or not saved for future generations. Artistic activities are also said to produce externalities that cannot be sold on the marketplace, such as civilizing effects, national pride, prestige, and identity (justifying, for example, the French position in their fight against the free trade of movies and TV programs), social cohesion, etc. (such arguments were suggested earlier by Stanley Jeavons, Adam Smith, and Arthur Pigou) which benefit all consumers.

(b) But the arts are also said to yield economic externalities. Old castles, well-known opera houses or orchestras, and art festivals attract visitors and tourists. So do museums with good collections, while newly constructed museums are claimed to contribute to city renewal (an argument used, for instance, to attract public support for the recent Guggenheim Museum in Bilbao). This is supposed to have spillover effects on hotels, nearby restaurants and shops, generate new activities, and this effect came to be called the 'arts multiplier.' Grampp (1989, p. 247), ironically, gripes that the arts multiplier takes 'its place besides the investment multiplier, the foreign trade multiplier, and the balanced budget multiplier in the kitchen midden of Keynesianism.' (See also the paper by Seaman 1987.)

(c) Art is a 'merit' good. It 'is a means of educating the public's taste and the public would benefit from a more educated taste' (Scitovsky 1972). Since consumers are not fully informed, they are unable to evaluate all its benefits without public intervention. Moreover, even if there is addiction to the arts, it develops only slowly, and consumers have to be exposed as much as possible.

(d) For equity reasons, art should be made available also to low-income consumers who cannot afford to pay. Poor artists should also be supported. Schemes for doing this will be discussed below.

(e) Culture is transmitted by education but also from parents to children. Since parents can hardly be considered as purely altruistic, an additional externality is generated, which needs support for efficiency (and equity) reasons.

(f) The last argument on the difficulty or impossibility of achieving productivity gains is more specific to the performing arts. It was put forward, more than 30 years ago, by Baumol and Bowen (1966), and came to be known as the Baumol cost disease. It can be stated briefly as follows. Since wages escalate in sectors other than culture, they must also do so in the performing arts to make these attractive enough for artists to enter, but since no productivity gains are possible, wage increases have to be passed fully to prices. Therefore, the relative price of the performing arts increases and, unless subsidized—or supported by donors and private funds—the sector will shrink and eventually disappear. (It is worth quoting the (now) standard argument by Baumol and Bowen: 'The output per man-hour of the violinist playing a Schubert quartet ... is relatively fixed, and it is fairly difficult to reduce the number of actors necessary for a performance of Henry IV, Part II.')

The issues just discussed have, of course, their supporters and their detractors. The main detractors base their case on the public choice theoretic claim that some people wish to use the state's resources for their own benefit, and on the regressive nature of supporting high-income groups who are more likely than others to attend, and who can afford to do so. In 1982, in the United States, for example, 38.5 percent of the high-income population (earning more than $50,000 per year) attend classical music live performances, while this percentage drops to 8.1 percent for low income groups (earning less than $10,000 per year) (see Heilbrun and Grey 1993, p. 43).

Several additional arguments can be set against the Baumol and Bowen reasoning. Empirical studies on the performing arts point to price elasticities which are smaller than one, so that there is still some room for price increases; the performing arts have not exhausted the possibilities of price discrimination (popular shows do not seem to charge more, most venues could be scaled in more sections than observed, intertemporal price discrimination and peak load pricing during certain days are seldom implemented, bundling—

bookstores at opera houses, museums, drinks during intermissions—can also be used more systematically); technical progress (sound and lighting, for instance) can make for larger audiences; broadcasts and records—though these forms may also be subject to the cost disease—could be used to cross-subsidize live performances, and make these less expensive; synthetic music is being composed, which needs no, or fewer, performers, and is even sometimes used in ballet or opera performances; opera music is performed in the form of concerts; contemporary theatre plays save on the number of characters, etc. In the visual arts, Marcel Duchamp and later, Andy Warhol, created ready mades and multiples by the hundreds. Reproductions of paintings in books pay royalties to artists, which is also a form of cross-subsidization.

The cost disease has led to a host of quantitative studies, which show that the curse is not as severe as Baumol and Bowen originally suggested. But there is still more empirical work needed to prove (or disprove) the reality of the other arguments which call for public support.

3. *Public Support of the Arts. How?*

In most developed countries, the arts are supported, though the volume of public intervention can be very different. It is very low in the United States ($3 to $4 per head), reaches $16 in the United Kingdom, $19 in Australia, and $30 to $40 in continental Europe, where private support is, at the present time, negligible (see Throsby 1994, p. 21 for more detailed data). No convincing argument has yet been put forward to explain these large differences in behavior between the Anglo-Saxon and other cultures.

Government intervention takes several forms. It can be direct: some art institutions or companies are state-owned (museums in most European countries, but also opera companies, theaters, symphony orchestras) and are, therefore, supported, at least in part, by public funds. Their efficiency has been questioned on many occasions. Arts education programs are also often supported by the state. In the 1960s, Peacock (1993, p. 122) suggested the distribution to poor consumers of art vouchers, exchangeable for seats or visits to museums.

In most cases, public funds, including lottery funds, are channeled to private companies, or directly to artists, through subsidies, or tax relief (reduced VAT rates, no tax or lower rates of taxation on profits or on income). In the United States, most of the effort is concentrated on tax deductions or exemptions to donors (individuals or corporations) for charitable contributions; gifts or bequests of artworks are also encouraged by tax concessions, and more and more often, inheritance taxes can be paid for by artworks. This indirect subsidization system is used much less in European countries, though the incentive schemes are also present.

The less direct (and, sometimes, most insidious) form of intervention is regulation, which is mainly concerned with (a) guaranteeing artistic freedom, though this right has often been breached—for example, to 'protect' consumers against pornography; (b) ensuring moral rights—that is, protecting artists against being plagiarized, or against alterations or destruction of their works; and (c) ensuring financial rewards to living artists and to their heirs during as much as 70 years after their death, in the European Union, in the form of copyright. Copyright has led to a very large literature on the confines of law and economics. Its economic justification is based on the idea that it provides incentives to create, and that the absence of protection would lead to underproduction—the same idea is used to justify protection of industrial patents.

Copyright applies mainly to plays, and literary or musical works. Authors usually do not 'sell' their creation, but get compensated through authors' rights for each copy (book or record) sold, or for each performance of a play or of a score. However, the idea has been extended to all other forms of art, including the performance itself (the staging of a play can be copyrighted), and the visual arts. Reproduction of a work pays rights to the artist even after it has been sold; resale rights (*droit de suite*) pay to the artist a percentage on the resale of a work on the secondary market, for instance between two dealers (note that since such transactions are difficult to follow, *droit de suite* is usually only enforced for sales at auctions). The photographer of a work by Rembrandt is, in some (European) countries, entitled to rights for his 'original' photography. One can wonder whether copyright laws still provide incentives for art creation, or whether they generate incentives to use Mozart's music in movies, and Schiele or Klimt paintings (no longer covered by copyright) to illustrate book covers, in order to avoid the intricacies of the law on contemporary scores and illustrations. Obviously, regulation has led to overregulation, perhaps driven by the rent-seeking behavior of author societies, which collect transaction fees, and not by artists themselves.

The international trade of cultural goods has also been the concern of regulators. Some countries prohibit completely the export of ancient artifacts—although illegal exports from Mexico, Italy, or Greece continue. Some countries (France and the United Kingdom) are more lenient and require export licenses for 'national treasures;' this procedure is often used to delay the export and give time to the potential exporting country to raise funds and buy the object at the price at which it could be sold abroad. More recently, during the 1994 GATT negotiations, France insisted on maintaining import quotas on American TV programs to 'protect' local culture and national identity. This is the so-called cultural exception argu-

ment, which is very reminiscent of its forefather, the infant industry argument.

4. *Rich Man, Poor Man, Beggar…*

A folk theorem states that most artists are poor—or have lower income than the average consumer—and die poor, while salerooms, their dealers, and editors become rich.

Using the 1980 US Census data, Filer (1986) concludes that, on average, artists do not earn any less than they would in a nonartistic employment (after standardizing for personal characteristics, productive attributes, and age). It has later been shown, however, that this is due to multiple job holdings, including in nonartistic activities (see, e.g., Wassal and Alper 1992). If these extra jobs are not accounted for, artists' average incomes are smaller than those of workers with comparable education. It is also said that artists devote less time to their work on art than do others to their main occupation, that they may have to go to lower paid jobs to supplement their income, and that their earnings are more variable and less directly influenced by education than those of other workers. To explain then why artists accept this income differential, one has to appeal to differences in motivation; this is summarized by Throsby (1994, p. 17) who suggests that 'the primary desire to create art as a principal occupation must be recognized as the essential driving force behind an artist's labor supply decisions.'

But the income distribution of artists is also markedly skewed, and there exist superstars whose earnings are impressive. In a beautiful paper, Rosen (1981) shows that talent alone does not explain these differences. He models income as a convex function of talent, so that small differences in this endowment may result in large differences in income. This is compounded by the fact that there is little if any substitution between various degrees of talent, or between quality and quantity. As Rosen points out, 'hearing a succession of mediocre singers does not add up to a single outstanding performance.'

5. *Issues in the Market for Visual Arts*

Art works are, with some exceptions, heterogeneous. Each creation is unique and markets can hardly be analyzed by the usual supply–demand mechanism. The very high prices reached by some works has led economists to study (a) what can be said about the characteristics that determine values, (b) whether the returns obtained on artworks outperform those of financial markets, and (c) why tastes change. None of these issues has been given a definitive or even a satisfactory answer.

Values are obviously determined mainly by the name (or the reputation) of the artist, but this explains little, and one should understand why reputations differ, and what makes a painting 'good' or 'bad.' Decomposing 'quality' in terms of (hopefully) objective characteristics should be possible. After all, this is what, long before Kevin Lancaster, the French art historian de Piles (1708) had in mind when he wrote that (the English translation is borrowed from Rosenberg (1969, p. 33) 'the true understanding of painting consists in knowing whether a picture is good or bad, in distinguishing between that which is good in a certain work and that which is bad, and in giving reasons for one's judgment.' This led him to grade, on a scale of 20, characteristics such as composition, drawing, color, and expression, for a group of painters, and rank them accordingly (note that quality concerns also the performing arts, movies, TV programs, etc.). Art historians and philosophers have strong objections to such views. Economists are used to working on horizontal and vertical differentiation, but consider quality in art to be the playground of art historians and philosophers. Some collaboration between the two sciences should therefore be possible!

Financial returns on works of art have been analyzed very often (see Frey and Eichenberger 1995) for a survey). Baumol's (1986) paper has probably been one of the most influential studies, since the conclusions are based on prices obtained at auction over 300 years (1650–1960). Baumol finds that the average real return rate is equal to 0.55 percent per year, some 2 percent lower than the return on bonds. The difference is understandable and, according to Baumol, attributable to the return provided by aesthetic pleasure. Buelens and Ginsburgh (1993) qualify the results and show that this conclusion does not preclude the existence of 20 to 40 years-long time intervals during which returns are much higher; since tastes change slowly, there may thus be opportunities to do better than bonds. In a recent paper, Landes (2000) shows that skillful collectors can even beat the stock market, as long as they spend time and effort and follow a buy and hold policy. Buelens and Ginsburgh show that when the 1914–49 period of turmoil is excluded, the rate of return is 2.5 percent, thus equal to the return on bonds. Art is thus attractive even if aesthetic returns are ignored.

Tastes change, and prices commanded by works of art often follow these movements. There are many examples of painters who have been 'rediscovered,' including Botticelli, Vermeer, Goya, or the pre-Raphaelites (see Haskell 1980 for an account of these changes in France and in the United Kingdom between the late eighteenth century and the early 1920s). It is unclear whether such changes are due to fads or fashion, or to more fundamental reasons. Grampp (1989, pp. 66–8) suggests that the rapid succession of styles in contemporary art is due to the rapid increase in consumers' income, 'who seek novelty more often

than they would if their income was lower.' The changing tastes issue has, to our knowledge, never been investigated seriously by economists. (At least empirically: Stigler and Becker 1977 have developed a theory of changing tastes in the neoclassical framework of unchanging preferences—see below.)

The status and the prices of copies (to be distinguished from fakes) have also varied over time. While copies were close substitutes for originals during the seventeenth century, and priced accordingly at about half the price of originals (see De Marchi and Van Miegroet 1996) they are considered to have hardly any value nowadays. Again, little is known about the reasons and the period at which the break occurred. Photography is sometimes said to have been at the root of the change.

The issues discussed above have often been analyzed on the basis of works sold and prices obtained at auctions. This has led to several observations on the possible inefficiency of auction mechanisms, which theory considers to be efficient—this is at least the case for the second-price auction mechanism often used in art auctions. Among these observations, let us single out the declining price anomaly (prices of homogeneous lots sold in sequence decrease over time, but this is also the case for the ratio between hammer prices and pre-sale estimates for heterogeneous works of art (Ashenfelter 1989, Beggs and Graddy 1997)), the existence of systematic price differences across salerooms and/or countries (Pesando and Shum 1996)—though this seems to make arbitrage possible, saleroom commissions and other transaction costs are usually high enough to reduce such possibilities, at least in the short run—the biasedness of pre-sale estimates by salerooms, and the fact that pre-sale estimates do not reflect all the information that is available (though theory shows that it is efficient for the auctioneer to reveal the truth).

6. *Cultural Heritage, Where Do We Go?*

Forty-five thousand monuments are listed in France, and this number is increasing every year, without any legal possibility of dropping a monument once it has been listed. In the United Kingdom, there are 40,000 scheduled monuments and sites, and 500,000 listed buildings. Maintaining this heritage obviously implies costs, and these costs are increasing. The number of specialists who are able to reconstruct and restore these sites is dwindling, the materials needed are becoming rare and often expensive to extract, and monuments deteriorate at an increasing rate, since they are visited more often, and are subject to damage by pollution (Benhamou 2000, p. 58). A curse similar to the one said to prevail in the performing arts (the previously mentioned cost disease) is ahead of us. The decision to list heritage sites less will have to be made, and perhaps also the decision to drop monuments and allow their demolition. Property rights may have to be redefined to induce private owners to care for their properties, and tools, such as contingent valuation, polls, or even referenda may be needed to elicit preferences and help decision makers.

The number of museums has also increased dramatically since the 1980s, and so have collections, generating serious constraints on exhibition space (the forms used by contemporary art installations, for example, make this constraint even more binding). It happens that as much as 80 to 90 percent of the works are not on show (97 percent in the case of the Art Institute in Chicago). Though the International Council of Museums (ICOM) recommends that each musuem should have a statement describing its collecting policy, many have no such written documentation. To the layman, and sometimes even to the expert, some transactions look bizarre, to say the least. In 1999, though it possesses several works by Breughel the Elder, the largest Belgian museum bought a copy by one of his descendents, Breughel the Younger, for the stunning amount of 3 million dollars. This amount should be compared to the museum's $150,000 annual public subsidy for new acquisitions! Why can't museums stop increasing in numbers, and dimensions. Why is it that if curators have the power to buy works of art, it is made difficult (in the United States) if not impossible or unlawful (in Europe) for them to sell works ('deaccession,' in museum language), and certainly those which are not and will probably never be shown. This would not only provide financial leverage to museums, but also reduce the incentive for illegal excavations and sales.

Should museums charge entrance fees? Curiously enough, the French, whose successive governments claim to have the largest budgets to support the arts, insist that museums should charge visitors—and they do so—while free admission at the six British national museums—some of which did make charges—was introduced in April 2001. Some (natural) experiments are being run in French museums on the effect of charging, and not charging entrance fees on Sundays once every four weeks, but the evidence that this increases the number of visitors is scant. More serious econometric work is obviously needed in this area.

How would the management of museums be affected if the value of their collections were considered as capital? How should museums (as well as many other cultural institutions) be evaluated? Their output can obviously not be measured by profits, nor by the sole number of visitors, as has often been suggested, and done. According to the ICOM definition, a museum 'acquires, conserves, researches and communicates, and exhibits for the purpose of study, education and enjoyment, material evidence of people and their environment.' This makes for an activity with multiple outputs; measuring its performance calls for the use of appropriate efficiency frontier methods.

7. *The Cultural Industries: How Will Newspapers and TV Programs Look in the Future?*

Here we turn to more conventional commodities, since the cultural industries mainly produce 'copies,' such as books (some books can be viewed as works of art; this is obviously the case with old manuscripts, but also with some contemporary books, often illustrated by painters, printed in limited numbers, and which become collectors' items), records, movies, newspapers, and TV programs, and the value of the work is not conferred by its uniqueness or its scarcity. Note that this is also partly true for the performing arts, though each performance can be considered as unique. As in other sectors, these industries are faced with globalization and follow the move to more concentration, both in terms of production and of distribution. This may open the road to more uniformity and is sometimes considered as presenting a threat for democracy, especially in the case of newspapers and TV or radio news programs.

At issue are also (a) the public support for (and even ownership by the state of) television and radio stations and, in some countries (e.g., France), newspapers, and the complex problems of (dis)information this may generate, (b) the import quotas on cultural programs in a world which moves to free trade in all other industries, and (c) the complex economic and legal copyright problems generated by the Internet.

8. *Other Issues and Why Not Culture for the Enjoyment of Life?*

We are left with many unresolved questions. The economics of certification or authentification ('authentic' works vs. copies or fakes) is one of these. While many art philosophers maintain that this does not change the aesthetic qualities of a work, it definitely changes its price! The formation of values also raises the interesting issue of who are the agents endowed with the power to discriminate between good and bad art (the 'gurus'). What is the expertise of those who grant prizes and awards? Who still reads Sully Prudhomme (Nobel literature winner in 1901), Paul von Heyse (Nobel 1910), Verner von Heidenstam (Nobel 1916), or of more recent vintage, Ivo Andric (Nobel 1961). But even worse, who still remembers their names? Who would today award the 1959 Oscar for best movie to *Ben Hur* and forget about *Some Like it Hot*, produced during the same year? Time obviously does a far better job than the experts.

Why did blockbuster exhibitions or music, opera, and theatre festivals become so numerous? Don't such events simply displace the public from more traditional venues? Or do they, as is sometimes claimed, attract visitors who also have a look at the permanent collections, and familiarize with music those tourists who would otherwise never attend a concert in their own city. Much has been said on the rent-seeking behavior of those who organize such events, but little is known about the long-term effects on the behavior of those who attend.

The last question, which is also one of the most important ones, is how culture affects the preferences of consumers. This is the subject of the important paper by Stigler and Becker (1977), who were among the first to discuss changing tastes and addiction to culture (as well as to other goods or bads) in terms of a household production function and the stock of past consumption (of culture) and not consumption itself, appearing as argument in the utility function.

Addiction (if positive) should enhance the role of education to culture. More education to culture would certainly lead to more participation in cultural activities (see Bergonzi and Smith 1996) and, therefore, to less need for public support. It would also increase efficiency, since we would have to accept that consumers possess the knowledge and have the right to choose in a sovereign way, and therefore also accept the consequences to which this could lead.

9. *Bibliography Notes*

For obvious reasons of space, it is impossible to do justice to and mention the many original contributions to cultural economics. The two volumes edited by Towse (1997) contain many of the important papers that have made cultural economics into a field. The book by Peacock (1993) is a delicious and highly informative account by an economist *cum* musician and composer, of the years he spent as Chairman of the Scottish Arts Council, and member of the Arts Council of Great Britain. It also contains references to his many and highly regarded other contributions to cultural economics. The iconoclastic views in Grampp (1989) make for very entertaining and witty reading that is also very serious economics. So is Frey's and Pommerehne's (1989) contribution, which contains a very complete and useful list of references written before 1989. O'Hagan (1998) covers most of what should be known on the relations between the art sector and the state. So does Schuster (1997) for the cultural heritage, Throsby and Withers (1979) for the performing arts, and Caves (2000) and Hoskins et al. (1997) for the main problems faced by the cultural industries. Throsby (2001) bridges the gap between economics and culture. The situation in the United States is described by Netzer (1978), Heilbrun and Gray (1997), and by Feldstein (1991) for museums. A very good overview of the French situation (which is almost polar to the American one) is given in Benhamou (2000). The two volumes by Merryman and Elsen (1998) are invaluable as a first approach to the understanding of the intricacies of law and the visual arts.

Art: Anthropological Aspects

The term 'art' has several meanings, all having to do with the performance and products of human skills, associated with aesthetic (rather than functional, sacred, or scientific) qualities appealing to the human senses. Art can appeal to a single sense (e.g., easel painting), or to multiple senses (e.g., ritual dances—vision, kinesthesia, sound). This essay focuses on the visual arts rather than on song, music, or dance.

1. The Term 'Art'

The meaning of 'art,' from the Latin *ars*, *artis* (skill), has changed over time, reflecting technological and social contexts. In English, 'art' is often twinned with 'craft' from the Germanic *kraft* ('skill, cunning' in English, since 850 AD). After the Norman Conquest and the Renaissance, 'craft' became associated with manual skills and lower-class occupations, and 'art,'

from the French *art*, with the conquerors and the Church, and hence with learned practices such as mathematics, rhetoric, logic, and grammar (as in Master of Arts).

In Enlightenment Europe, the meaning of 'art' changed again, becoming a synonym for '*beaux arts*,' a set of primarily expressive skills entertaining to the senses but with few practical aims. These arts were the enjoyment of the wealthy, educated classes, whose tastes brought into being nonecclesiastical forms such as opera, symphonic music, figurative painting, and choreographed dance (and later, ballet). Once detached from 'bread-and-butter' issues, art was justified as a superior expression of the human soul, whose practitioners embodied inner genius and were owed freedom of expression.

Many aesthetic practices of the unschooled members of European populations: folk song, dance, and handicrafts; and of women: quilting, lullabies, and sewing, were not considered to be arts. Others, having both aesthetic and practical aspects: architecture (vs. building), landscape architecture (vs. gardening), or cuisine (vs. cooking), bestowed 'artist' status only on trained practitioners, usually men. These distinctions are fading with the postmodernist revaluations of many folk and vernacular practices as 'arts.'

2. *The Challenge for Anthropologists*

All these arts are embedded in the historical, social and cultural structures of the Western world, and anthropologists find it difficult to identify 'art' in other societies. They have tackled the problem in two ways.

First, to identify practices and products resembling Western arts, in form (appeal to certain senses), and in relation to context, e.g., religion, hierarchy, ritual. This was easy in the West's encounter with other complex civilizations (often archaeological), but difficult in more egalitarian, nonliterate societies studied by early anthropology. In his *Primitive Art* (1955) Franz Boas emphasized the universality of arts as skill-based productions of aesthetically valued forms:

> When the technical treatment has attained a certain standard of excellence … such that certain typical forms [later identified as 'styles'] are produced, we call that process art … perfection is essentially an aesthetic judgement … [but] we cannot tell just where the aesthetic attitude sets in (1955, p. 10).

He added, 'the twofold source of artistic effect, the one based on form alone, the other on ideas associated with form' (1955, p. 13). Presumably, the former would be aesthetic universals and the latter culturally specific, but Boas admits that other authors claim that, iconically, all arts represent something.

For Maquet (1979) all societies have aesthetic foci, where excellence is judged by the senses. But 'Art' comprises only those productions which circulate within the metropolitan 'art world' (Becker 1982), and 'primitive art' only exists in the galleries and homes of Western societies. Arts are created two ways (a) *by intention*, made by self-conscious 'artists' for the art world; and (b) *by metamorphosis*, produced either in the past or elsewhere, outside the art world. For instance, eighteenth-century quilts were not considered art until late in the twentieth century, and contemporary Dogon granary doors made for use in West Africa, only become 'art' when imported to the West. The current globalization of commodities makes Maquet's suggestion cogent for almost everything that would be 'art' by Boas' definition.

3. *Meaning, the Content of Art*

Twentieth-century anthropological approaches to art have been concerned with the mechanisms and nature of the messages carried by art. They have drawn upon either psychology or linguistics, i.e., semiotics, reflecting functionalist and structuralist modes of anthropology.

3.1 *Psychological Approaches*

Psychoanalytic approaches treated art, like dreams and myths, as expressions of the subconscious, translated into forms acceptable to the conscious Ego. Most assume the universality of the Oedipus complex and the sublimation of aggression. Jungian approaches posit a universal set of archetypes, whose meanings are personally or locally adapted to solving problems.

Devereux (1961) said that art expresses taboos in palatable, aestheticized forms. Taboos may be universal (e.g., incest); culturally specific (e.g., sex in a puritanical society); or idiosyncratic (neurotic). Arts are admired locally when the taboos are cultural, and more widely when they relate to universal human problems. This 'aesthetics as alibi' approach also underlies the works of Margaret Mead, Bateson, Schieffelin, and to some extent Kardiner.

Fischer (1961), following Wallace and Barry, proposed that artists sense how their patrons receive satisfactions to needs generated by local sociopsychological contexts: the latent (nonrepresentational) content of art, the 'style,' presents aestheticized versions of social fantasies giving security or pleasure. For instance, symmetrical designs with simple, repetitive elements characterize the arts of egalitarian societies, whereas the arts of complex hierarchical societies present enclosed asymmetrical designs integrating disparate elements. He also found that preferences for

the curvilinear reflected male security and fantasizing about females. Teilhet (1978) suggested that the equivocal role of women artists in nonliterate societies resulted from men's jealousy of women's reproductive powers, compensating by control of artistic creativity and the hoarding of valuable materials.

3.2 Linguistic Approaches

Art, like language, is a communicative form, using a medium that carries a coded message understood by both creator and audience. Forge claimed that, for the Sepik peoples, visual art could be read directly, but not reduced to words. In contrast, Munn showed how Australian Walbiri painting consists of a number of iconic but polyvalent elements, combined in sentence-like structures, to make symbolic statements about dream-time ancestors, often suggesting speech.

Lévi-Strauss (1966) posits that 'art lies halfway between scientific knowledge and mythical and magical thought … midway between design [the scientist builds structures from first principles] and anecdote [the *bricoleur* makes things from the 'debris of past events'] … The aesthetic emotion is the result of this union between the structural order and the order of events.' Other structuralist analyses, such as Adams' on Sumbanese textiles, reveal underlying systems of meanings interpreted locally.

For Bloch (1974) relations between aesthetics and emotion may be summarized as 'You cannot argue with a song!' He makes the analogy: Phatic/illocutionary speech is to ritual/art as discursive/propositional speech is to secular behavior and mundane expression. Formal mechanisms, for example, repetition, symmetries, limited range of elements, fixed sequences, and archaic images, give the authorities who control ritual, rhetoric, and the arts, power over those enculturated to these patterns.

3.3 Sociopolitical Approaches

Social anthropologists have stressed the functions of art in maintaining the social. Turner showed how Ndembu political rites use normative and naturalistic symbols and colors to structure the event and foster *communitas* among the participants, and Biebuyck showed how human and animal figurines recall proverbs, having the function of training initiates in the Lega *bwami* cult. Gell (1998) asserts that anthropologists focused wrongly on aesthetics, and on relationships between formal style and other cultural characteristics, because (a) 'art' is not always about aesthetics; and (b) the expression of a culturally specific aesthetic system is *not* the function of art objects. Art is created to function in social relations to do something, that is, it has agency. In the West, art serves class and power interests, in gender exclusion (Nochlin) and the maintenance of hierarchy (Bourdieu).

3.4 Aesthetics, Ethno-aesthetics and Universals

Little is understood yet about aesthetic universals. A number of anthropologists have explicated the local, i.e., ethno-aesthetic systems of, for example, the Yoruba (Thompson), the Kilenge (Dark), and the Inuit (Graburn). Some have tried inconclusively to test the cross-cultural nature of aesthetic taste by, for instance, showing photographs of art objects both to their non-Western makers and to Western students of art (Child and Siroto). However, Graburn (1978), drawing on the work of Salvador among the Kuna, was among the first to use a test exhibit of the actual art objects in comparing Native (Inuit) and Euro-American preferences. Other approaches, drawing on Wittgenstein's philosophical work and works on Paleolithic and ethnographic arts (Conkey, Marshak) show promise; there are possibilities that underlying aesthetic universals are related to neuro-ocular phosphenes.

4. Art in the Contemporary World

Early anthropological analyses focused on embedded 'authentic, traditional' arts, known as 'primitive' or 'non-Western' arts (Gerbrands 1957). In *Ethnic and Tourist Arts* (1976) Graburn examined their entry into the 'World Art System,' looking at the primary audiences (locals or the external market) and the sources of aesthetic forms (traditional, external models, or novelties). Others have focused on such arts, in Africa and the Americas where traditional 'primitive' arts were found, and in literate civilizations such as Thailand which have fallen under Western influences (Phillips 1992). Questioning the historically contingent distinctions of hybrid/purebred, Morphy (1992) revealed identical structural and aesthetic patterns underlying functional (locally directed) and commercial (market) Yirrkala bark paintings. Neich examines a colonial era (1870–1910) form of Maori figurative painting influenced stylistically by *pakeha* (white) culture, but expressing Maori cosmology.

Cole, Appadurai, Clifford, and Thomas have recently shown the historical depth and sociocultural complexity of art production in colonial or post-colonial, often touristic, contexts. Dealers, curators, and tour directors may present historical artifacts as 'purebred' symbols of rich heritages, but practically everything in our ethnographic collections was acquired in colonial situations. They may be trade

replicas or, like the carved arts of the Northwest Coast Indians of North America, they may have enlarged and proliferated with new tools and economic stimuli. Often colonists both consumed and imitated contact arts, attempting to assume a new 'ethnic' identity by appropriating the culture of the conquered.

Recent works have focused less on the objects and more on the agency of the personnel of the art world. Ethnohistorical analyses (Cohodas, 1999, Batkin 1999) and ethnographic research (Steiner 1995) reveal the complex activities of artists, intermediaries, and consumers. Artists may work consciously in a variety of styles, aiming at a number of consumer markets, or they may themselves play the role of intermediaries.

When artists and consumers are culturally or geographically separated, mediating agents assume greater importance. They not only transmit the physical art object from the producer to the consumer, but they also control the flow of information about its origin, age, meaning, and status as a commodity or a treasure (Appadurai 1986). They also transmit back the demands and the ideology of the collectors, in terms of price, repeat orders, or information about form, content, color, and materials.

Artists dependent on the cross-cultural market are rarely socialized into its symbolic and aesthetic system, knowing little about the art world, or even about 'Art' itself. They live in a minefield of rules which they overstep at their peril, unless they assimilate into the 'art world' (Graburn 1993). The Australian Aborigine watercolorist, Namatjira, painted successfully in the style of his white mentor, engendering both praise and jealous racism among the Australian public, leading to his downfall. Today's Third and Fourth World peoples have increasing exposure to mainstream arts and art materials. Many have attended art schools and assumed the burdens of (Western) art history and the ideological values of originality, artistic freedom, and individual creativity.

The separation of the art circuits for Native arts and mainstream (Euro-American) arts is eroding. Many Native artists work in genres of the metropolitan world art. The contents of their art may not be recognizable as 'ethnic'—possibly because white artists have appropriated so many ethnic motifs! When competing in the world market, Native artists signal their ethnicity through the presentation of traditional content, inclusion of stereotypical motifs and color schemes; choice of title or use of a Native name (or 'tribal' designation with a nonethnic name); or the inclusion of written statements expressing a Native point of view (Sturtevant 1986). Inclusions of non-Native contents, motifs, names and titles may draw criticism or rejection by the market.

Ethnic artists are everywhere pressured to create arts conforming to the image desired by the mainstream market. Even 'Magiciens de la Terre' which exhibited 'world artists' in Paris in 1987, revealed by juxtaposition how the 'ethnic' artists were expected to create something stereotypically traditional, but the metropolitan (white) artists drew their motifs or materials from natural or cultural alterity (Otherness) without limitation.

Very few anthropologists have tackled the core institutions and activities of the metropolitan art world itself. De Berlo, Gerbrands, Graburn, Krech (1999), and Sally Price have all examined how this art world has classified and examined non-Western arts. Myers, in his work on contemporary Australian aborigine dual purpose (sacred and commercial) arts has best analyzed the Western art discourse about such arts (Marcus and Myers 1995). Plattner (1997) has showed how hierarchies of prestige, stemming from New York, control economic rewards which dictate the life choices of a range of professional artists in St. Louis. This is the field in which the disciplinary boundaries between anthropology, art history, and cultural studies dissolve in synthetic collections in books and in journals such as *Res*, *Art in America*, or *Visual Anthropology Review*, reflecting the final breakdown of the boundaries between art, craft, material culture, and perhaps of the singularity of 'Art' itself.

Art History

The task of art history is to collect, preserve, order, present, and interpret works of visual art. Its activity is particularly visible in the field of historic preservation, aimed at the conservation of historically significant objects as well as regional and urban ensembles, and in the establishment and maintenance of art museums. As invulnerable as the museum buildings may seem and as long-term as the effect of historic preservation can be, the foundations of art history nonetheless lie in a cultural consensus that is not axiomatic, but rather subject to continual fluctuation. Art history is bound to the value placed on its object. In the interest of its own legitimation, it is structurally conservative, yet must also untiringly evaluate whether current artistic developments run counter to the legitimating consensus. Since its invention, therefore, the discipline of art history has had simultaneously to adopt both an open and a defensive posture. Its current possibilities and problems are a product of this conflict.

1. *The Beginnings of Art History*

The Renaissance consciousness of the break between its own art and the stylistic forms of earlier epochs marks the birth of modern art history. These early attempts found their first canonical form in the artist biographies of the artist and theorist Giorgio Vasari, published in 1568 (Rubin 1995). Vasari's *Lives* number among the great achievements of historiography since they, like no other historical work, nourished a conception of the modern age as emerging victoriously from the shadow of the Gothic and Byzantine periods. Since Vasari's time, art historical stylistic designations such as Romanesque, Gothic, Renaissance, Mannerism, Baroque, and Classicism have defined the outline and physiognomy of historical epochs.

With their fixation on the Florentine Renaissance, Vasari's *Lives* imbued early art history with a particular stylistic, geographical, and political slant. The generations that followed saw a considerable expansion of the temporal and geographical context (Bickendorf 1998). With Bernard de Montfaucon's *Monuments de la monarchie françoise* (1729–33) the field of inquiry was expanded systematically to include the Middle Ages, while Comte de Caylus's *Recueil d'antiquités* (1752–67) sought to develop an almost physically precise stylistic history of the art of antiquity (Bazin 1986). More successful, however, was Johann Joachim Winckelmann's stylistic history in his *Geschichte der Kunst des Alterthums* (1764). By deriving the Greek artistic ideal from the political climate of freedom, the work became an element of prerevolutionary discourse (Bäumer 1986).

2. *The Art History of the French Revolution*

Accordingly, the French Revolution saw itself as proof of Winckelmann's conviction that only political freedom could provide a suitable forum for great art. On the basis of this premise, works of art confiscated from the church and the emigrated nobility became a

Figure 1
Benjamin Zix, allegorical portrait of Dominique-Vivant Denon, drawing, Paris, Louvre, Cabinet des Dessins

national legacy. Selected pieces on view in the *Musée des Monuments Français*, opened in 1795, constituted a first ensemble of native artistic development no longer bound to the norms of Vasari and Winckelmann. Art history had become a national affair (Wescher 1976).

No one person embodied this shift more completely than Dominique-Vivant Denon, the 'eye of Napoleon.' Denon was responsible for selecting and overseeing the vast quantity of works from all epochs and regions brought together in the Louvre as the booty of the French army. Benjamin Zix, who accompanied Napoleon's victorious advances with his draftsman's pen, drew an allegorical portrait of Denon surrounded by masses of antique and postantique works and books, an image that aptly characterized the situation (Fig. 1). The sheer range and quantity of works in question made a stylistically, dynastically, and religiously neutral art history, equipped with transepochal methods, an objective necessity. Since in the French view the works had been liberated from foreign captivity into the Louvre, this European perspective contained a national element as well (Denon 1999).

3. *Establishment in the Universities*

One effect of the Napoleonic plundering of works of art was an emphatic association of art history with national consciousness. The art museum erected by Karl Friedrich Schinkel between 1825 and 1830, for example, was intended to help give Prussia a new identity not only through the founding of the University of Berlin, but also through an art museum (Fig. 2). Among the curators of the museum, Gustav Hotho gave lectures at the university in Berlin, while Gustav Friedrich Waagen taught as an adjunct professor in order to build a bridge between the cultivation of taste as represented by the museum and the academic training in the university. This constituted the first step toward the academization of art history (Dilly 1979).

Elsewhere in German-speaking Europe, attempts were likewise made to cultivate art history as an academic discipline, but institutional establishment succeeded only with the appointment of Jacob Burckhardt as professor of art history at the *Eidgenössische Hochschule* in Zurich (1855). Burckhardt therewith became one of the founding fathers of academic art history. In the years that followed, professorships were likewise established at polytechnic universities (Stuttgart, Karlsruhe, and Berlin–Charlottenburg, 1865–1868), since the training of architects in the period of historicism required an art historical foundation (Beyrodt 1991).

The first professorships for art history at classical universities were established in Bonn and Vienna (1862 and 1868), followed by Strasbourg, Leipzig, and Berlin after the founding of the Empire (1871–1873). By the turn of the century, numerous other universities had followed suit, viewing art history as necessary not only for the specific training of museum curators, but for aesthetic education in general. A century after revolutionary France had appropriated for itself the status of homeland for all masterpieces, the cultural policies of imperial Germany aimed at cultivating the general public taste through art history had become the driving force behind the academization of the field.

In France, where art history had been taught in Lyon since 1876 and in Toulouse since 1893, the academic tradition began only in 1893 with the establishment of a professorship for Henri Lemonnier at the Sorbonne and Emile Mâle's appointment to Toulouse (Therrien 1998, pp. 314ff.). In the United States, efforts had been made since the 1920s to disengage art history from archaeology or general artistic education and to make it a separate academic discipline; the breakthrough, however, occurred with the arrival of such German emigrants as Erwin Panofsky and Max J. Friedländer (Michels 1999, Wendland 1999).

In England, individual researchers such as Herbert Horne had overcome the tradition of the erudite writer as represented by John Ruskin. With the foundation

Figure 2
Karl Friedrich Schinkel, Museum, Berlin

of the Courtauld Institute in 1932, art history was officially established as a scholarly discipline, a development furthered by the transfer of the Warburg Library from Hamburg to London in 1933 (Mann 1993).

4. *Methods*

Art history as an academic discipline was mainly the product of German-speaking Europe, a fact that had consequences for the development of its specific methods. These ranged from methods strictly oriented to the object to philosophical and cultural–historical approaches.

In analogy to the critical methods of the historians, Friedrich von Rumohr and Gustau Friedrich Waagen, director of the Gemäldegalerie in Berlin, developed a method of source criticism and a technique of formal observation that permitted the assessment and continuation of Vasari's *Lives* (Bickendorf 1991). The achievements of this school were embodied in the *Allgemeines Künstlerlexikon*, planned by the two private scholars Ulrich Thieme and Felix Becker and published in 37 volumes from 1907 to 1950, with entries for ca. 150,000 artists and craftsmen from 92 countries.

Post-Hegelian Berlin saw the emergence of Gustav Hotho's and Carl Schnaase's developmental histories, oriented to the philosophy of the world spirit, and Franz Kugler's history of world art encompassing all times and peoples, derived from the Kosmos lectures of Alexander von Humboldt. Burckhardt's cultural-historical orientation likewise drew essential inspiration from this climate. Burckhardt strove for an art history 'according to problems,' in other words in accord with external aims, in order, on the basis of this kind of investigation, to be able to define the autonomy of art even more precisely (Waetzold 1924, Vol. 2, pp. 47–92, 141–210).

The two poles of dependence on external conditions and the unmistakable uniqueness of art determine art historical methods to this day. A series of attempts undertaken around 1900 on the basis of Burckhardt's work, aimed at responding to modern experience, still maintain their essential validity (Podro 1982). Representatives of the Vienna School such as Alois Riegl operated with the concept of the *Kunstwollen* in order to develop an art history that transcended individual artistic personalities. Riegl's *Spätrömische Kunstindustrie* (1901), which sought to structurally analyze a hitherto unconsidered epoch, used late antiquity as a mirror to reflect the art industry coming to expression in the mass culture of Riegl's own time. With a view to an 'art history without names' in accord with the abstractions of modern art, Burckhardt's Swiss student Heinrich Wölfflin developed criteria of a stylistic history which, as a strict school of vision, rejected everything oriented to other disciplines.

With sensitivity to contemporary tensions between art and politics, the Hamburg art historian Aby Warburg developed a method diametrically opposed to that of Wölfflin: iconology. Already in his dissertation on Sandro Botticelli (1893), Warburg dealt with problems of the psychology of form connecting historical forces of action and image-making. His dictum, formulated in 1912, that art history should be written as cultural history in a struggle against the boundaries of the academic disciplines (Warburg 1999, p. 585) lives on in present-day efforts to understand artistic form in its liturgical, political, and social

function and its relation to literature and documentary sources. Warburg's foundation of the *Kulturwissenschaftliche Bibliothek Warburg* and the development of the iconological method constitute probably the most profound impulse art history has contributed to the history of scholarship in the twentieth century. The continuing publication and translation of his collected works into English will probably further increase his influence.

Another response to the problematization of the ego and the artistic personality in modern mass culture was the sociology of art, a field that moved between the poles of Burckhardt—who, although he wanted to write art history on the basis of defining 'problems,' nonetheless saw it as an equal partner alongside the political and social realm—and Karl Marx, who derived artistic activity from social conditions (Warnke 1970). The sociology of art has researched the changing social status of the artist, examined relations between patrons and artists, defined the determinative role of function for artistic form, explored the role of patronage, and reconstructed historical manifestations of the art market. In addition, stylistic forms have been associated repeatedly with socially determined ways of seeing and thinking.

Landmarks of the sociology of art were written on the Italian Renaissance. Fundamental works dedicated to the status of art and artists (Wackernagel 1938, Kempers 1992, Goldthwaite 1993) and to the sociology of style (Antal 1947, Meiss 1951). Meiss's work, inasmuch as it mediates between style and class structure far more flexibly than does Antal, numbers among the most important works of art sociology of all time. Hauser's handbook (1953) constitutes the most comprehensive work on the social history of art and is notable for having also included film as a genuine area of art history. In contrast to Hauser's social history, oriented to the bourgeoisie and the cities, Warnke's work on the court artist (1996) investigates the princely court as the motor of artistic development, while Bätschmann (1997) focuses his analysis on the modern market- and exhibition-oriented artist.

5. *Methodological Pluralism*

Postmodernism has not failed to leave its mark in art history, especially since the discipline played a determinative role in the establishment of the term through the medium of architectural criticism. The attacks on methodological certainties, historical teleologies, and one-dimensional perspectives have above all been directed at those areas of art history that focused on high art and studied it using the criteria of stylistic development. While the history of style and connoisseurship have asserted themselves as the basis for all art historical work, the overall picture of the discipline is defined by a plurality of methods such as previously existed only between ca. 1900 and 1933 (Preziosi 1989, Belting 1983, 1995).

The field of gender studies has been particularly active in recent decades, pioneering not only the reconstruction of works by women artists from the Middle Ages to the modern period, but also uncovering gender-determined ways of looking and representing (Pollock 1999).

The history of relations between semiotics and art history belongs in the broader field of methodological expansion. To what extent exponents such as Roland Barthes are the secret heirs of this interchange remains an open question. Although some representatives of art history have used semiotic approaches since around 1970, whether these methods can do better justice to the differentiated nature of complex works of art than traditional hermeneutics is still controversial. The same holds true for structuralist ethnology as represented by Claude Lévi-Strauss. He oriented himself to iconology, and the latter profited from his work as well (Bredekamp 1995b). Finally, an expanding field is the connection between art history and the history of science, extending from the sixteenth century to the present (Stafford 1991, Bredekamp 1995a, Crary 1990).

6. *Universalization*

From the fifteenth to the eighteenth century, the dominant language of art history was Italian, around 1800 it was French, from 1820 to 1933 German, and thereafter English. The Anglicization of art history, in which the work of German emigrants to England and the United States played a decisive role, also ensured that after World War II its field extended beyond Europe to all of world art. From the originally narrowly defined field of Italian art of the late Middle Ages and the Renaissance, art history has expanded to include everything from late antiquity to the present. Geographically, art history deals with the art of all continents, although for other continents besides Europe—where late antiquity constitutes a relatively clear line of demarcation to the field of archaeology—the temporal boundaries are less sharply defined. The universal aspirations of the discipline have enabled it to discover that other cultures such as China have a history of art as well, in which elaborate standards have been developed over centuries (Ledderose 2000). Today, the study of art history is established in all countries that have achieved an initial consolidation after the wave of industrialization.

This worldwide orientation has been embodied in encyclopedic form since 1983 in the publication of the *Allgemeines Künstlerlexikon*, a work that will include entries for several hundred thousand artists from all periods and countries. The symbol of art historical

Figure 3
Richard Meyer, Getty Center, Los Angeles

universalism is the research institute of the Getty Center in Los Angeles (Fig. 3), whose mere location makes it clear that European art history does not stand alone. This does not mean, however, that its methods are useless. The objection that the Western conception of 'art' as an elevated sphere is unsuitable for Eastern cultures and that art history can gain no suitable access to this hemisphere presupposes that the discipline is concerned only with high art. This, however, is a prejudice that serves to resist all new fields and all questions of medium.

Within architecture, sculpture, and painting, art history by no means deals only with high art. These artistic media have been joined by photography, video, computer art, and, in analogy to the historic interest in arts and crafts, the history of design and advertising. Despite promising earlier approaches, however, film and television have not been adopted into the canon of art historical objects with the same consistency, although more recent attempts are striving for a historical foundation in this field as well.

In this context, the question of the internal consistency of art history arises with unprecedented clarity. The art forms that have appeared in the twentieth century have provoked the question of whether art history should also devote itself to the images of the so-called New Media or leave them to other disciplines such as film studies or cultural studies (Belting 1995). Through a narrower definition of art history and its confinement to the traditional media of architecture, sculpture, painting, and perhaps photography the discipline would thus be a kind of art history of the predigital age, a 'second archaeology.'

Yet when we consider the recently published *Dictionary of Art* (1996)—a total of 36 volumes with 41,000 articles dealing with persons, artists, art historians, collectors, and all relevant geographical and object areas as well as photography, performance, and multimedia from the entire world, from which film has been excluded only because it is such a comprehensive area in itself—the conflict seems to have been decided in favor of an open conception of art history. Here the discipline manifests itself as the historical science of images defined by the early Warburg School already at the beginning of the twentieth century.

The same process of integration of the New Media is occurring in museums of fine art, applied arts, and related areas. In the last decades of the twentieth century even elaborate museums were built as in all preceding epochs put together, a trend that continues unbroken to the present. In many places in the world, for example, in Bilbao with its Guggenheim Museum (1997), museums form urbanistic landmarks that shape the character of entire regions and serve as points of attraction for cultural and mass tourism. They thereby come to represent a considerable cultural and economic force (Lampugnani and Sachs 1999). The media of video and digital art are included in many of these museums, and the *Zentrum für Kunst and Medientechnologie* in Karlsruhe (1996) has for the first time devoted an entire complex to these new media, consisting of both an art museum and a laboratory. As the response to a media revolution encompassing the world but remaining ephemeral in its production, museums as the primary seats of art history remain the fixed points of a locally accessible but materially permanent realm of experience, one that also incorporates the products of the art–technological revolution.

H. Bredekamp

Art, Sociology of

Evidently, the sociology of art experiences, to constitute itself as a specific domain, the same difficulties as those encountered at the end of the nineteenth century by sociology. Despite the numerous attempts made since the 1960s to bring about progression, one wonders to what extent the bitter statement established in 1960 by P. Francastel is appropriate today. In fact, despite the abundance of publications on the subject, the attempt to constitute a reasoned bibliography of the question leads us once again to discover that the best ways to constitute a sociology of art are found under different bibliographical headings. Having revealed this initial reserve, we rapidly need to present in this article the main work already carried out in order to constitute a sociology of art, then to indicate the methods which seem to be the most fruitful to achieve this.

Essentially three methods have already been widely explored. The first, which claims to be scrupulously loyal to a classical conception of sociology, situates its object, art, within the epistemological framework of

its discipline. It shows that art is a collective phenomenon, crossed over and invested through and through by the society and history. One can therefore link, to give an idea of this enterprise, the works of H. Becker, P. Bourdieu, R. Moulin and so many others with those of S. Alpers, M. Baxandall, and F. Haskell. The privilege which is given here to collective phenomena and denied of individual creations can result in two forms of reduction, that which Marxist sociology operated, that of Lukacs, Hauser, Goldmann, and that cultivated by P. Bourdieu, which criticizes both the Marxist sociologists and those who maintain according to them the fancy of a creating subject, freed from institutional constraints and history.

The second proceeds in the opposite way to the first and recommends the singularity of the artist and the work, singularity which tends towards the solipsism of a creator out of text, nonaltered by his belonging to a society and a history. Cultivated in this method is the biography and study of style, following which the artist, considered more as a creator than as a producer, appears to be the carrier of a singularity which could be entered into by nothing.

The third, more recent, will delve into the resources of analytical philosophy, and of ethnomethodological interactionism, pragmatism. What is of prime importance is no longer in general, neither the artist nor the work, in a word the world of art, but the method, the way in which the world is thought of and told about. The practice of works separates itself from what it considers to be hindrances to research. The descriptive concern incites us to refute the normative approach. One is no longer trying to define, legitimize, or invalidate values, but rather to take into account what actors have lived, how they define, legitimately or not, these values. It is therefore necessary for the sociologist, not or no longer to say what art is worth or what it means, but what it does, no longer what sociology does to art, but 'what art does to sociology.' There again, the results are unequal. A. Danto, N. Goodman, and N. Heinich, despite their differences, enter into these research perspectives.

The first two methods being classical, one must note here some difficulties and inherent aporias with this third method as presented by N. Heinich. The priority given to the description and questioned by the normal approach causes a series of epistemological prejudices which can arouse reservations. Indeed, the statement is expressed in a description based on an evaluation, which itself is based on values. The methodological concern which N. Heinich describes seems to reveal useless precaution: 'To be as attached as possible to description, while abstaining from all normativeness (…) implies for the sociologist an important reduction in his space for intervening.' The 'pragmatical' sociology which it claims to be chooses a method which claims to be a-critical, pluralistic, relativistic, also claiming the epistemological neutrality of Weber. This project, in the very terms of its wording, can seduce: nothing is more consensual as all these terms which rhetorically oppose, even in an implicit way, their solar face with severe shadows of criticism and univocity which are supposedly reducing. However, this sociological concern which gives way to the fetishism of methods and which deludes itself despite its pretensions about the nature of axiological neutrality, brings about a major drawback well conceptualized by analytical philosophy. From the moment we are interested in art, we must recognize that a work of art is not an object which is given and which can be observed and described in a neutral way, but a semiotic entity which is constructed within and by interpretation. In order to avoid an incorrect conception of the work of art, we must admit that it supposes intentionality and representation. The two together suppose an interpretation, which is not hermeneutic but constituting. 'The work and the interpretation are born together in aesthetic conscience' writes A. Danto whose important theses must be remembered. The path followed in the transfiguration of the ordinary is in two stages. The first stage, negative, claims that the ontological specificity of the work of art does not reveal a material or perceptual property: the work of art, as is stated above, is not given to us in the same way as the objects of the world. The second stage, positive, tries to establish the criteria which are no longer perceptual but conceptual, categorical, thanks to which works of art come about for us as works. Posture which, by disciplinary provincialism no doubt, claiming to be very descriptive, lacks an essential dimension of the art with which sociology must count if it wants to avoid the trap of sterility, be it or not disguised in methodological precaution or in ethical concern.

N. Goodman is quite right to notice that the real question 'what is art?' too often has as its implicit equivalent this less correct question 'what is good art?' (It is useless to evaluate here to what extent this question can fuel arguments or abuse of those who consider contemporary art as trickery.) If it is possible to not share these viewpoints on the answers he gives, it is difficult to not join him in the validity of this correct question 'when is there art?' One can connect to this interrogation another question which stems from what we will call a cognitive sociology of art: in what and how can art be a source of knowledge for the sociologist?

Very simply but very usefully, art can function as a sign or symptom for the sociologist, and therefore serves as a political and social revealer. Tocqueville already underlined this cognitive dimension: 'When I arrive in a country and I see the arts giving some admirable products, this teaches me nothing about the social state and the political constitution of the country. However, if I notice that the products of the arts are generally imperfect there, in large quantities and at low prices, I am certain that, for the people where this occurs, privileges are weakening and the

classes are starting to mix together and will soon be confused.' This cognitive dimension exists in all the areas where art is enrolled at least partially in institutional dimensions. Adorno gives an interesting demonstration of this in the sociology of music; it can also be observed for example in urbanism and in architecture: monuments, the choices made in terms of conservation and restoration, translate a political willingness whose monument as a work of art is the vector. A. Riegl established this more than a century ago.

The cognitive contribution of art to the sociology of the same name is demonstrated in the most diverse ways. Whatever the noticeable differences between A. Warburg and E. Panofsky are and even if iconology conjugates no doubt excessively the verb 'to see' with the verb 'to know,' it is true that it paves the way for a fertile route of sociological research, as it gives a distinguished place to the faculty of knowing and ensures the possibility of an objective reading of works, given that this knowledge in no way exhausts the richness of the perception of the work. According to the hypothesis of E. Panofsky, gothic architecture, full of rigor and harmony, would be the pendant, materialized in stone, the rules of academic education recommending severity, rationality, and conceptual hierarchy. The market study of art offers an undeniable interest: its evolution allows for example the measurement of liberties and constraints linked for the artist and the work to the substitution of the tradesman for the guardian. In very contemporary studies, R. Moulin and N. Heinich insist upon the essential cognitive resources for the evolution of the 'world of art.' It is an undeniably rich perspective for the art sociologist to study the factors of contextualization which function like parameters for the actors. In this way, the elements of cooperation and conflict which weave the threads of the 'world of contemporary art' are correctly interrogated: among the art critics, conservationists, experts, buyers, gallery agents, guardians, auctioneers, and the numerous institutions, galleries, museums, sales by auction, local councils, public ministries, the interactions are complex and as it is ultimately up to either the representative of the citizen, which means the political figure, or the cultural intermediary, the representative of the artist, to engage plots, jousts, whose most obviously materialistic stakes are of financial order. We can appreciate the passion which stirs simple citizens and a part of their income, whatever their taste in terms of art, will be allocated to the subvention of works which they appreciate or despise.

The sociologist can also be inspired by the original path cleared by N. Goodman to enrich the sociological theory. For the latter, two types of existence characterize works of art, essentiality and transcendence. Essentiality corresponds to the type of object in which the work is constituted and is distributed in these two regimes which make up the 'autographics' and the 'allographics.' In accordance with the first, the object of essentiality, be it a picture or a sculpture, is material and shows itself. In the second, this object, a text, a musical composition, an architectural plan, is ideal, it is conceived by reduction beginning with its physical demonstrations, books, scores, and performances. Transcendence is defined by the diverse ways according to which a work projects its essentiality, mainly for what is important to the sociologist when the work acts in a different way according to places, periods, individuals, contexts, to use the reformulation which G. Genette gives of it. It is in relation to this last field of investigation that the work does not limit itself to its object of essentiality, because its being is not separable from its action, which leads to answering the question 'when is there art?' Among other contributions, the cognitive virtues to which the art sociologist can be attached are considerable. The properties of works of art act upon the emotions which perceive them; by touching the receiver of the work, they intervene with their cognitive categories by renewing and questioning certain intellectual categories. N. Goodman is quite right to maintain that mental categories grow rich when, concerning an area of red created by Rothko, it becomes possible, in a strange way, but not easily disputable, to recall the 'resonance' of a color. The sociologist is capable of giving precision to the last question by asking for example, when is there modern art and what would a sociology of modern art be made up of. The answer to this question summons up the contributions of the most diverse authors, sociologists, philosophers, and art historians from G. Simmel to L. Steinberg, E. Gombrich and R. Krauss among others. If, to be brief, modernism is distinguished by the emergence of the individual and individuality, how can we characterize certain works as realizing this modernism and how can artistic creation, questioned by the sociologist, increase the sociological knowledge surrounding modernism? Is there, and if so which one, a register of expressiveness which is particular to an art which could be qualified as being modern by the sociologist?

This register is that of simultaneity which art entrusts in all its forms. Simultaneity is declined in different ways. Below are the main ones.

(a) In the species of time, simultaneity is shown in the triumph of the instant compared to time as succession, length, and flow.

(b) In terms of style, simultaneity adopts a non-narrative character which is combined with different effects of oxymore.

(c) Simultaneity in modern art is strongly connected to the notion of living metaphors (P. Ricoeur).

Simultaneity and instance are strongly linked. In 1917, G. Simmel gives a conceptual compulsion in sociology whose impact on the sociology of art is worth underlining, by saying that 'the coexistence of individuals having shared relationships amongst

themselves, causes within each of them what cannot be explained about only one of them.' It appears here that it is not or is no longer subjectivity which leads and precedes intersubjectivity, but the opposite: it is mutual action which generates within all protagonistical effects which inform, model, determine, and constitute their own subjectivity. One must therefore, and this is what Rodin suggests, 'read' by Simmel, give up the classical conception of an ego founder: the me, modern, is crossed, shaped by the encounter with others, it is not constituted in a previous way to the reciprocity of action, it is for a large part the result of it. With Rodin, interpreted by Simmel, but also by Rilke, it is the individual who loses his substantial stability to be, in the light of modernism, thought of as a process, as mobility. This radicalism of movement, displayed by the instant, is expressed no longer in terms of succession but in terms of simultaneity: man is no longer alternatively, following the course of time, happy then alternatively worried, frightened then reassured, gay then gloomy, he lives the harmony of these contrasts within the very moment.

Another perceptible demonstration of the instant in the actual style of works lies within the physical and technical means which, by the impression of incompletion, give priority to the instant, to a time whose length slips away. The importance can be measured not only with Simmel but with others also who dedicate, on this subject, their analyses to Rembrandt and to Rodin. S. Alpers notes that Rembrandt, and this is an element of rupture with his contemporaries, initiates a 'rugged' way of painting. This absence of the 'completed,' contrasted with his contemporaries who adopted as from 1650 a 'smooth' style, at the same time a security for the guardian or the seller, who read within this plainness an impression of toil almost convertible into hours of work, in a word, a guarantee for them. L. Steinberg, in the field of sculpture, notes with Rodin, not the indifference of the artist, but his or her choice to lead perception in the direction of the instant, materialized there again by the impression of incompletion. The sculptor, by deliberate choice, uses all the artifacts intended to show the work as an accidental product of a process. For example, the balls of wet clay, in principal temporary, that the sculptor or his assistants add by precaution in order to be able to give more dimension to a surface, remain within the bronze, even if Rodin is determined that he does not use this. In this perspective, many works of Rodin owe a part of their modern style to this welcoming of the accidental which marks the rise of the instant.

Modernism finishes with narrative, and what surrounds the narrative, the coherence of a univocal story. With Rodin (R. Krauss), the part devolving to time is retracted to that of the instant. The strategy used to do justice to this instantaneous character appears in the choice of the non-narrative procedure by excellence; on the contrary, the *Marseillaise de Rude*, low relief which ornates the *Arc de Triomphe*, chooses, compared with Rodin, to represent the fertile moment, the one which in some ways, in a narrative way, tells and reveals the historical sense of a moment freed from the pure contingency of the event. The 'reading' aroused by the architecture of the low relief invites the spectator to a deciphering regulated by an order of succession, leading the eye from right to left in a movement of elevation to demonstrate progressive awakening of the conscience in the sense of freedom. What the sociologist teaches Rodin is that the latter, in the classical sense of the term, teaches us nothing. He tells no story, teaches us nothing about the flow of an event, does not inform us. From him to us, nothing of any sort of educational ambition, but the distilling of a concern, of an uncertainty which nothing could remove, nor the knowledge of a master, nor the univocal interpretation of the interpreter. In his work *La Porte de l'enfer*, there is no trace of the univocity of a speech skilfully declined by the spatial organization of scenes which would follow each other. On the contrary, all the methods are summoned to erase the apparent narrative pretext which is the reference to Dante; this reference is totally subverted by numerous devices. One will be retained due to the richness of its effects, oxymore.

Oxymore, the fact, despite the logic and its requirement of the excluded third (a traffic light is red or green, it cannot be one and the other at the same time) that in the area of art, more or less and with modern art precisely, the polarity of logical contradictions is displayed and maintained, creates a new language of art. Referring to the paintings of Böcklin, Simmel speaks in an oxymorical way about a happy melancholy of living. This polarity of apparent opposites of which none will ultimately give way to another, is the most effective and concerning vector of modern individuality, conceptually inexpressible but perceptible in modern works. Simmel and E. Gombrich made no mistake. This uncertainty of the effect of oxymore, compared to the univocity of narration, is constant with Rodin. In a simultaneous way, opposed axes of interpretation are imposed upon us, without the receiver of the work having to solve an enigma in order to retain the 'right' interpretation: it is their maintained polarity which is the whole of the modern individual. Rodin thus chose the ambiguity of contradictory meanings. In this way, the *Le Fils prodigue*, with his enormous arms stretched upwards, expresses an indissociable unity of gratitude and despair, of entreaty and actions of grace. With Rembrandt, this procedure of oxymore can be found clearly, via which modern individuality becomes specific. The analyses of Simmel are congruous with those of E. Gombrich, without the latter having read Simmel. E. Gombrich, like Simmel, notices this ability that Rembrandt possesses to surpass and neglect conceptual expression, generalizing and therefore not individualizing passions embodied within such a singular person. The forger who tries to represent the disciples of *Emmaüs*

does not manage to represent the charge of emotion of this scene; he or she exaggerates the line in an expressionistic way. Instead of seizing the singularity of the emotion composed of contradictory and simultaneous emotions, he or she chooses one of them, terror, which he or she freezes in an academical general nature. Instead of this, the work of the hand of Rembrandt creates an effect of oxymore which translates the complexity of life into one of these instants: the sketch of a disciple allows us to see, in a simultaneous way, how the joy of the recognition of Christ is composed of an impression of fear.

Simultaneity in art is partly connected to the notion of metaphor as P. Ricoeur understands it, and with the notion of model as it is conceptualized by R. Boudon and M. Black. The model presumes, compared to a narrative text, a tabular reading, instantly right. Compared to R. Jakobson who stands for a substitutive conception of metaphor, and therefore allows no cognitive content, the metaphor is a method of interaction, in working within modern art, which produced in a cognitive way this sudden appearance, this new aspect, this supplement to knowing that one can hope for without having the means to anticipate it. The metaphor, as P. Ricoeur correctly states, maintains two thoughts of different things simultaneously active within an expression whose signification is the result of interaction. In this sense, the metaphor, towards which art sociologists should direct their thoughts as its effectiveness does not confine itself to this part of art which is modern art, is of the nature of creation of invention. A partial exploration of this is found with A. Danto, and more significantly with N. Goodman.

The consensual relativism currently in fashion in the 'art world' would be eased by an in-depth study of the metaphorical processes which are at the origins of art. Even the relativism of N. Goodman is moderated by this epistemological idea according to which the 'ways of making the worlds' emerge into a diversity without limits but are corrected by the possibility of distinguishing between correct and incorrect versions. Without intending to force the thoughts of N. Goodman, we can usefully come back to Aristotle who offers a definition of the metaphor which is capable of wavering ambient relativism: to metaphorize well is to notice the similar. The 'immeasurable' works of relativism, revisited by the riddle of the metaphor, could therefore be arranged, at least partially, according to a line of intelligibility which distinguishes the similar despite the difference.

Artificial and Natural Computation

1. Introduction

1.1 Survey

This article discusses the notion of computation in natural, as well as in artificial systems. Particular emphasis lies on artificial computation models which are derived from natural systems that perform computation. The term 'computation' here refers to all processes that systematically evaluate a certain (mathematical) function. That is, computation refers to all processes that determine a value or magnitude depending on one or more factors (parameters). The article sketches the main direction of research in the past decades on modeling computational processes in natural systems. This concerns on the one hand computation in nervous systems, such as the human brain and their artificial models. On the other hand, there is the process of biological evolution, of which artificial computer models proved useful as a general approach to solving difficult design and optimization problems.

State	Symbol		State	Symbol	Head
1	A	→	2	A	L
1	B	→	3	C	R
1	C	→	6	C	L

1.2 Historical Background

In the 1930s a precise mathematical notion of computation was developed, which also captures everything that can be computed in modern computers. What exactly natural computation is, and how it is conducted in natural systems, such as the human brain, is less well understood. However, the mathematical notion of computation has proved a convenient and very useful form for 'describing' information processing in natural systems.

Wiener (1948) introduced the discipline of cybernetics, which was concerned with control systems, including natural systems, such as the human body, in which feedback loops control the secretion of glands, etc. In the following decades, computational models of biological systems were developed and used to address a variety of difficult problems for which conventional solutions were not readily available. The research on models of natural computation has mainly focused on models of the human brain and its neurons on the one hand and on biological evolutionary processes on the other hand.

Another type of computation in 'natural systems' was shown by Adleman (1994), when he theoretically demonstrated the use of DNA molecules as a means of solving computational problems. The work showed the potential for building computers on the basis of molecular biology.

This article focuses on the main research efforts in the past decades and discusses artificial models of natural computation in neural systems. Furthermore, the use of models of biological evolution for solving computational problems will be sketched. The article is organized as follows: first, the mathematical notion of computation is discussed. This is followed by a description of computation in those natural systems, for which most of the artificial models of natural computation have been developed: the human brain and evolutionary processes in biology. The relationship between the natural computing processes and the artificial models of them are thereafter discussed.

2. The Mathematical Notion of Computation

In the 1930s it was an important problem in mathematics to delineate those functions for which the function value can be 'computed' for all possible arguments, from those functions for which the function value may not be effectively computable, i.e., for which the value cannot be determined by executing a finite number of 'calculations' or evaluation steps. (For functions, which contain themselves either directly or indirectly in their definition, it is not straightforward to decide whether a value can effectively be determined for all possible arguments.)

Turing (1937) developed a model for what a mathematician can possibly do, when computing the value of a function according to clearly defined rules, and he argued that no human mathematician could possibly follow other clearly defined rules, which are not covered by his model. This model became known as the 'Turing machine.' Other mathematicians developed alternative models for how to effectively compute mathematical functions. However, it was proved that with all these different models, exactly the same class of functions was effectively computable.

2.1 The Turing Machine

A Turing machine has a finite number of internal states. A tape on which the Turing machine can read and write symbols from a finite alphabet via its read/write head is unlimited on both sides. The Turing machine starts its operation in a particular internal state and terminates its operation in another particular state. The read/write head will focus on the first square on the tape, where the input string (in consecutive squares) to its computation is provided. The Turing machine will execute a sequence of operations. Each of these operations depends on the current symbol under the read/write head and its internal state, and is specified in the corresponding Turing table. The operation may erase the old symbol on the tape in the square under the read/write head and replace it by another symbol. Furthermore, the Turing machine may change its internal state and move (optionally) its read/write head one square to the left or to the right. The entire computation terminates when the Turing machine reaches the special internal termination state. The result of the computation is found at a pre-specified location on the tape relative to the position of the read/write head. An example is shown in Fig. 1.

An important concept is the 'universal Turing machine,' which is a special Turing machine that is capable of simulating any other Turing machine, if a description of that machine is provided as input on the tape. The existence of the universal Turing machine demonstrates the relativity of the actual device on which the computation is performed. Generally speaking, a computing device can behave in quite different ways depending on what data are provided to it. In the case of a computationally universal computing device, all other computing devices can be simulated, if appropriate data, i.e., an appropriate program, is provided.

Today's computers are generally said to be computationally universal, although they are not really as a physical computer has limited memory (a tape of finite length). Nevertheless, it is commonly assumed that all natural computation can be simulated on an artificial computation device. Strictly speaking, however, there is not enough known about what 'programs' are actually 'executed' in natural computation processes. While today's scientists commonly assume that the human mind works deterministically, it should be noted that this is really just a working hypothesis for which there is no proof whatsoever. Opposed to that are computations in Turing's sense deterministic by definition.

3. *Artificial and Natural Computation in Neural Systems*

3.1 *Artificial Computation in Neural Systems*

Artificial computation in artificial neural networks is a metaphorical model of natural computation in biological neural systems, such as the human brain. Usually, large sets of computing units, connected in a network like manner, are used to simulate the way natural neural networks in humans and animals perform information processing. Often, the computing units are all of the same type and compute some sort of linear threshold function, i.e., they sum up the weighted input signals and compare the sum against a threshold value. Today, output functions of a sigmoidal shape or a simple step function are common. The simple model of a neuron's functionality using a step function is due to McCulloch and Pitts (1943). The unit computes internally the function:

$$f(i_1,\ldots, i_n) = \sum_{j=1}^{n} w_j i_j$$

where i_j is the jth input and w_j is the weight associated to the jth input. This internal function is used to calculate the output value by applying, either a step function or a differentiable function, e.g., a sigmoid function to it, such as:

$$out(i_1,\ldots, i_n) = \frac{1}{1+e^{-af(i_1,\ldots, i_n)}}$$

with a scaling parameter a. This maps the internal function value in the range of $[-\infty, \infty]$ (often actually a rather small range instead) to a value in the range [0, 1] strictly monotonically as shown in Fig. 2 (right). The weights for each individual unit usually vary and are often determined by an automatic adjustment process, also called 'training' or 'learning.' The first well-known learning algorithm for such neuronal models was developed by Rosenblatt (1962), who used a step function as opposed to the mentioned sigmoid output function.

Artificial neural networks are usually composed of a large number of such units, e.g., in engineering applications, the number of units typically ranges between as few as ten and as many as several thousand. The units are normally arranged in a layered fashion, similar to the structure in Fig. 2 (left), where the outputs of the units on one layer are fed as inputs to the units on the next layer. Such networks are also known as Multi-Layer Perceptrons (usually abbreviated as MLP since the hallmark publication of Rumelhart et al. (1986)). In combination with learning techniques which find appropriate weights for each unit, these networks have been successfully applied to

Figure 2
Left: A feed-forward neural network (multi-layer perceptron). Right: A sigmoid output function

a large number of engineering problems, such as general classification problems, recognition of visual, acoustic and other patterns, and adaptive control of nonlinear systems.

It must be noted that the computational models of cognitive systems are not at all accurate replications of what is known about their biological functionality. To contrast the artificial neural networks, the following presents some of the current knowledge about the physiological basis of computation in the human brain.

3.2 Natural Computation in the Human Brain

The human brain is made up of a vast network of neurons coupled with receptors and effectors. The input to the network is provided by millions of receptors while the output of the brain is transformed into effects on the body and the external world via effectors. The receptors continually monitor changes in the internal and external environment. Hundreds of thousands of cells control the effectors, such as muscles and the secretion of glands.

The human brain is made up of thousands of millions of neurons. A typical estimate is about 10^{10}–10^{11}, i.e., 10–100 billion neurons. Many neurons have between 1,000 and 10,000 connections to other neurons in the brain. There are thousands of different types of neurons in the brain. This includes neurons whose purpose has been identified as being specialized to the processing of sensory information. Those specialized neurons which deal directly with the signals coming from sensors, which are receptors for light, sound, touch, etc., are called 'sensor neurons.' Other neurons are responsible for controlling muscles and are, therefore, called 'motor neurons.'

The brain can hardly be considered as a simple stimulus-response chain from receptors to effectors. The vast network of billions and billions of neurons is rather interconnected in extremely complex and diverse ways, including simple loops as well as complex feedback cycles. Thus, signals coming from the receptors are mixed with signals already traveling in this vast network resulting in a change of the signals traveling inside the network as well as generating signals for controlling the effectors.

In this way, the brain manages to generate actions which depend on both the current stimulation as well as on some residue of past experiences. Past experiences may be reflected in current activities of the network, i.e., certain signals traveling inside the network, as well as in the current pattern and strength of connections.

It is estimated that there are more than 1,000 different types of neurons in the human brain. As a consequence of this large variety of neurons, it is impossible to speak of 'the typical neuron.' However, a model of a neuron is sketched in Fig. 3, which captures some of the basic features and functionality found in many different types of neurons.

Figure 3
A schematic view of a neuron. The activity coming from receptors or from other neurons changes the membrane potentials on the dendrites and cell body (soma). The effects of these stimulations accumulate at the axon hillock where, for appropriate spatio-temporal patterns of stimulation, a threshold is reached which triggers a pulse of membrane potential to be propagated along the axon. This pulse is carried via the branching of the axon to the synaptic endbulbs, which in turn stimulate the membrane potential of the neurons or muscle fibers to which the synaptic endbulbs are connected. The dashed arrows indicate the direction of activity propagation through the axons

More than 40 properties of biological neurons are known to influence a neuron's information processing. One distinguishes three different parts in biological neurons: soma, axons, and dendrites (see Fig. 3). Biological neurons are connected with each other. Their connections are called 'synapses.' The axon may be considered as the output channel of the neuron which conveys its activation level to the synaptic connections with other neurons. The ends of the axons are called nerve terminals or 'endbulbs.' The dendrites on the other hand act as the neuron's input receptors for signals coming from other neurons. They convey the (electrical) input potential to the neuron's soma, i.e., to the neuron's body. The input potential in that case is also called 'post-synaptic potential.' The neuron's soma, in particular where it connects to the axon, i.e., in the 'axon hillock,' acts as an accumulator of input potentials and/or as an amplifier of these signals.

The tips of the branches of the axon impinge upon other neurons or upon other effectors. One says that the cell with the endbulb 'synapses upon' the cell with which the connection is made. In fact, the axonal branches of some neurons can have many 'endbulbs' that allow them to make synapses along their lengths as well as their ends.

3.3 Dynamics of Biological Neurons

Neural activations are mostly stimulated circularly. A neuron is activated by other neurons to which it is connected. In turn, its own activation stimulates other connected neurons to activation.

If an impulse is started at any one place on the axon, it propagates in both directions. However, if the pulse is started at one end of the axon (normally the axon hillock), it can only travel away form that end, since once a section has been triggered it becomes refractory until well after the impulse has passed out of range. An impulse traveling along the axon triggers new impulses in each of its branches, which in turn trigger impulses in their even finer branches. Axons come in two kinds: myelinated and unmyelinated. A myelinated fiber is wrapped in a sheath of myeline, a sequence of Schwann cells wrapped tightly around an axon with small gaps, called nodes of Ranvier, between adjacent segments. Instead of the somewhat slow active propagation down an unmyelinated fiber, the nerve impulse in a myelinated fiber jumps from node to node, thus speeding passage and reducing energy requirements. When an impulse arrives at one of the endbulbs, after a slight delay it yields a change in potential difference across the membrane of the cell upon which it impinges. The membrane of the endbulb is called the 'pre-synaptic membrane,' and the membrane of the surface upon which the endbulb impinges is called the 'post-synaptic membrane.' At most synapses the direct cause of the change in (electrical) potential of the post-synaptic membrane is not electrical but chemical. There are some exceptional cell appositions that are so large, or have so tight coupling, that the impulse affects the polarization of the post-synaptic membrane without chemical mediation. However, the normal process is that the electrical pulse that reaches the endbulb causes the release of 'transmitter' molecules from little packets called 'vesicles' through the pre-synaptic membrane. The transmitter then diffuses across the very small 'synaptic cleft' to the other side. When the transmitter reaches the post-synaptic membrane, it causes a change in the polarization of this membrane. The effect of the transmitter may be of two basic kinds: either 'excitatory,' tending to move the potential difference across the post-synaptic membrane in the direction of the threshold (depolarizing the membrane), or 'inhibitory', tending to move the polarization away from threshold (hyperpolarizing the membrane).

The many small changes in potential differences across the membrane of a neuron, due to the activity of many or all the synapses which impinge upon it, propagate—in most cases—passively through the membrane of its dendrites and its cell body. They decay as they propagate. At the axon hillock, many different and often small potential changes converge, so that the total contribution by which excitation exceeds inhibition may be quite large. In other words, the transmitter released when the impulse of a single synapse arrives at the endbulb, and generally causes a change in the postsynaptic membrane, is not usually large enough to trigger the neuron. Nonetheless, the cooperative effect of many such subthreshold changes may yield a potential change at the axon hillock that exceeds threshold, and if this occurs at a time when the axon has passed the refractory period of its previous firing, then a new impulse will be fired down the axon. See e.g., Arbib 1989, Arbib et al. 1997, Bower 2000, or the Journals *Biological Cybernetics*, *Journal of Neurobiology*, and others (see also *Connectionist Approaches*; *Perceptrons*)

From the foregoing it is clear that the current artificial neural networks are only very rough approximations of the natural neural systems. Furthermore, it has been proved that certain types of artificial neural networks (cellular automata) are even computationally universal. This, however, also implies that nothing has been gained from copying aspects of the human brain with respect to the function the cellular automata will compute. The function depends completely on the 'activity levels of the individual cells.' That is, with suitable initial activity patterns the system can compute any function one chooses.

4. Evolutionary Computation

Evolutionary computation is another field, that is strongly inspired by nature (see *Artificial Intelligence: Genetic Programming*). This field was pioneered independently in the 1960s by Fogel et al. 1966, Holland 1975, Rechenberg 1973. The latter two authors published their work in a widely accessible form only in the 1970s. Rechenberg used evolutionary strategies to develop highly optimized devices, such as irregularly shaped reduction pieces for pipes, e.g., for an air conditioning system, which proved to have a lower air flow resistance than ordinary reduction pieces.

In evolutionary computation, the process of natural evolution is used as a role model for a strategy for finding optimal or near optimal solutions for a given problem. In genetic algorithms, an important class of evolutionary computing techniques, candidates for a solution are encoded in a string, often a binary string only containing '0's and '1's. Evolution takes place by modifying the genetic code of a candidate.

Evolutionary techniques are generally applied to optimization problems. Many of those problems are combinatorial optimization problems, which are computationally hard (NP-hard) (see also *Algorithmic Complexity*).

This roughly means that programs are expected to require a computing time that grows exponentially with the size of the problem. One such problem is the traveling salesperson problem, where a number of

cities are given along with a distance matrix providing the traveling distance or cost for each pair of cities. The problem asks for the shortest possible round trip, i.e., the traveling salesperson departs from a given city and should visit all other cities before returning to the first city. For n cities, apart from the city of origin, there are $n!$ different round trips, provided there is a direct connection between every pair of cities. A substantial proportion of them has to be evaluated before one can be sure that the optimal round trip has been found. Hence, the number of computing steps grows exponentially with the number of cities to be visited. That is, the required computing time to find the optimal solution becomes impractical even for moderate numbers of cities on today's fast computers and those computers projected for the near future. As a consequence, one has to be content with a good solution as opposed to an optimal solution.

The traveling salesperson problem can be handled by a genetic algorithm according to the following sketch: a population of potential solutions (more or less randomly generated orderings of the cities) is created initially as the first generation in the evolutionary process. The fitness of each individual for a solution to the posed problem is assessed, i.e., the traveling distance is calculated. The next generation is created by retaining the better suited individuals in the population, i.e., those with smaller traveling distances. The less fit individuals are discarded. Furthermore, new individuals are created as 'offsprings' from the current population and added to the new generation. Offspring individuals are usually created by random mutations of the 'parents.' This may also include the combination of the genetic code of multiple parents, such as 'cross over' operators on the genetic code of two parent individuals.

From a more abstract point of view, such evolutionary approaches fall into the category of probabilistic algorithms. Other probabilistic algorithms, such as simulated annealing (which constitute another computer model of a natural, physical process), share the following common feature with the sketched genetic algorithms: a solution to the given optimization problem is developed by iteratively modifying one or more candidate solutions until a satisfactory solution is found. The iterative modification is based on some random decisions. Usually, a fitness measure is used to decide whether a new candidate solution is deemed any closer to an acceptable solution than previously generated candidates. Consequently, if a new candidate appears closer to an acceptable solution, the new candidate will normally be used to derive another modification. This is also called 'hill-climbing' in a search space. However, since no exact measure for the closeness of a candidate to an acceptable solution can generally be expected, a candidate that appears less close to an acceptable solution may still be selected for modification, but with less probability.

While the evolutionary strategies appear to be universally applicable, experience showed that in most cases problem-specific adaptations of the evolutionary scheme need to be made in order to allow the evolutionary process to generate a good solution in reasonable computing time. Such adaptations may consist of finding a suitable genetic encoding of a solution candidate, determining an effective size of the population, suitable probability parameters for generating certain mutations, etc. Another application of the sketched genetic techniques is the development of programs, as is done in the field of 'genetic programming' (see Koza et al. 1999 for more details). (See also *Artificial Intelligence: Genetic Programming*.) For more details on evolutionary computation, see e.g., Bäck et al. 1997.

5. *Summary and Prospects*

The presented artificial computing models of natural processes are the most studied models in recent years. They are models of biological neural systems and models of evolutionary processes in biology.

While nature inspired substantial research on these models, they are rather metaphorical models of the natural processes. Many known details of the natural processes are missing in these models. The models are not accurate and they are not meant to be accurate. Once simple models were developed, they were studied for their use in particular applications, such as solving certain combinatorial optimization problems or learning to classify images of characters. Hence, from an engineering perspective it is less important whether the models represent the natural processes authentically, as long as the models are useful for solving practical problems.

In regard to artificial neural networks, it is certainly desirable to enhance their capabilities, so that they come closer to the performance of the human brain. Given the substantial gap between the artificial models and what is known about the brain's physiology, an accurate computational model of the brain's physiology is not in sight. While it is unknown to what extent the brain's physiology needs to be modeled in order to produce a behavior, which would be comparable to a human, it seems likely that not all aspects of the physiology need to be modeled. Which aspects are necessary and sufficient is unknown at this stage.

The artificial evolutionary computation models are not accurate models of the biological processes either. However, their application in engineering and elsewhere are clearly directed towards artificial domains, i.e., engineering problems. Hence, one would not expect that the evolutionary computation models need to be accurate models of biological evolution.

However, it remains an open question how far the study of such metaphorical models of nature will lead? Perhaps there exist more suitable approaches which have no resemblance with nature. After all, there are

plenty of examples where excellent engineering solutions are very different from what is found in nature. For example, the invention of the wheel or the steam engine. On the other hand, there are also examples where a partial, metaphorical model of nature's solution to a problem can be supplemented with an artificial engineering approach. For example, the development of airplanes, which do not move their wings, but have rather 'artificial' propulsion mechanisms. See also Hoffmann (1998) for a discussion of the requirements of a computing model for being used as an engineering approach to the design of complex systems.

Artificial Intelligence: Connectionist and Symbolic Approaches

Perhaps the most significant feature of current artificial intelligence (AI) research is the co-existence of a number of vastly different and often seriously conflicting paradigms, competing for the attention of the research community (as well as research funding).

In this article, two competing paradigms of artificial intelligence, the connectionist and the symbolic approach, will lie described. Brief analysis and articism of each paradigm will be provided, and possible integration of the two will their respective shortcomings.

1. The Two Paradigms

The two main competing paradigms in artificial intelligence can be summarized as follows:

(a) The traditional symbolic paradigm (Newell and Simon 1976). The field of AI, since its inception, has been conceived mainly as the development of models using symbol manipulation. The computation in such models is based on explicit representations that contain symbols organized in some specific ways and aggregate information is explicitly represented with aggregate structures that are constructed from constituent symbols and syntactic combinations of these symbols.

(b) The more recently established connectionist paradigm (Rumelhart and McClelland 1986, Smolensky 1988). The emergence of the connectionist paradigm largely resulted from various dissatisfactions with symbol manipulation models, especially in their inability to handle flexible and robust processing in an efficient manner. The connectionist paradigm aims at massively parallel models that consist of a large number of simple and uniform processing elements interconnected with extensive links, that is, artificial neural networks and their various generalizations. In many connectionist models, representations are distributed throughout a large number of processing elements (in correspondence with the structure of such models). Sometimes the constituent

symbolic structures of aggregate information are embedded in a network and difficult to identify. Due to their massively parallel nature, such models are good at flexible and robust processing, and show promise at dealing with some tasks that have been difficult for the symbolic paradigm.

It should be emphasized that up until now, no single existing paradigm can fully address all the major AI problems. Each paradigm has its strengths and weaknesses, and excels at certain tasks while falls short at some others. This situation, in a way, indicates the need to integrate these existing paradigms somehow (see Sect. 4).

2. *Symbolic AI*

The *physical symbol system hypothesis* introduced by Newell and Simon (1976) clearly articulated the tenets of symbolic AI. They defined a *physical symbol system* as follows:

> A physical symbol system consists of a set of entities, called symbols, which are physical patterns that can occur as components of another type of entity called an expression (symbol structure). Thus a symbol structure is composed of a number of instances (or tokens) of symbols related in some physical way (such as one token being next to another).

They further claimed that symbols can designate arbitrarily: 'a symbol may be used to designate any expression whatsoever'; 'it is not prescribed *a priori* what expressions it can designate.' 'There exist processes for creating any expression and for modifying any expression in arbitrary ways.' Based on that, they concluded: 'A physical symbol system has the necessary and sufficient means for general intelligent action,' which is the (famed) *physical symbol system hypothesis*.

The physical symbol system hypothesis has spawned (and was used to justify) enormous research effort in traditional AI (and in cognitive science). This approach (classical symbolism) typically uses discrete symbols as primitives and performs symbol manipulation in a sequential and deliberative manner.

2.1 *Representation and Search*

Two fundamental ideas that originated in the earliest days of AI are search and representation,which have played central roles in symbolic AI.

Let us discuss the idea of search space first. In any problem (to be tackled by AI), there is supposed to be a space of *states* each of which describes a step in problem solving (inference). *Operators* can be applied to reach a new state from a current state. Search techniques adopted in the early days of AI include depth-first search and breadth-first search. In depth-first search, from the current state, the system examines one alternative (a 'path') at a time by applying one of the operators to the current state, which leads to a new state. Then from the new state, the same process is repeated, until it reaches a goal state or hits a dead-end where there is no operator that can be applied. In the latter case, the system backs up to a previous state and tries a different alternative. In breadth-first search, however, the system examines all alternatives ('paths') at once by applying each of all the applicable operators. Such exhaustive search techniques are inefficient. To speed up the search, many heuristic search algorithms have been proposed. The idea of search space has been applied in all the areas of AI, including in problem solving, natural language processing, robotics and vision, knowledge representation/reasoning, and machine learning (see Russell and Norvig 1995 for more details regarding search).

Another important idea is representation. It embodies the belief that knowledge should be expressed in an internal form that facilitates its use, corresponding to the requirement of the task to be handled and mirroring the external world (in some way). A variety of symbolic representational forms have been developed over the years in AI, and most of them are used in conjunction with search algorithms for inference. One of the earliest representational forms involves rule-based reasoning, in which discrete rules are used to direct search (inference). Rules are composed of both conditions, which specify the applicability of a rule, and conclusions, which specify actions or outcomes. Rules are modular: ideally each rule can be added to or deleted from a system, without affecting the other parts of the system (modularity may, however, inadvertently hamper computational flexibility and dynamic interaction in reasoning).

A popular form of rule-based reasoning is the production system, which evolved from some psychological theories that emerged in the 1960s and 1970s. A production system consists of (a) a production rule base (for storing all the rules), (b) a working memory (for storing initial, intermediate, and final results), and (c) a control structure for coordinating the running of the system. The inference process in a production system can be either forward chaining or backward chaining.

Formal logics constitute an alternative approach in rule-based reasoning, as advocated chiefly by John McCarthy (McCarthy 1968). They are relatively simple, formally defined languages capable of expressing rules in a rigorous way. Logic inference is performed in formally defined ways that guarantee the completeness and soundness of the conclusions, which can be carried out using a variety of algorithms beyond simple forward and backward chaining. Formal logics (and most production systems) are restrictive: one needs to have all conditions precisely specified in order to perform one step of inference. Thus, they are unable to deal with partial, incomplete, or approximate

information. There is also no intrinsic way for handling reasoning involving similarity-based processes (Sun 1994).

Another type of representation aims to capture the aggregate *structures* of knowledge (instead of dispersing such structures as in production systems). Knowledge can be organized in structured chunks, each of which is centered around a particular entity, and each can contain, or be contained in, other chunks. Each chunk contains all the pieces of information regarding a certain entity as well as their interrelations. For instance, a *frame* (as proposed by Marvin Minsky) represents a concept in terms of its various attributes (slots), each of which has a name (label) and a value. By organizing knowledge in frames, all the relevant pieces of information can be accessed in a structured way. A *semantic network* (as proposed by Ross Quillian) consists of a set of nodes, each of which represents a particular (primitive) concept, and labeled links, each of which represents a particular relation between nodes. Semantic networks also allow efficient and effective access of knowledge, albeit in a different way, by following links that go from one concept to all the others that have a particular relation to the original one, through, for example, 'spreading activation.' *Scripts* (proposed by Roger Schank and associates) are used for representing prototypical event sequences in stereotypical situations, for example, eating in a restaurant. In such a situation, there is an almost fixed sequence. Scripts help with the efficient recognition and handling of these sequences. The shortcomings of the above types of representations include: (a) structures often need to be determined *a priori* and hand coded, (b) they are usually fixed and cannot be changed dynamically, and (c) they can become too costly and unwieldy to capture the full extent of complex real-world situations.

Some more recent developments in the symbolic paradigm aim to remedy some of the problems with traditional symbolic representation, especially those of logic-based approaches, as discussed earlier. These extensions include Default Logic and Circumscription, among many others. For example, *Default Logic* is proposed to model default reasoning: it deals with beliefs based on incomplete information, which might be modified or rejected later on based on subsequent observations. These logics have some shortcomings, including the lack of capabilities for dealing with (a) approximate information, (b) inconsistency, and most of all, (c) reasoning as a complex, interacting process (Sun 1994). Thus, they are somewhat deficient from the standpoint of capturing human reasoning. For an overview of these models, see Davis (1990).

In a totally different vein, Zadeh proposed *fuzzy logic* (see Zadeh 1988), primarily to capture vagueness or approximate information in linguistic expressions, such as 'tall' or 'warm,' which have no clear-cut boundaries. The basic idea is as follows: for each concept, a set of objects satisfying that concept to a certain degree form a subset, namely a fuzzy subset. This fuzzy (sub)set contains as its elements pairs consisting of an object and its grade of membership, which represents the degree to which it satisfies the concept associated with the set. A fuzzy logic can therefore be constructed with which one can reason about the fuzzy truth values of concepts.

The *probabilistic approach* (especially the Bayesian network approach) treats beliefs as probabilistic events and utilizes probabilistic laws for belief combinations (Pearl 1988). Note, however, that human reasoning may not always conform to the assumptions and the laws of probability theory, probably in part because of the complexity of the formal models. In addition, it is not always possible to obtain adequate probability measures in practice.

2.2 Symbolic Learning

Learning is a major issue in AI, in Cognitive Science, and in other related areas. While very sophisticated representations have been developed in symbolic AI, learning is, comparatively speaking, difficult for symbolic AI. This is in part due to the fact that, from its inception, symbolic AI has been centered on representation, not learning.

Nevertheless, there have been some developments of symbolic learning, especially since the late 1980s (see Shavlik and Dietterich 1990). The majority of work in symbolic machine learning focuses on 'batch learning.' Typically, the learner is given all the exemplars/instances, positive and/or negative, before learning starts. Most of these algorithms handle the learning of concepts with simple rules or decision trees (Quinlan 1986). They typically involve (a) a division of all the instances/exemplars into mutually exclusive or overlapping classes (i.e., clustering), and/or (b) the induction of a set of classification rules describing the makeup of a concept (Michalski 1983, Quinlan 1986).

More recently, some symbolic learning algorithms have been extended to deal with noisy or inconsistent data and to deal with incremental learning. In addition, inductive logic programming, tries to induce more powerful first-order rules from data. Recently, there have also been some reinforcement learning algorithms that handle dynamic sequences, which necessarily involve temporal credit assignment (i.e., attributing properly a success/failure to some preceding steps). (See Shavlik and Dietterich 1990.)

2.3 Criticisms

Although the symbolic paradigm dominated AI and Cognitive Science for a long while, it has been steadily receiving criticisms from various sources (e.g., from Rodney Brooks, John Searle, and Hubert Dreyfus; see Dreyfus and Dreyfus 1986). The critics focused largely

on the disembodied abstractness of this approach, especially in relation to interacting with the world (Dreyfus and Dreyfus 1986). Some, such as John Searle, emphasized the importance of biological substrates of intelligence. Some other more specific criticisms have been identified earlier.

3. Connectionist AI

In the 1980s, the publication of the PDP book (Rumelhart and McClelland 1986) started the so-called 'connectionist revolution' in AI and cognitive science. The basic idea of using a large network of extremely simple units for tackling complex computation seemed completely antithetical to the tenets of symbolic AI and has met both enthusiastic support (from those disenchanted by traditional symbolic AI) and acrimonious attacks (from those who firmly believed in the symbolic AI agenda). Even today, we can still feel, to some extent, the divide between connectionist AI and symbolic AI, although hybrids of the two paradigms and other alternatives have flourished. However, much of the controversy was the result of misunderstanding, overstatement, and terminological differences.

Connectionist models are believed to be a step in the direction toward capturing the intrinsic properties of the biological substrate of intelligence, in that they have been inspired by biological neural networks and seem to be closer in form to biological processes. They are capable of dealing with incomplete, approximate, and inconsistent information as well as generalization.

3.1 Connectionist Learning

Connectionist models excel at learning: unlike the formulation of symbolic AI which focused on representation, the very foundation of connectionist models has always been learning. Learning in connectionist models generally involve the tuning of weights or other parameters in a large network of units, so that complex computations can be accomplished through activation propagation through these weights (although there have been other types of learning algorithms, such as constructive learning and weightless learning). The tuning usually is based on gradient descent or its approximations. The best known of such learning algorithms is the backpropagation algorithm (Rumelhart and McClelland 1986).

In terms of task types tackled, connectionist learning algorithms have been devised for (a) supervised learning, similar in scope to aforementioned symbolic learning algorithms for classification rules but resulting in a trained network instead of a set of classification rules; (b) unsupervised learning, similar in scope to symbolic clustering algorithms, but without the use of explicit rules; (c) reinforcement learning, either implementing symbolic methods or adopting uniquely connectionist ones.

Connectionist learning has been applied to learning some limited forms of symbolic knowledge. For example, Pollack (1990) used the standard backpropagation algorithm to learn tree structures, through repeated applications of backpropagation at different branching points of a tree, in an auto-associative manner (named which was auto-associative memory, or RAAM). Since trees are a common symbolic form, this approach is widely applicable in learning symbolic structures. Similarly, Giles and co-workers (see, e.g., Giles and Gori 1998) used backpropagation for learning finite-state automata, another common symbolic structure. Connectionist learning algorithms combine the advantages of their symbolic counterparts with the connectionist characteristics of being noise/fault tolerant and being capable of generalization. For an overview of both symbolic and connectionist learning, see Shavlik and Dietterich (1990).

3.2 Connectionist Knowledge Representation

Although it is relatively difficult to devise sophisticated representations in connectionist models (compared with symbolic models), there have been significant developments of connectionist knowledge representation. Many so-called 'high-level' connectionist models have been proposed that employ representation methods that are comparable with, and sometimes even surpass, symbolic representations, and they remedy some problems of traditional representation methods as mentioned earlier. For an overview of connectionist knowledge representation, see Sun and Bookman (1995).

Let us look into some of these developments in detail. First of all, logics and rules can be implemented in connectionist models in a variety of ways. For example, in one type of connectionist system, inference is carried out by constraint satisfaction through minimizing an error function. The process is extremely slow though. Another type of system, as proposed by Shastri and many others in the early 1990s, uses more direct means by representing rules with links that directly connect nodes representing conditions and conclusions, respectively, and inference in these models amounts to activation propagation. They are thus more efficient. They also deal with the so-called variable binding problem in connectionist networks. Those advanced logics as mentioned earlier that go beyond classical logic can also be incorporated into connectionist models (see, e.g., Sun 1994).

Aggregate information can also be incorporated into connectionist models. A system developed by Miikkulainen and Dyer (1991) encodes scripts through dividing input units of a backpropagation network

into segments each of which encodes an aspect of a script in a distributed fashion. The system is capable of dealing with incomplete (missing) information, inconsistent information, and uncertainty. There are also localist alternatives (such as those proposed by Lange and Dyer in 1989 and by Sun in 1992), in which a separate unit is allocated to encode an aspect of a frame.

Search, the main means of utilizing knowledge in a representation, is employed or embedded in connectionist models. Either an explicit search can be conducted through a settling or energy minimization process (as discussed earlier), or an implicit search can be conducted in a massively parallel and local fashion. Symbolic search requires global data retrieval and is thus very costly in terms of time. Global energy minimization (as in some connectionist models) is also time consuming. Local computation in connectionist models is a viable alternative. Knowledge is stored in a network connected by links that capture search steps (inferences) directly. Search amounts to activation propagation (by following links, similar to semantic networks in a way), without global control, monitoring, or storage.

The advantage of connectionist knowledge representation is that such representation can not only handle symbolic structures but goes beyond them by dealing with incompleteness, inconsistency, uncertainty, approximate information, and partial match (similarity) and by treating reasoning as a complex dynamic process. However, developing representation in highly structured media such as connectionist networks is inherently difficult.

4. *Hybrid Models*

Given the different emphases and strengths of connectionist and symbolic systems, it seems plausible that combining them would be a promising avenue for developing more robust, more powerful, and more versatile systems. The need for such systems has been slowly but steadily growing. There has been a great deal of research recently, leading to so-called hybrid systems.

The relative advantages of connectionist and symbolic models have been amply argued—see, e.g., Waltz and Feldman (1988), Smolensky (1988), and Sun (1994). The computational advantage of the combination thereof is thus relatively easy to justify. Naturally, we want to take advantages of both types of models and their synergy (see, e.g., Dreyfus and Dreyfus (1986), Sun and Bookman (1995), and Sun and Alexandre (1997) for further justifications).

There are many important issues to be addressed in developing hybrid connectionist-symbolic systems. These issues concern architectures, learning, and various other aspects. First, hybrid models likely involve a variety of different types of processes and representations. Multiple heterogeneous mechanisms interact in complex ways. We need to consider ways of structuring these different components; in other words, we need to consider *architectures*, which thus occupy a more prominent place in this line of research. Second, although purely connectionist models, which constitute part of any hybrid system, are known to excel in their learning abilities, hybridization makes it more difficult to perform learning. In a way, hybrid systems inherit the difficulty with learning from the symbolic side and mitigate to some extent the advantage that (purely) connectionist models have in terms of learning.

4.1 *Architectures and Representations*

We divide systems into two broad categories: *single-module* and *multimodule* architectures. Among single-module systems, along the representation dimension, there can be the following types (Sun and Bookman 1995): symbolic, localist (with one distinct node for representing each concept; see, e.g., Lange and Dyer 1989, Shastri and Ajjanagadde 1993) and distributed (with a set of nonexclusive, overlapping nodes for representing each concept; see, e.g., Pollack 1990). Among multimodule systems we can distinguish between *homogeneous* and *heterogeneous* systems. Homogeneous systems are similar to single-module systems, except they contains several replicated copies of the same structure, each of which can be used for processing the same set of inputs, to provide redundancy for various reasons.

Heterogeneous multimodule systems are more interesting. This category constitutes the true hybrid systems. As an example, CONSYDERR (Sun 1994) belongs to this category. It consists of two levels: the top level is a network with localist (symbolic) representation, and the bottom level is a network with distributed representation; concepts and rules are represented diffusely in the bottom level by sets of feature units overlapping each other. This is a similarity-based representation, in which concepts are 'defined' in terms of their similarity to other concepts in these representations. The localist network is linked with the distributed network by connecting each node in the top level representing one concept to all the feature nodes in the bottom level representing the same concept. Through a 3-phase interaction between the two levels, the model is capable of both rule-based and similarity-based reasoning with incomplete, inconsistent, and approximate information, and accounts for a large variety of seemingly disparate patterns in human reasoning data.

A variety of distinctions can be made here. First of all, a distinction can be made in terms of representations of constituent modules. In heterogeneous

multimodule systems, there can be different combinations of different types of constituent modules, for example, a system can be a combination of localist modules and distributed modules (as in CONSYDERR discussed above) or it can be a combination of symbolic modules and connectionist modules (either localist or distributed, e.g., as in SCRUFFY described by Hendler in Barnden and Pollack (1991)). Some of these combinations can be traced to the ideas of Smolensky (1988), who argued for the dichotomy of conceptual and subconceptual processing.

Another distinction which can be made among heterogeneous multimodule systems is in terms of the *coupling* of modules: a set of modules can be either loosely coupled or tightly coupled. In loosely coupled situations, modules communicate with each other, primarily through message passing, shared memory locations, or shared files, as in, for example, SCRUFFY (see Hendler's chapter in Barnden and Pollack 1991). Such loose coupling enables some loose forms of cooperation among modules. One form of cooperation is in terms of pre/postprocessing vs. main processing: while one or more modules take care of pre/postprocessing, such as transforming input data or rectifying output data, a main module focuses on the main part of the task. Another form of cooperation is through a master-salve relationship: while one module maintains control of the task at hand, it can signal other modules to handle some specific aspects of the task. For example, a symbolic expert system, as part of a rule, may invoke a neural network to perform a specific classification or decision making. Yet another form of cooperation is the equal partnership of multiple modules. In this form, the modules (the equal partners) can consist of (a) complementary processes, such as in SOAR/ECHO (Johnson et al. in Sun and Alexandre 1997), or (b) multiple functionally equivalent but structurally and representationally different processes, such as in CLARION (Sun and Peterson 1998), or (c) they may consist of multiple differentially specialized and heterogeneously represented experts each of which constitutes an equal partner in accomplishing a task.

In tightly coupled systems, on the other hand, the constituent modules interact through multiple channels (e.g., various possible function calls), or may even have node-to-node connections across two modules, such as CONSYDERR (Sun 1994) in which each node in one module is connected to a corresponding node in the other module. There are a variety of forms of cooperation among modules, in ways quite similar to loosely coupled systems.

4.2 Learning

Learning, which can include (a) learning the content (knowledge) in a hybrid model or (b) learning and developing the model architecture itself, is a fundamental issue that is clearly difficult. However, learning is indispensable if hybrid systems are ever to be scaled up. Over the years, some progress on learning has been made. While some researches have tried to extend connectionist learning algorithms to learn complex symbolic representations, others have instead incorporated symbolic learning methods. For example, Sun and Peterson (1998) presented a two-module model CLARION for learning sequential decision tasks, in which symbolic knowledge is extracted on-line from a reinforcement learning connectionist network and is used, in turn, to speed up connectionist learning and to facilitate transfer. The work showed not only the synergy between connectionist and symbolic learning, but also that symbolic knowledge can be learned autonomously on-line, from subsymbolic knowledge, which is very useful in developing autonomous agents.

Learning methods that may be applied to hybrid systems include gradient descent and its many variations (extending typical connectionist learning algorithms), Expectation-Maximization and its many instantiations (including hidden Markov model algorithms), search algorithms, evolutionary algorithms, and heuristic methods (such as decision trees or rule induction; see Shavlik and Dietterich 1990). Some of these methods may be combined with others (as in Sun and Peterson 1998), which likely results in improved learning. There are a variety of other learning approaches being proposed also, including many rule extraction or insertion algorithms.

There is a sense that future advance in this area is dependent on progress in the development of new learning methods for hybrid systems and the integration of learning and complex symbolic representations. As mentioned above (see Sun and Peterson 1998), symbolic representation and reasoning may well emerge from subsymbolic processes through learning, and thus an intimate and synergistic combination of symbolic and subsymbolic learning processes should be pursued.

4.3. Discussion

Despite the diversity of the approaches discussed thus far, there is an underlying common theme: bringing together symbolic and connectionist models to achieve a synthesis of the two seemingly radically different paradigms.

There is no doubt that we need to invest substantial efforts in comparing and analyzing various paradigms, especially the symbolic paradigm and the connectionist paradigm, to reveal their respective strengths and limitations, as well as underlying assumptions, which can lead to better understanding and more rapid advancement of this field. Although significant advances have been achieved so far, this process is still on-going today, and it appears that it will not be concluded until a better understanding is achieved of the nature of intelligence in computational terms.

In the meantime, it is an appealing idea that representation and learning techniques from both symbolic processing models and connectionist network models shall be brought together to tackle problems that neither type of model alone can apparently handle very well.

One such problem is the modeling of human cognition, which requires dealing with a variety of cognitive capacities. Several researchers (e.g., Smolensky 1988, Dreyfus and Dreyfus 1986) have consistently argued that cognition is multifaceted and better captured with a combination of symbolic and connectionist processes. Many methods and frameworks reviewed above share the belief that connectionist and symbolic methods can be usefully integrated, and such integration may lead to significant advances in our understanding of cognition. It thus appears that hybridization is a theoretically sound approach, in addition to being a practically expedient approach.

Artificial Intelligence: Genetic Programming

1. Introduction

The term genetic programming (GP) describes a research area within artificial intelligence (AI) that deals with the evolution of computer code. The term evolution refers to an artificial process analogous to natural evolution of living organisms, but which has been abstracted and stripped of most of its intricate details. The resultant algorithms then yield approximate solutions to problems in machine learning or induce precise solutions in the form of grammatically correct (language) structures for the automatic programming of computers.

Genetic programming is part of the growing set of evolutionary algorithms which apply search principles analogous to those of natural evolution in a variety of different problem domains, notably parameter optimization. Evolutionary programming, evolutionary strategies, and genetic algorithms are three other

branches of the area of evolutionary algorithms which mostly find applications as optimization techniques.

All evolutionary algorithms follow Darwin's principle of differential natural selection. This principle states that the following preconditions must be fulfilled for evolution to occur via (natural) selection:

There are entities called individuals which form a population. These entities can reproduce or can be reproduced.

There is heredity in reproduction, that is to say that individuals produce similar offspring.

In the course of reproduction there is variety which affects the likelihood of survival and therefore of reproducibility of individuals.

There are finite resources which cause the individuals to compete. Due to overreproduction of individuals not all can survive the struggle for existence. Differential natural selection exerts a continuous pressure towards improved individuals.

The representation of programs, or generally structures, in GP has a strong influence on the behavior and efficiency of the resulting algorithm. As a consequence, many different approaches toward choosing representations have been adopted in GP. The resulting principles have been applied even to other problem domains such as design of electronic circuits or art and musical composition.

2. *The Mechanisms Behind Genetic Programming*

Genetic programming works with a population of programs that are executed or interpreted in order to judge their behavior. Usually, a scoring operation called fitness measurement is applied to the outcome of the behavior. For instance, the deviation between the quantitative output of a program and its target value (defined through an error function) could be used to judge the behavior of the program. This is straightforward if the function of the target program can be clearly defined. Results may also be defined as side-effects of a program, such as consequences of the physical behavior of a robot controlled by a genetically developed program. Sometimes, an explicit fitness measure is missing, for instance in a game situation, and the results of the game (winning or losing) are taken to be sufficient scoring for the program's strategy. The general approach is to apply a variety of programs to the same problem and to compare their performance relative to each other (see Fig. 1).

The outcomes of fitness measurement are used to select programs. There are a number of different

Figure 1
The variation selection loop of GP

Figure 2
The primary operations of GP, mutation, and crossover are applied here to programs represented by the sequences of instructions. The instructions are coded as integer numbers which allows easy manipulation by access to these numbers

methods for selection, both deterministic and stochastic. Selection determines (a) which programs are allowed to survive (overproduction selection), and (b) which programs are allowed to reproduce (mating selection). Once a set of programs has been selected for further reproduction, the following operators are applied: reproduction, mutation, and crossover. Reproduction simply copies an individual, mutation varies the structure of an individual under control of a random number generator, and crossover mixes the structure of two (or more) programs to generate one or more new programs (see Fig. 2). Additional variation operators are applied in different applications. Most of these contain problem knowledge in the form of heuristic search recipes which are adapted to the problem domain.

In this way, fitness advantages of individual programs are exploited in a population to lead to better solutions. A key effort in GP is the definition of the fitness measure. Sometimes the fitness measure has to be iteratively improved in order for the evolved solutions actually to perform the function they were intended for. The entire process can be seen in close analogy to breeding animals. The breeder has to select those individuals from the population which carry the targeted traits to a higher degree than others.

Researchers (Turing 1950, Friedberg 1958, Samuel 1959) suggested ideas similar to GP already in the early days of AI, but did not get very far. So it was only after other techniques in evolutionary algorithms had been successfully developed that GP emerged. Earlier work concerned genetic algorithms (Holland 1975), evolution strategies (Schwefel 1981), and evolutionary programming (Fogel et al. 1966). These methods have been applied successfully to a wide spectrum of

problem domains, especially in optimization. However, it was unclear for a long time whether the principles of evolution could be applied to computer code, with all its dependencies and structural brittleness. Negative results from early experiments seemed to indicate that evolution of computer code was not possible. Successes were all in the area of constraint optimization (Michalewicz 1996), where methods were made available for how to deal with structural brittleness. These methods found their way into programming and gave rise to the new field of GP (Koza 1992).

3. *Progress and State-of-the-art*

In his seminal work of 1992, Koza established the field of GP by arguing convincingly that manipulation of symbolic tree structures is possible with evolutionary algorithms and that the resulting technique would have a wide variety of applications. In subsequent years, the field experienced both broadening and deepening (Banzhaf et al. 1998). Many different representations for GP were studied, among them other generic data structures such as sequences of instructions or directed graphs, as well as more exotic data structures such as stacks or neural networks. Today, different approaches are considered as GP, from the evolution of parse trees to the evolution of arbitrary structures. The overarching principle is to subject structures with variable complexity to forces of evolution by applying mutation, crossover, and fitness-based selection. The results must not necessarily be programs.

An ever-present difficulty with GP is that the evolution of structures of variable complexity leads often to large structures with considerable redundancy. Notably, variable complexity often leads to inefficient and space-consuming code. It was subsequently recognized that the evolutionary forces exerted a pressure toward more complex solutions, most of which could be removed after evolution without doing any harm to the evolved solution. By drawing an analogy from biological evolution of genomes, this phenomenon was called 'intron growth,' or growth of ineffective code. Thought the explanation for this phenomenon is not fully understood yet, it was found that at least two different influences were at work promoting the growth of complexity during evolution. The most important one has to do with the protection effect of redundant code if subjected to the action of crossover or mutation. Redundant code was resistant to crossover and mutation and allowed its carrier solution to survive better, compared to other individuals which did not possess the redundancy.

Currently, many researchers are working to transfer results from research in genetic algorithms to genetic programming. To achieve results in GP is generally more difficult since it works with variable complexity and multiple fitness cases for fitness scoring. The schema theory of genetic algorithms (Goldberg 1989, Vose 1999) has been a primary target of knowledge transfer. In the meantime, a number of different schema theorems have been formulated for GP.

When analyzing search spaces of programs it was realized that their size is many orders of magnitude larger than search spaces of combinatorial optimization problems. A typical size for a program search space might be $10^{100,000}$, as opposed to a typical search space for a combinatorial optimization problem of the order of 10^{100}. Although this might be interpreted as discouraging for search mechanisms, it was also realized that the solution density in program spaces is, above a certain threshold, constant with changing complexity (Langdon 1999). In other words, there are proportionally many more valid solutions in program spaces than in the spaces of combinatiorial optimization problems.

4. *Applications*

The main application areas of GP are (from narrow to wide) (Banzhaf et al. 1998): computer science, science, engineering, and art and entertainment. In computer science, the development of algorithms has been a focus of attention. By being able to manipulate symbolic structures, genetic programming is one of the few heuristic search methods for algorithms. Sorting algorithms, caching algorithms, random number generators, and algorithms for automatic parallelization of code (Ryan 2000), to name a few, have been studied. The spectrum of applications in computer science spans from the generation of proofs for predicate calculus to the evolution of machine code for accelerating function evaluation. The general tendency is to try to automate the design process for algorithms of different kinds.

Typical applications in science are to modeling and pattern recognition. Modeling certain processes in physics and chemistry with the unconventional help of evolutionary creativity supports research and understanding of the systems under study. Pattern recognition is a key ability in molecular biology and other branches of biology, as well as in science in general. Here, GP has delivered first results that are competitive if not better than human-generated results.

In engineering, GP is used in competition or cooperation with other heuristic methods such as neural networks or fuzzy systems. The general goal is again to model processes such as production plants, or to classify results of production. Control of man-made apparatus is another area where GP has been used successfully, with process control and robot control the primary applications.

In art and entertainment, GP is used to evolve realistic animation scenes and appealing visual graphics. It also has been used to extract structural in-

formation from musical composition in order to model the process so that automatic composition of music pieces becomes possible.

Many of these problems require a huge amount of computational power on the part of the GP systems. Parallel evolution has hence been a key engineering aspect of developments in GP. As a paradigm, genetic programming is very well suited for a natural way of parallelization. With the advent of inexpensive parallel hard- and software (Sterling et al. 1999), a considerable proliferation of results is expected from GP systems.

5. *Methodological Issues and Future Directions*

In recent years, some researchers have claimed human-competitive results in the application of genetic programming to certain problems (Koza et al. 1999). These claims are based on a comparison between the best known at present human solution to a problem and its GP counterpart. Usually, a large amount of computational power had to be invested in order to gain human-competitive results from genetic programming runs. Due to the ability of the human mind quickly to grasp the recipes of problem solution an artificial system has applied, the question remains open whether GP solutions will stay better than human solutions.

Theory of genetic programming is presently greatly underdeveloped and will need to progress quickly in order to catch up with other evolutionary algorithm paradigms. Most of the obstacles stem from the fact of variable complexity of solutions evolved in GP. Implementation of GP will benefit in the coming years from new approaches which include research from developmental biology. Also, it will be necessary to learn to handle the redundancy forming pressures in the evolution of code.

Application of genetic programming will continue to broaden. Many applications focus on controlling behavior of real or virtual agents. In this role, genetic programming may contribute considerably to the growing field of social and behavioral simulations. Genetic algorithms have already been found beneficial in optimizing strategies of social agents (Gilbert and Troitzsch 1999). With its ability to adjust the complexity of a strategy to the environment and to allow competition between agents, GP is well positioned to play an important role in the study and simulation of societies and their evolution.

Artificial Intelligence in Cognitive Science

Artificial intelligence (AI) and cognitive science are, at the turn of the twenty-first century, two distinct disciplines, with overlapping methodologies, but rather different goals. AI is a branch of computer science and is concerned with the construction and deployment of intelligent agents as computer programs, and also with understanding the behavior of these artifacts. The core scientific goal of AI is to understand basic principles of intelligent behavior that apply equally to animal and artificial systems (Russell and Norvig 2000). Almost all of the work is math-

ematical or computational in character and much of the literature is technique oriented.

Cognitive science (see *Cognitive Science: History*; *Cognitive Science: Overview*) is an explicitly interdisciplinary field that has participation from AI, but also from linguistics, philosophy, psychology, and subfields of other social and biological sciences. The unifying goal of cognitive science is to understand and model human intelligence, using the full range of findings and methodologies of the complementary disciplines. As one would expect, a wide range of techniques from the mathematical, behavioral, social, and biological sciences are employed. Cognitive science, in contrast with AI, is defined more by phenomena than by methodology (Posner 1985). There are research groups that are active in both AI and cognitive science, but they tend to produce different papers for journals and conferences in the two areas.

1. *Shared Origins in the Postwar Cognitive Revolution*

Both AI and cognitive science evolved after 1950 and, in their early development were more tightly integrated than at present (see *Cognitive Science: History*). For much of the first half of the twentieth century, the Anglo-American study of cognition was dominated by the behaviorist paradigm, which rejected any investigation of internal mechanisms of mind. The emergence of both AI and cognitive science was part of a general postwar movement beyond behaviorist theories, which also included new approaches in linguistics and the social sciences. The idea of computational models of mind was a central theme of what is sometimes called the postwar cognitive revolution. One of the leading early AI groups, under the leadership of Allen Newell and Herbert Simon at Carnegie Mellon (Newell 1990), was explicitly concerned with cognitive modeling using the symbolic processes of AI. The current version of this continuing effort is described in the article on SOAR (see *Cognitive Theory: SOAR*). Another traditional symbolic approach to modeling intelligence is presented in the article on ACT (see *Cognitive Theory: ACT*). But there is very little work in contemporary AI that is explicitly focused on modeling human behavior as opposed to intelligent systems in general. There is some continuing work on human and machine game playing (see *Chess Expertise, Cognitive Psychology of*), but it is not integrated into either field.

The central idea of AI is computational modeling of intelligent behavior and this is its main contribution to cognitive science. The basic notion of a computational model is now commonplace in all scientific fields and many other aspects of contemporary life. One builds a detailed software model of some phenomenon and studies the behavior of the model, hoping to gain understanding of the original system. Much of the work in AI has the engineering goal of producing practical systems, and there is no sharp boundary between AI and other applied fields of computer science and engineering. AI techniques are now commonplace in the full range of business, scientific, and public applications. While all fields *use* computational models, researchers, in computer science in general and AI in particular, *invent* and study computational techniques for constructing models, presenting the results of simulations, and understanding the limitations of the simulation. AI has traditionally studied the modeling of the most complex phenomena—those relating to intelligence. Because of the technical challenges arising in the construction of these complex simulations, many innovations in computing have arisen in AI and then been more widely applied.

2. *Domain-focused Research that Cuts Across AI and Cognitive Science*

The relationship between AI and cognitive science is further complicated by the fact that there are currently several distinct research fields that cut across both disciplines, but have separate journals, meetings, etc. The most prominent of these research areas are speech, language, vision, and neural networks. Each of these fields has thousands of practitioners, many of whom are interested in AI, cognitive science, or both. Appropriately, each of these areas is represented by multiple articles in this encyclopedia. As AI and cognitive science have grown, specialized areas such as language and vision modeling have become largely independent, but they do continue to share the development of underlying methodologies. The main areas that have remained as core AI include knowledge representation and reasoning, planning and problem solving. The study of learning has evolved somewhat differently and this will be discussed below. There are some common scientific paradigms that cut across all of these fields and this article will try to outline them as they relate to the social and behavioral sciences. The common thread linking AI to cognitive science is reliance on computational models of different kinds.

3. *The Role of Formal Logic in AI and Cognitive Science*

To a great extent, the early development of AI was based on symbolic, as opposed to numerical, modeling. This led to the introduction of some novel representations such as those of SOAR (see *Cognitive Theory: SOAR*), but the main effect of this was to align AI with formal logic for much of its early history. In fact, much of the driving force for the creation of the

field called cognitive science came from people who saw mathematical logic as its unifying theme. This remains a fruitful approach to AI and constitutes one major area of overlap with cognitive science. Mathematical logic is elegant and well developed and can be shown to be, in some sense, general enough to represent anything that can be described formally. There remains a significant community of linguists, philosophers, and computer scientists for whom logic is the only scientific way to study intelligence (Posner 1985).

But the twentieth century was not kind to categorical, deterministic theories in any field and cognitive science was no exception (see *Imagery versus Propositional Reasoning*). A central issue in the study of cognition has been how to describe the meaning of words and concepts. In formal logic, a concept is defined by a set of necessary and sufficient conditions. For example, a bachelor might be defined as a male who never married. The limitations of classical, all-or-none, categories were already recognized by Wittgenstein, who famously showed that concepts such as 'game' could not be characterized by necessary and sufficient conditions, and were better described as family resemblances. Even the definition of bachelor becomes graded when we consider cohabitation or how old a male needs to be before being considered a bachelor (see *Word Meaning: Psychological Aspects*).

Starting in the 1960s, a wide range of cognitive science studies by Rosch and others showed the depth and complexity of human conceptual systems and their relation to language. This helped give rise to the subfield called cognitive linguistics (Lakoff 1987), which overlaps with cognitive science, but has its own paradigms, journals, and conferences. The graded and relational nature of human categories undermined the attempt to create a unified science of mind based on formal logic. Another attack on the formalist program arose from the growing understanding of the neural basis of intelligence, also discussed in several articles (see *Cognitive Control (Executive Functions): Role of Prefrontal Cortex*; *Declarative Memory, Neural Basis of*; *Dreaming, Neural Basis of*; *Episodic and Autobiographical Memory: Psychological and Neural Aspects*; *Emotion, Neural Basis of*; *Implicit Learning and Memory: Psychological and Neural Aspects*). A crucial insight was that basic human concepts are grounded in direct experience and that more abstract concepts are mapped metaphorically to more embodied ones. This undercuts the formalist program, and also leads to a separation of AI, which studies intelligence in the abstract, from cognitive science, which is explicitly concerned with human minds. While much excellent work continues to be done using logic, it is now generally recognized that there are a wide range of phenomena that are better handled by biologically based models and/or some form of numerical, often probabilistic, modeling. For a variety of reasons, the movement to quantitative numerical models followed somewhat different paths in AI and cognitive science, but there are some recent signs of reconvergence.

4. *Learning and the Connectionist Approach to Cognitive Science*

As it happens, while the formalists were trying to establish a cognitive science based on formal logic, an antithetical neural network movement was also developing, and this approach has become a major force in cognitive science. The two contrasting approaches to cognitive modeling, neural modeling and logic, were mirrored in the two different methods by which early computer scientists sought to achieve AI. From the time of the first electronic computers around 1950, people dreamed of making them 'intelligent' by two quite distinct routes. The first, which was described above as conventional AI, is to build standard computer programs as models of intelligence. This remains the dominant paradigm in AI and has had considerable success. The other approach was to try to build hardware that was as brain-like as possible and have it *learn* the required behavior. The history of this 'neural modeling' approach is described in several articles (see *Artificial Intelligence: Connectionist and Symbolic Approaches*; *Connectionist Approaches*; *Connectionist Models of Concept Learning*; *Connectionist Models of Development*; *Connectionist Models of Language Processing*). After some promising early mathematical results on learning in simple networks, the neural learning approach to modeling intelligence fared much less well for three decades and had little scientific or applied success. Around 1980, a variety of ideas from biology, physics, psychology, and computer science and engineering coalesced to yield a 'new connectionist' approach to modeling intelligence that has become a core field of cognitive science, and also the basis for a wide range of practical applications (McClelland and Rumelhart 1986). Among the key advances was a mathematical technique (back-propagation) that extended the early results on learning to a much richer set of network structures.

Connectionist computational models are almost always computer programs, but programs of a different kind than those used in, for example, word processing or symbolic AI. Connectionist models are specified as a network of simple computing units, which are abstract models of neurons. Typically, a model unit calculates the weighted sum of its inputs from upstream units and sends to its downstream neighbors an output signal that is a nonlinear function of its inputs. Learning in such systems is modeled by experience-based changes in the weights of the connections between units. The basic connectionist style of modeling is now being used in three quite different ways in neurobiology, in applications, and in cognitive science. Neurobiologists who study networks of neurons employ a wide range of computational mod-

els, from very detailed descriptions of the internal chemistry of the neuron to the abstract units described above. The use of connectionist neural models in practical applications is part of the reconvergence with AI and will be discussed in the final section.

In cognitive science, connectionist techniques have been used for modeling all aspects of language, perception, motor control, memory, and reasoning. This universal coverage represents a potential breakthrough; previously the computational models of, for example, early vision and problem solving used entirely different mathematical and computational techniques. Since the brain is known to use the same neural computation throughout, it is not surprising that neurally inspired models can be applied to all behavior. Unfortunately, the existing models are neither broad nor deep enough to ensure that the current set of mechanisms will suffice to bridge the gap between structure and behavior, but the work remains productive.

Connectionist models in cognitive science fall into two general categories, often called structured and layered (also called PDP) networks. Most modelers are primarily interested in learning, which is modeled as experience-driven change in connection weights. There is a great deal of research studying different models of learning with and without supervision, different rules for changing weights, etc. Because of the focus on what the network can learn, any prewired structure will weaken the results of the experiment. The standard approach is to use networks with unidirectional connections arranged in completely connected layers, sometimes with a very restricted additional set of feedback links. This kind of network contains a minimum of presupposed structure and is also amenable to efficient learning techniques such as the back-propagation method described above. Most researchers using totally connected layered models do not believe that the brain shares this architecture, but there is an ongoing controversy about the implications of PDP learning models for theories of mind, discussed in Sect. 4.1.

Structured connectionist models are usually less focused on learning than on the representation and processing of information. Essentially all the modeling done by neurobiologists involves specific architectures, which are known from experiment. For structured connectionist models of cognitive phenomena, the underlying brain architecture is rarely known in detailand sometimes not at all at the level of neurons and connections. The methodology employed is to experiment with computational models of the behavior under study which are consistent with the known biological and psychological data and are also plausible in the resources (neurons, computing time, etc.) required. This methodology is very similar to what are called spreading activation models, widely used in psycholinguistics. Some studies combine structured and layered networks (Regier 1996), or investigate learning in networks with an initial structure that is tuned to the problem area or the known neural architecture.

4.1 Nature and Nurture: Rules vs. Connections

Perhaps the most visible contribution to date of connectionist computational models in cognitive science has been to provide a new jousting ground for contesting some age-old issues on the nature of intelligence. Much of the current debate is being published in *Science* magazine, which suggests that it is considered to be of major importance by the US scientific establishment. The nature/nurture question concerns how much of some trait, usually intelligence, can be accounted for by genetic factors, and how much depends on postnatal environment and training. Some PDP connectionists have taken very strong positions, suggesting that learning can account for everything interesting (Elman et al. 1996). In the particular case of grammar, an important group of linguists and other cognitive scientists take an equally extreme nativist position, suggesting that humans only need to choose a few parameters to learn grammar. A related issue is whether human grammatical knowledge is represented as general rules or just appears as the rule-like consequences of PDP learning in the neural network of the brain. There is ample evidence against both extreme positions, but the debate continues to motivate a great deal of thought and experiment.

5. Current and Future Trends

Although the fundamental split between the AI focus on general methods and the cognitive science emphasis on human intelligence remains, there are a growing number of areas of overlapping interest. As was discussed above, quantitative neural models are playing a major role in cognitive science. It turns out that the mathematical and computational ideas underlying learning in neural networks have found application in a wide range of practical problems, from speech recognition to financial prediction. The basic idea is that, given current computing power, back-propagation and similar techniques allow large systems of nonlinear units to learn quite complex probabilistic relationships using labeled data. This general methodology overlaps not only with AI but also with mathematical statistics, and is part of a unifying area called computational learning theory. There is also a large community of scientists and engineers who identify themselves as working on neural networks and related statistical techniques for various scientific and applied tasks, along with conferences and journals to support this effort.

While probability was entering cognitive science from the bottom up through neural models, AI experienced the introduction of probabilistic methods from general theoretical considerations, which only later led to practical application. As was discussed in Sect. 3, the limitations of formal logic became well recognized in the 1960s. Over the subsequent decades, AI researchers, led by Judea Pearl of UCLA (Pearl 1988), developed methods for specifying and solving large systems of conditional probabilities. These belief networks are now widely used in applications ranging from medical diagnosis to business planning. A growing field that involves both symbolic and statistical techniques is 'data mining,' processing large historical databases to search for relationships of commercial or social importance. Recent efforts to learn or refine belief networks from labeled data are another area of convergence of AI and cognitive science in computational learning theory.

Of course, the explosion of Internet activity is affecting AI along with the rest of the computing field. Two AI application areas that seem particularly important to cognitive science are intelligent Web agents and spoken-language interaction.

As the range of users and activities on the Internet continues to expand, there is increasing demand for systems that are both more powerful and easier to use. This is leading to increasing efforts on the human–computer interface, including the modeling of user plans and intentions—clearly overlapping with traditional concerns of cognitive science. One particularly active area is interaction with systems using ordinary language. While machine recognition of individual words is relatively successful, dealing with the full richness of language is one of the most exciting challenges at the interface between AI and cognitive science, and a problem of great commercial and social importance.

Looking ahead, we can be confident that the increasing emphasis on intelligent systems will continue. From the scientific perspective it is very likely that most of the interdisciplinary research in cognitive science will remain focused on specialized domains such as language, speech, and vision. General issues including representation, inference and learning will continue to be of interest, and will constitute the core of the direct interaction between AI and cognitive science. With the rapid advances in neurobiology, both fields will increasingly articulate with the life sciences, with great mutual benefits.

Artificial Intelligence: Search

Search is the study of computer algorithms designed to solve problems by systematic trial-and-error exploration of possible solutions. Problem-solving tasks include single-agent path-finding problems, such as Rubik's Cube, two-player games such as chess, and constraint-satisfaction problems, such as the Eight Queens problem. We will consider each in turn.

1. Single-agent Path-finding Problems

A classic example of a single-agent path-finding algorithm is the *Fifteen Puzzle* (see Fig. 1). It consists of a 4×4 frame containing 15 numbered tiles, and an empty or blank position. Any tile horizontally or vertically adjacent to the blank can be slid into the blank position. The goal is to rearrange the tiles from some random initial configuration to a particular goal configuration. The *states* of the problem are the

	1	2	3
4	5	6	7
8	9	10	11
12	13	14	15

Figure 1
Fifteen Puzzle

different permutations of the tiles. The *operators* are the legal moves. The Fifteen Puzzle task is to find a sequence of operators that map the initial state to the goal state, and ideally a shortest such sequence.

A search algorithm may be systematic or nonsystematic. A systematic search algorithm is guaranteed to find a solution if one exists, and may in fact guarantee a lowest-cost or optimal solution. If no solution exists, a systematic algorithm may or may not detect this fact. Nonsystematic algorithms, such as simulated annealing, genetic algorithms, heuristic repair, and other local search or stochastic approaches, are either not guaranteed to find a solution at all, or are not guaranteed to find an optimal solution, and are not considered here.

The simplest systematic search algorithms are called *brute-force search* algorithms, and do not use any knowledge about the problem other than the states, operators, initial state, and description of the goal state. For example, *breadth-first search* starts with the initial state, then considers all states that can be reached from the initial state with one operator application, then all states two operator applications away, etc., until a goal is reached. *Uniform-cost search*, or *Dijkstra's* single-source shortest-path algorithm (Dijhstra 1959) allows operators to have different costs, and visits states in increasing order of their total cost from the start, where the cost of a state is the sum of the operator costs incurred in reaching that state. A drawback of each of these algorithms is that they require enough memory to hold all the states considered so far, which is prohibitive in large problems.

Depth-first search more closely approximates how one would search using a single physical copy of a puzzle, such as the Fifteen Puzzle. From the current state, depth-first search applies a sequence of operators, until some depth limit is reached. It then backtracks to the last state that hasn't been completely explored, and applies a new sequence of operators from there. The advantage of depth-first search is that it only requires enough memory to hold the current operator sequence from the initial state.

A drawback of all brute-force search algorithms is that they are uninformed about the location of the goal. Heuristic search, however, is directed toward the goal. A heuristic search, such as the *A* algorithm* (Hart et al. 1968), makes use of a *heuristic evaluation function*, which estimates the cost to reach the goal from any given state. For example, the *Manhattan distance* is a common heuristic estimate for the Fifteen Puzzle. It is computed by counting the number of grid units each individual tile is away from its goal position, and summing these values over all tiles. For every state n visited by A*, it adds the number of moves made from the initial state to reach the current state, $g(n)$, to the heuristic estimate of the number of remaining moves to the goal, $h(n)$, to estimate the total number of moves on a path from the initial state to the goal that passes through the current state, $f(n) = g(n) + h(n)$. A* starts with the initial state, and generates all the states immediately adjacent to it. It then evaluates those states n using the cost function $f(n) = g(n) + h(n)$. At each step, it generates and evaluates the neighbors of the unexplored state n with the lowest total cost estimate, $f(n)$. It stops when it chooses a goal state to explore next.

A* is guaranteed to find a solution if one exists. Furthermore, if the heuristic function $h(n)$ never overestimates actual cost, A* is guaranteed to find a shortest solution. For example, since each move only moves one tile one grid unit, the Manhattan distance is a lower bound on the actual number of moves required to solve a Fifteen Puzzle state, and A* using the Manhattan distance heuristic function is guaranteed to find a shortest solution to the Fifteen Puzzle, given sufficient memory.

The bane of all search algorithms is *combinatorial explosion*. For example, the Fifteen Puzzle contains $16!/2 \approx 10^{13}$ different reachable states. Even at ten million states per second, a brute-force search examining all these possibilities would take over 12 days. The 5×5 *Twenty-Four Puzzle* contains $25!/2 \approx 10^{25}$ states. At ten million states per second, brute-force search would take over 24 billion years, longer than the age of the universe! With heuristic search techniques, optimal solutions have been found for both the Fifteen and Twenty-Four Puzzles, but for no larger versions.

2. *Two-player Games*

The classic two-player game is chess and has been an object of research in artificial intelligence for over fifty years. The current best programs are comparable to the best human players. The standard algorithm for these problems is *minimax search* with static evaluation, described below, and *alpha-beta pruning*, a technique that makes minimax search much more efficient. The states of the problem are the legal board positions, and the operators are the legal moves of the game. From the current board position, we consider all the legal moves we can make, then all the possible responses by our opponent, then all our possible countermoves, etc. In small games, like tic-tac-toe, there is sufficient time for the machine to explore the entire game tree, or all possible plays by both players, allowing the machine to play perfectly.

In more complex games, brute-force search and hence perfect play are impossible. For example, the chess game tree is estimated to contain over 10^{40} different board positions. In that case, the machine searches ahead as many moves as it can, given the time available to make each move. The limit of how far it can look ahead is called the *search horizon*. Each of the game states at the search horizon is then evaluated by a heuristic function that returns a number, which estimates the relative merit of that board position for

Figure 2
Minimax search tree example

each player. A large positive value is advantageous for one player, called MAX, and a negative value of large magnitude is beneficial to the player called MIN. For example, the simplest evaluation function for chess would sum all the pieces on the board belonging to MAX, weighted by their relative values, and subtract the weighted sum of all of MIN's pieces on the board, to get the relative material advantage of MAX over MIN. For example, a weighting function for chess might count the queen as worth nine points, the rooks as five points each, the bishops and knights as three points, and one point for each pawn.

Given the numeric evaluation of the board positions at the search horizon, the move to make is computed by the minimax algorithm. We compute the value of each position in the game tree recursively from the value of the positions that result from each different legal move. If the MAX player is to move in some position, the value of that position is the maximum of the values of the positions that result from each legal move. Similarly, if the MIN player is to move in some position, the value of that position is the minimum of the values of the positions that result from each legal move. By backing these values up the tree, we can compute the value of the current game state, and make a move to the position that gave rise to this value.

Figure 2 shows an idealized four-level game tree, where the square nodes represent the game states where MAX is to move, and the circle nodes represent states where MIN is to move. The numbers at the bottom level of the tree from the heuristic evaluation function, and the numbers at the interior nodes are computed from the nodes immediately below them by the minimax rule. The move recommended by this procedure is to the left child of the root node. A much more efficient version of this algorithm, known as alpha-beta pruning (Knuthand Moore 1975), is used in practice.

3. *Constraint-satisfaction Problems*

A classic constraint-satisfaction problem is the Eight Queens Problem. The task is to place eight queens on a standard 8×8 chessboard so that no two queens are attacking along the same row, column, or diagonal. Figure 3 shows one solution to the Eight Queens problem. In a constraint-satisfaction problem, the task is not to find a sequence of moves, but to identify a state that satisfies a set of constraints. The standard algorithm for these problems is known as *backtracking*. We systematically place queens on the board one at a time, one per row, so that no two queens on the board are in the same column or diagonal. If we get to a state in which no additional queens can be placed without attacking an existing queen, and all the queens have not yet been placed, we backtrack by moving the last queen that was placed to the next column where it doesn't attack any of the previously placed queens. The algorithm continues until either one solution is found, all solutions are found, or it is determined that no solutions exist.

Artificial Intelligence: Uncertainty

Artificial intelligence (AI) is the discipline of computer perception, reasoning, and action. Dealing with uncertainty is a central challenge for artificial intelligence. Uncertainty management capabilities are required to combine evidence about a new situation with knowledge about similar situations, to draw inferences, and predict the effects of actions. Numerical computing has traditionally focused on problems where measurement imprecision is the sole source of reasoning uncertainty. AI researchers aim to develop software systems for applications such as automated learning, perception, natural language, and speech understanding. Such systems must deal with many sources of uncertainty: including equally plausible alternative explanations; missing information; incorrect object and event typing; diffuse evidence; ambiguous references; prediction of future events; and deliberate deception.

AI researchers in the late 1950s worked with computing environments inferior to a wristwatch calculator in 2000. As computing power increased, emphasis shifted from optimizing speed and memory to increasing expressiveness in knowledge representation and reasoning strategies. Automating intellectual, symbolic, and common-sense activities turned out to be daunting tasks, still mostly exceeding the grasp of computable representations. Over decades several common and interdependent themes emerged that explained key and repeating sources of failure in AI programs.

One such failure is incorrect categorization of object types. An example of incorrect categorization is to call a cat a dog because it is a housepet with four legs. Another problem is inadequate treatment of uncertainty or ambiguity with respect to explanations for a given pattern of evidence. Examples include pronouns with multiple possible antecedents, or multiple chains of inference to explain the same event, e.g., the ground is wet because it rained, because the sprinkler was on, or both. A third source of failure is incomplete, inadequate, or nonexistent models for explaining events, often due to unstated common-sense assumptions. An example is failure of the computer to appreciate that a truck at a loading dock will not wait indefinitely for someone to load it. All of these failures can be viewed as issues in automated handling of uncertainty in reasoning.

It has become clear that effective treatment of such uncertainty requires considering multiple alternatives throughout the incremental accrual of evidence. Although this ability appears to be innate in humans, naïve computations of alternatives in the face of ambiguous evidence quickly become a combinatorial nightmare, exploding memory and computational requirements at exponential rates.

Remarkable innovations in computing have arisen out of the search for efficient methodologies for representing multiple alternatives in the face of conflicting, ambiguous, and multiple sources of evidence, for weighing evidence in favor of different alternatives, and for deciding among multiple options. These innovations include logic-based theorem proving, expert systems, neural networks, fuzzy set theory, belief function theory, and Bayesian networks. The following sections present a roughly chronological view of key developments in the history of managing uncertainty in AI.

1. Symbolic Computing, Confidence and Class Membership

In the 1960s the AI community established the importance of symbolic computing as distinct from traditional numerical computing. Mainstream AI research focused on purely qualitative, symbolic approaches to reasoning with uncertainty such as default or non-monotonic logic, and the application of heuristic strategies for selecting among alternative world models and resolving conflicts (McCarthy 1960).

With algebraic and other equation-oriented representations, the focus tends to be on the result of the computation. Logic representations, being sentence-like with typed categorical terms, lend themselves naturally to being stored as 'declarative' knowledge. Declarative knowledge is expressed in the form of data structures that can be manipulated, decomposed, and analyzed by a reasoner independent of content. Expert systems apply theorem provers, or algorithms capable of deriving true propositions from other true propositions, to declarative knowledge in the form of facts and rules of inference specific to a domain of application. Successful expert systems have been deployed with great success in a variety of application areas, and are regarded as one of the great engineering successes of artificial intelligence.

Rule sets proved to be a natural way to represent computable systems that did not have complete knowledge of the problem to be addressed. Such a system begins with what is initially known and infers additional facts, as evidence becomes available. As richer rule-based representations were developed and larger-scale problems were tackled, technological limitations became apparent. Key issues included confidence in applicability of rules to particular situations as well as in their derived consequences. A related issue was uncertain typing of logical variables. The third was combinatorial explosion of alternatives as uncertain evidence activated multiple and often conflicting rules.

Medical diagnostic expert systems provided some of AI's great initial successes, but the complexity of applying medical knowledge required estimates of the confidence that rules and their conclusions applied in specific situations. Buchanan and Shortliffe (1974) developed the first calculus for confidence in expert

systems, called 'certainty factors.' Heralded as a breakthrough at the time of their invention, certainty factors were later proven by one of Shortliffe's students (Heckerman 1986) to be mathematically inconsistent and formally superseded by Bayesian probabilistic reasoning.

At the same time that certainty factors were in development, others pursued different formalisms for numerical representations of uncertainty. Shafer (1976) was concerned with representing situations in which evidence for estimating probability values is incomplete. He adapted the work of Dempster to develop a formal calculus for inductive reasoning with incomplete evidence.

Zadeh (1975) addressed the issue of uncertain typing of variables with the invention of fuzzy set theory. Fuzzy set theory extends traditional set theory by allowing varying degrees of membership in a set. For example, a man 2.3 meters tall would be assigned a high degree of membership in the fuzzy set 'very tall', a lower degree of membership in the fuzzy set 'tall', and a zero degree of membership in the fuzzy set 'short.' By contrast, a man 1.5 meters tall would be assigned a high degree of membership in the fuzzy set 'short', a low degree of membership in the fuzzy set 'tall', and a zero degree of membership in the fuzzy set 'very tall.' Zadeh's fuzzy calculi were later extended over logical representations to yield fuzzy logic and fuzzy expert systems.

By the late 1970s, a growing segment of AI researchers recognized the combinatorial explosion inherent in rule-based systems, as well as in straightforward combinations of logic with other theories such as fuzzy sets. Proposals to incorporate new structures for numerical uncertainty measures were sometimes dismissed by arguing that, with the exception of highly trained individuals such as statisticians and weather forecasters, humans rarely reason explicitly with numerical likelihoods. Critics argued that if humans can behave intelligently using heuristic processes that appear to be primarily based on qualitative symbolic rules, then qualitative processes should be the solution of first, and last, resort for AI. Somewhat paradoxically, it was also argued that computational complexity precluded the application of probability theory and related numerical uncertainty management approaches.

2. *Graphical Networks of Alternatives*

Several related trends coalesced into a shift in AI community consensus in the 1980s. One trend was the resurgence of interest in connectionist models (e.g., Rumelhart and McClelland 1985). The connectionist movement, which includes the development of neural networks (see *Neural Networks and Related Statistical Latent Variable Models*; *Neural Networks: Biological Models and Applications*), lent strong support to the thesis that fundamentally numerical approaches could give rise to computational systems that exhibited intelligent behavior. Connectionism also sparked interest in symbol-level representations that integrated smoothly with numerical sub-symbolic representations, especially for reasoning from perceptual signals to higher level abstractions.

The development of this research direction culminated in a series of breakthroughs in automated inference and the development of graphical models and associated algorithms for automated probabilistic decision making (Pearl 1988, D'Ambrosio 1999 and *Bayesian Graphical Models and Networks* and *Latent Structure and Casual Variables*). Graphical models combine qualitative rule-like and object-like knowledge structures with quantitative measures of the uncertainty associated with inferences. Alternative inferences are represented in all the possible chains of reasoning implicit in the graphical structure, and need not be explicitly enumerated. The loosely coupled, modular architecture of graphical models enables the creation of knowledge representations and tractable algorithms for inference, planning, and learning for realistically complex problems. Directed graphical probability models are called 'Bayesian networks' and undirected graphical probability models are called 'Markov graphs' (Pearl 1988, Jensen 1996). Shafer and Shenoy combined Dempster-Shafer calculus and Bayesian network concepts to build even more general knowledge structures out of graphs encoding dependencies among variables, and proved the existence of a universal representation for automating inductive inference (Shafer and Shenoy 1990). Graphical models became increasingly popular as a common framework, independent of uncertainty calculus, for representing the loosely coupled dependency relationships that give rise to the modular representations that are basic to AI. Graphical models are also useful for expressing the causal relationships that underlie the ability to predict the effects of manipulations and form effective plans (Pearl 2000, Spirtes et al. 2000).

Many uncertain attributes of knowledge, including belief, credibility and completeness, can be expressed using graphical models and their related computational calculus. The most prominent issue in the field of uncertainty in AI has been the representation and reasoning about belief in alternatives given uncertain evidence. More recently there has been increased focus on planning and action, as well as approaches integrating perception to symbolic-level reasoning, planning, and action.

3. *Incremental Model Construction: An Example*

A limited example, originally due to Max Henrion, serves to illustrate key concepts such as the interplay between structural assumptions and numerical beliefs, the distinction between causal and evidential reasoning, the benefits of loosely coupled modular representations, the integration of uncertainty management

Figure 1
Initial model for Maria's sneezing episode

into knowledge representation and reasoning architectures, and the role of learning. The example uses a Bayesian network to represent uncertainty; nevertheless, the issues illustrated by this example are common to all belief calculi.

Maria is visiting her friend Jose when she suddenly begins sneezing. 'I must be getting a cold,' she thinks. Fig. 1 illustrates how such a human reasoning pattern can be encoded in a directed graphical model, or Bayesian network. This Bayesian network represents both the deductive knowledge that colds cause sneezing, and the inductive knowledge that sneezing constitutes evidence for a cold. The probability bars in Fig. 1a represent the prior probabilities assigned to whether or not Maria has a cold and whether or not she will be sneezing. Fig. 1b shows how these probabilities change after incorporating the evidence that Maria is sneezing.

After concluding that she probably has a cold, Maria notices scratches on the furniture. 'Oh, it's nothing but my cat allergy acting up,' she sighs in relief. Fig. 2 shows how the Bayesian network can be extended to incorporate this additional knowledge. Each time a new item of evidence is incorporated, an inference algorithm is applied to update the probabilities of the propositions for which truth-values remain unknown. When Maria began sneezing, the probability she had a cold increased from about 8 percent to about 53 percent. When she saw the scratches, however, the probability of having a cold dropped back to about 15 percent.

This non-monatomic change in probabilities that occurs with the incorporation of evidence for a competing explanation is known as explaining away. The evidence for Maria's having an allergic reaction explains the symptom for which the cold hypothesis had been nominated as an explanation. The cold hypothesis, which has no corroborating evidence and is no longer needed to explain the sneezing, consequently drops in probability as evidence mounts for the allergy hypothesis. Only the final probability of Maria's having an allergy is shown in the figure. In fact, this hypothesis increases monotonically in probability from about 3 percent prior to the onset of sneezing, to about 20 percent after sneezing is observed, to 88 percent after seeing the scratches.

The phenomenon of explaining away is a well-known structural feature of causal argumentation. It is an instance of a more general phenomenon known as intercausal dependence, in which two, heretofore unrelated, causes become relevant to each other when information about a common effect becomes known. The ability of Bayesian networks to model intercausal dependence comes about as a natural consequence of the independence assumptions encoded by directed graphs as representations of dependence among pro-

Figure 2
Revised model for Maria's sneezing episode

Figure 3
Generic model for sneezing episodes

positions. The two causes of sneezing are independent of each other prior to observation of the sneezing episode. They become negatively related due to their roles as competing explanations for an observed episode of sneezing. Bayesian networks exhibit intercausal dependence as a consequence of the mathematics of probability theory, and the manner in which directed graphs are applied to represent conditional independence assumptions. Observing the value of a node at the head of converging links in a directed graphical model opens the flow of information through the link. This enables information favoring one cause of sneezing to flow through the converging link and decreases the probability of the other cause of sneezing (Jensen 1996).

A different kind of dependence relation is exhibited by diverging links, such as the links connecting the node Cat-Near-Maria to its two children, and serial links, such as the links entering and leaving the node Allergic-Reaction-Maria. Observing a node at a diverging or serial link cuts off the flow of evidence through the link. Thus, learning about the scratches increases the probability that a cat is present, which in turn increases the probability of an allergic reaction. However, if we already know whether or not a cat is present, the additional information that there are scratches is no longer relevant to the question of whether Maria is having an allergic reaction.

These different types of relevance relationships exhibit the kinds of qualitative behavior one expects of common causes of an effect (converging links), independent effects of a common cause (diverging links), and nonsynergistic causal chains (serial links). For this reason, it has been argued that directed graphs are natural structures for representing knowledge about causal relationships in a domain (Pearl 2000, Spirtes et al. 2000). This makes Bayesian networks useful for applications such as planning and diagnosis that depend on the ability of models to reason appropriately about cause-and-effect relationships. However, Bayesian network arcs can represent relationships other than causality, including correlation, imputation, and credibility. The only required condition for a directed graph to encode a domain's dependence relationships is that each node (i.e., variable or logical expression of variables) is probabilistically independent of its nondescendants given its parents (e.g., Jensen 1996).

Fig. 3 shows how the Bayesian network model of our example can be extended to form a generic knowledge structure that can be applied to other individuals in other situations. The name 'Maria' has been replaced by the variable 'X', indicating that this Bayesian network applies to any individual in the population it represents. Fig. 3a applies this Bayesian network model to the available evidence for Maria's case. The probabilities of Fig. 3a apply to Maria, as well as to any individual in the domain who has a history of allergies, experiences a sneezing episode, sees scratches on the furniture, and does not know whether s/he has been exposed to a cold or whether or not there is a cat or other cause of allergic reaction nearby. Fig. 3b represents the same situation for an individual with no history of allergies, but who is known to have been exposed to a cold. Using the same Bayesian network with different evidence, it is concluded that Maria is probably suffering from allergies, whereas the second individual probably has a cold. The simpler Bayesian network of Fig. 2 can be obtained from the more complex network of Fig. 3 by conditioning, on the assumption that the person in question has a history of allergies. The Bayesian network of Fig. 1 can be obtained by a process called marginalization. A major research advance of the past decade has been the development of methods for ensuring incrementally constructed models remain

Variable	Parent Variable Values		True	False
Cold_Exposure_X			10%	90%
Has_Cold_X	Cold_Exposure_X=True		75%	25%

Figure 4
Local probability tables for sneezing model

consistent and are no more complex than necessary (Wellman et al. 1992, Goldman and Charniak 1993).

Fig. 4 shows the probability information for the Bayesian network of Fig. 3. The probability information in a Bayesian network is encoded as one or more local probability distributions at each node. There is a single probability distribution for each root node and a distribution for each combination of values of the parents of each non-root node. Additional structural assumptions can be applied within these local probability distributions to further simplify both knowledge acquisition and inference. Several authors have noted that a Bayesian network such as Fig. 3 can be defined by augmenting standard AI knowledge structures such as frames or objects to include information about probabilistic relationships. A probability model involving many variables can be represented as a collection of frames or objects, each encoding a small portion, or fragment, of the overall network. A mathematical foundation for such systems has been established by extending symbolic logic to incorporate probabilities, and then establishing conditions under which a knowledge base encodes a coherent probability model for problem instances in a given domain (e.g., Goldman and Charniak 1993).

Many common knowledge-based system architectures use a generic inference engine to apply a knowledge base of rules to facts stored in a database or in working memory. Facts about an entity in a domain can be represented as logical statements in existential/conjunctive form (Sowa 2000). For example, the facts in the cat allergy problem can be represented as the existentially quantified conjunction, viz., that there exists an individual in the domain, to whom the label 'Maria' is given, about whom the propositions Sneezing-Maria, Allergy-History-Maria, and Maria-Sees-Scratches, all take on the value 'True.' A standard knowledge-based system might have a Sneezing-Episode object type to organize information about sneezing episodes for individuals in the domain. Entering the fact Sneezing-Maria = True into the system triggers creation of an object instance Sneezing-Episode-Maria. The object would have attributes for each of the variables in the Bayesian network of Fig. 3. Traditional knowledge-based system architectures such as CLIPS or Prolog apply rules from the knowledge base to draw inferences about the causes of sneezing from the available evidence about Maria's case. By contrast, the Bayesian network described here calculates probabilities for the different causes by constructing the relevant portion of a globally consistent probability model of the application domain, and then applying a belief propagation algorithm.

4. *Belief Propagation*

Although rules are represented as universally quantified generalizations, most applications require the ability to qualify rules to allow for the possibility of exceptions. The Bayesian network of Fig. 3 can be thought of as a collection of rules with probabilistic qualifiers organized in a structure that ensures the existence of a consistent joint probability distribution over logical propositions related to the sneezing episode. The existence of such a consistent joint probability distribution guarantees that, at least in theory, any new information about entities in the domain can be incorporated and evidence can be propagated consistently to compute updated probabilities for the rest of the propositions of interest.

The propagation of evidence in a Bayesian network is bi-directional. Information can flow in the same direction as the arcs, as when evidence of exposure to a cold increases the probability of a cold, or in the opposite direction from the arcs, as when evidence of scratches increases the probability that there is a cat nearby. Furthermore, the direction of evidential flow is automatically performed by the solution algorithm.

A knowledge-based system whose generalizations consist of a complete and consistent set of Bayesian network fragments has 'possible worlds' semantics with an associated probability measure. That is, each assignment of values to the variables in the Bayesian network corresponds to a 'possible world', and the collection of local probability distributions implicitly specifies likelihood for each world. From this information, a probability can be computed for any logical proposition involving features of the world included in the Bayesian network.

Observation of evidence amounts to restricting the set of possible worlds to those consistent with the observed evidence. This results in a revised probability distribution obtained by applying the probability updating formula known as Bayes' Rule:

$$\frac{P(H_1|E,K)}{P(H_2|E,K)} = \frac{P(E|H_1,K)}{P(E|H_2,K)} \frac{P(H_1|K)}{P(H_2|K)}.$$

The left-hand side of this expression is the 'posterior odds ratio', which measures the relative likelihood of hypotheses H_1 and H_2 after observing evidence E, where K represents the information assumed in the reasoning context. The second factor on the right-hand side is the 'prior odds ratio', which measures the relative likelihood of the hypotheses prior to observing the evidence. The first factor on the right-hand side is the 'likelihood ratio', which measures how likely the evidence E is under each of the two hypotheses. This expression demonstrates that evidence E increases (decreases) the probability of H_1 relative to H_2 if it is more (less) likely to occur under H_1 than under H_2.

A knowledge-based system based on graphical models can implicitly encode an infinite number of probability statements. Research in knowledge-based model construction (Wellman et al. 1992) focuses on incremental construction of finite models to respond to specific queries. A typical query is to compute the probability of one or more target propositions given evidence in the form of facts about domain entities. The example above illustrates model construction in response to receipt of a sequence of facts about Maria's sneezing episode.

The probability measure over possible worlds can be used to express modal propositions about beliefs and knowledge of an agent. Beliefs of different agents having consistent ontologies (i.e., knowledge vocabularies and structures) can be represented by encoding different agent-specific probability distributions over the same set of possible worlds.

Incomplete probability distributions can be represented using interval probabilities or belief functions. Fuzzy logic enables the representation of ambiguous, as distinct from uncertain, truth-values (Zadeh 1975). Counterfactual or causal logic augments the semantics to include information about causality and the effects of manipulations. Temporal reasoning is represented by dynamic Bayesian networks. Planning problems can be treated by incorporating actions into graphical models. Partially observable Markov decision processes (POMDPs) are graphical probabilistic models that also represent actions available to agents and permit the computation of optimal actions given available information.

5. *Discovery, Learning, and Numerical Estimation*

Although the semantics of their associated numerical measures vary, all certainty calculi require prior numerical valuations. For example, Bayesian networks require prior conditional probabilities; fuzzy logic requires a priori fuzzy set membership estimates; Dempster-Shafer calculus requires estimates of prior values for basic probability masses. The need to acquire and calibrate prior numerical estimates is both a challenge and a standard argument against the use of belief calculus. There are several answers to this challenge.

First, any source of exemplar cases provides a source of prior numerical estimates. Second, a history of successful knowledge engineering efforts has demonstrated that, at least for certain sorts of variables and problems, humans can provide the necessary judgments to build models that perform well on a variety of tasks (e.g., Heckerman 1991). Third, techniques for data mining and for learning graphical models from data, or from a combination of expert judgment and data (Jordan 1999; See *Bayesian Statistics*), can be applied to discover numerical estimates 'on the fly.' In particular, Bayesian learning methods have been developed that exhibit both accuracy and simplicity suggesting, via an Occam's razor argument, that researchers are successfully meeting this technical challenge (see *Hierarchical Models: Random and Fixed Effects*).

6. *Conclusion*

Since 1980 there have been major advances in automating inductive reasoning in AI systems. Modular, tractable, and cognitively plausible representations for uncertainty in AI systems have been developed and implemented in widely available software tools. Uncertainty management is widely recognized as a science

and corresponding engineering technology is required for effective knowledge representation and reasoning architectures for all AI systems. The capabilities achieved so far point the way to a much broader set of issues and objectives, many of which concern the possibilities of automated acquisition of inductive knowledge relationships. Graphical network representations combined with data mining, automated learning, and other recent developments are a natural computational environment in which to develop scientific hypotheses and model experimental and other evidential reasoning in support of complex hypotheses. Uncertainty management-driven advances in automated inductive reasoning raise the hope that AI systems might soon accelerate the rate of scientific discovery.

The web site of the Association for Uncertainty in Artificial Intelligence, is a good source of up-to-date information on topics related to uncertainty in artificial intelligence. This site contains links to the online *Proceedings of the Conference on Uncertainty in Artificial Intelligence*, which contains abstracts for all papers since the conference started in 1985, as well as soft-copy versions of many papers. The web site also contains links to a number of tutorials on subjects related to uncertainty in AI. Good introductions to Bayesian networks can be found in the seminal work by Pearl (1988), the more recent books by Jensen (1996) and Cowell (1999), and a good nontechnical introduction by Charniak (1991). A review of recent work in decision theoretic methods in artificial intelligence is provided by Haddawy (1999). A recent overview of fuzzy set methodology is presented in Dubois and Prade (2000). Smets and Gabbay (1998) describes different approaches to representing uncertainty. The anthology by Pearl and Shafer (1990) compiles a number of seminal articles in the field of uncertainty in artificial intelligence.

Artificial Neural Networks: Neurocomputation

A neurocomputer is an abstract mathematical neural network model capable of computing solutions to specific information processing problems. Neurocomputers are usually referred to as 'neural networks,' 'artificial neural networks (ANN),' 'connectionist systems,' or 'parallel distributed processing (PDP) systems.' Neurocomputers are important to neuroscientists since they may implement specific theories of information processing in brain subsystems. The behavior of a neurocomputer may also be systematically compared with animal and human behavior within restricted behavioral task domains in order to explore the implications of a particular psychological theory. Finally, neurocomputers are important because they may suggest novel approaches to solving data analysis and computational problems which occur in an engineering context. This article introduces neurocomputation from a historical perspective.

The typical neurocomputer consists of a collection of *units* where each unit is assumed to be a highly abstract model of either a neuron, a portion of a neuron, or a group of neurons. Each unit has a state represented by a real number which is referred to as the unit's *activity level* which is typically assumed to be abstractly related to neuronal firing frequency (seeFig. 1). The set of activity levels of all units in the network is called an *activation vector* whose magnitude corresponds to 'signal strength' and whose direction corresponds to 'signal identity.' Learning in a neurocomputer usually involves some algorithm for adjusting connections among the units as a function of the neurocomputer's past experiences. Figures 2 and 3 illustrate two typical neurocomputer architectures.

Figure 1
A formal neuron common to many neurocomputer architectures. The *net input* to the ith unit, ϕ_i, is given by the formula: $\phi_i = \Sigma w_{ij}\, x_j + b_i$ where w_{ij} is the synaptic connection weight associated with the jth input to unit i and x_i is the activation level of the ith unit in the network. The quantity b_i is often referred to as the *bias* for the ith unit. Choosing S such that $S(\phi_i) = 1$ if $\phi_i > 0$ and $S(\phi_i) = 0$ otherwise gives a popular version of the McCulloch–Pitts formal neuron. Choosing S to be a differentiable monotonically nondecreasing (i.e., 'sigmoidal') function yields the 'quasilinear' formal neuron

Figure 2
An example 'feed-forward' neurocomputer architecture. In Rosenblatt's (1962) generic 'feed-forward' perceptron neurocomputer, incoming information (e.g., light intensities generated from a photographic image) is detected using an array of input units called 'sensor units' or 'S-units.' The S-units are then randomly connected through unmodifiable connection weights to a set of hidden units called 'association units' or 'A-units.' The A-units are then connected to the output unit called the 'response unit' or 'R-unit.' All units in the perceptron were McCulloch–Pitts formal neurons. The 1986 Rumelhart, Hinton, and Williams generic 'feed-forward' back-propagation network architecture is essentially identical to the perceptron architecture except: (a) the units are differentiable sigmoidal functions (see Fig. 1), and (b) the input to hidden unit connection weights are modifiable through a learning process as well

1. *The Origins of Neurocomputation (1890–1965)*

1.1 *Hebbian Learning*

In 1890, the psychologist William James argued that it is more fruitful to consider associations between 'brain-processes' (and not 'ideas') as the basis for human associative memory. Information retrieval, according to James, was proposed to arise by a process where:

> The amount of activity at any given point in the brain-cortex is the sum of the tendencies of all other points to discharge

Figure 3
An example 'recurrent' neurocomputer architecture. In contrast to the 'feed-forward' architecture shown in Fig. 2, feedback connections among units are permitted as well. Activation is passed back and forth among the units until the activation pattern over all units 'stabilizes.' This figure depicts the architecture used in the 1986 Rumelhart and McClelland Interactive Activation Model (see Anderson and Rosenfeld 1988a for further details). Notice how the recurrent connections permit letter string orthographic structure to influence perception of the component individual letters

> into it…(James 1890 cited in Anderson and Rosenfeld 1988a, p. 5).

Moreover, William James also suggested that information such as the past history of intensity and co-occurrence of such brain processes influenced actual physical changes in the brain such that:

> When two elementary brain-processes have been active together or in immediate succession, one of them, on re-occurring, tends to propagate its excitement into the other (James, 1890 cited in Anderson and Rosenfeld 1988a, p. 5).

In many respects, these ideas can be viewed as marking the origins of the concept of neurocomputation since James was providing a sketch of how mechanisms for storing and retrieving information in the brain might operate.

An elaboration of these ideas was developed a half century later by the psychologist Donald Hebb in 1949 using a 'neuron model.' A *neuron* consists of incoming or 'afferent' fibers and an outgoing fiber called the *axon*. Hebb knew that a voltage pulse could be propagated along the neuron's axon in situations where the neuron's afferent fibers were connected to axons of other neurons that were propagating voltage pulses. The term *firing* was used to refer to the process of voltage pulse propagation in the neuron.

These neuroscience concepts appeared in Donald Hebb's famous Hebbian learning rule which expressed the now common neurocomputer learning principle.

> When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes place in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased (Hebb 1949 cited in Anderson and Rosenfeld 1988a, p. 50).

1.2 McCulloch–Pitts Formal Neurons

McCulloch and Pitts in 1943 (see Anderson and Rosenfeld 1988a) proposed an abstract mathematical model of a neuron which today is referred to as a 'McCulloch–Pitts neuron.' A McCulloch–Pitts neuron (MP-neuron) has two states: 'active' and 'inactive.' Physiologically, the activation level of an MP-neuron measured the likelihood the MP-neuron would generate at least a certain number of voltage impulses within some fixed time frame.

As illustrated in Fig. 1, the MP-neuron summed its active excitatory synaptic inputs and compared that sum to some internal threshold value. If the summed activity of its active excitatory synaptic inputs exceeded the MP-neuron's threshold value and no inhibitory synaptic input to the MP-neuron was active within some given timeframe, then the MP-neuron would become active and could consequently activate excitatory and inhibitory synaptic inputs of other MP-neurons. One key theoretical result obtained by McCulloch and Pitts was that deductive logic could be implemented by networks of MP-neurons. This theoretical result had an important impact on the field of neurocomputation and strongly influenced the conceptual development of the modern digital computer concept.

1.3 Learning Networks of McCulloch–Pitts Neurons

By the mid-1960s several researchers such as Frank Rosenblatt, Bernard Widrow, Oliver Selfridge, Nils Nilsson, and E. R. Caianiello were focusing on the problem of building networks of MP-neurons which could learn (see Anderson and Rosenfeld 1988a; Anderson et al. 1990). Since McCulloch and Pitt had pointed out that a network of MP-neurons could realize any arbitrary logical function, it would seem useful to postulate learning mechanisms that could create appropriate networks of MP-neurons for different statistical environments.

Rosenblatt was a psychologist who analyzed and simulated multilayer networks of MP-neurons capable of 'learning.' He called such networks *perceptrons*. Although Rosenblatt discussed many different types of perceptrons, the 'generic perceptron' (as shown in Fig. 2) consisted of a set of *S-units* (i.e., 'sensor units'

or 'input units') whose outputs were randomly connected to the inputs of a set of *A-units* (i.e., 'association units' or 'hidden units'). The outputs of the A-units, in turn, were connected to an *R-unit* (i.e., the 'response unit' or 'output unit').

The connections from the S-units to the A-units were nonmodifiable and chosen according to a particular probabilistic law. The connections from the A-units to the R-unit could be modified by a learning process called the *perceptron learning rule*. The learning rule worked as follows. First, the perceptron would generate an activation level for the R-unit based on the current stimulus. The R-unit activation level, R, would be equal to either zero or one. The *desired response D* for the R-unit (generated by the 'training data') is also equal to zero or one. Let A_i be the activation level of the ith A-unit. The connection weight from the ith A-unit to the R-unit would then be incremented by an amount $\gamma(D–R)A_i$. The positive number γ is called the *learning rate* and the quantity $(D–R)$ is often called the *error signal*. Note that no weight adjustments are made when the perceptron makes the correct classification (i.e., $D = R$).

An important consequence of the perceptron learning rule was the famous *perceptron convergence theorem* (see Anderson and Rosenfeld 1988a and Minsky and Papert 1969 for reviews) which essentially stated that if at least one network architecture exists to solve a particular classification problem, then the perceptron learning rule was guaranteed to find a solution after a sufficiently large (but finite) number of training samples have been presented! This theoretical result was strengthened further by the work of McCulloch and Pitts which basically had shown that the multilayer perceptron architecture consisting of S-units, A-units, and an R-unit was sufficiently rich (given enough correctly wired A-units) to represent the solution to any possible classification problem! Such theoretical results in conjunction with extensive empirical research provided an exciting and stimulating environment for research in neurocomputation (Anderson and Rosenfeld 1988a, Anderson et al. 1990).

2. Neurocomputation: The Dark Ages (Late 1960s–Early 1980s)

By the late 1960s, research in the field of neurocomputation was less popular. The early (and important) successes of the field had been excessively popularized, and promises had been made and broken. Rosenblatt's research, in particular, had been oversold by the popular press. By the late 1960s, many researchers were more interested in attacking (rather than developing) a methodology for neurocomputation. For example, in their well-known book titled *Perceptrons*, Minsky and Papert (1969) formally explored the computational limitations of a single generalized MP-neuron but their chosen book title implied that the generic multilayer perceptron network architecture was being discussed! The time period beginning in the late 1960s might be viewed as the 'dark ages' of neurocomputing in the sense that a climate of skepticism regarding neural computation prevailed. However, this same time period was an amazingly productive period of research as well, where many of the key fundamental ideas of the field were initially developed.

2.1 Quasilinear Formal Neurons and Learning

By the late 1960s, the biological assumption underlying generalized MP-neurons began to be reconsidered. First, neuroscientists such as Vernon Mountcastle had shown that the *firing rate* of a sensory neuron (i.e., the number of voltage pulses generated per second) in response to a stimulus could sometimes be realistically modeled as a linear function of the stimulus magnitude. Experiments of this type suggested that the 'relevant informational state' of a neuron might be better modeled as a continuous numeric quantity (i.e., a real number) as opposed to a categorical binary variable. Second, work by Ratliff, Hartline, and others had shown that the peripheral visual system of the horseshoe crab could be effectively modeled using linear systems theory. Research of this nature encouraged modelers to consider a 'quasilinear' continuous-state neuron model (as opposed to the 'two-state' MP-neuron model) for the purposes of neurocomputation. Figure 1 illustrates the key idea underlying the quasilinear neuron model which is essentially that the change in the model neuron's activation level can be approximately modeled as a linear transformation of the activation levels of the other model neurons in the system. In the early 1970s the quasilinear neuron model became relatively popular and researchers such as James Anderson, S. I. Amari, Stephen Grossberg, and Teuvo Kohonen independently published papers concerning Hebbian learning in networks of abstract quasilinear neurons (see Anderson and Rosenfeld 1988a, Grossberg 1982, Levine 1991, and Lau 1992, for relevant reviews).

2.2 Recurrent Networks of Quasilinear Neurons

In the late 1960s, neuroscientists had obtained experimental evidence suggesting that some biological neural networks were organized in a *recurrent on-center off-surround anatomy*. In this configuration, an excited neuron activates a few selected neurons while simultaneously 'inhibiting' a large group of neighboring neurons (see Fig. 3). Thus, in some cases, positive as well as negative feedback is present. This combination of positive and negative feedback implements

a general type of neural categorization mechanism where the network is constructed such that only a small number of neurons are permitted to respond to a stimulus, while the responses of the remaining neurons tend to be diminished in magnitude. Following the research in the early 1970s concerned with associative linear networks involving Hebbian-like learning mechanisms, a number of researchers began to consider problems of neurocomputation using recurrent networks (such as on-center off-surround) of quasilinear neurons. This research led to both theoretical and simulation work which showed how recurrent networks could function as 'feature detectors,' 'pattern amplifiers,' and 'categorization mechanisms.'

2.3 Self-organizing Maps

It had been known since the early 1960s that: (a) feature detection units existed in visual cortex, and (b) feature detection units with similar response properties tended to physically cluster together. Malsburg in 1973 (see Anderson and Rosenfeld 1988a) hypothesized that the development and organization of such feature detection cortical cells might be understood in terms of a learning process. To examine this hypothesis, Malsburg simulated a highly simplified mathematical model of the visual cortex that shared important similarities with concurrent theoretical work by Grossberg (Anderson and Rosenfeld 1988a, Grossberg 1982).

The key ideas of the Malsburg computer simulation model were as follows. First, the initial pattern of neuronal connectivity was random. This initial random connectivity pattern is important because it implicitly provides a set of 'biases' encouraging different cells in the simplified formal model of the visual cortex to have different response characteristics. Second, a Hebbian-type learning rule was instantiated which increased the strength of a connection between two cells when both cells became simultaneously active within some timeframe. Constraints on the weight vector for each neuron were introduced in order to prevent the weights from growing without bound.

From a computational perspective, the initial random connectivity principle and the Hebbian learning principle are sufficient to account for the development of neurons which respond to specific features in their environment. These two principles by themselves, however, cannot account for the qualitative finding that feature detection neurons with similar response properties tend to cluster together in the visual cortex. The third essential property of Malsburg's model was that his model incorporated an on-center, off-surround architecture which had the effect of forcing physically close feature detection neurons to have similar response properties.

3. The Renaissance of Neurocomputation (1980–90)

By the early 1980s, enough progress in the field of artificial intelligence had been made for many researchers to appreciate the strengths as well as the limitations of methodologies entrenched in deductive logic. Second, the cost of computing resources was dropping rapidly. This meant that the implications of complex mathematical neural models could be systematically explored through simulation studies. Thus, obscure mathematical neural models suddenly became more accessible and understandable to a much larger scientific community through the use of computer simulation examples. Moreover, using the new computer simulation technology, new ideas regarding the capabilities and limitations of a potential mathematical model could be explored long before complete or even partial mathematical analyses had been accomplished.

3.1 Recurrent Networks of Sigmoidal Neurons

In 1981, the experimental psychologists McClelland and Rumelhart proposed a neurocomputer for letter perception which had the behavioral property, common to human behavior, that letters in words were perceived more efficiently than letters by themselves (Anderson and Rosenfeld 1988a). The model was designed using an on-center, off-surround anatomy (similar to Grossberg's late-1970s work) such that activation of a concept resulted in decreasing the activation of its competing concepts (see Fig. 3).

McClelland and Rumelhart demonstrated, through a series of careful and systematic computer simulation studies, that the patterns of errors generated by the mechanism were both qualitatively and quantitatively similar to both old and novel experimental data. The McClelland and Rumelhart model eventually became a highly influential example of how a computer simulation methodology could be exploited to empirically evaluate the performance of a neurocomputer from a purely behavioral perspective.

In 1982, Hopfield (see Anderson and Rosenfeld 1988a) showed how symmetrically connected recurrent networks composed of MP-neurons could be mathematically analyzed using Lyapunov function techniques from nonlinear dynamical systems theory (see Golden 1996 for a relevant discussion of Lyapunov function methods; also see *Optimal Control Theory*; *Self-organizing Dynamical Systems*). The Lyapunov function technique was shown to provide a methodology for expressing the computational goal of a recurrent network as minimizing some nonlinear objective function. Shortly thereafter, similar analyses of closely related networks of quasilinear neurons (e.g., Cohen–Grossberg, Cohen–Grossberg–Kosko,

BSB, Hopfield, Harmony Theory, and Boltzmann neural networks) were analyzed using Lyapunov function methods (see Anderson and Rosenfeld 1988a, Anderson et al. 1990, Golden 1996 for relevant reviews).

3.2 Self-organizing Maps

Kohonen (1984) discussed a highly abstract version of Malsburg's (1973) self-organizing map model whose computational performance was comparable to the original Malsburg neural model. From a neuroscience perspective, this was informative because it emphasized those aspects of the neuroscience model which were especially relevant for realizing a useful information processing model. From an engineering perspective, this was interesting because the resulting mathematical model was much simpler and more amenable to computer implementation and mathematical analysis. Kohonen applied his model to a variety of engineering problems concerned with the problem of extracting features for speech recognition systems.

In 1987, Carpenter and Grossberg introduced into the literature what is now called 'fuzzy' Adaptive Resonance Theory (ART). In the ART model, a set of input units is initially randomly connected to a set of hidden units. When a stimulus is presented to the input units, the hidden units compete among themselves until the maximally active hidden unit inhibits the activation levels of all other hidden units. The winning unit then generates a feedback signal to the set of input units. If the feedback signal agrees with the incoming stimulus pattern, then 'resonance' occurs and the connections from the input units to the winning hidden unit are adjusted so the stimulus is more likely to activate the winning hidden unit in the future. If no agreement occurs, then a 'reset operation' occurs and the winning unit is temporarily disabled and the process repeats itself. A useful feature of the ART methodology is that new units can be recruited on an as-needed basis to solve a given pattern recognition problem. In addition, unlike many other neurocomputing architectures, the ART methodology incorporates an 'attentional component' which plays a role in determining whether or not resonance in ART has occurred.

3.3 Multilayer Network Architectures

An important difficulty with the original generic perceptron architecture was that the connections from the input units to the hidden units (i.e., the S-unit to A-unit connections) were randomly chosen. Thus, in many important situations, the chances of obtaining a useful network architecture were relatively small. Rumelhart, Hinton, and Williams in 1986, Le Cun in 1985, Parker in 1985, Werbos in 1974, and Amari in 1967 independently contributed key components to the solution of this problem which is now referred to generically as 'back-propagation' or 'multilayer perceptron' learning methods (for relevant reviews see Chauvin and Rumelhart 1995, Golden 1996, Werbos 1994). The essential idea of such approaches involved 'smoothing' the sigmoidal nonlinearity of the generalized MP-neuron by substituting a differentiable sigmoidal function (see Fig. 1).

Using this device, a standard nonlinear optimization method for differentiable objective functions known as 'gradient descent' could be used to simultaneously estimate the input to hidden unit and the hidden unit to output unit connections. In order for this approach to work, it was also necessary that the initial pattern of connections among the units be randomly chosen so that (like the Malsburg's 1973 model) different hidden units would be biased to detect different features in the input pattern set.

4. Modern Neurocomputation

Today, neurocomputer architectures have proven to be useful tools for developing, evaluating, and modifying theories in the fields of both neuroscience and psychology (for relevant reviews of both neuroscience and psychology research see Anderson 1995, Anderson and Rosenfeld 1988a, Anderson et al. 1990, Durbin et al. 1989, Ellis and Humphreys 1999, Golden 1996, Grossberg 1982, Levine 1991, McClelland and Rumelhart 1986). For example, Kleinfeld and Sompolinsky in 1988 proposed a biologically plausible neurocomputer model of the swimming escape response in the sea mollusk *Tritonia* (see Golden 1996 for a review). Grajski and Merzenich in 1990 (in an extension of the previous work by von der Malsburg in 1973) have described a self-organizing biologically plausible neurocomputer for modeling the development of somatosensory topographic maps in the adult monkey (see Golden 1996 for a review).

Kruschke in 1992 developed a neurocomputer for modeling qualitative aspects of human category learning (see Ellis and Humphreys 1999; see *Connectionist Models of Concept Learning*). In 1991, Plunkett and Marchman developed a neurocomputer type architecture for explaining patterns of 'undergeneralization' and 'overgeneralization' in child language acquisition (see Ellis and Humphreys 1999; see *Connectionist Models of Development*).

Neurocomputer architectures have also made important contributions towards the development of new approaches to solving complex optimization and pattern recognition problems in real-world engineering contexts (for relevant reviews see Anderson 1995, Anderson and Rosenfeld 1988a, Anderson et al. 1990,

Golden 1996). Neurocomputer architectures have been successfully applied to solving real-world engineering problems in areas such as image analysis, data analysis, robot control, adaptive signal processing, financial prediction, medical prediction, inductive reasoning, and speech recognition (for additional examples see Anderson and Rosenfeld 1988a, Anderson et al. 1990, Dagli et al. 1991, Golden 1996). In addition, appropriate techniques for proving theorems regarding the behavior of neurocomputers are becoming more widely recognized. Such techniques are crucial for not only guaranteeing 'correctness of design' in engineering applications but also for advancing our theoretical understanding of neurocomputer-based theories of the mind and brain (see Golden 1996, for an introduction to such methods).

Finally, it is important to emphasize that the field of neurocomputation is still in its infancy. Indeed, it is likely that the diversity of neurocomputer architectures will continue to increase as our understanding of the neural basis of computation evolves in future years. Highly abstract models of neurocomputation will continue to be developed and will continue to play important roles in theory development in psychology and neuroscience. The brain is extremely complex and it is clear that multiple neurocomputer models associated with multiple overlapping levels of abstraction will play a critical role in theory development in psychology, neuroscience, and neuropsychology (see *Connectionist Approaches*).

Moreover, as our understanding of the mathematical basis of neurocomputation increases, the formal implications of specific neurocomputer modeling assumptions will become more apparent. Golden (1996; also see Smolensky et al. 1996) reviews mathematical methods for neurocomputer analysis and design showing how such methods are closely related to previous and current work in theoretical mathematical psychology (see *Mathematical Psychology*; *Mathematical Psychology, History of*). Extremely detailed models of neurocomputation (Bower and Beeman 1998) which incorporate detailed knowledge of the neurophysiology will also play an increasingly larger role in theory development and evaluation in neuroscience and psychology. Another new but promising research trend will be the role of genetic algorithms for formally exploring how evolutionary pressures might influence the development of mechanisms for neurocomputation (Husbands and Meyer 1998).

Artificial Social Agents

A fundamental question in the social sciences is what makes human beings social? What is the root of sociality? Today, computational models are being used to address this issue. Computational social theorists

are not simply providing descriptions of society at a particular point in time. Rather, they are in the business of providing insight into the fundamental basis of socialness, understanding of how societies change, and how individuals negotiate, constrain, enable, and are constrained by the social world in which they live. They are in the business of explaining the dynamics by which social agents, groups, teams, organizations, societies, cultures evolve and co-evolve.

Computational analysis is playing an increasingly important role in the development of our understanding of what it means to be a social agent (Weiss 1999, Bainbridge et al. 1994). Computational analysis using social agents has been used to theorize about a large number of social behaviors. These include but are not limited to: organizational exploration and exploitation, cooperation, coordination, diffusion and social evolution, organizational adaptation, change in social networks and exchange networks, collective action, emotions, markets, and transactive memory. This exploration provides insight into the fundamental nature of the social agent (Carley and Newell 1994) and the laws by which artificial societies operate. The conceptualizations coming out of computational social science are building on, yet moving us far beyond, traditional conceptualizations of the social agent. Such traditional conceptualizations include Rousseau's noble savage, *homo economicus*, Skinner's contingently reinforced human, Simon's boundedly rational human (see *Bounded and Costly Rationality*), the imperfect statistician, Mead's social symbolic human, Blau's bundle of sociodemographic parameters human, the structuralist's human as a social position, *homo faber* (human, the toolmaker), and Huzinga's *homo ludens* (playful human).

The work on artificial agents asks—what is the fundamental basis of socialness? You might assume that a computational approach to socialness will become trapped in the simplicity of machine-like systems. However, exactly the opposite is the case. Current theories of human cognition, based on information-processing notions, are in many ways quite rich. Such theories include SOAR, ACT, and neural networks. Moreover, these formalisms provide an analytical tool to ask critically what more is needed to attain social behavior? Computational models allow us to: peel away what is understood about cognition, and consequently reveal the basis of socialness; theorize about the possible joint effects on social behavior of cognitive architectures and complex social environments; and examine dynamic social systems.

Artificial social agents are being used in all branches of the social and organizational sciences. These agents range from simple cellular automata-type agents to detailed and highly cognitively realistic agents (such as SOAR agents). Artificial social agents range from: whether or not they can learn and adapt; the level of knowledge with which they are endowed; and the type of social activities in which they can engage. In a sense, this work can be divided into three categories—A-life, organizational, and cognitive. In the A-life models (artificial life) there are large numbers (hundreds to thousands) of simple agents (few rules) interacting in a two-dimensional space and collectively generating socially realistic behaviors (such as aggression and segregation) (Epstein and Axtell 1997). The Sugarscape and Schelling agents are of this type. In the organizational models, there are a moderate number (tens to hundreds) of moderately cognitively complex (some rules) agents. Each of these agents has a specific organizational position, which constrains and enables access to information. The agents collectively perform organizational tasks (such as resource assignment, classification, or search) theory (Carley and Prietula 1994). The VDT, Orgahead, and Construct agents are of this type. In the cognitive models, there are a few (two to 10) highly cognitively realistic agents (many rules) each with specific detailed expertise and often a specific task-based role. Examples are the SOAR-IFOR agents and Plural-SOAR agents.

1. *The Model Social Agent*

Carley and Newell (1994) construct a definition of the social agent—a Model Social Agent. They developed their definition by asking the question, 'What is necessary in order to build an adequate artificial social agent?' They describe the social agent using two dimensions: processing capabilities and differentiated knowledge of the self, task domain, and environment. The processing dimension reflects limitations to the agent's capabilities that enable it to be social. The knowledge dimension reflects the richness of the agent's perceived environment that evokes and supports social behavior. As the agent's information-processing capabilities become more limited and the agent's knowledge becomes more complex (both in type and in quantity) the Model Social Agent is achieved. As the agent's information processing capabilities decrease, task performance may degrade, but different, and often more complex, behaviors emerge. Basically, agents with more information processing capabilities do not need certain behaviors, for example, the omnipotent agent does not need to gather information. Regardless of an agent's capabilities, if its situational knowledge is impoverished, it will not behave as a social agent. For knowledge, there is a cumulative sequence of information types. The agent can engage in distinct actions as it gains more types of information. In Table 1, the Newell–Carley Scheme is displayed and common agent types placed in the relevant location.

2. *Social Agents in the Loop*

Computational agents have served as 'conspirators' and agents in human laboratory experiments. For

Table 1
Model social agent and artificial social agent models

	Knowledge (increasingly rich situation)					
Information processing capability	Nontask specific	Multiple agents	Real interaction	Social–structural	Multiple–goals	Cultural–historical

example, in the artificial markets project at MIT (http://web.mit.edu/lfe/www/Research/artificial-mkts.html), researchers are running experiments with both humans and artificial social agents in order to examine the rich dynamics arising from interactions between human and artificial agents in a stochastic market environment. This work is at the very heart of electronic commerce.

Whether or not artificial agents are used in the laboratory, social agent models can be used to fine tune human experiments. For example, Markovsky (1987) used a model of triads of simple social agents to explore the power associated with position in a three-person social network, where person A could interact with persons B and C, who however could not interact with each other. In a typical round in this virtual experiment, each agent makes an offer of dividing 24 points between itself and another agent. Agent A compares the offers of B and C, and selects one of them. The points are then divided between A and the selected partner using the average of the B and C's offers. After the first round (when the offers are randomly determined), each agent adjusts its offer as follows. If the previous offer was accepted, the new offer will be more demanding. If the previous offer was rejected, the new offer will be less demanding. Given these simplistic agents, Markovsky was able to build a series of 19 experiments that varied the strategies employed by bargaining agents. These results then informed laboratory experiments, and directed future research in exchange theory (see also Markovsky et al. 1993).

Computational agents have served as players in computer tournaments. An example is the 'prisoner's dilemma' computer tournament organized by Robert Axelrod. The prisoner's dilemma is a classic game-theory problem that explores the conditions under which cooperation may arise between self-interested agents who have the potential to garner short-term gains if they violate agreements to cooperate (Rapoport and Chammah 1965). Researchers submit artificial social agents—computational models—that do the 'task' of the tournament. Tournaments enable theories, realized as social agents, to 'compete' with each other. This leads to a better understanding of their relative efficacy, common features, and differences. For Axelrod's prisoner's dilemma tournament, the submitted programs were agent models following strategies for playing the iterated game. Rapoport's winning social agent employed the 'tit for tat' strategy in which it cooperated on the first move and then imitated the previous action of its partner.

3. *Social Agents and Virtual Worlds*

At a high level of abstraction, there are two generic approaches to doing social science with artificial social

agents: bottom up and top down. In the top down approach, the computational social scientist utilizes social agents to search for underlying fundamental principles of sociality by endowing those agents and the worlds they inhabit with known constraints on social and cognitive behavior. The virtual social worlds are populated with the constraints known to exist in the real world, and a small number of highly realistic agents. The expectation is that the interaction among these agents and the world will lead to fundamental insights about the nature of social life and predictions about how to affect social behavior. In the bottom up approach, virtual social worlds are populated with large numbers of minimally intelligent agents. The expectation is that through interactions among these social agents, social realities will emerge in the virtual world.

Virtual worlds are computer simulated worlds of particular social and/or physical environments. Within a virtual world, there is a particular set of physical, temporal, social and cultural laws that must be obeyed. These worlds are populated by artificial agents. Examples range from game systems such as SimCity to research worlds for understanding the complexities of biological and social life such as Sugarscape. Virtual worlds become scientific test-beds in which researchers can grow artificial life and social theory from the ground up. Virtual worlds enable the researcher and student to reason about social behavior in a controlled setting, like a human experiment. However, unlike a human experiment, these worlds can be quite large. Thus, issues of scale, emergence, and time varying behavior can be addressed.

One of the earliest examples of a virtual world in sociology is Bainbridge's (1987) sociological laboratory. Bainbridge created worlds in which the student could explore classic theories of social behavior. Within these worlds, the student could run virtual experiments to see the impact of changing norms of social behavior. Another classic example of a virtual world is Schelling's (1969) segregation game. In this world, agents on a grid choose to move or stay in neighborhoods, based on a preference to be in a neighborhood with at least a minimum number of agents of their own kind. Using this model, he demonstrates that the optimization of local choices leads to globally destructive consequences—complete segregation and ghettos.

Much of the early work used cellular automata. Today, this same branch of research is being reborn in the work on artificial life, or A-Life. A typical A-Life model is Sugarscape (Epstein and Axtell 1997). Epstein and Axtell argue that they are using computers to do 'bottom up' social science. Given a collection of very simple agents with very simple rules, they try to grow complex social behavior in the Sugarscape world. In Sugarscape, multiple simple agents engage in social interactions in the processes of consuming sugar, moving across planes, giving birth, and dying. Sugarscape is a virtual world where agents can live, eat, die, and engage in social interactions. In its simplest form, the Sugarscape world is a torus made by wrapping a grid of 50 by 50 squares, such that sugar grows in some of the squares and not others. This world is populated by a number of agents, each of whom can consume sugar or move one square on the von Neuman grid (NSEW) each time period, as long as they do not occupy a square occupied by another agent. Consumed sugar translates into energy, or can be stored for later usage. Energy is needed for movement, reproduction, trade, engagement in conflict, etc. Without energy, the agents die. Agents placed randomly on the grid will, over time, develop a collective intelligence that will move them towards the 'fields of sugar.' Additional rules, for example, the inheritance rule, produce more social behavior. The more factors and rules added, the more social are the behaviors, which can be explored. For example, introducing a second resource, such as spice, leads to the emergence of trading and an economic market. Epstein and Axtell demonstrate that complex social outcomes need not have complex causes. As noted by Schelling, simple behaviors on the part of individual agents can have major social consequences.

4. *Social Agents and the Generally Intelligent Agent*

Research on individual cognition has generated a number of models of general intelligence and learning that extend beyond task-specific models of performance. Examples include SOAR (Laird et al. 1987), ACT (Anderson 1996), and neural networks (Rumelhart and McClelland 1987). These models take a more system level approach to cognition. If these general models of individual cognition are sufficient models of social behavior, then a group composed of such agents, each realized using one of these cognitive models, should account for all forms of social and organizational goal-oriented deliberation, which underlie social behavior (Carley and Newell 1994). Multiagent models can be constructed by weaving into organizational design sophisticated computational models of individual cognitive agents, tasks, and social situations.

According to ACTs, organizations are composed of agents who are cognitively-restricted, task-oriented, and socially-situated. The actions of these agents are constrained by the human cognitive architecture, the characteristics of the task, and the nontask characteristics of the environment in which the agents are situated (the social situation). An agent's actions are a function of the agent's cognitive architecture and knowledge. Consequently, manipulating the organizational design or social structure manipulates the

constraints on agent action imposed by the agent's knowledge, task and social situation.

ACTs theory is consistent with Simon's (1981) comment that the seeming complexity of human behavior is due, not to the reasoning mechanisms, but to the task environment. That is, the agent's cognitive architecture is seen as immutable and affects the process by which the agent gathers and communicates information, makes decisions, and learns. Each agent's knowledge changes over time through learning and forgetting, as a function of the agent's position within the organization or society, the task in which the agent is engaged, and various stresses on behavior. Knowledge mediates the constraints on agent actions, dictated by social and cultural situations.

5. *Theoretical Breakthroughs: The Nature of the Social Agent*

Models employing artificial social agents have a long history in the development of social theory and methodology. Results derived from computational models have led to a number of important theoretical breakthroughs that collectively generate a more complete understanding of the social agent.

One of the earliest and most profound uses of computational models was to develop the theory of bounded rationality (see *Bounded and Costly Rationality*). Prior to the 1960s, most formal theories of social and organizational behavior assumed rational actors with complete information and total insight. Arising out of the Carnegie School, Herb Simon, and others, argued that humans were boundedly rational, that is, social structure limits their access to data, and human cognition limits their ability to process that information. As a result, decisions are made by 'satisficing' rather than 'optimizing.' In *A Behavioral Theory of the Firm* (Cyert and March 1962) and in the *Garbage Can Model of Organizational Choice* (Cohen et al. 1972), the authors demonstrate, through computational theorizing, that human limitations affect what choices are made when and how. Further, by taking such bounds into account, theoretical propositions better match actual observations. This work was instrumental in revolutionizing theoretical and empirical work on group and organizational behavior. The resulting information processing view is now an integral part of many social theories.

Another theoretical breakthrough is in the area of chaos (see *Chaos Theory*). The notion of deterministic chaos has captured the imagination of scholars and the public. Social behavior can become chaotic. This in itself is not a novel theoretical proposition. However, they ran a series of social agent simulations that demonstrated that when the agents are social, that is have the capacity to base their actions on beliefs about others' strategies and on the observed behavior of the collection of agents, meaningful order emerges. This suggests that, for recognizable social behavior to emerge, the content of individual cognition needs to contain mental models of others and their actions.

A related breakthrough is in the area of transactive memory. Wegner (1995), using a computer system as a metaphor for human memory, developed the powerful idea of transactive memory. Transactive memory refers to the ability of a group to have a memory system exceeding that of the individuals in the group. The basic idea is that knowledge is stored as much in the connections among individuals as in the individuals. Wegner argues that factors relevant in linking computers together such as directory updating, information allocation, and coordination of retrieval, are also relevant in linking the individuals' memories together into a group memory. Empirical evidence provides some confirmation and suggests that for a group, knowledge of 'who knows what' is as important as the task knowledge. Transactive knowledge can improve group performance. Thus, for recognizable social behavior to emerge, the content of individual's mental models needs to include knowledge of who knows what and who knows who.

Today, important advances in the social sciences are made possible by the use of artificial social agents. This work has led to a new paradigm, the neo-information processing paradigm, in which social and cognitive behavior is jointly determined by both cognition and interaction. Social behavior realizes social outcomes as the result of changes in interaction among agents and agents whose mental models take into account what others know, who they know, and what they are likely to do. This is the interaction-knowledge perspective.

Artisans and Guilds, History of

1. Definitions

Artisanal labor is a particular form of labor that has existed in most—if not all—human societies. Historically, it first appeared as non-agricultural production, and during the last 200 years primarily as small scale or small commodity production, in contrast to mass production and mechanized factory industry. The focus of the definition is on production, thus also distinguishing artisanal labor from economic activities such as commerce. Indeed, one cannot draw strict boundaries here. The English term 'trade,' for instance, has been in use for artisanal production as well as for commerce and exchange. Furthermore, artisanal labor is not necessarily limited to production, but also includes some activities that in modern economic thought are assigned to the tertiary or service sector. Artisan is a narrower concept than artisanal labor. While artisanal labor may be performed by men and women as one activity among many others, artisans can be defined as persons who specialize in artisanal labor and make their living mainly, if not exclusively, from this kind of work. There are some almost universal elements in the concept of the artisan: manual labor and the use of tools; specialization of labor, which connects the concept of the artisan with the concept of profession or occupation; skill and some kind of training as a precondition of skill; and work not for subsistence but for consumers or markets. Besides these universal elements, there are also some historically variable ones that fluctuate in accordance with broader social and economic change.

2. Artisans: Concepts and History

The origins of artisans are connected with social changes at the end of the Neolithic Revolution (see *Work, History of*) in approximately the fourth millennium BC. Foremost among these was the development of technology, above all in the fields of metallurgy, ceramics, and woodworking. This promoted specialization in the production of metals as well as in the fashioning of tools, weapons, and a growing number of practical implements. Second, the emergence of social stratification brought about increased demand for luxury goods by the upper classes, the production of which called for special training and particular skills. Third, there was the formation of urban cultures, especially in the Near East and the Mediterranean. Artisans were concentrated in cities, and it was here that the division of labor within artisanal production accelerated and specialized crafts and trades came into being. During the first millennium BC, dozens of different artisanal occupations emerged in the urban cultures of India, the Near East, and the Mediterranean.

The value assigned to labor in the crafts and trades and the social position of the artisan has been characterized by a high degree of ambivalence. In all societies in which work was held in low esteem, this applied to artisanal labor too. In European history, though, there is also a long tradition of valuing the work of artisans more highly than other forms of manual labor. Whereas in some non-European cultures, such as ancient China, artisans were assigned a lower social status than peasants, in the European tradition they enjoyed a relatively high level of prestige. In early ancient Greece, this was expressed in the myth of Prometheus the god of fire, pottery, and metallurgy. 'In the eighth century BC the crafts of blacksmith, pottery, and weaving were considered in the same light as that of priests, bards and doctors (…). All these activities were called *technai*, that is, activities implying the use of secret processes, specialized knowledge based on long apprenticeship and an initiation ritual.' (Godelier 1980) Some crafts appeared as sacred in Gallic and Germanic mythology as well, and in the European Middle Ages, for instance, in the scale of social values in early Germanic law, artisans clearly had a higher rank than persons engaged in agricultural activities. 'The craftsmen who

forged the weapons for the aristocratic warriors (…); and the goldsmiths who decorated these weapons and created jewels for the women of these warriors (…) were important personages who upheld the prestige of technical skill' (Le Goff 1980).

2.1 Artisans in Corporate Society

The urbanization process in twelfth- to fourteenth-century Europe strongly influenced the concept and the social standing of the artisan. Most importantly—and not at all usual for people working with their hands—artisans, as urban citizens, were freemen. In many English towns, for instance, completion of an apprenticeship entitled an individual to the freemanship of the respective town (which meant permission to take up residence, claim to social relief if the need arose, and often some form of political participation). The increasing division of labor in towns created a wide range of artisanal occupations, and the expanding guild system (cf. guilds, See Sect. 3) served as an institutional framework for training and work in these occupations. Both of these developments had consequences, which became basic to the concept of the artisan in the corporate societies of Europe from the late Middle Ages until the eighteenth century.

First, artisanal work—even if it was manual labor—was not simply regarded as labor. The negative connotations of labor (travail, hard work) as toil, pain, burden, or penitence were replaced by an understanding of artisanal labor as art. *Arts et métiers* (arts and trades) was the common French term used to group together all artisans (a generalizing term which appeared in the sixteenth century). In eighteenth-century France, artisanal crafts were regarded as honorable because they were based not only on the 'effort of the body' but also on the 'subtlety of the mind' (Sewell 1980, p. 23). Second, by organizing in guilds or other associations, artisans had a recognized standing in society and the state. Whether they enjoyed royal privileges, municipal statutes, or the permission of the church to form a confraternity, all these defined them as a corps or as an estate (French: *état*; German: *Stand*). In both respects, inherent in the concept of the artisan, was a sharp destinction vis-à-vis unskilled laborers.

2.2 The Ambiguous Journeyman

Traditionally, the concept of the artisan referred primarily to the master artisan—an independent craftsmen who ran his own workshop and casually or regularly employed a few hands. As head of the household, the master was part of the corporate structure and exercised domestic authority over his family and his workforce. On the other hand, the conception of the artisan also included different categories of employees. First, it referred to apprenticeship, which was understood as a period (and a social position) of training—generally, although not necessarily, connected with adolescence. In the late Middle Ages, there appeared a further group: artisans who had finished their apprenticeship but had not—or not yet—become masters. In English, the term journeyman (which stems not from the journey of the tramping artisan, but from the French word *jour* meaning day, and designating one who works and is paid by the day) became most widespread to describe this group. While the concepts of apprentice and master are relatively clear, the concept of the journeymen is fluid and ambiguous. On one hand, it refers to a life-cycle stage, as the completion of training, mainly by tramping a couple of years. From this perspective, journeymen were young, single men subject to the domestic authority of the master (when at work and not on the road), until they themselves became masters and householders. On the other hand, the concept of journeymen refers to wage laborers—often on a life-long basis—having their own households and families. In practice, it is almost impossible to make a clear distinction between these two concepts and modes of life. Very roughly, the first type prevailed in small-scale production (bakers, tailors, and the like), the second in textiles (particularly where the craft was transferred into outwork or domestic industry) and in the building trades. Furthermore, the first seems to be more common in Central Europe, whereas the second is more familiar in the West, particularly in England. Many historians also believe that over the course of the late medieval and early modern history, the first type was gradually replaced by the second, but this is probably a far too general and too linear model (cf. Reith 1999). Generally, the relations between masters and journeymen included solidarity and moral community as well as conflict.

2.3 Redefinition of the Artisan in Class Society

In the emerging class societies of eighteenth- and nineteenth-century Europe, the concept of the artisan became redefined both in *petit bourgeois* and in proletarian terms. On one hand, the concept still focused on the independent master craftsman working in his own workshop with his own tools. Apprentices and journeymen were included in this concept as future or anticipated masters. On the other hand, the concept of the artisan increasingly referred to life-long employed workers working in a wide range of economic settings—even in factories—but being distinguished from ordinary laborers by their common 'property of skill.' Artisans were 'those who through apprenticeship or its equivalent had come to possess a

skill in a particular craft and the right to exercise it' (Rule 1987, p. 102).

In social theory, the first model became predominant. In Enlightenment philosophy as well as in political economy, the artisan began to be regarded as a counter-model to capitalism. Karl Marx conceptualized the artisan as a personification of a non- (or pre-) capitalist mode of production, which he called small commodity production (*kleine Warenproduktion*). At the turn of the century, the German social scientist Werner Sombart regarded the artisan as the 'ideal type' of the pre-capitalist economic system, which, in his view, was characterized by empiricism and traditionalism (as opposed to rationality) and a lack of interest in accumulation and profit. This perspective became extremely powerful and shaped more or less completely the historical interpretation of the artisan.

In practice, however, in the economically advanced regions of Western Europe, most of the workmen who identified themselves as artisans were in wage employment. Adam Smith in his 'Wealth of Nations' (1776) estimated that in England there were 20 men working for wages for every one who was his own master (Rule 1987, p. 103). Here, the artisan as a skilled workman became central to the self-image, identity, and rhetoric of the emerging working class. On the continent, and particularly in Germany, even in the mid-nineteenth century, the number of masters almost equaled the number of journeymen in the crafts and trades. Here, the concept of the artisan became synonymous with independent master craftsmen and their respective *petit bourgeois* political movements.

3. Guilds: Concepts and History

In Western history, both the concept and the practice of artisans are closely connected with guilds. Associations of artisans existed in many historic societies and cultures. For example, there is evidence of their existence in classical India, ancient Rome, Tokugawa Japan, and Colonial America. Nevertheless, the term guild or craft guild refers to a particular type of artisanal association, which had its place in the corporate societies of Europe from the late Middle Ages to the nineteenth century. Despite enormous variations from city to city, region to region, and one historical period to another, the concept of the guild refers to a combination of several characteristics. First, a major organizational principle was occupation. Usually, although not necessarily, guilds organized artisans of the same occupation or of related/similar occupational groups, and occupation formed the major line of differentiation separating one guild from another. Changes in the division of labor and in occupational structures are therefore the major dynamic forces in the development of the guild system. Second, guilds were strongly concerned with economic matters in their respective sector of the economy. Market regulation—both in respect to commodity markets and labor markets—was an essential part of their economic activities. Third, guilds were primarily organizations of master craftsmen. Occasionally they also included apprentices and journeymen in minor positions; on other occasions, they definitely excluded these groups, thus providing the impetus for journeymen to found their own clandestine or legal associations. Fourth, guilds were formally constituted and officially recognized bodies. Statutes or privileges granted by municipal or state authorities made them a solid part of the corporative structures of society. In this context, guilds also performed political functions, casually participating in the political system, occasionally even dominating urban politics. Lastly, guilds were not only economic and political bodies, but also multifunctional institutions engaged in religious, cultural, and social activities.

The first guilds—in the sense of this definition—were established in France, England, Germany, and Italy in the twelfth century. In the thirteenth and fourteenth centuries, guilds existed almost everywhere in urban Europe with a wide variety of titles and designations. Latin sources use terms such as *officium*, *ministerium*, *magisterium*, *artificium*, *collegium*, and many others. The French language speaks of *métiers*, *corps des métiers*, or *corporations*; in English they are called guilds, crafts, or mysteries; in German *Zunft*, *Zeche*, *Innung*, or *Amt*; in Italian *arti*, *gremi*, and so on.

3.1 Guilds in Corporate Society

Despite these obviously medieval roots, European guilds became a mass phenomenon and a nearly universal institution in the Early Modern Era. In the Netherlands and France, Spain and the various Italian states, German-speaking Central Europe, and the Nordic countries, most guilds were founded in the sixteenth, seventeenth, and eighteenth centuries. Even in England with its highly developed market economy, many guilds were re-established in the Restoration, and in cities like Bristol and Bath, there were even new guilds being founded as late as the mid-eighteenth century. A guild system also developed in the Ottoman Empire, particularly in the Balkans, the Near East, and Northern Africa. In the Russian Empire, on the other hand, guilds were unknown. In Colonial America during the early eighteenth century, many artisans took an interest in setting up craft guilds. Even though some associations were actually founded (such as the Carpenter's Company of the City and County of Philadelphia in 1724), no general guild system came into being.

Even when guilds were at the pinnacle of their importance in Europe, not all artisans were incor-

porated. In Western Europe and particularly in France and England, guilds were limited to cities, and did not even exist in all cities. In many Central European states—for instance, Austria—guilds transcended municipal boundaries and became regional or nationwide institutions organizing urban artisans as well as craftsmen from villages and the countryside. In those places where guilds did exist, there were few instances in which all artisans belonged to them. A large proportion of artisanal labor always took place outside of the guild system.

Mercantilist theorists and political leaders of the seventeenth and eighteenth centuries regarded guilds as instruments of unified state regulation of trades, labor, and taxes. During this period, many European states indeed tried to make guilds universal and to establish the guild system as a framework for all economic activities; one such example is the effort of French Prime Minister Colbert in his trade laws of 1673.

3.2 The End of the Guild System

A hundred years later, the opinion of guilds held by political and intellectual elites had changed completely. During the second half of the eighteenth century, an antagonistic discourse emerged. Mainstream economic and political thought—expressed in the fields of political economy, physiocracy, or in Enlightenment thought in general—came to regard guilds as obsolete relics of the past that sought to retard or prevent economic development. Proponents of this approach called for complete freedom of trades and the abolition of guilds. Conclusions diametrically opposed to these were drawn by conservative thinkers who saw guilds as the embodiment of a corporative ideal and as a means of combating the assumed decay of authority and order.

When the leading physiocrat and Enlightenment thinker Turgot served briefly (1774–76) as French prime minister, he issued a decree in 1776 completely abolishing all guild privileges as well as expressly forbidding 'all masters, journeymen, workers, and apprentices (…) to form any association or assembly among themselves (…), (Sewell 1980, p. 73). Despite the fact these measures were repealed only a few months after Turgot's fall from power, they nevertheless initiated the process of the elimination of guilds from Europe over the course of the next 100 years. Revolutionary France took a radical step as early as 1791 and banned guilds along with all other labor organizations. England's Combination Acts of 1799/1800 also mandated the 'prohibition of all combinations'—those of masters as well as of journeymen (Chase 2000, p. 84). Most Central European states oscillated between anti-guild and pro-guild principles. They indeed forbade the organization of artisanal workers, but permitted the guilds—as organizations of masters—to remain in existence. It was not until the 1860s that the guilds were dissolved once and for all in the German states and in the Habsburg Monarchy. This process reflected the guilds' loss of their social function. In most countries, dissolving the guilds met no opposition, but it was precisely in Central Europe that guilds remained alive as the object of the projections engendered by a corporative social ideal and conservative nostalgia.

3.3 Guild Traditions in Petit Bourgeois and Labor Movements

The end of the guild system did not also mean the end of artisanal organizations. These developed over the course of the nineteenth century in two separate directions. On one hand, there was the organizational continuity of master artisans, independent craftsmen, and employers. This line of tradition was significant above all in Central Europe. In the German and the Habsburg Empires, in Denmark, and is some other countries, cooperative organizations in the crafts and trades continued to exist even after the dissolution of the guilds. From the 1880s on, these organizations were granted wide-ranging authority in their respective fields, such as control over the training of apprentices. Politically, these trade associations were closely associated with the 'middle class movements,' the political movements of the *petits bourgeois*. They demanded the restoration of guilds and developed corporative ideals in the framework of conservative and right-wing politics (cf. Haupt 1996).

The tradition of guild crafts and trades, however, also played an important role in the emerging labor movement. Although journeymen's associations had been banned in many European countries at around 1800, confraternities, *compagnonnages*, houses of call, and similar institutions continued to exist on an informal or illegal basis. Although there was no direct institutional continuity between guilds and trade unions, there was nevertheless a close connection on the conceptual, experiential, and personnel levels. Artisanal workmen who came out of guild traditions were used to organizing in such associations, which they considered their political right. They were likewise accustomed to settling labor disputes collectively, be that in the form of negotiations or job actions. Furthermore, they also carried on the tradition accentuating and defending their social status, which was based upon the 'property of skill.' All these traditions were important incentives for the founding of the first trade unions in the first half of the nineteenth century.

In a broad sense, artisans were also the driving force behind the early political labor movement. Of course the concept of class contradicted the tradition of craft consciousness, since it stressed the common experiences of all working men, skilled or unskilled, in whichever craft or trade they engaged. Nevertheless,

there is almost universal agreement 'that skilled artisans, not workers in the new factory industries, dominated labor movements during the first decades of industrialization. Whether in France, England, Germany, or the US, whether in strikes, political movements, or incidents of collective violence, one finds over and over the same familiar trades: carpenters, tailors, bakers, cabinetmakers, shoemakers, stonemasons, printers, locksmiths, joiners, and the like. The nineteenth-century labor movement was born in the craft workshop, not in the dark, satanic mill' (Sewell 1980, p. 1).

4. *Revisionism in Guild and Artisan Historiography*

The negative assessment of guilds in eighteenth and nineteenth century thought also characterized historiography. Until recently, most historians had assumed that guilds were technologically regressive, that they restricted economic growth and straitjacketed the development of free market capitalism.

All of these assumptions have been subjected to critique since around 1980. A growing number of historians is now engaged in a 'revisionist version of guild history' (cf. Epstein et al. 1998, Ehmer 1998). With respect to early modern Europe, artisans and guilds have become reintegrated into the mainstream of the development toward capitalism. The Dutch case shows most clearly what can be seen in many other European regions as well: 'guilds were part and parcel of commercial capitalism,' showing extensive growth particularly in the 'Golden Age' (Lucassen 1995). The increasing dependency of Europeans on markets, the growing variety of available goods and of artisans who made them is now seen as evidence of a 'dynamic, flexible and creative craft economy' (Farr 1977, p. 25). The guilds' emphasis on skill, their system of formalized training, and the technological transfer through tramping artisans, is now said to explain, 'the undisputed technological leadership of guild-based production,' particularly in comparison to the rural putting-out system (proto-industry) and early centralized factories (Epstein 1998, p. 705).

Furthermore, guilds are no longer regarded as stable institutions of equals, but as highly stratified and dynamic fields of social relations. Merchant capitalists used some guilds to control and discipline economically dependent masters and journeymen, whereas other guilds were instruments of resistance to merchant capital. There are also new perspectives on artisanal cultures, conceptualizing them as historically variable and adaptable sets of practices. In this new light, customs that were regarded as 'ancient' by the artisans themselves as well as by the historians who came after them are now often being shown to have a rather brief history. For instance, French *compagnonnages*, journeymen's associations with highly elaborate rituals and an aura of mystery, experienced their 'golden age' from the mid-eighteenth century to the 1830s/1840s—the very period of redefinition of the position of artisans and guilds in society. (cf. Sonenscher 1987, pp. 31–63).

Another area in which revision is taking place is the role of the artisans in the Industrial Revolution. In eighteenth- and nineteenth-century Britain, small-scale and labor-intensive production, skill and 'hand technology' drawn from a huge reservoir of urban and rural artisans played a key role, not as a mere remnant of the past, but as a central and dynamic component of industrial capitalism (cf. Berg 1985). Generally, artisanal small-scale production displayed remarkable persistence in industrializing societies, adapting to the needs of industry, and benefiting from the growing demand of consumer society. The generally successful process of adaptation was not harmonious and free of conflict. Some artisanal branches survived, some new ones were born, but others—including all textile production and most metal manufacturing—declined and vanished. Artisans in these trades experienced the devaluation of their skills. The same happened to the journeymen of the metropolitan garment industries, which left the artisans' workshops and became reorganized as an urban domestic industry based on the cheap labor of women and children instead of that of skilled workmen.

The role of women in the world of the artisans is a major point of recent discussions (Hafter 1995, Hanawalt 1986). It is generally agreed that women in most human societies regularly performed artisanal labor, but rather seldom became artisans in the sense of professional, organized, and honorable workers. In European history, the concept of the artisan and, to an even greater extent, that of the guild were male concepts. Artisans who practiced crafts and trades in European cities during the late Middle Ages produced commodities that had previously been produced in households by women as well as by men. The difference was that the professional artisans then produced for the market and their labor became regulated by a set of formal and informal rules. Even if 'the early guild ordinances (…) did not regard skilled guild labour as a male preserve,' in the long run the switch from household production to market production, from unregulated artisanal labor to a 'craft,' excluded women (Wiesner 1989).

Recent research clearly shows that women participated in artisanal labor in many respects, as masters' wives and daughters, as domestic servants in artisans' households, as widows, and, last but not least, as autonomous independent producers. Nevertheless, in all these roles they were not officially recognized as skilled workers. This shows that the very concept of skill, which is central to the conception of the artisan, is highly ambiguous. On one hand, skill indeed requires a certain body of knowledge, experience, and training; on the other hand, skill is a historically

variable social construct. Not all labor activities that require some expertise are regarded as skilled work. In European history, skill was defined by male artisans and guildsmen not only with respect to actual work practices, but also as property, status, and a means of social distinction.

Arts Funding

1. The Term 'Arts Funding'

The term 'arts funding' comprises those processes that are aimed at providing the frameworks for the production, dissemination, and consumption of art objects. Furthermore, a description of arts funding focuses particularly on the economic aspects of these processes. That is, how individuals, groups, institutions, and agencies, over time have been willing to pay for art objects to be produced, disseminated, and consumed. Thus, arts funding research has been exploring economic preconditions for creative and performing artistic work, the various social settings in which this has taken place, *who* has paid for such activities, and *why* they have done so. 'Patron' is the term for various funding sources. 'The arts' is often associated with the visual arts. When describing arts funding, other art forms such as music and literature are equally important. This means that studies of arts funding can be concerned with creative artists such as painters, sculptors, composers, and writers, and with performing artists such as musicians and actors, all being funded directly by patrons and by institutions where they have worked, or indirectly through various regulatory means.

Arts funding is a social phenomenon in the sense that its existence and organizational form depend on persons and institutions constituting certain configu-

rations which differ over time. These configurations may also differ across societies and political systems. In this article, these configurations will be examined in turn. The last section describes some issues in current arts funding research.

2. Why the Arts Have Been Funded

Arts funding research is interested in those individuals or institutions willing to put money into artistic activities, and their intentions in doing so. The reasons vary from wanting art for art's sake, to viewing the arts as fulfilling different instrumental purposes. Some functions are more closely connected with some specific patrons than with others. Furthermore, the connections between patrons and functions have changed throughout history. The presentation below also shows that the term 'public' has manifested itself differently throughout history.

Art as a phenomenon can be traced back to prehistoric times. In *The Story of Art*, Gombrich (1995) alludes repeatedly to 'art patrons' and 'patronage,' beginning around 700 AD. This article's historic overview of arts funding begins here, indicating the most important art patrons over time. It is mostly about Europe and North America, but examples from Asia, Africa, and Latin America are also included:

(a) ca. 700–1300: the church,
(b) ca. 1300–1660: the aristocracy,
(c) ca. 1600–1770: royal courts,
(d) late eighteenth century: the bourgeoisie in private clubs and associations,
(e) primarily after World War II: the state, government,
(f) at all times, but particularly since the 1960s: private patrons,
(g) particularly after the 1960s: corporations and other private patrons.

2.1 Church and Aristocratic Patronage

In 326 AD, a Vatican church in Rome was consecrated in memory of the Apostle Peter. In 1506, Pope Julius II (1443–1513) tore down this basilica, commissioning the architect Donato Bramantes to build St. Peter's Church on the same spot. The purpose was twofold—to create a room for religious worship, and fulfilling a genuine artistic interest, including a desire to support individual artists.

The Medici family, ruling from 1434, made Florence the center for renaissance culture, supporting artists like Michelangelo and Leonardo da Vinci. They were funded for their artistic excellence, but also as tutors and coordinators of apprentices and skilled workers who decorated church walls and ceilings. Thus, they were artists as well as experts in a certain handcraft, serving representative as well as aesthetic functions. The Medici family also established Europe's first public libraries in Florence, thus enhancing access to literary art. However, the idea of autonomous art was not yet relevant.

Religious and aristocratic patronage also explains the construction of magnificent temples between the tenth and fifteenth centuries in, example, India, Korea, Afghanistan, and Nepal. For instance, in Sri Lanka (Bandara 1972): 'Buddhism [...] determined the aims of artistic creation and functioned as the common link among the ruler (sponsor), the artist (creator), and the public (recipient).'

2.2 The Royal Court as Patron

During the fifteenth century the royal courts increasingly became the primary arenas for artistic endeavors. Royal arts patronage reached its peak during Louis XIV's reign from 1643. Art should illuminate the splendor of the king and his court, which left the artists in the role as servants. Thus the representative function was more important than artistic content. This posed a dilemma for artists who focused primarily on their creative abilities, like Wolfgang Amadeus Mozart (1765–91). Mozart began composing when art was still regarded as a useful handicraft, at the same time that the idea of art for art's sake began to emerge. He was torn between an artistic role in which he could compose 'pure' music, and a representative role, being obliged to serve patrons commissioning and paying for familiar, and popular, types of music.

The courts offered a direct relationship between the artists, the art objects, and the art consumers, making art presentation a somewhat personal, but rather exclusive affair, being isolated from the rest of the population and its plebeian culture. The artists' prestige was closely connected with the king's personal interest in the arts. King Christian IV (1588–1648) in Denmark, the Swedish King Gustav III (1746–92), as well as several kings in France and Great Britain were active art patrons, commissioning murals and portraits, and giving grants to artists for travel abroad. A major part of Nepal's cultural heritage consists of wonderfully decorated temples that were built during the Malla dynasty (1350–1768) to honor and appease certain gods, and to impress their subjects and other royalty. In Nigeria, tribal kings bestowed prestige upon artists in return for masks, music, clothing, etc., for use in everyday life and during ceremonies.

With the rise of liberal political ideas, culminating in the French Revolution of 1789, the royal courts lost their role as centers for art and culture. Instead, artistic activity and presentation were moved outside the walls of the castles and into the rooms of private clubs and salons where the bourgeoisie reigned, establishing them as meeting places for a variety of people wanting to participate in the arts world, each having particular interests at stake. The owners of the salons obtained

prestige as the patrons of such meeting-places, and art dealers and collectors became the dominant art patrons, either as private individuals or as representatives of galleries and museums.

This new configuration had consequences for the functions of art, for the position of artists, and for arts funding. Art objects continued to serve representative purposes, but the content came in focus. For instance, when the kings lost their political power—particularly during the reign of Louis XV (1715–74)—writers were approached by political parties and asked to write propaganda pamphlets. With new interpretations of art and its functions followed an interest in, and concern for, the individual artist as a creative and independent personality. Art works were no longer seen as handcraft only, but had become autonomous objects with intrinsic value, that is, art for art's sake.

2.3 Diversification of Art Patrons

The expansion of arts audiences gave the artists a more prominent position in society. The number of literate people increased, and the opening of concert halls and art galleries for the general public made the arts more accessible. Artists obtained a variety of funding sources: dealers and buyers of visual arts, publishing companies for books and music sheets, and the general public as cultural consumers. These changes within the arts world indicate the beginning of a democratization process that made the arts available to an expanding 'public.' While jeopardizing a fairly secure income at court, the diversification also freed the artists from restricting themselves to the changing fashions among the aristocracy. Arts funding had become a matter of artists producing goods that were offered on a market. For instance, the expanding literary audience demanded a variety of content: mysteries, romantic fiction, sensations, drama, and social novels. Daniel Defoe (1660–1731), Jonathan Swift (1667–1745), Victor Hugo (1802–85), and Charles Dickens (1812–70) were among authors meeting this demand.

Thus, the diversified art market at the beginning of the nineteenth century comprised a diversity of art forms, offering a variety of options for artists as well as the audience. The significant change was the expansion of popular art forms, like vaudeville within theater, and the serial realistic novel about issues in contemporary society. Classical art forms were still created, but had to compete with the more popular art forms. The art objects had become goods for sale on a market, the artist had become an independent individual who had to deal with the market, and the audience had developed into consumers who had the privilege to choose. This also meant more differentiated arts funding structures than before with a variety of patrons: members of private clubs and associations, audiences at public exhibitions and performances, and consumers in bookseller's shops. Artists were faced with different options. They could cater to popular demands from the new audiences. It was a good way of earning money, but was looked down upon by those who regarded themselves as genuine creative artists. Their patrons had to be found among a niche audience.

The period from the late eighteenth to the early twentieth century is characterized by the dominant position of the bourgeoisie, particularly the new middle class that came with industrialization and increased business and commerce. Similarly to the church and the royal courts, people within the bourgeoisie also wanted to distinguish themselves from peasants and industrial workers. Showing interest in the arts was one convenient option, either by being seen at public places such as concert halls, theaters, and art exhibitions, or by commissioning and buying visual art. The meaning of the term *public* also expanded during this period. First, the public comprised an invited audience, modeled on the eighteenth century events at the European courts. Then came a period when such events, for instance classical concerts, were open to subscribers and members of music associations. Finally, around 1880, everyone could buy tickets to arts performances, making the event truly public. Thus, arts funding involved more patrons than before, although people from the middle class were the dominant contributors. In some countries, its social, political, and cultural dominance was so profound that it excluded government arts funding. This was particularly the case in Britain, where the landed aristocracy put money into portrait paintings to decorate their estates, thus: 'culture that required a public rather than a private setting, such as theater, opera, and ballet, had only a limited place in this pattern' (Ridley 1987, p. 225).

2.4 Corporations as Patrons

The expanding industrial production brought business corporations into arts funding, particularly in the United States. In 1903, the Atchison, Topeka, and Santa Fe Railway commissioned artists to paint pictures of the western parts of the United States. Not in order to decorate train compartments and waiting rooms, but to develop visuals for advertising, menus, posters, travel brochures, etc. Such material was ordered directly from the artists. At the end of the 1930s, artists were funded indirectly when corporations began assembling their own art collections, IBM being among the first to do so. This type of arts funding became more pronounced during the 1970s when most corporations began purchasing art for their own collections. Individual business owners and company presidents had already supported the arts from personal interest, while corporate giving to art institutions must be viewed in connection with the Federal Revenue Act from 1935. This allowed a certain percentage of corporate deductions of net income for contributions to charitable and educational organ-

izations that had been designated as not-for-profit according to Section 501(c)(3) in the Federal tax code. European countries and Australia also have a tax incentive system for arts funding, but it does not play as crucial a role as in the United States.

In 1967, the Business Committee for the Arts (BCA) was created, confirming the vital role of corporate arts funding in the United States. At a meeting for business leaders, David Rockefeller (1966) stated that traditional art patrons—primarily wealthy individuals and foundations— were no longer able 'to cope with the growing needs.' Neither did Rockefeller think that the government could meet the need, despite the establishment of the National Endowment for the Arts in 1965. The BCA should encourage corporate arts funding by providing expert counseling about opportunities in the arts, and assist arts organizations in becoming reliable and accountable partners. *Nonprofit Enterprise in the Arts* (DiMaggio 1986) describes how and why corporations get involved in arts funding.

3. *The State and Arts Funding*

Several arts funding partners have been described in the section above. The crucial issue is that different people and institutions have filled the role as public patron. *The Patron State* (Cummings and Katz 1987) documents that government funding of the arts in most countries dates back to the middle of the nineteenth century. State involvement in the arts is related closely to each country's political system, particularly to whether the state is active or passive. Since the end of the nineteenth century, most European countries have had an active state whose primary concern has been to develop social welfare programs. State arts funding began as support to individual artists of 'high quality' and in order to establish national cultural institutions as part of the nation-building process during the nineteenth century. In Italy, government arts funding was aimed—and still is—primarily towards preserving the national heritage, leaving creative arts to private funding sources. This has also been the case in Asian and African countries. The strong decentralized tradition in Germany has given the *Länder* most of the responsibility for support of the arts as well as other policy areas. The opposite is the case in France, with its strong, centralized system. Public arts funding in Great Britain has been characterized as a 'night watchman' type, the state being responsible for arts education and cultural heritage, leaving most of the performing and creative culture and arts activities to the market place. Canada represents an example of how arts funding systems can emerge from an existing social structure. Canada lacked a strong tradition of royal and aristocratic patronage of the arts. There were also almost no financially endowed individuals or estates comparable to those of Western Europe who could or would support the arts. Thus arts funding became the responsibility of the state.

Some of the most spectacular examples of indirect government arts funding were the New Deal arts programs in the USA during the 1930s and early 1940s (Mankin 1995). In 1933 and 1934, the Public Works Art project employed painters and sculptors to create arts works for public buildings. Despite its short existence, it was nevertheless 'the first time the government had subsidized an art project of national dimension' (Mankin 1995, p. 77). The following Section of Fine Arts administered several programs, the most famous being the Works Progress Administration (WPA) Art Projects, running from 1935 until 1943. It was the most comprehensive program, including writing, music, theater, and visual arts. All three projects were not aimed at arts funding as such, but reflected the Roosevelt administration's general worry about the high unemployment rate, also among artists. Thus, Relief Administrator Olin Dows stated (quoted in Mankin 1995):

> Human economic relief was the motive behind all the New Deal's art programs. This is why they were so easily accepted by the public and the politicians. If it had not been for the great depression, it is unlikely that our government would have sponsored more art than it had in the past.

These economic based programs nevertheless had long-lasting cultural effects. For instance, many of the symphony orchestras established in the United States with money from the New Deal arts programs continued after World War II and are still active.

The American government has been called the 'reluctant patron.' This is appropriate also for the British government. Before 1940 there was virtually no government support of the arts in Britain. Early in World War II, a group of private citizens established the Council for the Encouragement of Music and the Arts (CEMA) aimed at 'brightening the lives of factory workers, military personnel, and isolated civilian groups, thus fortifying national morale' (Ridley 1987, p. 228). Government became a funding partner only after the organization had been established. However, in 1945, the work done by CEMA was continued and expanded by the Arts Council, a government agency. Despite the government's reluctant stance, the British Arts Council was the first among all councils, agencies, and endowments for the arts that, during the following decades, particularly around 1964–5, were established in the United States, in Canada, and in European, Asian, African, and Latin American countries (see the UNESCO Series 1970s/1980). One recent type of indirect government arts funding is the money granted to arts programs at single events such as the World's Fair (e.g., Expo 1967 in Canada) and the Olympic Games (e.g., Albertville, France in 1984, and Lillehammer, Norway in 1994).

There are two theoretical arguments for state funding of the arts. The first is to compensate for

market failure, and the other is that the arts serve collective needs, having what cultural economists call 'external benefits.' The arts' external benefits are (Heilbrun and Gray 1993, pp. 205–9): (a) availability, that the arts are available regardless of regular use, (b) legacy for future generations—cultural heritage, (c) national identity and prestige, (d) supplementing liberal education, and (e) artistic innovation. Securing the cultural heritage and promoting national identity are the most frequently mentioned cultural policy goals throughout the world (UNESCO Series 1970s/1980s).

4. *Issues in Arts Funding Research*

Systematic arts funding research began during the 1960s, often within a broader cultural policy perspective. It can aim at explaining certain relationships in arts funding, or at finding the most effective means to implement policy goals. Schuster (1996) emphasizes the importance of distinguishing between 'pure' social science research, searching for explanations, and the more applied-oriented policy research. They are not, however, mutually exclusive. For instance, knowing that one country's tax exemption regulations enhance corporate donations to the arts may encourage new policy initiatives in other countries.

Arts funding research has been concerned with conditions within one country, it has been cross-national, or comparative. Section 2 has described how, throughout history, the dominant art patrons in different countries have changed over time, depending upon their social and political position in society, and the functions that the arts had for them. Cross-country descriptions and analyses (e.g., Cummings and Katz 1987) shed light on similarities and differences between countries. This can, in turn, lead to comparative studies, the major issues being governments' cultural policy goals and organizational structure for funding of arts and culture. The crucial question has been: does it make any difference whether the arts are funded by a government based or market based system? Heeding the problems and pitfalls involved (Schuster 1996), comparative research has revealed some tendencies.

Most European nations have a strong welfare state, being based on the principle of equal citizen rights. Thus, the arts are regarded as collective goods, the use of which can be facilitated by state appropriations directly to cultural institutions such as public libraries, museums, theaters, and orchestras. The government compensates for market failure. A market-based system, such as in the United States, emphasizes the individual's freedom as consumer. The state has no obligations towards its citizens, leaving funding of the arts to the private sector. Despite this difference in the arts funding structure, comparative research indicates that both systems favor cultural institutions that potentially can reach large audiences. The state is interested in justifying spending the tax payers' money on the arts, and potential private art patrons, corporations in particular, are looking for arenas offering large exposure. Looking at the art forms, however, research indicates that a market based funding system to a higher degree steers, for example, concert repertoires and book publishing toward popular content than a government arts funding system (Bakke 1996).

Entering the new millennium, arts funding research is faced with four crucial tendencies (Boorsma et al. 1998, Lewis 1995, Pankratz and Morris 1990). First, market elements in traditionally strong government-based arts funding countries are increasing. Will this imply more commercial art forms? Second, the fact that government comments to appropriations to the arts have changed from alluding to general arts policy goals to specifying result goals indicates increased emphasis on efficiency in government spending. What are the relevant quantitative and qualitative result indicators within the arts? This also shows that efficiency demands are not the result of privatization above. Third, will arts patronage become more diversified in the age of electronic media, bringing, for instance, art consumers in more direct contact with the artists? Also, will artists' copyrights be at stake? Fourth, these issues are linked to the ongoing globalization process, inviting researchers to look for converging tendencies in arts funding patterns as well as diversification of cultural tastes and art forms (Johnson 1993). Globalization also challenges one of the traditional purposes of state patronage, particularly in small countries and in former colonial nations, to preserve national culture identity (Chen 1998).

M. Bakke

Asceticism

The term 'asceticism' basically means a type of behavior that tends to submit an individual's impulses and desires to a systematic way of life in order to permanently gain specific virtues (athletic-heroic, ethical-moral, or religious) which are considered important by these individuals to reach ethical self-fulfillment. Such behavior, when conducted systematically and consciously, is inseparable from a real ethical doctrine that renders it desirable and even dutiful. Asceticism, often also defined by the term 'ascetism' (from Greek *ásketés*), thus means the extreme will of inner transformation by means of a strict practice to achieve what individuals consider their elective nature and which they feel called to. Giving up one's desires and restraining one's impulses become more important the more the physical and moral nature of individuals consider themselves unable to achieve the virtues they pursue throughout the course towards asceticism. From this point of view, asceticism is based, at least implicitly, on a conflict between nature and spirit, and between passion and desire on the one side and ethical-religious imperatives on the other.

1.1 The Rise of Asceticism as a Problematic Concept: A Religious Behavior

In Greek culture, the term 'ascetism' implies the methodical application to an art just as much as constant training of an athlete's or warrior's physical strength. In classical philosophy (in particular in the Sophists, Stoics, and Pythagorean schools), ascetism denotes a systematic effort of the spirit towards wisdom. In the work of Filone d'Alessandria, ascetism became a systematic effort, both moral and religious, to perfect the soul and prepare it for God's contemplation. It was, however, within a religious environment that the concept of asceticism paved the way towards its first and most widespread practice. Ascetism, considered as an attempt at a radical allegiance to the divine law by fighting against the temptations of human nature, can be found in all salvation religions based on the constant practice of virtues which are pleasing to God. Examples of this can be found in the Old Testament of Judaism, where the virtues of wisdom imply an arduous practice of moral virtues, in the first Christian communities, and in the Patristics philosophy.

It is in the context of third century Christianity that the weaving together of theological considerations and Greek philosophy came about. Ascetism became a methodology of perfection which, through self-reflection, positively coincides with meditation, prayer, and charitable work; or more negatively viewed it implies the estrangement from any alternative bond with respect to absolute unity with God. In the fourth century monastic ascetism initially arose in the form of retreat from the world so as to fight against the inner enemy which every monk sees within himself. The changeover from a hermit's life to the cenobitic community reveals the importance of practicing charity towards neighbors, as well as using everyday life as an essential means to achieve such. The Rule defines ascetism as a means of perfection, imposing, through the needs of the spiritual path, virtues of obedience (alongside those of poverty and chastity), and stresses the inner character of the search for virtues.

Following the move from Egypt and Syria towards central Europe, after the Arabian conquest, monastic asceticism had to temper the need for prayer and meditation alongside that of demanding agricultural work. With the beginning of town life and the search for unity with God in the world, asceticism continued to develop its characteristics of inner silent discipline, very different from the penitential meditation of oriental asceticism, but also completely integrated in

the social world, where it established itself with the sacramental hierarchy, life in the world, and urban ethics. In *devotio moderna*, closely related to the artisan town life in the Dark Ages, the ascetic was no longer isolated by the desert nor protected by the walls of the monastery, and had to achieve a real discipline of inner life. With the Reformation, the blessing, seen as a gift of God, became no longer a result of a subject's personal effort. A completely inner-worldly asceticism emerged, aimed at self-renunciation in career and professional service for the benefit of everyone. In this way, ascetism tended, ever more clearly, actually to integrate into the coextensive secularization process establishing itself in the modern world. In some cases, as with Puritanism, the ascetic behavior did not give rise to any specific institution; in others, like monasticism and subsequent religious orders, it gave rise to statutes, rules, orders, and institutions.

2. *Asceticism in the Secular City*

For Emile Durkheim, the detachment from worldly profane things (objects, passion, physical needs) is the root of every religious learning. All religions introduce restrictions to be observed and thus sacrifices to be made, and asceticism is therefore the actual element of each of these. In light of this, it is not a prerogative of the virtuous class only and neither does it coincide with penitential hardships, actually hypertrophies of the negative cult. Asceticism, the core of every religion, can also be found in the 'positive cult' by worshiping God with prayers, offerings, and actions pleasing to him. Not considering oneself, sacrificing one's time, renouncing, and other acts are just as much elements of separation from the profane world. Moreover, the religious rites become more sound and effective the more one disengages from activities which are in some way loved and useful.

In addition, ascetism is not only a prerogative of the religious world, but in so far as every community claims a superior identity over individuals, they also tend to demand the same methodology of renunciation that permeates religious practice from the people who are part of it. In this perspective, ascetism loses every voluntary characteristic to stand as a required substantive methodology of deprivation (negative ascetism) in order to properly approach the community where sacred means expression and an identifying point of reference. The link which Durkheim constantly outlines between religion and society shows how ascetism works in the first as well as the second. Society, therefore, similar to religion, also needs to appeal to asceticism which thus entails deprivation, renunciation, and above all, subordination of personal interests and passions to public interest: duty towards the city prevails over every other duty.

Max Weber, differently from Durkheim, does not see a structural characteristic of the sacred in asceticism, but a method to obtain the state of grace needed for the salvation of one's soul. Ascetic procedures are therefore found, at least in principle, in salvation religions. Salvation may be placed between two opposite extreme poles: on one side it is apparently a result of a subject's completely personal behavior while on the other it may be regarded as a completely free, inexplicable gift of grace from God himself. Consequently, asceticism ends up by giving rise to two strategies that are completely different in social behaviors.

Whereas awareness prevails within the determined role of an individual, ascetism becomes a search to constantly receive grace obtained through rationalization of a salvation method: from ancient Buddhism to the Jesuit Order, through the anchorites of the third and fourth century, the problem involves the constant and completely vigilant rule over one's thoughts as well as actions. All those who reach this objective develop a truly religious level within the believers' community. The ascetics end up being given privileged positions: this also occurs in Indian salvation religions as well as the Christian faith (where such religious elites paved the way to religious orders), including the Protestantism of the ascetic sects and pietistic conventicles. Ascetic religiousness takes the shape of an actively ethical behavior in this case: a religious methodology of salvation combined with the awareness that God guides such behavior. The world, along with the social relations of the average person, are not only a danger because they show signs of ethically irrational receptive pleasures, but are also profoundly conventional and utilitarian. It is this concept of banality in ordinary social relations that confers to the ascetic, at least initially, along with the rejection of the world, the undertaking to witness and transform the world as God's instrument (inner-worldly acestism). If aascetics, in rejecting the world, turn their practice toward a sensitive discipline and look towards God as a constant path of existence, in the case of inner-worldly commitment, they may become reformers of the world: examples range from Cromwell's parliament of 'saints' to the Quaker's state and different forms of radical communism practices in the pietistic conventicles.

If the whole world cannot be raised to the demanding ethics of the virtuous elite, it however remains the only possible place where such people can prove to themselves that they have full possession of their state. The worldly orders thus become a vocation that the ascetic has to achieve in a rational way. Rationality of social relations free from worldly passions (power, wealth, erotic deification of the being, violence as irrational behavior…) become a way of life that ascetics can make their own in a world which is, however, desired by God.

The methodology of salvation, in order to seek constant possession of grace, can also find expression in mystical union. The contemplative mystic actually

breaks away from the world and lives estranged from it to 'rest' in God's contemplation. Only in this extreme case does ascetism become a true *fuga mundi* and the mystic ascetic, considering it unlikely that God needs 'instruments' to carry out his will, is pleased to be a simple receptacle for the divine spirit.

Asceticism takes a different form if salvation is regarded as a completely free gift of grace given by God, who is absolutely unsearchable as to his decisions. We, therefore, face a predestined grace in which believers are sure of their salvation only when they are certain that they belong to the group of the chosen ones. Since God expresses certain rules on behaviors pleasing to him, the calling to a vocation is not only an invitation to cooperate in order to accomplish God's will but also true evidence of being among the chosen ones. Acting in compliance with God's will becomes much more than a duty: it is already a sign of salvation.

If a person devoted to good (or evil), regardless of his or her personal merits, is a result of the predestination dogma, then the world is nothing else but the outcome desired by the divine power to increase its glory. The believer may be nothing else but a precious and tireless collaborator in such project. The Weber thesis is extended and refined by Ernst Troeltsch. He distinguishes between Jesus's ethics (closer to heroism than to true ascetism) and Paolo's ethics, which is linked to depreciation of worldly life. Monarchism brings such asceticism towards rationalization of the Rule while Lutheranism completely opposes monastic ascetism to favor ascetism in the world, a self-renunciation that takes place through actively and systematically performing one's profession. Troeltsch developed various ascetic experiences in the Protestant sects by combining ascetic needs with social protest, wherein asceticism is no longer a free choice of the elite few but a dutiful behavior for all those who are part of the new church.

3. *Contemporary Developments: Asceticism as Element of Rational Social Behavior*

Durkheim, Weber, and Troeltsch all question the importance of asceticism in the edification of the modern world. For Durkheim, asceticism, once confirmed as an essential expression of the sacred, experiences notable changes but becomes inevitable in the behavioral ethos of the secular citizen at the moment religion and society end up by amalgamating, thus becoming indistinguishable since they are reciprocally functional. For Weber, asceticism, taken in its historical evolution, is the transposition, in the forum of inner spirituality, of the same principle of systemization and rationalization that forms the essence of Western civilization. For Weber and Troeltsch, the ascetic dimension is not separated by a sort of implicit protest (and also explicit in some cases) toward the surrounding society. The sectarian dimension, studied in particular by Troeltsch, is often given body by abandoning activities, behaviors, and principles of political and social rule considered to conflict with Old Testament ideals. Ascetism of entire communities which reject behaviors and acts considered unacceptable for those who, by the Grace of God, regard themselves as already redeemed, stands against the monastic ascetism of those who abandon the world to reach perfection that constantly evades them.

In contemporary sociology, the term asceticism has often been used with its general meaning relating to deferment of pleasures and unnecessary consumption. Ascetic behavior, understood as voluntary deprivation from seeking unnecessary possessions, was used in the study of consumption behaviors of social groups. In the sociology of religion it still defines the spiritual methodology of ascetics of every creed, group, or religious denomination. In particular, links with social protest forms were studied and, through these, the messianic and millenarian utopias which such protests feed on.

As far as epistemology is concerned, asceticism is quite comprehensible not only as a historical concrete form of perfection methodologies aimed at salvation but also, and above all, as the ideal Weberian type. The 'unilateral exaggeration' of one or more elements characterizing asceticism are historically traceable both in outer-worldly ascetism of the religious elite of the fourth century as well as in the sectarian inner-worldly ascetism of modern times. When traced back to its inner-worldly setting, whether religiously or laically oriented, asceticism shows its heuristic potentiality, so accounting for the wide range of religious behaviors. It not only explains the professional ascetism of the Calvinistic entrepreneur but all the lay variations—that is, the actual combinations of the ideal-typical model—of the ethics of the city.

Being the latter turned to legitimize the approval of the social contract as well as to oppose it whereas some principles diverge from the religious doctrines on which the single methodology of perfection is based.

If asceticism is destined to disappear as a historical feature, since the world rests on mechanical foundations, it continues to determine the driving principle of every constantly practiced axiological rationality. Only by systematic and constant practice of a completely vigilant conscience does axiological rationality cease to be occasional or temporary, to rise to a permanent passage of an individual's social existence. From the cells of the monks to the austerity of the revolutionary militants in every age, to the sacrifice for the city or country, through all different levels of public duties, asceticism—understood from an ideal-typical viewpoint—remains one of the elements that structures ethical behaviors raised to a voluntary methodology of social behaviors, considered as building behaviors of a new community or of rebuilding of

an already existing community. As a methodology of life, asceticism can be regarded as the crowning achievement of the utopian projects for the transformation of the world as well as a pattern of systematic practice of given historical values (more or less explicitly religious, however perceived so in their inviolability) with the object of constantly maintaining these as informing and ruling principles of the entire social existence of individuals. The principle of rationalization, implicit in inner-worldly asceticism as a methodology of life oriented towards constant preservation of virtues, makes it a structural component of social behavior able to continuously invite participants towards a strict and not just occasional coherence of conformity with values.

Assessment and Application of Therapeutic Effectiveness, Ethical Implications of

1. Definitions

Medical therapy is an intervention which aims at removal or at least attenuation (and in a broader sense also at prevention) of diseases or disorders, as well as at subjective suffering due to such illnesses of the individuals concerned. In general, understanding the first aspect is focused in the term cure (and prophylaxis), the second one in the term care. Medical cure comprises somatic (by drugs, surgery, ray, or physical) and psychotherapeutic (by a broad range from counseling to psychodynamic to behavioral) interventions. Medical care comprises the embedding of the cure in a sufficient (in number) and satisfying (by personal quality and qualification) setting of personnel, facilities (beds or treatment places), and supply. Removal is related more to a causally, attenuation more to a symptomatically effective therapy.

Intervention has effects, wanted and unwanted. Wanted effects with regard to the aim of therapy are called therapeutic effectiveness (or efficacy) and unwanted effects are side-effects. Occasionally effectiveness is limited to application in everyday practice, and differentiated from efficacy in controlled clinical trials. The relation of therapeutic effectiveness to its costs, both medically in terms of side-effects and risks, and particularly economically in terms of financial burdens, is labeled as efficiency. The assessment of these different outcome aspects of therapeutic interventions has some implications.

Effects, both physiological and psychic ones, can be observed directly. The assessment of effectiveness, however, implies presuppositions with regard to more or less complex theoretical constructs such as illness or needs or therapeutic aims (Winterer and Herrmann 1996). A behavioral model of mental illness will give reason for aiming therapeutically at symptom relief whereas an intervention based on a psychodynamic model may be oriented towards a maturing development of personality, i.e., to follow either an adaptational or an emancipatory model of psychotherapy (Helmchen 1998); or, a sociogenic or even an antipsychiatric model of mental illness may lead rather to social interventions with the aim of acceptance of the disorder or the disordered subject respectively, by

both the individual and society, whereas the medical model aims more likely at symptom relief and recovery of functional capacity by drug treatment. Furthermore, the aims of therapy may be different from the perspectives of the patient (e.g., well-being), of the therapist (e.g., maturation of personality), and of the insurance company (e.g., fitness for work) (Kottje-Birnbacher and Birnbacher 1998). Finally, but not the least, these constructs depend on contemporary context.

Hence, assessment of effectiveness of a therapeutic intervention means to evaluate the fitness of achieving these construct-related aims. This will be done either in general by research in order to establish the strength and specificity of the relatedness of the intervention to the aim, i.e., to find an evidence-based indication, or in the individual case, by judging whether the indicated intervention actually did achieve the aim. The strength of the specific relatedness of an intervention to a defined aim may be a continuous variable, but will be categorized by cut-offs for being usable as an indicator of therapeutic effectiveness, e.g., the reduction of a symptom score below a defined threshold. Here, again, different standards are in use: some accept a symptom reduction of already 50 percent, others admit only a complete relief of symptoms as therapeutic effectiveness. Therefore, universally accepted aims for therapeutic interventions do not exist as well as 'there are no universally accepted standards of efficacy and safety' (Kane and Borenstein 1997).

This seems to be even more valid for the assessment of efficiency because it has to deal with much more complexity: a divorce as a side-effect of strengthening the autonomy by psychotherapy may be acceptable for one patient, but not for the other (notwithstanding the problems of informed consent with regard to such a potential side-effect). Tardive dyskinesia as an irreversible side-effect of a neuroleptic long-term medication urgently needed for suppression of agonizing schizophrenic symptoms will be put up with by one patient but not by another. Although from the medical point of view in this case the application of a drug with the same antipsychotic effectiveness, but without the risk of this unwanted effect, undoubtedly indicated the doctor to be efficient with regard to his limited budget, nevertheless he or she is urged to decide in favor of a less expensive drug. If he prescribes the most effective but also the most expensive drug, he perhaps cannot prescribe drugs urgently needed by other patients. With regard to subsequent burdens to society, it could be much more efficient to choose a cost-intensive treatment for help-seeking people with subthreshold morbidity (morbid states below the threshold of officially used operationalized diagnostic systems such as *DSM-IV* (*Diagnostic and Statistical Manual* of the American Psychiatric Association) or *ICD-10* (*International Classification of Diseases* of WHO)) than to withhold therapeutic interventions from them (Helmchen 1999).

The assessment of effects, effectiveness, and efficiency of a medical intervention is most developed in drug therapy. Therefore, the following considerations will be related to drug therapy, although the criteria of its evaluation cannot simply be applied to other types of medical interventions. Both the assessment of effectiveness and safety of a potentially therapeutic drug by research, and the efficient application of a marketed drug to ill persons in practice, imply ethical problems.

2. *Assessment*

In therapeutic research the basic ethical problem on the one hand is to expose the participating subject to a potentially ineffective intervention or to unknown risks. However, without such research on the other hand, the risk is to expose people to the uncontrolled risks of an intervention with a drug, the effectiveness and safety of which are not really known. This had been called the ethical-paradox of therapeutic research: it may be unethical to subject a person to a controlled clinical trial, and it may be even more unethical to introduce an unproven drug into the market (Helmchen and Müller-Oerlinghausen 1975) because in practice the application of an ineffective intervention will not only produce unnecessary costs for the patient but, much worse, may withhold him from an effective therapy. Thus, the scientific evaluation of therapeutic effectiveness is a moral imperative (Wing 1981). Also the refunding of medical interventions by the insurance companies is made increasingly conditional on the scientifically proven efficacy of new treatments. The need and the risks of therapeutic research have produced highly specified regulations (laws and guidelines) which among other things define standards of efficacy and safety as well as of participation of fully informed and voluntarily consenting subjects in such therapy research. They oblige the researcher to minimize the risks and inconveniences for patients (Helmchen 1990), particularly:

(a) to formulate the research question as specifically as possible as the basis of a biometric calculation of the needed sample size in order to avoid the inclusion of more persons than needed and, thus, to worry patients unnecessarily, as well as of fewer people than needed for a valid result and thus to burden all participants for nothing.

(b) to choose adequate selection criteria in order to minimize the drop-out rate and to achieve at least some generalizability of the results. Otherwise the results may be invalid or not applicable to other patients than those of the study sample and in that case patients may be burdened unnecessarily. Often therapy-resistant patients will be excluded from clinical trials. However, the need to overcome therapy-resistance is much more urgent than, for example, to test a further antidepressant drug of an assumed

known therapeutic mechanism for a questionable quantitative improvement of existing standard therapies.

(c) to not withhold effective therapies from patients, e.g., by use of placebo-controls. However, in order to control the effect of subjective influences and spontaneous remissions on the evaluation of effectiveness placebo-controls may be unavoidable. Thus, e.g., in the case of depression, a placebo-controlled trial may be ethically justifiable only in mild depressions in which the effectiveness of available antidepressant drugs is questionable (Paykel et al. 1988) or in therapy-resistant depressions. Otherwise there remains no alternative but to test the experimental drug against a standard drug. However, in order to avoid both the beta-error and a large sample size, one should test for falsification of the zero-hypothesis, i.e., that the investigational drug is more effective than the standard. Since, as in many countries regulatory agencies do not demand evidence of superiority of the investigational drug, an investigator can decide for himself to choose criteria of superiority, e.g., more than 20 percent of effectiveness.

All such details of testing therapeutic interventions have to be considered with regard to ethical principles, the primary essential ones of which in medicine are (a) respect for autonomy and dignity of the patient, (b) beneficence, (c) nonmaleficence, and (d) justice (Beauchamp and Childress 1994). Respect for autonomy requires improving the patient's understanding of the disorder (its symptoms, course, outcome, and perhaps causes) and of the benefits and risks of both, the recommended and alternative therapeutic interventions as well as the elucidation of their meaning for the patient's personal values, especially his expectations towards the therapy with the consequence of an informed consent. Most therapeutic interventions do not fulfil the therapeutic ideal (Ehrlich's 'therapia magna sterilisans'): to achieve immediate and complete elimination of the disorder in all patients with the disorder for which the therapy is indicated (specific efficacy) with no unwanted effects (safety). Usually some benefit can be obtained only at the cost of some more or less serious unwanted effects. Therefore, the relationship between beneficence and nonmaleficence must be evaluated and this risk-benefit-estimation should be imparted to the patient—but only in the case the physician comes to the conclusion that this estimation ethically justifies the intervention, e.g., to expect better as existing effectiveness and/or lesser or only minimal risks and burdens for the patient.

Furthermore, all scientifically based therapeutic trials do not aim only at the benefit of the study patient but also at a better knowledge for the benefit of other patients too. The problem becomes more difficult if such broadening of the perspective beyond the individual patient leads to a benefit-risk-estimation which may be less favorable for the study patient than for other patients in other stages of the disorder or in the future. The ethical consequence is the obligation to minimize both the burden and the number of patients needed for a valid result. In this context the understanding of the principle of justice means predominantly an equal distribution of burdens and benefits, i.e., among all members of a group, e.g., all patients with a defined disease, or among all participants of an insurance company. Patients receiving an effective therapy are beneficiaries of the trial burden of former patients and, therefore, could be asked to participate in a new trial for improving existing therapies.

The steadily increasing specification (and red tape) of controlled clinical trials of new drugs does not only reflect these problems as well as further relevant difficulties such as those of full information of the patient, or of assessment of his competence to consent, or of subjecting him to strong standardization procedures; it also may point to corresponding difficulties in much less elaborated fields of psychotherapeutic or social interventions. These latter mentioned difficulties may be both greater and less considered as a still valid quotation from Wing may illustrate:

> There is nowadays a fairly general acceptance of the view that new drugs should not be introduced without being tested. There is no similar consensus in respect of social treatments, most of which become firmly adopted before they have been thoroughly examined. The harm that may come from the application of misguided social theories, or the misapplication of sensible theories, is at least as great that can follow the prescription of a harmful drug or an unnecessary course of psychotherapy. In fact, it can be much greater, since harmful social practices can become institutionalized into the structure of a complete psychiatric service. The "custodial era" in psychiatry, although it was not as black as it has sometimes been painted, nevertheless illustrates how the practices inherent in the concept of the "total institution" can become generally and uncritically adopted, even though many of them were quite unnecessary and demonstrably harmful' (Wing 1981, p. 278).

3. *Application*

The efficacy of a drug developed in the highly artificial setting of a controlled clinical trial may be considerably altered in the natural setting of therapeutic practice due to uncontrollable influences such as co-morbidity, co-medication, compliance, lifestyle, etc. The evaluation of these effects of natural settings upon effectiveness as well as upon safety of a drug in the individual patient is the task of the treating physician, with regard to general knowledge it is the purpose of so-called phase IV research (Linden 1999).

The therapist has to consider the consequences to treat against the consequences not to treat, not only from a factual point of view but also in an ethical perspective. To treat predominantly requires the evalu-

ation of the risk of unwanted effects against a possible worsening of the patient's condition, e.g., the risk to apply lithium, a drug with proven effectiveness for relapse prevention in recurrent affective disorders, in a patient with unreliable compliance may be worse with regard to—principally controllable but in this case uncontrolled—side-effects than a relapse of the disease. Not to treat evidently has much more ethical implications. Nowadays, in times of managed care, the physician has to keep strongly (under penalty of recourse) to his limited budget and this means that he has to ration principally available therapies not only according to their evidenced effectiveness but also to the severity and acuity of need of patients and to their costs (APA 1997). Costs nowadays are predominantly paid from (third party) collective resources. Therefore, the therapist has obligations not only towards his individual patient but also towards the according collective. Physicians from a traditional and well reasoned point of view argue against this double-agent role of physicians as unethical (Simon 1987). However, Physicians Associations at least in some countries such as Canada, Germany, and the UK, tell their members that 'Finite resources can never match potentially infinite demands or expectations…' (consequently)… 'it is doctor's ethical duty to use the most economic and efficacious treatment available' (British Medical Association, cit. Sabin 1996). But besides the efficient application of effective therapies in terms of costs (both side-effects and financial burdens) the therapists as well as society are asked to justify ethically, with regard to justice, to apply or not to apply an effective therapy. This question arises particularly in cases such as antidementive drugs which have a significant but only small effectiveness on the progression of dementia making it possible for a demented person to stay longer in his familiar home before a transfer to institutional care becomes unavoidable (Max 1996) or, lipid reducing drugs which are effective in the prevention of arteriosclerotic diseases and which are so expensive that a treatment of all persons who are in need of it cannot be paid for (Kübler 1999). Furthermore, the physician has to consider the scope of informing the patient, e.g., whether he or she has to give information of a better alternative of which the patient cannot get hold.

4. Conclusion

Therapeutic effectiveness can be assessed only by relating the effects of a therapeutic intervention to a therapeutic aim. Its elucidation with and by the patient is one objective of the informed consent process which is required by respect for autonomy and dignity of the patient. Relating beneficence to nonmaleficence is the medical part of the assessment of efficiency of a therapy, relating this to the financial costs and limitations is its economical part. Particularly the latter provokes the question of justice. It belongs to the obligations of therapists and society to reflect the ethical implications of the medical, as well as the financial aspects, of assessment and application of therapeutic effectiveness and efficiency.

Asset Pricing: Derivative Assets

1. Introduction

A derivative instrument is a financial contract in which the *cash flow* received by the holder is linked to the *price* of another asset or to another financial variable (such as an interest rate). Typical examples of such contracts include forward contracts, swaps, and, of particular importance here, *options*.

This article is about the theory of derivative pricing, that is, the valuation of derivative contracts. Although there are a number of important early contributions, these tended to founder on the problem of determining a discount rate that would account correctly for the risk of the cash flows (see, for example, Sprenkle 1961). The modern theory essentially begins with the seminal contributions of Black and Scholes (1973) and also of Merton (1973). (Scholes and Merton shared the Nobel Prize for economics in 1997. If Black had not died (in August 1995) it seems certain that he would have shared the prize. For an account of the development of the Black–Scholes model see Black 1989; for further discussion see Duffie 1998, Schaefer 1998, and Jarrow 1999.) This theory shows that, under certain conditions, it is possible to determine the price of an option, *relative to the price of the asset on which the option is written*, using only the condition that the prices do not offer investors an opportunity for pure arbitrage (a free lunch). Beyond that, the theory makes no assumptions regarding the preferences of agents. In particular, it shows that the relation between the price of an option and that of the underlying asset does not depend on the attitude of agents towards risk.

Although options, forward contracts, and, perhaps, other forms of derivatives have probably existed since the earliest times (Ingersoll 1989 gives the example of the code of the Hammurabi (c. 1780 BC) which contains a provision for contingent debt contracts), the last 30 years of the twentieth century have witnessed a vast increase in the number and variety of contracts and also in the volume of trading. A precise estimate of the scale of derivatives trading is difficult to obtain, but a recent report by the Group of Thirty (1993) estimated the total notional amount of over-the-counter (OTC) derivatives on interest rates and currencies worldwide at around $30 trillion. For the 50 largest US banks the replacement cost (roughly, the net present value) of their derivatives portfolios was $140 billion, or 11 percent of their total asset values. Derivative instruments, by any measure, are now of central importance to the world financial system and it is interesting to speculate whether this revolution would, or indeed could, have occurred without the development of derivative pricing theory.

Interestingly, at the time of Black, Scholes, and Merton's [BSM] seminal contribution, financial options (a *financial option* is one in which the underlying asset is a financial asset, for example, a stock or a bond, as distinct from, say, a commodity) themselves were, in Merton's words, '… specialized and relatively unimportant financial securities …' (Merton 1973, p. 141). Then, the most promising applications of the new theory appeared to be those that arose from the isomorphism between financial options and corporate liabilities. An important example, noted in the original paper by Black and Scholes, is corporate debt where the equity holders in a limited liability firm that has debt outstanding have an option to default if the amount owed to lenders is greater than the value of the firm. As things have turned out, however, the unpredicted and dramatic growth in the market for financial options markets has made this, rather than corporate liabilities, the principal area of application.

2. What is a Derivative?

Consider a security, for example, a stock, with current (time t) price S_t and another security, for example, an option on the stock, which, at some future date T, pays a single cash flow, Y_T, that depends on the price of the stock at that time. Thus

$$Y_T = g(S_T) \tag{1}$$

where $g(.)$ is some function. The security defined by Eqn. (1) is called a *derivative* security because its cash flow, Y_T, and therefore its value, derives from the price another security, the *underlying* security. The function $g(.)$ defines the type of derivative and is, in effect, specified in the contract. Some common examples are given below

$$\begin{aligned}
&\text{Forward (buy) contract} && g(S_T) = S_T - X \\
&\text{Forward (sell) contract} && g(S_T) = X - S_T \\
&\text{Call Option} && g(S_T) = \mathrm{Max}(S_T - X, 0) \\
&\text{Put Otion} && g(S_T) = \mathrm{Max}(X - S_T, 0)
\end{aligned} \tag{2}$$

In Eqn. (2) X is the *contract* (or *strike*) price at which the underlying asset is bought, in the case of a call option and a forward contract to buy the asset, or

sold, in the case of the put option and a forward contract to sell. The examples given in Eqn. (2) are the simplest and commonest forms of derivatives but there are many others. In some the cash flow on the derivative depends on the *history* of the price of the underlying asset up to the payment date, T, rather than on S_T alone; in others it depends on the prices of several underlying assets rather than one. In yet others the cash flow depends on some quantity that may be neither an asset price (e.g., the yield-to-maturity on a bond) nor even a function of an asset price (e.g., changes in the credit rating of a corporate bond).

Finally, the word derivative, although accurately suggestive of one important feature of these instruments, is unfortunate in that it may suggest that they are in some sense 'less important' than the underlying assets to which they are linked. Often this is quite untrue. Many derivative markets are large and highly liquid and, in some cases, for example, the interest rate swap markets in countries such as the US and the UK, some traditional contracts, for example, loans, may be priced with reference to the derivative rather than the other way around. In such cases it becomes difficult to tell the tail from the dog.

3. Derivative Pricing vs. General Asset Pricing

The price of every risky asset, including derivatives, depends on agents' expectations of the future cash flows and on their willingness to bear risk; in other words, on their preferences. (For a description of modern asset pricing theory see Duffie 1996: Campbell 2000 reviews both the theory and empirical evidence.) What, then, is special about the problem of pricing derivatives as distinct from other risky assets? The key difference is that in a number of important cases, including the Black–Scholes model, while the prices of *both* the derivative and the underlying security depend on expectations and preferences, the *relation* between the two does not. In this case, given the price of the underlying security, the price of a derivative may be determined independently of agents' expectations of future cash flows and their preferences.

The economic principle that is used to establish the link between the price of a derivative and the price of its underlying asset is *no-arbitrage*. An arbitrage opportunity is defined as one that requires no capital, has a positive probability of a profit, and a zero probability of a loss. In other words, it provides 'something for nothing' and any rational investor, who prefers more to less, irrespective of their attitude towards risk, would choose to exploit such opportunities. In a well-functioning market, therefore, arbitrage opportunities should not exist and, in the economy studied by Black and Scholes, it turns out that the conditions which eliminate the possibility of arbitrage between a derivative and its underlying asset are also sufficient to determine the relation between their prices.

4. Pricing Nonlinear Contracts Where Prices Follow a Binomial Process

The most important and distinctive aspect of derivative pricing theory is its application to contracts where the function $g(.)$—the relation between the cash flow on the derivative and the price of the underlying asset—is nonlinear. This is the case for options while for forward contracts and many swap contracts the relation is linear (see Eqn. (2)). As a first step we analyze a linear contract; the treatment of options, while more complex, is conceptually very similar.

4.1 Pricing a Forward Contract

Consider a forward contract to buy one unit of an asset at a price of X. Using the notation introduced above, the value of the contract at maturity is given in Eqn. (2) and is a linear function of the price of the underlying asset:

$$g(S_T) = S_T - X$$

The key concept in computing the value of this and all other derivative contracts is that of the *self-financing replicating portfolio*: a position containing the underlying asset, combined with borrowing or lending, which, after it is initially established, (a) neither requires additional investment nor generates cash outflows ('*self-financing*') and (b) is guaranteed to have exactly the same value at time T as the forward contract ('*replicating*'). If the cost of the replicating portfolio at some earlier time $t < T$ is V_t, say, then this must also be the *price* of the forward contract, H_t. If this were not the case, arbitrage profits could be made either by buying the forward contract and selling the replicating portfolio (if $H_t < V_t$) or doing the reverse (if $H_t > V_t$). In other words, to prevent arbitrage, the price of a derivative security must be equal to the cost of its replicating portfolio.

In the case of the forward contract in the example, the replicating portfolio consists simply of holding one unit of the underlying asset and borrowing an amount equal to the present value of the contract price, X. Thus, the cost of this portfolio at time t, V_t, is given by:

$$V_t = S_t - e^{-r(T-t)}X \tag{3}$$

where r is the (continuously compounded) riskless interest rate. Clearly, at time T the value of this portfolio is equal to S_T–X, the cash flow on the forward contract. Notice that the *price* of the forward contract is to be distinguished from the so-called *forward price* of an asset. The latter is simply the contract price, X, that sets the price of the contract to zero. Solving Eqn. (3) for the value of X at which V_t is zero, the forward price, F_t, is obtained as

$$F_t = e^{r(T-t)}S_t \tag{4}$$

Figure 1
(a) Single period binomial model. (b) Two-period binomial model

that is, the current spot price compounded up to the maturity date at the riskless interest rate.

Although straightforward, this example illustrates accurately the logic of valuation by replication used in the BSM approach. However, it is by no means clear that, in the case of nonlinear contracts, replication is actually *feasible*. Whether it does depends mainly on the process followed by the price of the underlying asset—and, to some extent, on the nature of the payoff function, $g(.)$. In some cases, notably (a) the Brownian motion case considered by BSM and (b) the binomial case that we discuss next, replication remains feasible. In others, for example, where price of the underlying asset experiences 'jumps' of a random size, replication is not possible and, in these cases the relation between the price of a derivative and the underlying asset cannot be established from no-arbitrage conditions alone.

4.2 Pricing an Option

We consider first the problem of pricing an option where the underlying asset price follows a binomial process in discrete time (Fig. 1(a)). Thus, if the current price of the underlying asset is S, then, at time $t+1$, the price will take one of two values. S^u (the 'up' price) and S^d (the 'down' price). In this example, the timing of prices is clear and, to simplify notation, the time-subscript has been dropped. Interestingly, the probability of these two states is not important; what is critical is that these are the only two states with a nonzero probability.

The cash flows to the option buyer in the two states are denoted C^u and C^d. If the option were a call, for example, then C^u and C^d would be given by Eqn. (5) below but the argument below does not, in fact, depend on the type of option

$$\begin{array}{ll} \text{'up'} & C^u = Max(S^u - X, 0) \\ \text{'down'} & C^d = Max(S^u - X, 0) \end{array} \tag{5}$$

Now, exactly as in the case of the forward contract, we calculate the price of the derivative as the cost of its replicating portfolio. The composition of this portfolio is simple to compute: suppose that we hold Δ units of the underlying asset and purchase B units of a riskless 'bond' which pays one unit at time $t+1$. Denoting the riskless interest rate, as before, as r per unit time, the price per unit of this bond is e^{-r}. Equating the time $t+1$ value of this portfolio and the value of the option in the two possible states, we have

$$\begin{array}{ll} \text{'up'} & \Delta S^u + B = C^u \\ \text{'down'} & \Delta S^d + B = C^d \end{array} \tag{6}$$

From Eqn. (6) the composition of the replicating portfolio is easily calculated as

$$\Delta = \frac{C^u - C^d}{S^u - S^d} \quad \text{and} \quad \mathrm{B} = \left[\frac{C^d S^u - C^u S^d}{S^u - S^d} \right] \tag{7}$$

As before, because this portfolio replicates exactly the payoff on the option *at maturity*, the *current* cost of the portfolio and the *current* price of the option must be

equal. If not, pure arbitrage is possible. Thus, the option price, C, is given by

$$C = \Delta S + Be^{-r} \tag{8}$$

where Δ and B are given in Eqn. (7).

4.3 State Prices and Risk Neutral Probabilities

A little rearrangement of Eqns. (7) and (8) allows us to write the pricing relation in way that provides a different, and very useful, perspective on the pricing formula. First, defining

$$\phi^u = \frac{S - e^{-r}S^d}{S^u - S^d} \quad \text{and} \quad \phi^d = \frac{e^{-r}S^u - S}{S^u - S^d} \tag{9}$$

we may write the option price as

$$C = C^u\phi^u + C^d\phi^d \tag{10}$$

In Eqn. (10) ϕ^u and ϕ^d may be interpreted as 'state prices,' that is, the prices of 'pure securities,' analogous to Arrow–Debreu prices, which pay one unit in a particular state and zero in all other states. The option price is then simply the sum of the cash flow in each state times the corresponding state price. The fact that the state prices are uniquely identified here shows that the market is *complete*, that is, that for each state it is possible to construct a portfolio that replicates the cash flow on the corresponding pure security. If the market is complete then it possible to replicate the cash flows on *any* security, irrespective of the pattern of cash flows across states. In particular, we can replicate the cash flows on nonlinear contracts.

Market completeness is thus a critical element in the theory of derivative pricing. In the binomial case the market is complete both in the single period case just discussed and in the multiperiod case (see Fig. 1b). As we discuss below, completeness also holds in the continuous time framework of the BSM model.

Eqn. (10) may be further restated in a different and highly intuitive form. First, using Eqn. (10) to value a riskless bond paying one unit at time $t+1$ we have that

$$e^{-r} = \phi^u + \phi^d \tag{11}$$

Second, since they represent the prices of claims on positive (unit) cash flows in particular states, the ϕ's are strictly positive and may therefore be normalized to add to one. Defining

$$\pi^u \equiv \frac{\phi^u}{\phi^u + \phi^d} \quad \text{and} \quad \pi^d \equiv \frac{\phi^d}{\phi^u + \phi^d} \tag{12}$$

and using Eqn. (11) we have that

$$\pi^u = e^r\phi^u \quad \text{and} \quad \pi^d = e^r\phi^d \tag{13}$$

Substituting for ϕ^u and ϕ^d in Eqn. (10), the option price may be written as

$$C = e^{-r}(\pi^u C^u + \pi^d C^d) \equiv e^{-r}\hat{E}(\tilde{C}) \tag{14}$$

where, for the second equality, we interpret the π's as 'probabilities'—since the π's are positive and add to one, we are free to do this—and $\hat{E}(.)$ means 'expectation under the probability distribution defined by the π's.' In Eqn. (14) the expected cash flow under the π's is discounted at the riskless interest rate, as if agents were risk-neutral, and for this reason the π's are termed *risk-neutral probabilities*. We emphasize, however, the economic content of this representation comes from the fact that the ϕ's are *prices*. In fact, as Eqn. (13) shows, each π is simply equal to the corresponding ϕ compounded up at the riskless interest rate. From Eqn. (4) we see that this implies that the risk neutral probabilities are simply the *forward prices* of Arrow–Debreu securities.

4.4 The No-arbitrage Condition in Terms of Risk-neutral Probabilities and State Prices

The no-arbitrage argument presented above shows that if a self-financing portfolio exists which replicates exactly the cash flows on another asset (e.g., an option) then the price of the option must equal the cost of this portfolio or an arbitrage opportunity exists. This is what Eqn. (8) represents: the option price is equal to the sum of the price times the quantity of each asset in the replicating portfolio. This Eqn. is easily recognizable as a no-arbitrage condition. However, Eqns. (10) and (14) are merely reformulations of this same condition—in terms of state prices and risk-neutral probabilities, respectively—and are, therefore, equivalent expressions of the no-arbitrage condition.

Equivalence between the absence of arbitrage and the existence of state prices or risk-neutral probabilities holds very broadly and is by no means limited to the binomial setting. We now derive this result in a more general, discrete state setting.

We first show that there is no arbitrage if and only if there exists of a set of ϕ's under which the value of each asset is equal to its price. To see this, let $\boldsymbol{A}$ $(N \times M)$ denote a matrix of cash flows to N securities in M states and $\boldsymbol{p}$ $(N \times 1)$ denote the vector of prices of the N securities. (In our example, the number of assets is three—the stock, the bond, and the option—and the number of states is two—'up' and 'down'). An *arbitrage portfolio*, $\boldsymbol{x}$ $(N \times 1)$ is a vector of portfolio holdings which satisfies:

$$\begin{aligned} x'p &= 0 \\ x'A &\geqslant 0 \end{aligned} \tag{15}$$

where $\geqslant$ denotes semipositive. (A 'semipositive' relation, $a \geqslant 0$, is one in which all elements are non-

negative and at least one is strictly positive). Thus, a portfolio, $\boldsymbol{x}$, which satisfies Eqn. (15) has a zero cost and provides nonnegative cash flows in all states and a strictly positive cash flow in at least one state; in other words it promises something for nothing.

If there is no solution to (15)—i.e., if there is no arbitrage—then, from Farkas's lemma (see, e.g., Gale 1960), there exists an $(M \times 1)$ vector $\phi > 0$ such that:

$$A\phi = p \tag{16}$$

The ϕ's in Eqn. (16) correspond to the state prices introduced in Eqns. (9) and (10) above. Thus, Eqn. (16) states that there is no arbitrage if and only if there exists a strictly positive vector of state prices such that the value of each security is equal to its price. If such a vector, ϕ, exists then, as before, we may define a corresponding vector, π, of risk-neutral probabilities by normalizing the ϕ's (and noting that $\sum_i \phi_i = e^{-r}$)

$$\pi_j \equiv \frac{\phi_j}{\sum_{i=1}^{M} \phi_i} = e^r \phi_j \quad j = 1, \ldots, M \tag{17}$$

which allows Eqn. (16) to be rewritten as

$$p = A\phi = e^{-r} A\pi = e^{-r} \hat{E}[CF] \tag{18}$$

In Eqn. (18) $\hat{E}[CF]$ denotes the expected value of the cash flows computed using the π's, defined in Eqn. (17), as 'probabilities,' exactly as in Eqn. (14). Eqn. (18) is exactly equivalent to Eqn. (16); in other words there is no arbitrage if and only if there exists a vector of (risk-neutral) *probabilities* such that the price of each asset is equal to its expected payoff under these probabilities, discounted at the riskless interest rate.

4.5 Market Completeness

Notice that if Eqns. (16) and (18) hold for *some* ϕ's and, therefore, for the equivalent π's, then there is no arbitrage irrespective of the uniqueness of the ϕ's and the π's. Without uniqueness, however, Eqns. (16) and (18) cannot be used constructively to value derivatives, or other assets, with arbitrary cash flows. When unique ϕ's and π's exist and the market is 'complete' and any pattern of cash flows across states may be replicated and valued using existing securities.

5. The Black–Scholes Theory

The B–S model is developed in continuous time using a model in which security prices follow a process related to Brownian motion. The continuous-time framework is a critical element of the theory but space unfortunately does not permit us fully to develop this analysis here. For a good general introduction to option pricing (as well as option markets and derivatives in general) see Hull (2000). For a collection of key papers in the development of the field see Constantinides and Malliaris (2001).

We assume that the value of the derivative at time t, $V_t(.)$, is a function of the current asset price, S_t, and time alone and that $V_t(.)$ is twice continuously differentiable in S_t and once t; this will turn out to be correct but a proof lies outside the scope of this article. (This assumption is made in the original Black and Scholes 1973 paper. The first proof that dispensed with this assumption was Merton 1977; also, see Harrison et al. 1979). Thus we assume

$$V(.) = V(S_t, t) \tag{19}$$

In the binomial model described above, the market is complete, which means that it is possible to replicate the payoff on a derivative using just the underlying asset and riskless borrowing and lending. The surprising—and deep—result of the Black–Scholes theory, is that exactly the same holds good in their model, even though it is clear that completeness does not derive, as it does in the binomial case, from the number of available assets being at least as great as the number of states. To understand the intuition behind this remarkable result it is useful to go back to the example discussed in Sect. 4 where we discussed valuing a forward contract via replication. In this example replication was feasible, even though the distribution of the stock price was continuous—and the number of states infinite—because the payoff on forward contract is linear in the price of the underlying asset. Derivatives with payoffs which are nonlinear in the underlying asset cannot, in general, be replicated with a portfolio containing only the underlying asset and borrowing or lending because the payoff on the latter is linear. The size of hedging 'error,' that is, the difference between the value of the derivative and the price of the portfolio, depends on two variables. The first is the degree of nonlinearity in the derivative—the curvature of the relation between the value of the derivative and the underlying asset—and the second is the variability of the underlying asset price. The greater the curvature or the variability, the larger, in general, is the error. In the case of a linear contract, such as the forward contract discussed earlier, the curvature is zero and so, therefore, is the hedging error.

In the Black–Scholes model, the properties of Brownian motion combined with the fact that the composition of the hedge portfolio is revised continuously through time, means that the hedge error is (surprisingly) completely predictable. The hedge portfolio composition can therefore take this effect into account initially and a perfect hedge can be constructed.

This means that, in effect, the price of the derivative and the underlying asset are perfectly correlated over

short intervals and, in this case, a simple relation exists between their risk premia and the volatility of returns:

$$\frac{\mu_S - r}{\sigma_S} = \frac{\mu_V - r}{\sigma_V} \tag{20}$$

where μ_S is the instantaneous or 'local' mean rate of return on the underlying stock, r is the instantaneous riskless interest rate, σ_S is the local volatility of the rate of return on the stock, and μ_V and σ_V are the corresponding quantities for the derivative. Eqn. (20) has a very simply interpretation: it says that if two assets are perfectly correlated, and therefore exposed to exactly the same *type* of risk, the risk premium (the numerator) per unit of risk (the denominator) must be the same for two assets. The common risk in this case is the risk of price fluctuations in the underlying asset.

Using a result known as Îto's lemma, the values of μ_V and σ_V may be calculated from μ_S, σ_S and the derivatives of V with respect to the underlying asset price and time. Substituting these values into Eqn. (20) gives the famous partial differential equation obtained by Black and Scholes

$$\tfrac{1}{2}\sigma_S^2 S^2 V_{SS} + rSV_S + V_t - rV = 0 \tag{21}$$

This equation applies to all derivatives written on the same underlying asset. Solving this equation, subject to boundary conditions specific to the particular contract under analysis, gives the price. For example, the price at time t of a European call option maturing at time T with strike price X is given by

$$V_t = S_t N(d_1) - e^{-r(T-t)} X N(d_2) \tag{22}$$

where:

$$d_1 = \frac{\ln[S_t/(e^{-r(T-t)}X)]}{\sigma_S\sqrt{T-t}} + \tfrac{1}{2}\sigma_S\sqrt{T-t}$$
$$d_2 = d_1 - \sigma_S\sqrt{T-t} \tag{23}$$

and the function $N(.)$ is the cumulative normal distribution.

Just as in the binomial case, the 'risk neutral' probability distribution can also be identified. Under this distribution, instantaneous rates of return on the underlying asset have the same variance as under the natural distribution but, again as before, an expected rate of return equal to the riskless interest rate. The value of a derivative may, therefore, also be written as the expected value of its payoff under this distribution, discounted at the riskless interest rate, exactly as in Eqn. (14) for the binomial case.

6. *Generalizations of Black and Scholes*

While the papers by Black and Scholes (1973) and Merton (1973) provided formulae for the values of some of the simpler derivatives, the methodology they introduced—pricing by replication—has been applied successfully to a vast and still increasing number of derivative instruments (see a recent monograph on the mathematical theory of derivative pricing by Musiela and Rutkowski 1997 that lists over 1,000 references). Although many of the recent applications are much more complicated than the problem of pricing European call and put options considered by Black and Scholes, and Merton, in terms of economic principles, there is little, if anything, that is fundamentally new in what has followed.

Some of the generalizations of the original theory have been developed in response to the increasing complexity of contracts traded in actual markets. One early problem was the valuation of American options which carry the right to exercise at any point up to maturity, as distinct from European options which may be exercised only at maturity. A canonical problem is the valuation of the American put option, for which no closed form solution is available, and this stimulated the application of numerical methods to the valuation of derivatives.

Among the techniques that have been applied are finite difference schemes, a variety of other lattice methods, including the binomial model, and Monte Carlo. Recent treatments of numerical methods applied to derivatives pricing include Rogers and Talay (1997) and Clewlow and Strickland (1998).

A large body of literature has developed devoted to so-called 'exotic options'; contracts that may retain some flavor of simple call and put options but are in other respects much more complicated. An important early contribution is Margrabe (1978) who analyzed options to exchange one risky asset for another. Other examples include 'lookback' options, which are similar to conventional options except that the exercise price is set at the minimum or maximum price of the stock over a given period prior to maturity; 'Asian options,' where the asset price used to compute the payoff is the average over a period prior to maturity and 'Quanto' options where the contract pays a number of units of one currency, for example, US dollars, equal to the price of an asset expressed in another currency (e.g., pounds sterling). Rubinstein (1991) gives an excellent discussion of many exotic options.

A second important area of application is to assets which are not in themselves derivatives but which have characteristics in common with derivatives.

One important example is the valuation of credit risky debt, discussed by Black and Scholes in their original paper. This was also the subject of an early paper by Merton who considered the case of a firm whose liabilities consist of a single zero-coupon loan (see Merton 1974). The relation with derivatives arises because, at maturity, the cash flows received by the lenders in this case may easily be shown to equal those on an equivalent default-free loan minus a put option on the assets of the firm. Black and Cox (1976) generalized Merton's work in a model where the firm

may default prior to the maturity of the debt. Recently, several authors have tackled the same problem in a rather different way and have modeled directly the firm's probability of default. These 'reduced form' models contrast with the traditional approach where the event of default is modeled as the first time the value of the firm's assets reach a given threshold. Lando (1997) provides an excellent survey of recent work on the valuation of credit risky debt.

A third major area of application for the theory has been the term structure of (default-free) interest rates. In some early work, for example, Vasicek (1977), both the dynamics of the short-term interest rate and the functional form of the price of risk are specified exogenously and the BSM no-arbitrage approach is then used to derive the prices of bonds and related derivatives. The same approach, and the same partial differential equation can be used to obtain the prices of interest rate contingent claims more generally, for example, options on bonds and interest rate options as well as bonds themselves. In an important paper, Cox et al. (1985) use a general equilibrium model to derive both the dynamics of the short rate and the price of risk. More recently, many authors have addressed the problem of constructing term structure models that are 'calibrated' to market data such as the term structure of zero coupon rates and/or the prices of particular options. Much of this literature is excellently reviewed in Sundaresan (2000). Ross (2000) contains a collection of many important contributions.

The real options often faced by firms undertaking real investments represents a further important application of the concepts of derivative pricing. Examples of the options in this case include the opportunity to abandon a project (and avoid continuation costs) or to make follow-on investments (see Dixit and Pindyck 1994).

7. *Future Directions*

Measured either by the volume of research it has generated or the extent of its application in practice, the theory of derivative pricing has been an astonishing success and, despite what has already been achieved, the intensity of research activity shows little sign of slackening. Some of this work is devoted to problems in application and much of the work devoted to numerical solutions to derivative pricing problems falls in this category. However, much activity is currently directed towards those aspects of the theory, or methods of application, which are viewed, to a greater or lesser extent, as unsatisfactory.

One example is the theory of the term structure of interest rates where no one formulation has yet been developed which appears to fit all the features of the data. A second concerns the assumptions on the properties of price paths in the standard model and whether it may be important to include the possibility of jumps (see Bates 1996). A third has to do with differences in liquidity between assets and the inclusion of transaction costs and a fourth with the fact that most derivatives pricing theory is inapplicable when the market is incomplete. Finally, there is still much debate about the best way to carry out empirical tests of derivative pricing models.

As mentioned earlier, when Merton wrote his seminal paper on derivative pricing he thought that they were 'unimportant financial securities (Merton 1973). Although a sound judgment at the time it was a poor prediction. The market in derivatives has grown out of all recognition and the development of derivative pricing research has followed a similar path. It would be a brave man who would predict the imminent demise of either.

Asset Pricing: Emerging Markets

Asset pricing theory is a framework designed to identify and measure risk as well as assign rewards for risk bearing. This theory helps us understand why the expected return on a short-term government bond is a lot less than the expected return on a stock. Similarly, it helps us understand why two different stocks have different expected returns. The theory also helps us understand why expected returns change through time. The asset pricing framework usually begins with a number of premises such as: investors like higher rather than lower expected returns, investors dislike risk, and investors hold well-diversified portfolios.

These insights help us assess the 'fair' rate of return for a particular asset. Such information is critical for the investment decision facing both corporations evaluating projects, and investors forming portfolios. In the corporate setting, the theory helps us characterize the risk of a particular project or acquisition, and assign a discount rate that reflects the risk. In choosing projects that have a higher promised rate of return than what would be assumed by the risk theory, corporations create value. In the portfolio investment setting, the theory helps us identify overvalued and undervalued assets. The theory is also integral to establishing a framework to help the investor understand the risk to be faced with a particular portfolio.

The foundation work in asset pricing originated with Nobel Laureate William Sharpe (1964) and the late John Lintner (1965). While there have been many advances in asset pricing since 1964, to understand the issues that we face with asset pricing in emerging markets, it is useful to follow the framework of the first asset pricing theory, the Capital Asset Pricing Model (CAPM) of Sharpe and Lintner. The key to understanding the complexities of emerging market asset pricing lies with the assumptions of the asset pricing theory.

The CAPM suggests that investors hold well-diversified portfolios. Investors like higher expected returns and dislike variance. This is the framework pioneered by Nobel Laureate Harry Markowitz (1959).

There is an important implication of the notion of well-diversified portfolios. The risk of the well-diversified portfolio is its variance—and the risk of a particular asset is not its own variance. The logic works as follows; you care about the variance of the portfolio—not of individual assets. A particular asset might have greater or lower variance than the portfolio. However, it does not make any sense to reward the asset based on its own variance. Correlation is the missing ingredient. It is possible that a very high variance asset can reduce the overall portfolio variance because it has low or negative correlation with the portfolio returns. Indeed, one can think of this high volatility asset with low correlation as providing insurance or hedging for the overall portfolio.

Let's follow this example further. Investor's don't like variance in their portfolio returns. The particular asset with high variance and low correlation is not judged on its own variance. It is judged on how it contributes to the variance of the well-diversified portfolio. In the example, it reduces the variance of the portfolio. As a result, this asset is valuable (investors like variance reducing assets) and the expected return is low as a result. In other words, because investors value the variance reducing properties of this asset in the context of their portfolio, the price is bid up to the point that the future expected returns are low.

So, to be clear here, it is possible that a high volatility asset has a low expected return and it is also possible that the high volatility asset has a high-expected return. It is not the variance of the asset that matters—it is the contribution to the variance of the portfolio. This contribution is the covariance.

The model of Sharpe (1964) and Lintner (1965) formalize this. Expected returns on assets are different

because the assets have different covariances with a well-diversified portfolio. The model also includes a reward for covariance risk. That is, in order to translate the covariance into expected return, we need the price of covariance risk—how this risk is treated in the marketplace.

There are numerous ways to derive the CAPM and we will not go into the different ways in this article. However, some of the most important assumptions are: investors only care about mean and variance; asset returns are multivariate normally distributed (or equivalent assumptions on investor utility could be made to replace this assumption); capital markets are perfect (all information is correctly reflected in prices as in Fama (1970); there are no transaction costs, no taxes, etc.); and there are no disagreements about the returns distributions. All of these assumptions are counterfactual. However, they provide a framework to derive a simple model that has rich implications.

One serious problem in applying this model to international finance is the assumption of perfect capital markets. In an international setting, this assumption also means that markets are perfectly integrated. This means the following: the same risk asset commands the same expected return regardless of location (country). A sufficient condition for this to work is that there are no effective barriers to portfolio investment across borders. That is, local investors are free to add any stock in the world to their portfolio and international investors are free to choose any stock within a particular country.

With capital market integration, we get a world version of the Capital Asset Pricing Model. That is, assets within a particular country are rewarded in terms of their contribution to a well-diversified world portfolio. What matters is the covariance with the world portfolio. There is also a world price of covariance risk that translates the contribution into expected returns. The world price is directly linked to the weighted average risk aversion in the world. Higher risk aversion implies a higher world price of covariance risk.

The world CAPM is a powerful model and has met with some success in being applied to developed market returns (see Harvey 1991). However, the same model fails when applied to emerging market returns (see Harvey 1995). There are many reasons why the model fails in emerging markets—but a leading and logical candidate is the lack of market integration in some emerging markets.

To understand the impact of market integration, consider a completely segmented (non-integrated) country. In this country, local investors are not allowed to own foreign securities. Foreign investors are not allowed to own local securities.

If the CAPM is held in this segmented country, then the relevant risk that investors face is the asset's contribution to variance of a diversified portfolio within the particular country—not the world. The risk that investors face is the variance of the country portfolio.

Let us make the distinction clear. In the integrated world, a country portfolio's risk is its covariance with world returns. This covariance is rewarded with a common world price, which is linked to weighted average risk aversion in the world. In the segmented world, a country portfolio's risk is it variance. The variance is rewarded with a country specific price, which is linked to a weighted average risk aversion within the particular country. These scenarios, integrated/segmented, are polar extremes. Early capital markets research on emerging markets recognized the importance of market integration and realized that it was likely that many markets were not completely integrated into world capital markets but they were not completely segmented either. For example, Errunza and Losq (1985) proposed a model of partial integration. Roughly speaking, one could think of expected returns in a partially segmented emerging market as reflecting some reward for the covariance with world returns as well as some reward for the market's own variance. One gets a hybrid CAPM that includes both variance as well as covariance with the world.

Bekaert and Harvey (1995) critique the usual implementation of the partial integration/segmentation model. The traditional model assumes that the degree of integration/segmentation is fixed over time. However, this flies in the face of substantial liberalizations of equity markets in many emerging countries in the late 1980s. That is, the traditional framework does not handle the dynamics of capital market integration. Bekaert and Harvey (1995) present an alternative framework for the valuation of emerging market assets. This framework explicitly recognizes that the integration process is gradual. Bekaert and Harvey parameterize and estimate a model that allows for a time-varying market integration. In the polar case of market integration, their model reduces to the world capital asset pricing model. In the case of market segmentation, their model reduces to a local CAPM. In the partial integration world, the expected rate of return is a weighting of world covariance times world price of covariance risk and the local volatility and the reward for the local volatility. To make the model dynamic, this weighting changes through time. The model assumes that the weighting is a function of two variables that proxy for the openness of the market: the size of the trade sector and the capitalization of the local equity market.

What happens when an emerging market liberalizes and becomes more integrated into world capital markets? This is a growing area of research that sheds much light on asset pricing in emerging markets. We will first consider what the theory suggests and second we will consider the evidence.

As previously mentioned, in the segmented capital market, variance counts. In addition, the variance of

the country portfolio is high (because it is not a truly diversified portfolio in a world context). To make matters worse, many emerging markets do not have the breadth of industrial sectors that Developed Countries have. That is, the firms come from very few industries. Further, most of the local firms' prospects are tied to the local economy. As a result, the returns of these firms tend to move in the same direction on any given day. This is another reason why variance is so high in segmented markets. Expected returns are also high. The local investors do not want to bear this extreme volatility. However, local corporations need to raise funds for investment projects. In order to get local investors to purchase local equity, the price must be low (expected rewards must be high). A subsidiary, but important point is that local corporations decline to pursue a number of seemingly profitable capital projects because the cost of equity capital is so high. For example, a project might promise a 25 percent rate of return, which is extraordinary in the context of developed markets. However, this project might be rejected because the cost of equity capital is 30 percent.

Now consider the integration process. Suppose regulations are changed such that local investors can purchase stocks outside their country and foreigners are allowed into the local market.

The most important impact will come from foreigners. They will be attracted to the emerging market for two reasons. First, at current values, the prices are cheap and the expected returns are high compared to what could be earned in developed markets. Second, because of the different industrial compositions of emerging markets relative to developed markets, the correlation of these markets' returns with world returns is lower than the correlation of developed markets' returns with world returns. This second point is important. Even though the volatility of the individual emerging market is high, the correlations are low or negative, which implies that the addition of emerging markets to a well-diversified world portfolio could reduce portfolio volatility.

When the foreign investors pour money into the market to take advantage of the low correlation/high expected return opportunities, prices rise and expected returns decrease. So, one immediate implication of capital market liberalization is that expected returns should decrease. Remember that the expected returns started out from quite a high level. There is plenty of room for the expected returns to decrease.

Bekaert and Harvey (2000) and Henry (2000) document this phenomenon. Bekaert and Harvey propose a set of dates that reflect capital market liberalization. They find that the expected returns decrease after liberalizations.

There are powerful implications to the decrease in expected returns. An immediate implication is that the cost of equity capital decreases. For local firms, this means that the investment projects that in the past were rejected because of expensive equity financing—are now profitable. We would expect to see an increase in capital investment as a proportion to GDP with a decrease in the cost of capital. We would also expect to see high GDP growth.

The evidence in Bekeart et al. (2000) provides convincing evidence in favor of these implications. In a cross-country study of the determinants of GDP growth, Bekaert et al. find that liberalization of capital market leads to a 1.5 percent increase in real GDP growth.

There are other potential implications of capital market liberalization. Policy makers, in particular, are often concerned with the volatility of capital market returns. Is it the case that liberalization or the move to more integrated capital markets increases local equity volatility?

In the case of volatility, there are many possible theories. It might be that capital market integration brings new trading volume and many new analysts watching emerging market stocks thereby increasing the informational efficiency. As a result, these stocks react faster to relevant information and we may see a natural increase in volatility. Volatility might also increase as so-called 'hot' foreign portfolio investment is withdrawn from a particular country on the hint of economic/financial/political unrest. Volatility may also increase as local firms specialize their product line to focus on the goods that they have a demonstrable competitive advantage in producing.

There are reasons for volatility to decrease too. Financial integration is often accompanied or preceded by economic integration. As firms trade their goods and services in world markets, they become less susceptible to shocks or economic fluctuations from the local economy. That is, world trade provides a natural economic hedge. Less sensitivity to the local economy can reasonably be translated into lower volatility of equity returns.

The evidence presented in Bekaert and Harvey (1997, 2000) suggests that there is no significant impact on volatility. Market integration sometimes leads to higher volatility and sometimes leads to lower volatility—it depends on the country. This ambiguous result is consistent with the different theories of volatility.

What about correlation with world returns? Historically, many researchers have looked at increases in correlation as evidence of capital market integration. However, this approach is potentially flawed. Two countries may be completely integrated and, at the same time, their equity returns are uncorrelated. The low correlation could simply reflect the different industrial mixes in the two countries.

The argument articulated in the previous paragraph that local companies might find more of their business in world product markets, is a powerful reason why correlations may increase. In an integrated world, the same type of world shocks that companies in developed markets experience will influence local com-

panies. For example, if the US falls into recession, this is bad news for many stocks in Developed Countries because the US is a major consumer of their goods. While segmented, the local economy may have been largely shielded from such fluctuations. However, as both the economic and financial integration processes are initiated, local companies could be very much affected by, for example, a US recession. Correlations should increase as a result.

The evidence in Bekaert and Harvey (2000) suggests that correlations increase after financial liberalizations. Note that one of the important reasons for foreign investors to enter these emerging markets and purchase securities is the low correlation. Importantly, the evidence in Bekaert and Harvey does not suggest that the diversification potential be eliminated. Even the new higher level of correlation provides substantial benefits to international diversification and is well below the threshold level set by developed markets.

For asset pricing theory, it is critical to know when and if an emerging market has effectively liberalized. Notice the use of the word 'effective.' Bekaert and Harvey (1995) argue that a country might be liberalized to the letter of the law but effectively segmented. That is, new laws might be passed that make it easier for foreigners to access the local capital markets—but it is possible that no foreigners bother to enter the market. This might happen if the liberalization was not credible—or if there was a threat of future policy makers reversing the liberalizations.

Conversely, it is possible, by the letter of the law that a country appears completely segmented but it effectively integrated Indeed, the growth of country closed-end funds as well as American Depository Receipts (ADRs) has made it possible for foreign investors to access local securities without directly purchasing the securities on the local market (where they might not be allowed to transact).

So, it is potentially problematic to judge the degree of integration by looking at particular regulations. The analysis in Bekaert and Harvey (2000) considers a number of different dating schemes: regulatory, introduction of first ADR, introduction of country fund, and a composite indicator of the first sign of liberalization (first date of regulatory, ADR, and country fund). Bekaert and Harvey also examine US portfolio flows. Indeed, if the market were truly open, then supporting evidence of integration would be a dramatic pickup in foreign portfolio flows to the emerging market.

The idea of portfolio flows as a proxy for market integration is analyzed in Bekaert et al. (2000a). Using the econometrics of break point analysis, they examine the interrelationship between capital flows and expected returns in emerging markets.

Indeed, it is possible that the market integration process fundamentally impacts a number of financial and economic variables. Bekaert et al. (2000b) presents the first multivariate tests that try to date the integration of world capital markets. The idea of this paper is to let the data speak for itself. They simultaneously examine a number of important aggregates and use endogenous break point analysis to reveal the common break point. They link this break point to capital market liberalization. For example, we expect to see a decrease in the cost of capital and an increase in foreign portfolio flows. The technology in this paper uses the information in many different economic aggregate series to come up with a composite break point.

The analysis in Bekaert and Harvey (2000) as well as Bekaert et al. (2000a, 2000b) suggests that many emerging markets have successfully liberalized their capital markets. There was a clustering of liberalizations in the late 1980s and early 1990s. This suggests that it is more likely that some version of the world capital asset pricing model holds more today than 10 years ago in 1990 for emerging markets. This is consistent with the results presented in Harvey (2000) who studies the ability of a world version of the CAPM to explain expected returns in 20 developed markets and 27 emerging markets.

There is one additional important issue. Traditional asset pricing theory operates in a world of mean and variance. The assumption of multivariate normality is often invoked. However, the evidence in Bekaert and Harvey (1997) strongly suggests that emerging market returns are highly non-normal. There is also evidence that the returns in many Developed Countries are non-normal. In addition, there is considerable discussion of the 'downside risks' of investing in emerging markets. That is, emerging markets are known to suffer from sharp crises. Two recent memories are the Mexican crisis of December 1994 and the Asian crisis of July 1997.

The analysis of downside can be handled within the traditional asset pricing frameworks. For example, Rubinstein (1973) and Kraus and Litzenberger (1976) developed an asset-pricing framework that explicitly considers the skewness of portfolio returns. Harvey and Siddique (2000) present tests of an asset-pricing model with a dynamic measure of skewness.

The logic of these models is much like that of the CAPM—indeed, it is a straightforward extension of the CAPM. Investors like expected returns, dislike variance, and dislike negative skewness (but like positive skewness). Investors' preference for positive skewness is evidenced by the unusually high price that they will pay for a lottery ticket (which has an expected return of –50 percent). We also see evidence in the options markets where 'put' options on the S and P indexes have very high prices. Investors are using these 'put' options to protect against extreme downside moves in the equity market. These options reduce negative skewness in an investor's portfolio. As a result, they are valuable (high price).

Like variance, it is not the skewness of the particular asset that matters—it is the contribution of that asset to the portfolio's skewness. This is called the coskew-

ness. If the coskewness is negative, it means that the asset is contributing negative skewness to the portfolio. In order to get people to purchase an asset with such an undesirable property, the price must be low (expected returns high). If the asset offers to increase the portfolio skewness (which is desirable), the price will be bid upwards (expected returns will be low).

Harvey and Siddique (2000) present tests of an asset-pricing model that incorporates skewness. They find some success in explaining the cross-section of US equity returns with this framework.

Harvey (2000) looks at a model with skewness for 47 international stock markets. His analysis is broken into three groups: Developed Countries, emerging markets, and all countries. He only considers data from 1988 which marks the beginning of an intense period of capital market reforms in emerging markets.

If markets were completely segmented, then what counts is the country's variance and total skewness. If markets are completely integrated, what counts is the covariance and coskewness. Harvey presents evidence that developed markets are not impacted by variance and total skewness, which is consistent with them being integrated. Evidence is also presented that covariance and coskewness also do a reasonable job in emerging markets—suggesting that many of these markets have successfully integrated into world capital markets. However, his evidence suggests that these emerging markets be not completely integrated. In some of his tests, both variance and total skewness provide an incremental ability to explain the cross-section of expected returns in emerging markets. The evidence suggests that it is unwise to assume that emerging markets are fully integrated into world capital markets.

There are a host of additional issues that we face in investing in emerging markets. Transaction costs (execution fees, bid-ask spread, and market impact) are higher than developed markets. Acute information asymmetries can exist (local investors may have better information than foreign investors may). Regulations, such as insider trading laws, may not exist or even if they exist, are not enforced. Many securities suffer from chronic infrequent trading making the price data unreliable. There is also the general issue as to how to handle foreign currency risk within asset pricing theory (see Dumas and Solnik 1995 as well as the early work of Solnik 1974 and Stulz 1981).

Each of these additional issues increases the probability that standard asset pricing models will fail when applied to emerging markets.

Finally, there is one overriding issue that impacts the study of asset pricing in emerging markets—as well as a more general study of asset pricing. It is not clear that the standard models are adequate to capture the complexities of security valuation in developed markets, let alone in emerging markets. Recently, in a number of studies of US equity returns, the traditional CAPM has come under attack. Indeed, most view the US market as one of the most efficient markets in the world, which would maximize the chance that the CAPM would work.

However, the international evidence is more generous to the traditional framework. It is paramount to explicitly allow for the role of capital market integration. After doing so, the traditional frameworks, perhaps augmented with measures of coskewness, are able to do a reasonable job in explaining the cross-section of expected returns.

Assimilation of Immigrants

Immigration is a transformative force, producing profound and unanticipated social changes in both sending and receiving societies, in intergroup relations within receiving societies, and among the immigrants themselves and their descendants. Immigration begets ethnicity—collectivities that perceive themselves and are perceived by others to differ in language, religion, race, national origin or ancestral homeland, cultural heritage, and memories of a shared historical past. Their modes of incorporation across generations may take a variety of forms—some leading to greater homogenization and cultural solidarity within the society (or within segments of the society), others to greater ethnic differentiation and heterogeneity. Assimilation is a multidimensional process of boundary reduction that blurs an ethnic or racial distinction and the social and cultural differences and identities associated with it. At its end point, formerly distinguishable ethnocultural groups become effectively blended into one. At the group level, assimilation may involve the absorption of one or more minority groups into the majority, or the merging of minority groups. At the individual level, assimilation denotes the cumulative changes that make individuals of one ethnic group more acculturated, integrated, and identified with the members of another. Ideologically, the term has been used to justify selective state-imposed policies aimed at the eradication of minority cultures. But in the social scientific study of immigration and intergroup relations, it remains an indispensable concept (Alba and Nee 1997, Yinger 1981).

1. Evolution of the Concept of Social Assimilation in American Social Science

A May 15, 1880, editorial in *The New York Times* reflected the popular usage of the concept on the eve of a new era of mass immigration:

> There is a limit to our powers of assimilation and when it is exceeded the country suffers from something very like indigestion … We know how stubbornly conservative of his dirt and ignorance is the average immigrant who settles in New York … these wretched beings change their abode, but not their habits in coming to New York.

But in Chicago a generation later, with immigration unabated and the large majority of the city's residents already consisting of first- and second-generation immigrants, Robert Park, the leading sociologist on the subject, could write (in Park and Burgess 1924, pp. 757–8):

> In America it has become proverbial that a Pole, Lithuanian, or Norwegian cannot be distinguished, in the second generation, from an American born of native parents … As a matter of fact, the ease and rapidity with which aliens, under existing conditions in the United States, have been able to assimilate themselves to the customs and manners of American life have enabled this country to swallow and digest every sort of normal human difference, except the purely external ones, like color of the skin.

What had become proverbial in America would become canonical in American sociology.

Ironically, Park is best known for the formulaic notion that assimilation is the final stage of a natural, progressive, inevitable and irreversible 'race relations cycle.' But in a prolific career, Park wrote about a 'race relations cycle' only twice: first in a sentence near the end of a 1926 article, 'Our racial frontier in the Pacific;' then a decade later (Park 1937) in a brief introduction to a book on interracial marriage in Hawaii written by one of his former students. In the first instance he was arguing against the likelihood that a 'racial barrier'—which the passage of exclusionary laws sought to establish by barring Asian migration to the USA—could be much of a match against global economic, political, and cultural forces that have brought about 'an existing interpenetration of peoples … so vast and irresistible that the resulting changes assume the character of a cosmic process' (Park 1926, p. 141). And in his 1937 introduction, he explicitly rebutted any notion of a predictable assimilative outcome to race conflict and change ('what are popularly referred to as race relations'), arguing instead that when stabilization is finally achieved, race relations would assume one of three configurations (Park 1937, p. xii):

> They will take the form of a caste system, as in India; they will terminate in complete assimilation, as in China; or the unassimilated race will constitute a permanent racial minority within the limits of a national state, as in the case of the Jews in Europe … All three types of change are involved … in what we may describe as the 'race relations cycle.

Park and Burgess gave the concept of assimilation its classic formulation: 'a process of interpenetration and fusion in which persons and groups acquire the memories, sentiments, and attitudes of other persons and groups, and, by sharing their experience and

history, are incorporated with them in a common cultural life' (Park and Burgess 1924, p. 735). They distinguished systematically between 'four great types of interaction'—competition, conflict, accommodation, and assimilation—which they related respectively to economic, political, social, and cultural institutions. *Competition* and *conflict* sharpen ethnic boundaries and the consciousness of intergroup difference. An *accommodation* (of a conflict, or to a new situation) may take place quickly, and the person or group is typically a highly conscious protagonist of the process of accommodating those circumstances. In *assimilation*, by contrast, the changes are more subtle and the process is typically unconscious, so that the person is incorporated into the common life of the group largely unaware of how it happened. Assimilation is unlikely to occur among immigrants who arrive as adults. Instead, accommodation most closely reflects the modal adaptation of first-generation adult immigrants, while assimilation can become a modal outcome ultimately only for the malleable young and for the second generation, and then only if and when permitted by structural conditions of inclusion at the primary group level. Indeed, the research literature on the adaptation of twentieth-century European immigrant groups in the USA suggests that evidence of assimilation was not manifestly observed at the group level until the third or even fourth generation.

Assimilation takes place most rapidly and completely in primary—intimate and intense—social contacts, including intermarriage; accommodation may be facilitated through secondary contacts, but they are too distant and remote to promote assimilation. Because the nature (especially the interpersonal intimacy, 'the great moral solvent') of the social contacts is what is decisive, it follows that 'a common language is indispensable for the most intimate associations of the members of the group,' and its absence is 'an insurmountable barrier to assimilation,' since it is through communication that gradual and unconscious changes of the attitudes and sentiments of the members of the group are produced. But language and acculturation alone cannot ensure assimilation if a group is categorically segregated, racially classified, and 'regarded as in some sense a stranger, a representative of an alien race'—which is why the English-speaking Protestant 'Negro, during his three hundred years in this country, has not been assimilated … not because he has preserved in America a foreign culture and an alien tradition, for with the exception of the Indian … no man in America is so entirely native to the soil' (Park 1930, p. 282). Race and place (or more precisely, racial discrimination and residential segregation) become critical structural determinants of the degree of assimilation precisely insofar as they delimit possible forms of primary social contact; social relations are inevitably embedded and bounded in space, which is why social distance is typically indexed by physical distance.

In *The Social Systems of American Ethnic Groups*, perhaps the definitive statement on the subject near mid-century, Warner and Srole (1945) described the progressive advance of eight European-origin immigrant groups in the major status hierarchies of 'Yankee City' in Massachusetts, explicitly linking upward social mobility to assimilation, which they saw as determined largely by the degree of ethnocultural (religion and language) and above all racial difference from the dominant group. While racial groups were subordinated and excluded through caste restrictions on residential, occupational, associational, and marital choice, the clash of ethnic groups with the dominant institutions of the host society was not much of a contest, particularly among the young. The industrial economy, the polity, the public school, popular culture, and the American family system all undercut and absorbed ethnicity in various ways, so that even when 'the ethnic parent tries to orient the child to an ethnic past … the child often insists on being more American than Americans' (Warner and Srole 1945, p. 284). And for the upwardly mobile, with socioeconomic success came intermarriage and the further dilution of ethnicity. Or at least, as qualified by a contemporary analysis (Kennedy 1944), the assimilation process was segmented in a 'triple melting pot,' with ethnic intermarriage and blending occurring within Protestant, Catholic, and Jewish religious groupings and not across religious lines.

That general view of assimilation as linear progress, with sociocultural similarity and socioeconomic success marching in lock-step, was not so much challenged as refined by Milton Gordon in *Assimilation in American Life* (1964), published ironically on the eve of the beginning of the latest era of mass immigration to the USA—and of the denouement of the concept itself in the wake of the 1960s. He broke down the assimilation sequence into seven stages, of which 'identificational assimilation'—a self-image as an unhyphenated American—was the end point of a process that began with cultural assimilation, proceeded through structural assimilation and intermarriage, and was accompanied by an *absence of prejudice and discrimination* in the 'core society.' Once structural assimilation had occurred (that is, extensive primary-level interaction with members of the 'core group'), either in tandem with or subsequent to acculturation, 'the remaining types of assimilation have all taken place like a row of tenpins bowled over in rapid succession by a well-placed strike' (Gordon 1964, p. 81). For the children of white European immigrants, in fact, the acculturation process was so 'overwhelmingly triumphant' that the greater risk consisted in alienation from family ties and in role reversals of the generations that could subvert parent–child relationships. Still, what it was that one was assimilating to remained largely taken for granted.

Gordon was aware of the ways in which the ideal and the ideological get wrapped up in the idea of

assimilation, and saw 'Anglo-conformity' as the most prevalent ideology of assimilation in American history, but he did not focus on the historical contexts that have shaped the ideas and ideals embodied in the notion of assimilation. Kazal (1995) sees the apogee of the concept in the 1950s and early 1960s as reflecting the need generated by World War II for national unity and the postwar tendency to see American history as a narrative of consensus rather than conflict; and the political and social upheavals of the 1960s as shattering the 'consensus school' and the rationale for studying assimilation, bringing back instead a focus on the ethnic group and ethnic resilience, and more inclusive conceptions of American society. 'To know how immigrants came to fit in, one had to understand what it was they were fitting into … When the notion of an Anglo-American core collapsed amid the turmoil of the 1960s, assimilation lost its allure' (Kazal 1995, p. 437). It took until the 1990s, once more in a new era of mass immigration, for a systematic reevaluation of the concept of assimilation to emerge, and its application in contemporary scholarship seeking to contrast differences and similarities between the old and the new immigration.

2. *Dimensions and Determinants of Assimilation*

Assimilation, as shown by this brief overview of the evolution of the concept, involves a series of interrelated cultural (acculturation), structural (integration), and psychological (identification) processes. These may be elaborated further, with some additional consideration of contextual and group factors shaping each of these dimensions—either by promoting or precluding assimilative outcomes (Cornell and Hartmann 1998, Yinger 1981).

Acculturation, involving complex processes of cultural diffusion and changes producing greater cultural similarity between two or more groups, is generally more extensive among members of smaller and weaker groups, and particularly immigrant groups. Nonetheless, acculturation is never exclusively one-sided; dominant groups, too, are culturally influenced by their contacts with other ethnocultural groups in the society, from cuisine and music to language and religion. In the American experience, language shifts have been overwhelmingly one-sided, with the switch to monolingual English typically being accomplished by the third generation. At the individual level, a key distinction to make is that between *subtractive* (or *substitutive*) acculturation and *additive* acculturation. The first is essentially a zero-sum game that involves giving up some elements of a cultural repertoire (such as language) while replacing them from another; the second does not involve losing but gaining to form and sustain a more complex repertoire (bilingualism and biculturalism). Available research has yet to examine systematically the multiplicity of conditions and contexts yielding subtractive vs. additive acculturative outcomes.

The degree of acculturation, as noted previously, is by itself not a sufficient condition for assimilation. Structural integration was the crux of the matter for Gordon (1964), although he focused on the entrance of the minority group into 'the social cliques, clubs, and institutions of the core society at the primary group level.' Given the many different institutions involved here—and the fact that integration in the economy, the polity, and the community at the secondary group level tends to be ignored by that formulation—a conceptual distinction can be made between secondary structural assimilation and primary structural assimilation. The former refers to a wide range of key integrative processes, including socioeconomic and spatial (residential) assimilation, and the acquisition of legal citizenship. The latter—extensive interaction within personal networks, and intermarriage—is unlikely to take place under conditions of status inequality. While it is clear that all of these dimensions are interdependent—acculturation, integration, intermarriage—the linkages between them are historically contingent and will vary depending on a number of factors, particularly the context of reception within which different immigrant groups are incorporated (Portes and Rumbaut 1996).

Conventional accounts of ethnic identity shifts among the descendants of European immigrants, conceived as part of a linear process of assimilation, have pointed to the 'thinning' of their ethnic self-identities in the USA. For their descendants, at least, one outcome of widespread acculturation, social mobility, and intermarriage with the native population is that ethnic identity became an optional, leisure-time form of 'symbolic' ethnicity (Gans 1979, Waters 1990). As the boundaries of those identities become fuzzier and less salient, less relevant to everyday social life, the sense of belonging and connection to an ancestral past faded. This mode of ethnic identity formation, however, was never solely a simple linear function of socioeconomic status and the degree of acculturation—that is, of the development of linguistic and other cultural similarities with the dominant group—but hinged also on the context of reception and the degree of discrimination experienced by the subordinate group. Identity shifts, like acculturative changes, tend to be from lower to higher status groups, *mutatis mutandis*. But where social mobility is blocked and hindered by prejudice and discrimination, members of lower status groups may react by reaffirming their shared identity. This process of forging a *reactive ethnicity* in the face of perceived threats, persecution, discrimination, and exclusion is not uncommon. On the contrary, it is another mode of ethnic identity formation, accounting for the 'thickening' rather than the dilution of ethnicity.

However, compared to language loyalty and language shift, generational shifts in ethnic self-

identification are far more conflictual and complex. Paradoxically, despite the rapid acculturation of European immigrants in the USA, as reflected in the abandonment of the parental language and other ethnic patterns of behavior, the second generation remained *more* conscious of their ethnic identity than were their immigrant parents. The parents' ethnic identity was so much taken for granted that they were scarcely explicitly aware of it, but the marginality of their children made them acutely self-conscious and sensitive to their ethnicity, especially when passing through adolescence. Moreover, as parents and children acculturated at different rates, a generational gap grew so that by the time the children reached adolescence 'the immigrant family had become transformed into two linguistic subgroups segregated along generational lines.' Finally, by the third generation 'the grandsons became literally outsiders to their ancestral heritage,' and their ethnic past an object of symbolic curiosity more than anything else (Nahirny and Fishman 1965).

By the end of the twentieth century a new era of mass immigration—and hence of ethnogenesis—now overwhelmingly non-European in composition, again raised familiar doubts about the assimilability of the newcomers and alarms that they might become consigned to a vast multiethnic underclass, on the other side of a new color line. It also raised questions about the applicability of explanatory models developed in connection with the experience of European ethnics, despite the fact that contemporary immigrants are being incorporated in a more complex, post-civil-rights context characterized more by ethnic revivals and identity politics than by forced Americanization campaigns. Relative to the first generation, the process of ethnic self-identification of children of immigrants is more complex, and often entails the juggling of competing allegiances and attachments. Situated within two cultural worlds, they must define themselves in relation to multiple reference groups (sometimes in two countries and in two languages) and to the classifications into which they are placed by their native peers, schools, the ethnic community, and the larger society.

While assimilation may still represent the master process in the study of today's immigrants, it is a process subject to too many contingencies and affected by too many variables to render the image of a relatively uniform and straightforward path convincing. Instead, the present second generation of children of immigrants is better defined as undergoing a process of 'segmented assimilation' where outcomes vary across immigrant minorities, and where rapid integration and acceptance into the American mainstream represent just one possible alternative. Why this is so—and how it is that different groups may come to assimilate to different sectors of American society—is a complex story that hinges on a number of factors, among which the following can be considered decisive: the history of the immigrant first generation, including the human capital brought by immigrant parents and the context of their reception; the differential pace of acculturation among parents and children, including the development of language gaps between them, and its bearing on normative integration and family cohesiveness; the cultural and economic barriers confronted by second-generation youth in their quest for successful adaptation; and the family and community resources for confronting these.

These factors combine in ways that magnify the relative social advantages or disadvantages of particular immigrant groups as they make their way in America, and mold both the character of parent–child relations within immigrant families and the adaptive experiences and trajectories of the children. Internal characteristics, including the structure and cohesiveness of their families, interact in complex but patterned ways with external contexts of reception—government policies and programs, the state of the economy in the areas where they settle, employer preferences in local labor markets, the extent of racial discrimination and nativist hostility, the strength of existing ethnic communities—to form the conditions within which immigrant children adapt, react, and assimilate to different segments of American society.

Associative Modifications of Individual Neurons

What is known about the learning of associations at the cellular level? Can associative learning be attributed to the changes in the membrane properties of a single cell, or a change in the efficacy of a specific synapse? The answers to these questions are beginning to be understood for the two major forms of associative learning: operant conditioning and classical conditioning.

1. *Operant Conditioning*

Operant conditioning is a process by which an animal learns to associate consequences to its own behavior. In an operant conditioning paradigm, the delivery of a reinforcing stimulus is contingent upon the expression of a designated behavior. The probability of expression of this behavior will then be altered. In order to understand the mechanisms underlying conditioning, it is often helpful to develop cellular analogues of the behavior. These cellular analogues attempt to capture the essence of the behavior, while also being amenable to experimental manipulations to uncover the processes mediating learning.

It is commonly believed that reinforcement is mediated by certain endogenous neurotransmitters. Self-administration experiments support this view. First, consider drug self-administration, where an animal will consistently make responses that lead to drug injection into the brain. Animals will ardently self-administer only a few substances. One of these substances is dopamine. Next, consider electrical self-stimulation experiments. These experiments demonstrate that the electrical stimulation of certain brain areas can reinforce the response leading to the stimulation. Often the brain areas that give positive reinforcement are coincident with areas rich in dopaminergic tracts or cell bodies and dopamine levels increase after self-stimulation of these areas (a). These results suggest that dopamine can act to reinforce a behavioral response. The reinforcing role of dopamine has been further characterized in rat hippocampal slices (b). Since the CA1 region is known to be a target for endogenous dopaminergic tracts, it was hypothesized that the electrical bursting activity in a pyramidal cell might be strengthened when there was a contingent application of dopamine. Indeed, when contingent reinforcement was applied, the bursting was strengthened, whereas a noncontingent application of dopamine produced no burst strengthening. This preparation demonstrated successful conditioning, indicating that dopamine was capable of mediating the reinforcement.

Feeding behavior in *Aplysia* has been used to gain insights into the modification of a behavioral response by reinforcement. This system is highly tractable. *Aplysia* have a relatively simple nervous system and the neurons are large and accessible, making it possible to consistently record from a single identified neuron. These advantages have led to identification of much of the cellular circuitry controlling feeding behavior. Thus, it is possible to monitor and experimentally manipulate neurons with known behavioral significance. One such neuron is denoted B51. This cell is implicated in the expression of ingestive behavior.

Aplysia ingest food by protracting a toothed grasping structure called the radula. The radula contacts seaweed and closes, grasping the food. The radula then retracts, completing the cycle. The rejection of food (known as egestion) starts by protracting the radula, which is grasping the soon to be rejected food. The radula then opens while it retracts, which releases the food. The timing of radula closure determines whether the behavior is ingestive or egestive. When radula closure occurs only during the protraction phase, the behavior is egestive. However, if radula closure occurs primarily during the retraction phase, then the behavior is ingestive. The cellular network responsible for generating feeding behavior has been largely identified. Both extracellular recordings from nerves and intracellular recordings from individual neurons have shown patterns of activity that correspond to feeding behavior (e.g., protraction, retraction, and closure). Neuron B51 is active only during the retraction phase. Furthermore, when B51 is recruited into a pattern, it both lengthens the retraction phase and recruits radula closure motor neurons (see Fig. 1). Thus, B51 recruitment contributes importantly to the expression of ingestive behavior.

An *in vitro* analogue of operant conditioning has been developed utilizing the ganglion responsible for generating feeding motor patterns (c). The ganglion expresses both ingestion-like and rejection-like patterns. The type of pattern expressed is not predictable. Ingestion-like patterns were selectively reinforced with a contingent shock to the esophageal nerve, which contains dopaminergic tracts. Following conditioning, ingestion-like patterns were more likely to be expres-

Figure 1
Model of operant conditioning of feeding in *Aplysia*. The circles represent the cellular network that mediates feeding motor programs. The rectangles below represent motor activity comprising a feeding pattern. (A) The radula protraction generating neuron (Prot.) is initially active followed by the radula retraction generating neuron (Ret.). In this naïve state, neuron B51 needs a relatively large magnitude stimulus to become active. Consequently, B51 is not recruited into the feeding motor pattern. Radula closure occurs only during the protraction phase, so this pattern is rejection-like. (B) Following contingent reinforcement, B51 now has a lower threshold for recruitment. Thus, B51 is recruited into the motor pattern. B51's activity in the pattern leads to radula closure occurring primarily during the retraction phase, so this pattern is ingestion-like

sed compared to noncontingent controls. Thus, the conditioning was successful. Contingent reinforcement also modified the membrane properties of neuron B51. The magnitude of the stimulus required to elicit electrical activity in the cell and the resting conductance were both decreased. Both of these changes in the membrane properties acted in the same direction and made the cell more likely to be active in the future. In another set of experiments utilizing the isolated ganglion, induced electrical activity in B51 was used as the analogue of ingestion-like behavior (d). Shocks to the esophageal nerve remained as the analogue of reinforcement. After conditioning, both the resting conductance and the amount of stimulus needed to elicit activity were decreased similarly to the previous experiment. Again, cell B51 was modified such that it would be more likely to be recruited into the motor pattern. This change in the recruitment probability can account for the shift in the likelihood of future ingestion-like patterns. Furthermore, the conditioning of B51 was blocked by the dopamine antagonist methylergonivine. Dopamine appears to act as an agent of reinforcement in invertebrates also.

The analogue has been further reduced to the level of the single cell (e). B51 was removed from the ganglia and placed in culture. Induced electrical activity in this isolated B51 was the analogue of behavior and a direct, temporally discrete, application of dopamine

was the analogue of reinforcement. After conditioning, B51 was more likely to be active in the future. Thus, it appears that the conditioned expression of a behavior can be attributed to associative modifications made at the level of the single cell.

2. *Classical Conditioning*

The mechanisms underlying classical conditioning are also being revealed at the cellular level. Classical conditioning occurs when an animal learns to associate a typically neutral stimulus with a later salient event. The animal learns that the stimulus can serve as a predictor. For example, a conditioned stimulus (CS) is paired with an unconditioned stimulus (US). Typically, the US produces an unconditioned response (UR). After successful paired training, the CS can invoke a conditioned response (CR) in anticipation of the US.

In *Aplysia*, analyses of simple withdrawal reflexes have provided the substrate for mechanistic studies of classical conditioning (f, g, h, i). A diagram of the general scheme is presented in Fig. 2. The US pathway is activated by a shock to the animal, which elicits a withdrawal response (the UR). When a CS is consistently paired with the US, a CR of withdrawal will develop. Activity-dependent neuromodulation is proposed as the mechanism for this pairing specific effect. The US activates both a motor neuron (UR) and a modulatory system. The modulatory system delivers the neurotransmitter serotonin (5-HT) to all the sensory neurons (parts of the various CS pathways). Sensory neurons whose activity is temporally con-

Figure 2
Model of classical conditioning of a withdrawal reflex in *Aplysia*. (A) Activity in a sensory neuron (SN1) along the CS+ (paired) pathway is coincident with activity in neurons along the reinforcement pathway (US). However, activity in the sensory neuron (SN2) along the CS– (unpaired) pathway is not coincident with activity in neurons along the US pathway. The US directly activates the motor neuron, producing the UR. The US also activates a modulatory system in the form of the facilitatory neuron, resulting in the delivery of a neuromodulatory transmitter to the sensory neurons. The pairing of activity in SN1 with the delivery of the neuromodulator yields the associative modifications. (B) After the paired activity in A, the synapse from SN1 to the motor neuron is selectively enhanced. Thus, it is more likely to activate the motor neuron and produce the conditioned response (CR). The synapse between SN2 (whose activity is not paired with the US) and the motor neuron is much less enhanced compared to the synapse between SN1 and the motor neuron. (Modified from Lechner and Byrne 1998)

Figure 3
Model of associative facilitation at the *Aplysia* sensorimotor synapse. This model has both a presynaptic and postsynaptic detector for the coincidence of the CS and the US. Furthermore, a putative retrograde signal allows for the integration of these two detection systems at the presynaptic level. The CS leads to activity in the sensory neuron, yielding presynaptic calcium influx, which enhances the US-induced cAMP cascade. The CS also induces glutamate release which results in postsynaptic calcium influx through NMDA receptors if paired with the US induced depolarization of the postsynaptic neuron. The postsynaptic calcium influx putatively induces a retrograde signal, which further enhances the presynaptic cAMP cascade. The end result of the cAMP cascade is to modulate transmitter release and enhance the strength of the synapse. (Modified from Lechner and Byrne 1998)

tiguous with the US mediated reinforcement are selectively modulated. Spiking in sensory neurons during the presence of 5-HT leads to changes in that cell relative to other sensory neurons whose activity was not paired with reinforcement. Thus, a subsequent CS will lead to an enhanced activation of the reflex (Fig. 2(B)).

Figure 3 illustrates a model of the proposed cellular mechanisms responsible for this example of classical conditioning. The modulator (US) acts by increasing the activity of adenylyl cyclase (AC), which in turn increases the levels of cAMP. Spiking in the sensory neurons (CS) leads to increased levels of intracellular calcium. The increased calcium in a spiking sensory neuron enhances the action of the modulator to increase the cAMP cascade. This system determines CS–US contiguity by a method of coincidence detection at the presynaptic terminal. Now, consider the postsynaptic side of the synapse. The postsynaptic region contains NMDA (N-methyl-D-aspartate) receptors. These receptors need concurrent delivery of glutamate and depolarization in order to allow the entry of calcium. The glutamate is delivered by the sensory neuron (CS) and the depolarization is provided by the US (h, i). Thus, the postsynaptic neuron provides another example of coincidence detection. The increase in intracellular calcium putatively causes a retrograde signal to be released from the postsynaptic to the presynaptic terminal, ultimately acting to further enhance the cAMP cascade in the sensory neuron. The overall amplification of the cAMP cascade acts to raise the level of protein kinase A (PKA). The increase in PKA leads to the modulation of transmitter release. These activity-dependent changes enhance the synaptic efficacy between the specific sensory neuron of the CS pathway and the motor

neuron. Thus, the sensory neuron along the CS pathway will be better able to activate the motor neuron and produce the CR.

Another example of associative modifications in an individual neuron can be found in the marine mollusc *Hermissenda* (j). Light is paired with 5-HT application in an analogue of classical conditioning. As with classical conditioning of the withdrawal reflex in *Aplysia*, 5-HT can also act to mediate reinforcement in *Hermissenda*. The conditioning results in both an increase in the excitability of a single cell and an enhancement in the strength of a specific type of synapse.

3. Conclusion

With classical conditioning of the *Aplysia* withdrawal reflex, the paired CS and US form an association by converging on a second messenger cascade within a single cell. This convergence results in the enhancement of a specific synapse. With operant conditioning of *Aplysia* feeding behavior, the association is made through contingent reinforcement. Contingent reinforcement of the response results in the alteration of a cell that mediates the expression of that response. Conditioning occurs through a modulation of the membrane properties of this single cell. Thus, modifications made to individual neurons (via intrinsic membrane properties and synapses) can account for both types of associative learning phenomena.

Asymmetry of Body and Brain: Embryological and Twin Studies

An individual's behavior is generated and modulated by the structure and function of the brain and body. The nervous system, which becomes the physical substratum of human cognitive processes, is formed during embryogenesis. During life, environmental stimuli are perceived, processed, and eventually manifest as behavior through the action of the brain and body. Thus, the structure of the body in general, and the brain in particular, are crucial factors in behavior and psychological processes. Therefore, an understanding of the embryonic processes which pattern the human organism is crucial to a complete understanding of cognition and behavior. Because of the ease of experimentation on animal embryos, and the high evolutionary conservation of molecular embryonic mechanisms from invertebrate animals through man, studies in animal embryos have shed much light on how the complex structure of the organism is formed during embryonic development.

1. Concepts in Molecular Embryology

The complex biochemical events which create an organism from a single fertilized egg produce intricate pattern on many scales, from the molecular to the organismic. This is accomplished through complex

Figure 1
Caption on next page

programs of gene expression which are turned on and off as the egg begins to divide and grow. The cells which are formed as the result of this proliferation have different fates in the embryo, in that they take up different positions and biochemical functions. The genes and maternal products stored in each of the embryo's cells are transcribed into mRNA and translated into proteins which can perform physiological functions or regulate the expression of other genes. Thus, the embryo is a complex dynamical system where a precisely orchestrated interplay of information and materials takes place to generate an organism with a well-defined shape.

2. *Left–Right Asymmetry*

The most basic aspect of any organism's structure is the large-scale symmetry of the body plan (see Fig. 1(A)–(D)). While some invertebrates possess chirality (snail shells), radial symmetry (sea anemonies), or no symmetry at all (sponges), the vertebrate body plan is bilaterally symmetric (defined as having two sides, each of which is identical to its mirror reflection across a midline axis of symmetry). While the general plan of the human body and nervous system is bilaterally symmetric, it contains important and consistent asymmetries of the brain as well as visceral organs such as the heart. The normal human anatomy features lungs which are trilobed on the right and bilobed on the left, a left-pointing cardiac apex and aortic arch, a right-sided liver and gall-bladder, and a left-sided stomach and spleen (Casey and Hackett 2000, p. 32). In particular, lateralization of the brain is involved in many aspects of higher mental function such as speech (Corballis 1983).

The left–right (LR) axis itself follows automatically from the definition of the anterior–posterior (AP) and dorsal–ventral (DV) axes, as it is perpendicular to both; however, consistently imposed asymmetry across it is fundamentally different from patterning along the other two axes. First, while the AP and DV axes can be set by exogenous cues such as gravity, or sperm entry point, there is no independent way to pick out the left (or right) direction, since no obvious macroscopic aspect of nature differentiates left from right. This problem can be most acutely felt by imagining trying to explain to someone using only words which hand is the 'Left' hand: unless an asymmetric object exists to which one can refer, it is an extremely difficult task.

Second, all normal members of a given species are asymmetrical in the same direction (e.g., the heart is always on the same side in normal individuals). However, animals with complete mirror reversal of internal organs can arise (*situs inversus*) and are otherwise phenotypically unimpaired. Thus, while it is possible to come up with plausible evolutionary reasons for why organisms might be asymmetric in the first place (optimal packing of viscera, etc.), there is no obvious reason for why they should all be asymmetric in the same direction. It is, after all, much easier to

(A)–(D) *Symmetry types in the animal kingdom*: starfish have a fivefold radial symmetry (A); some insects such as Drosophila are bilaterally symmetric (B); Interestingly, some invertebrates such as crabs have a bilaterally symmetric bodyplan with conspicuous asymmetries such as claws (C). The vertebrate body plan is also bilaterally symmetrical, but contains conserved asymmetries of the viscera and heart (D). (E)–(I) *Left–right asymmetry in chick embryos*: the early chick embryo is a flat, radially symmetric two-layer disk of cells (E). The radial symmetry is broken into a bilateral symmetry by the appearance of the primitive streak at one point on the periphery. As the streak grows away from the periphery, its base becomes the posterior end of the embryo, while its tip becomes the anterior, and will induce the formation of the head and other nervous structures (F). Several genes have asymmetric expression patterns in early embryos; for example, the gene *Nodal* is expressed in two domains on the left side of the midline, shown here in the chick embryo (G). The asymmetric genes function in a pathway (H): activin on the right side inhibits the expression of *Shh*, which is then present only on the left. *Shh* induces expression of *Nodal* (only on the left side), which induces *Pitx-2*, and then transduces this information to the forming heart (I) and viscera. (J)–(L) *Conjoined twinning and asymmetry*: conjoined twins occur in embryos of chick (such as the triplets in panel I), frog (J), and other animal models. Human twins which are joined at the midline (J) are known to often exhibit disturbances of laterality. In the chick, conjoined twins sometimes occur by the appearance of two primitive streaks which begin far apart in the embryonic field (K) but then grow together with time. As the tips of the streak near each other, the expression of *Shh* on the left side of the tip of the primitive streak can induce an ectopic nodal domain on the right side of the left twin (L). This is observed in spontaneous twins which are examined for expression of nodal (M); such twins show laterality disturbances in the left twin because of the extra nodal domain on the right side. (N)–(P) *Gap junctions and asymmetry*: gap junctions are tunnels formed by connexin proteins on either side of the membrane of two opposing cells. In early frog embryos, radial patterns of open gap junctions allow the traversal of small molecular signals (morphogens) across embryonic fields; these molecules then accumulate on one side of a junctional barrier on the ventral midline (N). A very similar process occurs in the chick (O), where the junctional paths allow morphogens to flow across the blastoderm to accumulate on one side of the primitive streak. This process is schematized in (P): junctional paths allow signals to traverse embryonic fields to preferentially accumulate on one side of the midline, thus converting a cell-level asymmetry (which drives one-way transfer through gap junctions) to an embryo-wide asymmetry

imagine a developmental mechanism for generating asymmetry (such as positive feedback and amplification of stochastic biochemical differences) than for biasing it to a given direction. The left–right axis thus presents several unique and deeply interesting theoretical issues.

Normal asymmetry (*situs solitus*) can be perturbed in one of several ways, and various human syndromes recapitulate all of these (Burn 1991, Winer-Muram 1995). *Situs inversus* is a complete mirror image inversion of asymmetry, and does not usually cause complications because all interconnections are made properly. However, isomerism (a loss of asymmetry, where an embryo has two left or two right sides, which can result in polysplenia or asplenia, a midline heart, etc.) and heterotaxia (a loss of concordance, where each organ makes an independent decision as to which side it will go towards) are associated with serious medical complications.

3. *The Molecular Basis of Asymmetry*

Molecular embryology has made great strides in understanding the patterning of the antero-posterior and dorsoventral axes. However, prior to 1995, very little was known about the molecular mechanisms which give asymmetric cues to the left and right sides of the body. A large catalog of asymmetries in the animal kingdom was available (Neville 1976). Besides the human syndromes which exhibited alterations in laterality, a variety of mouse mutants existed which displayed various laterality phenotypes. However, the nature of the mutations responsible for these effects was unknown. It had been observed that a variety of drugs was able to induce asymmetry phenotypes in embryos (Levin 1997), and timing experiments using these drugs indicated that processes which lead to asymmetry function very early in embryonic development (prior to neural tube formation).

The identification of a chicken gene, *Sonic Hedgehog* (*Shh*), cloned in 1993 because of its role in limb and neural tube patterning (Riddle et al. 1993) turned out to be pivotal in understanding left–right patterning. The chick embryo begins as a flat disk only three cell layers thick and is radially symmetric (Fig. 1(E)). However, soon afterwards a structure appears which is called the primitive streak (see Fig. 1(F)). This groove of special cells which are undergoing gastrulation is common to mammals and many other types of embryos, and marks the breakage of symmetry from the radial to the bilateral, since it defines the midline of the embryo, and sets up the antero-posterior axis. When the chick embryo at this stage is examined for the presence of mRNA of the gene *Shh* by a procedure which deposits blue stain wherever the gene is active, it is seen that this gene is only transcribed on the *left* side of the tip of the primitive streak, and not the right; this is even more obvious for a gene called *Nodal*, which is expressed in a wide domain on the left flank. The identification of several other asymmetric genes followed, and now a variety of genes is known which are active on the left or right sides (Levin 1998b). More importantly, by a variety of experiments involving artificial retroviruses, gene cloning and misexpression, and transgenic mouse technology, it was shown that these genes function in a pathway: they turn each other's expression on and off in a spatially and temporally specific manner to give each side of the body an identity. The presence of the *Shh* gene defines the left side as left; its absence defines the right side. These gene cascades provide information which is interpreted by asymmetric organs such as the heart to enable them to know which direction is left and which is right (summarized in Fig. 1(H)). For example, it was shown that if the normally left-sided *Shh* expression is artificially induced on the right side as well (thus producing an embryo both of whose sides think they are 'left'), the heart forms properly, and loops correctly in 50 percent of the cases, but loops to the opposite side in the other 50 percent. In effect, the heart (and other viscera) must choose randomly when presented with conflicting information. The details of the molecular cascade of asymmetric genes can be seen in reviews such as Burdine and Schier (2000), Fujinaga (1996), and Wood (1997).

Several of these genes are of particular interest to behavioral science, as they presage signals for the determination of brain laterality. For example, the chick gene *Cerberus* is expressed on the left side of the embryonic head, shortly after neural tube closure (Zhu et al. 1999). The same is true of genes such as *Pitx-2* in zebrafish embryos (Essner et al. 2000). It should be kept in mind that though most of this data comes from animal models, there is a high degree of conservation of embryonic mechanisms, and these gene cascades are very likely to be crucial in patterning all vertebrates including man (Casey and Hackett 2000).

4. *Conjoined Twins and Laterality Defects*

The identification of asymmetrically expressed genes whose protein products specify the spatial asymmetry of the viscera and brain made it possible to explain, on a molecular level, an observation which had been found in conjoined human twins. Twins and the twinning process have had a relevance for laterality research ever since the tantalizing experiments of Spemann (Spemann and Falkenberg 1919). It has been noted (Burn 1991, Morrill 1919, Newman 1916, Schwind 1934, Winer-Muram 1995) that conjoined twins in human beings, mice, and frogs tend to exhibit laterality defects. Animal models of twinning have been instrumental in understanding this defect in embryogenesis (Fig. 1(I), (J)).

In reviewing the human literature on conjoined twins, it was observed that parapagus and thoracopagus twins (twins joined at the chest or side-to-side) tend to exhibit *situs* abnormalities (Levin et al. 1996); these are twins thought to originate from two adjacent embryonic streaks developing side by side, either in parallel or obliquely (schematized in Fig. 1(K)). Guided by the LR pathway, Levin et al. (1996) examined the expression of the asymmetric genes in analogously positioned chick twins and proposed two models explaining laterality defects found in conjoined twins. These are both based on molecules in the LR pathway crossing some distance in the blastoderm and affecting the conjoined embryo. The precise details of geometric arrangement and timing determine which members of the LR cascade affect the twin, and thus control which twin exhibits the *situs* anomaly.

For example, when primitive streaks arise far apart, but grow towards each other during gastrulation (Fig. 1(K), (L)), *Shh* expression proceeds normally in both twins on the left side of the tip of the primitive streak. However, during head-fold stages, the *Shh* expression of the right twin induces not only the normal left-sided *Nodal* expression, but also induces aberrant *Nodal* expression on the right side of the left twin (Fig. 1(L)). When head-fold stage spontaneous chick twins with oblique streaks are examined for *Nodal* expression (Fig. 1(M)), as predicted it was seen that the right twin has *nodal* expression only on the left side (i.e., normal expression), while the left-most twin has expression (black arrows) on both the left and right sides (which leads to laterality defects). Thus, studies of twins in model systems such as the chick have provided a crucial arena in which to test molecular models which explain clinical findings in human teratology.

5. *Nonconjoined Twins and Asymmetry*

The models discussed above present plausible explanations of laterality defects in conjoined twins. There is, however, an interesting set of observations which suggest that they do not tell the whole story, and that even in mammals, chirality is determined as early as the first few cell divisions, and certainly before the streak appears. Nonconjoined monozygotic twins, while not exhibiting the kinds of visceral laterality defects that occur in conjoined twins, do manifest many subtler kinds of mirror-image asymmetry ('bookend' or enantiomer twin pairs), where some characteristic is left-sided (or counterclockwise) in one twin but right-sided (or clockwise) in the other.

Pairs of such twins have been noted to present such mirror asymmetries in hand preference, hair whorl direction, tooth patterns, unilateral eye and ear defects, and even tumor locations and undescended testicles (Beere et al. 1990, Carton and Rees 1987, Cidis et al. 1997, Gedda et al. 1981, Morison et al. 1994, Newman et al. 1937, Townsend and Richards 1990, Yager 1984). Most healthy, nonconjoined twins presumably result from separation of cleavage, morula, or early blastocyst stage embryos (James 1983). Thus, some chiral information may be present in the very early mammalian embryo, manifesting itself in hair whorls etc. if the cells are separated at an early stage. In contrast, the asymmetry of the major body organs seems to be unspecified (or at least plastic enough to be respecified) at those stages, and is developed correctly for both monozygotic twins. This may be related to the fact that heterotaxic reversals in hair whorls and tooth patterns would not be expected to be disadvantageous, while discordant *situs* for internal organs clearly is subject to negative evolutionary pressure.

6. *Upstream of Asymmetric Genes*

Pathways of asymmetric gene expression beg the question: what determines the sidedness of the first asymmetric gene? The very first step of asymmetry at the cellular level is presently unknown, but is thought to perhaps involve a chiral (handed) molecule which is tethered with respect to the other two axes, and has an activity which distinguishes left from right (Brown and Wolpert 1990). Interestingly, the identification of such a mechanism would still leave an important question unanswered, because for a cell, knowing which direction is left vs. right is a very different problem than knowing which side of the midline it is on. Knowing its position relative to the midline is crucial for proper expression of asymmetric genes. Thus, what is needed is a mechanism for transducing left–right directional information at the level of a single cell into embryo-wide fields of asymmetric gene expression.

Recent experiments have shown that a system of cell–cell communication exists by means of which the two sides of very early embryos decide which side is to be the right side and which is to be the left (Levin and Mercola 1999). Such a system involves cell–cell channels known as gap junctions, through which small molecular signals can pass (Fig. 1(N)). Once crucial LR decisions are made in a small group of cells, this information can be distributed to the whole organism through circumferential paths of open gap junctions (Fig. 1(O), (P)). Twin embryos will be crucial in testing these models because the gap junction models make specific predictions about what should happen to circumferential paths when more than one primary axis exists in an embryonic field (as in conjoined twins growing side by side, in parallel).

7. *Twins and the Origin of the Primary Axis*

Bilateral asymmetry presupposes the existence of a midline axis, across which symmetry or asymmetry is observed. In the chick this is accomplished by the

primitive streak growing out of a specific point on the periphery of the blastoderm, and thus breaking radial symmetry into bilateral symmetry. However, it is known that when suitably stimulated, any point on the periphery is able to serve as the site of streak initiation. Yet, in the great majority of embryos, only one primary axis is observed (singleton embryos). What is responsible for the appearance of one and only one streak, when many points could potentially initiate streaks?

Research has showed that at very early stages, many chick embryos in fact consist of more than one primary axis, and are conjoined twins. Interestingly, at this crucial stage of embryogenesis, the streaks secrete a streak-inhibitory factor in an attempt to suppress the appearance of other streaks (Levin 1998a). In most embryos, this competition results in the primary dominant streak inhibiting other streaks and in fact causing the extra streaks to dissolve. Thus, twinning illustrates the mechanisms underlying the control of the number of primary axes in the embryonic field—a key component of embryogenesis.

8. *Prospects for the Future*

The phenomenon of twinning provides crucial insight into the earliest steps of embryonic pattern formation; luckily, twins can be experimentally induced in various systems with ease (Fig. 1(I), (J)). Conjoined animal twins allow researchers to answer questions regarding mechanisms by which primary axes arise from a competent embryonic field. Moreover, conjoined twins are the perfect system in which to characterize paths which facilitate, and barriers which block, the flow of left–right information during embryogenesis. This information is of vital importance in understanding normal mechanisms of embryonic development.

Nonconjoined twins provide a special challenge to molecular embryology. The bookending phenomenon, which displays a conservation of chirality in nonconjoined twins, provides tantalizing clues about the very first steps in the generation of embryonic asymmetry, and has implications for evolution of the vertebrate body plan. The data suggesting that the head and brain have a system of asymmetry determination distinct from the rest of the body have far-reaching implications for cognitive science. Progress on this issue will be a key part of a molecular understanding of the embryonic development of systems which generate and shape human behavior.

Atomism and Holism: Philosophical Aspects

In the philosophy of the social sciences, atomism is the view that human beings can be thinking, rational beings independently of social relations. Holism, by contrast, is the view that social relations are essential to human beings insofar as they are thinking, rational beings. This article first provides an overview of different sorts of atomism and holism (see Sect. 1). It then briefly sketches the historical background of these notions in modern philosophy (Sect. 2). The main part is a systematic characterization of atomism and holism (Sect. 3) and a summary of the most important arguments for both these positions (Sect. 4).

1. *Types of Atomism and Holism*

If one speaks of atomism or holism, one has to specify with respect to what atomism or holism is claimed. Atomism with respect to one thing or aspect can go with holism with respect to another thing or aspect, and *vice versa*. In the social sciences, the discussion on atomism vs. holism focuses on the question whether social relations to other humans are essential to human nature. The question thus is whether society in the sense of a social community of human, thinking beings is an atomistic or a holistic system. The question is neither whether a human being can exist in the biological sense without social relations nor whether a human being is dependent on social relations for maintaining a fully satisfactory human life. The point at issue is whether a human being is dependent on social relations to other humans insofar as he or she is a thinking, rational being. Since, on most accounts, thought in the full sense of the term as exhibited by adult human beings is tied to rationality constraints and since rational agency, including moral agency, presupposes thought, the point at issue can be formulated thus: are social relations necessary for a human being to have thoughts with a determinate conceptual content? Social atomism is the thesis that an individual considered in isolation can have thoughts with a determinate conceptual content. Social holism, by contrast, is the thesis that social relations are essential for a human being in order to have thoughts with a determinate conceptual content. Social holism thereby implies that having thoughts is tied to speaking a public language; social atomism does not have such an implication.

The discussion on atomism vs. holism concerns not only the conditions under which humans can have thoughts; it extends also to aspects of thoughts. The most important issue in this respect is the question whether meaning is atomistic or holistic. Semantic atomism is the thesis that each thought or sentence has a meaning independently of other thoughts or sentences. Semantic holism, in reverse, is the thesis that the meaning of a thought or a sentence consists in its inferential relations to other thoughts or sentences in a system of thoughts, a theory, etc. There is a middle position, namely semantic molecularism. This is the thesis that only some particular inferential relations to other thoughts or sentences, most prominently the analytic ones, constitute the meaning of a thought or a sentence.

Atomism and holism are put forward with respect to further aspects of thoughts. Confirmation atomism is the thesis that thoughts or sentences can be empirically confirmed or disconfirmed one by one. Confirmation holism, by contrast, is the thesis that only a whole system of thoughts or a whole theory can be confirmed or disconfirmed by experience. Consequently, if a conflict between theory and experience occurs, there are several possibilities for adapting the theory to experience. Justification atomism is the thesis that there are some thoughts or sentences which can be justified without referring to other thoughts or sentences. These thoughts or sentences are the foundation of knowledge. Justification atomism is, therefore, known as foundationalism. Justification holism, by contrast, is the thesis that the justification of any thought or sentence consists in relations to other thoughts or sentences. Justification holism is, therefore, known as coherentism: the justification of a thought or a sentence is its being integrated into a coherent system of thoughts or sentences. Although there are arguments which link all these sorts of atomism or holism together, endorsing any one sort of atomism or holism does not logically commit one to endorse any other sort of atomism or holism as well.

2. *The Historical Background of Atomism and Holism*

The issue of atomism vs. holism in the social sciences is linked closely with philosophical reactions to what is perceived as the methodology of modern physics.

Thus, social atomism starts when Hobbes applies the method of physical science to social science. Hobbes—in contrast to, for instance, Gassendi—is not a physical atomist: he does not commit himself to the thesis that there are smallest, indivisible bodies which have a few basic properties such as position and motion and of which every complex body is composed (*De corpore/Of Body*, Chap. 15, Sect. 2, Chap. 27, Sect. 1). However, he transfers to the social sciences the method of (a) dividing a complex system up into its constituent parts, (b) considering the parts and their properties in isolation from each other, and (c) understanding the nature and function of a complex system on the basis of the properties of its constituent parts considered in isolation (*De cive/Of the Citizen*, Preface). Hobbes is famous for applying this method to political science. He thereby commits himself to social atomism: in his political philosophy, he presupposes individuals each of whom is a thinking, rational being independently of the other ones (*De cive/Of the Citizen*, Chap. 8, Sect. 1). He reconstructs social and political relations on that basis.

Despite the widespread acceptance of the sketched methodology of the natural sciences as a paradigm for philosophy, holism is proposed as an ontology in early modern philosophy. Most prominently, Spinoza maintains in his *Ethics* that there is only one substance and that everything is a way of being (a mode) of that substance. However, it is only when the supposition that the methodology of physical science is a paradigm for philosophy is challenged in romanticism and its predecessors that social holism emerges as an option. This development is linked with a focus on language and the thesis that language is essential to thought. Thus, for instance, Herder claims (a) that thought is tied to language and (b) that language is tied to social relations. Consequently, he comes to the conclusion that a human can be a thinking being only in virtue of social relations to other humans (see, in particular, *Abhandlung über den Ursprung der Sprache*; partial English translation in Herder 1993 and see Spencer 1996). Hegel systematizes this conception and integrates it into his holistic ontology according to which the world is the dialectical development of a spiritual substance. He goes as far as considering individual thinking beings as accidents of a collective substance (for instance, *Grundlinien der Philosophie des Rechts*, Sect. 156; English translation Hegel 1991). He can be seen as thereby transforming social holism into collectivism.

Social holism in the romanticists is part of their reaction against conceiving philosophy on the model of the methodology of the physical sciences. But the romanticists do not go as far as developing a proper methodology for the social sciences. It is only from the beginning of the twentieth century on that social holism is proposed as a proper methodology for the social sciences. Most prominent in that respect are the works of Durkheim (1927) and Mead (1934). This development again links up with a development in the natural sciences, namely the emergence of systems theory. Systems theory seeks to understand a system on the basis of its constituent parts—but not on the basis of properties which these parts have independently of each other; on the contrary, systems theory sets out to understand a complex system on the basis of the relations into which its constituent parts enter (von Bertalanffy 1968). Applied to social systems, systems theory can therefore lead to social holism. Moreover, as regards physics, it is claimed that atomism is replaced with a comprehensive holism in our description of the microphysical level consequent upon quantum theory (for instance, Teller 1986). However, this holism has—as yet?—no repercussions for the social sciences.

3. *A Characterization of Atomism and Holism*

Both atomism and holism, taken in a general sense, are about complex systems in which constituent parts can be distinguished. Having constituent parts is not sufficient for something to be an atomistic system. In reverse, there is no reason to recognize something which does not admit of parts as a holistic system; such a thing would rather be an atom in the literal sense. Both atomism and holism therefore presuppose the analysis of a complex system in terms of parts. For a characterization of atomism in opposition to holism, it is crucial to consider (a) the sort of independence or dependence that holds among the parts and (b) the properties of the parts with respect to which that sort of independence or dependence holds.

Relations of causal dependence among the parts of a complex system are not sufficient to settle the issue of atomism vs. holism, even if they are complicated relations of mutual or circular causal dependence. No one denies that the development of thought and rationality in a human being causally depends on the social environment and that these social relations can be complex ones of mutual and circular causal dependence. But this commonplace does not amount to a refutation of social atomism and an argument for social holism, on pain of trivializing social holism and turning social atomism into an absurd position.

It is, therefore, appropriate to focus on whether or not there are relations of ontological dependence among the parts of a complex system. Ontological dependence is about something depending for its very existence on the existence of some other thing. Two sorts can be distinguished. (a) If an individual *a* cannot exist unless there is a particular individual *b*, then we have a case of rigid ontological dependence. (b) If there can be no individual of a certain kind unless there is some other individual of a certain kind, then we have a case of generic ontological dependence (Simons 1987, Chap. 8.3). The issue of atomism vs. holism is about generic ontological dependence among

the parts of a complex system. The holist claims that some social environment is necessary for thought, but not that it has to be, say, one's family, or one's tribe.

According to the standard account of modal sentences in today's philosophy, the necessity which ontological dependence implies is to be analyzed in terms of possible worlds. One can claim that the necessity is metaphysical and thus concerns all possible worlds. But one does not have to go as far as that: one can restrict the scope of ontological dependence so that it applies, for instance, only to all physically possible worlds, i.e., all those worlds in which the same physical laws hold as in our world. Consequently, one can take the followig position: social atomism or social holism applies only to human thinking beings, i.e., to those who share a human nature and who are subject to the physical and biological laws of our world. One thereby refuses to commit oneself as to whether or not in the imagined case of Maritians, who are thinking beings, but who do not have a human nature, social relations are necessary for thought. Hence, one can conceive social atomism or social holism in such a way that these positions formulate a conceptual necessity about all possible thinking beings; or one can restrict these positions in such a way that they apply only to us humans.

When it comes to atomism vs. holism, we can further specify generic ontological dependence: (a) we are interested in generic ontological dependence as a symmetric relation; for we are enquiring into the sort of dependence that captures the way in which the parts of a holistic system depend on each other. (b) In cases such as social atomism vs. social holism and atomism vs. holism with respect to meaning, confirmation, or justification of thoughts, generic ontological dependence concerns the dependence of things of one sort on there being other things of the same sort (Fodor and Lepore 1992, pp. 1–2). In social atomism vs. social holism, the question is whether there have to be other human thinking beings if there is one human thinking being. This point does, however, not apply to all cases of holism: if an organism is a holistic system, then something which is a heart is not ontologically dependent on there being other hearts, but on there being blood, kidneys, etc.

Most importantly, (c) the issue of atomism vs. holism can be formulated in a more fine-grained way than being about generic ontological dependence that concerns the existence as such of the parts of the kind of systems in which we are interested. The issue is about generic ontological dependence among the parts of a complex system with respect to certain of their properties. The claim of social holism is not that a human being cannot exist unless there are other humans. The claim is that a human being is ontologically dependent on social relations to other humans with respect to the property of thought and rationality, i.e., insofar as it is a thinking, rational being. Otherwise, social holism would be an absurd position: it would have to claim either that a baby already has thoughts in the full sense of the term, or that a baby and an adult cannot be the same individual. Thus, for a characterization of atomism vs. holism, it is necessary to filter out properties for which it is a substantial issue whether or not the parts of a complex system are ontologically dependent on each other with respect to these properties.

For every system of a qualitative kind, there is a family of nondisjunctive, qualitative properties which make something a system of the kind in question. Such a family of properties can include both nonrelational and relational properties. Something is a system of the kind *S* if and only if it has all—or by far most of all—the properties which make something an *S*. For instance, if something is a grain of sand, a certain molecular structure as well as a shape, seize, and mass within a certain margin count among the family of properties which make something a grain of sand. Applied to the parts of an *S*, this notion is to say: There is a family of qualitative, nondisjunctive properties which make something a part of an *S*—in case the thing is arranged with other things in a suitable way. Having all or nearly all the properties that belong to such a family of properties is a necessary condition for something to be a part of an *S*; it is a sufficient condition in conjunction with the condition of a suitable arrangement with other things.

The condition of a suitable arrangement has to be imposed in order to exclude those properties for which it is trivial that something can have them only by being part of a complex system. For instance, a human being can exercize a social role—such as being a judge, or being a salesman—only by being part of a social system. Social roles are arrangement properties. Pointing out social roles is not sufficient to make a case for social holism, again on pain of trivializing social holism and turning social atomism into an absurd position. The question is whether properties that are the prerequisite for exercising a social role—such as the property of thought and rationality in the sense of having thoughts with a determinate conceptual content—require social relations. By excluding from the mentioned family of properties those relational properties in which the arrangement with other things consists, we pick out the properties which underlie the arrangement. There is a substantial case of holism if and only if these properties are relational as well—in the sense that one thing can have these properties only if there are other things together with which this thing is arranged in such a way that there is an *S*. Consequently, there is a substantial case of atomism if and only if something can have these properties independently of whether or not there are other things with which this thing is arranged in such a way that there is an *S*.

The issue of atomism vs. holism can now be characterized as follows: Consider a system of the kind *S* and its constituent parts. For every constituent part

of an *S*, there is a family of qualitative, nondisjunctive properties which make something a constituent part of an *S* provided that there is a suitable arrangement. The issue whether or not an *S*is holistic depends on whether or not the following condition is satisfied by all the things which are its constituent parts: with respect to some of the properties that belong to such a family of properties, a thing is ontologically dependent in a generic way on there being other things together with which it is arranged in such a way that there is an *S* (Esfeld 1998). If there are some properties which satisfy this condition, the system is holistic with respect to these properties. With respect to all those properties within the mentioned family of properties that do not satisfy this condition, the system is atomistic.

This is a fine-grained characterization of atomism and holism: one and the same system can be atomistic in regard to some properties, but holistic in regard to other properties. Apart from the above mentioned variable of the scope of ontological dependence, there are two variables with respect to the properties that atomism or holism concerns: (a) the number of these properties: for instance, in the case of a system of thoughts, one can maintain that holism concerns both confirmation and meaning, but also that it concerns only confirmation; one can hence claim that a system of thoughts is a holistic system with respect to confirmation, but an atomistic system with respect to meaning (Fodor and Lepore 1992, Chap. 2); (b) the importance of these properties: all the properties which atomism or holism concerns are important in that they belong to the family of properties which make something a constituent part of a system *S* provided that there is a suitable arrangement. Nonetheless, the properties which are touched by atomism or holism can be more or less important as far as the identity of the system and its constituents is concerned. For instance, in the case of a thinking human being who is a constituent part of a social community, the property of having thoughts is not necessary for the identity of the human being concerned. If a human being develops from a baby into a normal adult and then goes insane, she nevertheless remains the same human being throughout this development. By contrast, consider the case of atomism or holism of thought with respect to meaning: if a constituent of a system of thoughts changes its meaning, it is no longer the same thought.

The outlined characterization makes clear that the issue of atomism vs. holism is distinct from the issue of individualism vs. collectivism. The former issue is about the way in which the constituent parts of a complex system are interrelated with each other. It is noncommittal on the issue of whether or not there are forces or regularities by means of which a whole influences the behaviour of its parts. Collectivism is the claim that there are such social forces; this claim is not implied by social holism. Social holism can go with individualism: it can be conceived as being about the requirements under which a human being can develop into an individual personality (Pettit 1993, Chaps. 3, 4); see *Individualism versus Collectivism: Philosophical Aspects*.

4. *Arguments for Atomism and Holism*

The main argument for social holism and the main challenge which social atomism has to meet stem from the work of the later Wittgenstein, in particular the *Philosophical Investigations* and the interpretation of that work by Kripke (1982). Kripke sets out what is known as the problem of rule-following, i.e., the problem how the thoughts of finite thinking beings can have a determinate conceptual content. He raises the following issue: any finite sequence of examples or of actions including linguistic actions of persons can in principle be described in terms of infinitely many different rules. Consequently, (a) there are infinitely many possible ways of continuing any such sequence in any new situation, and (b) for any new situation, it is not determined what is the correct way to go on. The problem of rule-following then is this one: What can select for us one of infinitely many rules so that for us one way of going on is singled out as the correct one? See *Meaning and Rule-following: Philosophical Aspects*.

According to Kripke's interpretation of Wittgenstein, to the extent that there is rule-following at all, social interactions are necessary in order to (a) select for a person one of infinitely many meanings in a finite sequence of examples or of actions and (b) enable a person to have a distinction between correct and incorrect rule-following at their disposal. This is the main argument for social holism. This argument speaks against the programme to reduce the description of thoughts to a description in terms of the natural sciences.

There are two main ways in which social holism can be spelled out. One possibility is to conceive social holism in terms of an asymmetric I–we relation: an individual becomes a thinking being by being integrated into a social community. The members of the community assess the actions of the individual according to what they take to be fit and proper. In this case, norms are reduced to social facts: the fact of community approval or disapproval is identified with correctness or incorrectness. The actions on which the members of a community agree are not themselves liable to an assessment as being correct or incorrect. This position consequently is a social relativism. Its most extreme version is a radical meaning finitism that considers the extension of a concept only to be determined insofar as factual communal agreement reaches at a time (Bloor 1997, Chap. 2).

The other possibility is to conceive social holism in terms of symmetric I–thou relations between individuals assessing each other's actions as correct or incorrect. This conception does not have to identify

norms with social facts. Instead, it can regard these assessments as an open-ended process. Each normative attitude of taking something to be correct or incorrect, including those attitudes which are shared by all the members of a community at a time, can be challenged as not being correct. This position makes it possible to conceive the normative attitudes of taking something to be correct or incorrect as being responsive and responsible to the way the world is. It thus combines social holism with a realism (Pettit 1993, Chap. 4, Brandom 1994, Chaps. 1, 8).

If one intends to defend social atomism, one has to meet the challenge which Kripke poses. Two strategies can be distinguished. One strategy is to make a case for meanings as entities beyond the physical including persons and their interactions (Katz 1990, Chaps. 2–4). Having thoughts with a determinate conceptual content then does not depend on social relations, but on standing in an appropriate relation to such entities, i.e., grasping meanings. The other, most widespread strategy is to argue for some sort of a naturalization of semantics, i.e., an account of meaning in the vocabulary of the natural sciences. One then has to show how an account in terms of dispositions to behavior can solve both the infinity and the normativity problem which Kripke raises. Prominent proposals are an account in terms of computation (Miscevic 1996) and a teleofunctional account (Millikan 1990). According to these accounts, certain dispositions which each human being has considered in isolation from other human beings are sufficient for a human being to have thoughts with a determinate conceptual content—although, of course, social relations influence the way in which the thoughts of a person develop.

Social holism is a social externalism: the thoughts of a person are externally individuated, namely by the person's relations to her social environment. Social atomism, by contrast, is an internalism: the thoughts of a person are individuated by factors which are internal to that person such as her dispositions to behavior. Independently of Kripke's argument, Burge (1979) makes a case for social externalism by claiming that the meaning of the thoughts of a person depends on the way in which the terms in which that person expresses her thoughts are used in her social community. Burge's method is to develop thought experiments in which he keeps all the factors that are internal to a person fixed and varies the social environment. He thereby intends to show that the social environment enters into fixing the meaning of the thoughts of a person. Burge's argument fits into the method which dominates the discussion on externalism in general. A common reply to the externalist arguments is to distinguish between narrow and wide content of thoughts: the externalist argument is granted as far as wide content is concerned. But it is claimed that there is a narrow content of thoughts which is internally individuated and which is all that is needed to explain behavior. Thus, social atomism is vindicated as far as narrow content is concerned.

Social holism can be combined with semantic holism if one maintains that social relations determine a content for a thought of one type only by determining a content for other types of thoughts as well which constitute an inferential context for the thought in question (Brandom 1994). However, one does not have to combine semantic holism in form of an inferential semantics with social holism. The most widespread version of semantic holism is an inferential semantics applied to narrow content (Block 1986). Hence, a semantic holism can go with a social atomism. Moreover, subsequent to the influential criticism of semantic holism by Fodor and Lepore (1992), arguments for semantic atomism as well as semantic molecularism have gathered new momentum (Devitt 1995).

By contrast, holism with respect to the confirmation of thoughts or sentences is widely accepted owing to Quine (1951). Confirmation holism is one of the backgrounds of the view of science of Kuhn (1962), which is also influential in the social sciences. It is in dispute to what extent confirmation holism and Kuhn's view of science lend support to social relativism. Because of the presumed relativistic consequences, Quine (1969) rejects Kuhn's view of science and excludes observation sentences from both confirmation and semantic holism, defending atomism with respect to these sentences.

Attachment Theory: Psychological

Cross-cultural attachment research in Africa, China, Japan, Indonesia, and Israeli kibbutzim showed that attachments emerge inevitably between helpless offspring and protective parents. Similar antecedents of attachment security arise, and similar perceptions of the value of a secure attachment relationship seem to be prevalent. As attachment has also been observed in a wide variety of nonhuman primates and in other species, the bond between protective parents/caregivers and offspring is considered to be a universal phenomenon.

Although attachment is universal, three different organized attachment patterns have been detected in several hundreds of studies across the world. Infants who actively seek proximity to their caregivers upon reunion, and then readily return to exploration are classified as secure (B; 65 percent). Infants who ignore or avoid the caregiver following reunion are classified as insecure-avoidant (A; 20 percent). And infants who combine strong proximity with contact resistance and who are not able to return to play are classified insecure-ambivalent (C; 10 percent). Caregivers of secure infants are found to respond sensitively to their infants' attachment signals. Caregivers of insecure-avoidant infants have been found to reject their infants' negative emotions. Caregivers of insecure-ambivalent infants have been found to be inconsistently sensitive to their infants' attachment signals. There is growing evidence for the continuity as well as lawful discontinuity of these basic attachment patterns across the life span.

1. *The Concept of Attachment*

In a strange environment, infants become distressed when they are left alone by their parents for a brief period of time. Some infants will start crying, whereas other infants will move around to search for the absent parent. These responses to a brief separation are attachment behaviors and they indicate the attachment relationship that infants and parents usually establish during the first year after birth. The concept of attachment describes the enduring affective bond between children and their primary caregivers; from this bond children derive comfort in times of stress and distress. The attachment relationship enables them to explore new objects, persons, or environments and the attachment figure serves as a safe haven to which the child can return when exploration becomes too dangerous or stressful. Children can become attached to their (biological) mother and father, but also to other caregivers such as step-parents, babysitters, or professional caregivers in daycare centers. John Bowlby, British child psychiatrist, developed attachment theory to account for striking similarities in the ways in which children respond to major separations: with protest, despair, and detachment. The Second World War disrupted the life of many families, and many children became orphans. He sought to explain why children depend on their parents and caregivers, not only for food and shelter, but more importantly, for feelings of security and confidence.

1.1 *Historical, Cultural, and Biological Context*

Attachment is not an invention of modern times; attachment behavior is not restricted to modern, industrialized countries and cultures, and it is not an exclusively human characteristic. About 3,000 years ago, Homer had already described an example of infant attachment behavior to mother, father, and professional caregiver. In the famous *Iliad*, the Trojan

hero Hector returns from the battlefield to his family, smeared with mud and blood of the previous fights. Achilles is waiting for him to revenge earlier assaults on the Greek warriors, and he will defeat Hector in an atrocious fight. Hector wants to spend the remaining time with his wife, Andromache and his son, Skamander who is in the arms of his 'nanny.' Hector scares Skamander with his imposing helmet and with the traces of the earlier battle. In response to the reunion with Hector, Skamander seeks close physical contact with his nanny because he does not recognize his father. Hector notices the signs of fear that his son displays, takes off his helmet, and starts to play. His sensitive interactions stimulate Skamander to smile and play with his father; Andromache looks at this peaceful and moving scene in tears as she foresees the death of her husband in the fight with Achilles. After a while Hector carries his child to Andromache who cuddles him, and takes leave. Mother and son will never meet with their husband and father again.

The empirical study of attachment did not start in a Western culture. In fact, Ainsworth's first investigation of attachment was conducted in Uganda, a former British protectorate in East Africa. Here, she discovered the now-famous tripartite classification of insecure-avoidant, secure, and insecure-ambivalent attachment relationships (see later). It was in this African culture that she also studied, for the first time, the antecedents of attachment, in particular parental sensitive responsiveness. After this path-finding field-study of attachment, the development of attachment between parents and infants in several other African cultures has been studied, for example in the Gusii, the Dogon, the Hausa, the Efe, and the !Kung San. Furthermore, cross-cultural attachment research has been carried out in China, Japan, and Indonesia, and in the unique setting of the Israeli kibbutzim. In these diverging cultures attachments seem to emerge inevitably between helpless offspring and protective parents, similar patterns of associations between antecedents and sequelae of attachment security seem to arise, and similar perceptions of the value of a secure attachment relationship for the individual, the family, and for society seem to be prevalent. Cultural diversity in the expression of attachment is, however, acknowledged. In the Gusii culture, for example, infants are accustomed to being greeted by their returning mothers with a handshake instead of a hug, and accepting or refusing the handshake can be considered indications for the security of the attachment relationship in the Gusii dyad. The patterning of attachment behaviors is independent of the specific attachment behaviors that express the children's emotions, and these patterns of attachment have been found in all cultures studied thus far. Attachment, therefore, appears to be a universal phenomenon, and attachment theory claims universal validity (Van IJzendoorn and Sagi 1999, see also *Cultural Variations in Interpersonal Relationships*).

Attachment has been observed in many species, and John Bowlby drew heavily on the results of ethological investigations of attachment in nonhuman primates for the construction of attachment theory. Harlow's experiments with rhesus monkey infants showed that the development of attachments is not dependent on the provision of food and, thus, the result of reinforcement schedules, but seemed to be 'instinctive' behavior directed at objects providing warmth and protection. Field studies of rhesus monkeys showed that in the first few months after birth the infants develop enduring and unique bonds with the mother who protects the infants against predators and other environmental dangers. Rhesus monkey infants use their mother figure as a secure base to explore the environment, and to regulate their negative emotions and stresses. This role of a secure base is fulfilled uniquely by the mother and not by other members of the group or even by relatives. Bowlby derived from these ethological findings the idea that human infants were born with an innate bias to become attached to a protective adult because the affective bond would have evolutionary advantages (see also *Psychological Development: Ethological and Evolutionary Approaches*). Infants may differ in the expressions of their attachment 'needs,' and the patterns of their attachment behavior may diverge, but, basically, every representative of the human species would show attachment behaviors. In his later work he introduced the concept of 'inclusive fitness' into attachment theory to take into account the parental side of the first attachment relationship. It should be noted that nonhuman primates differ widely in the emergence and display of attachment relationships between infants and mothers. For example, capuchin monkey infants do not only rely on their mothers, but also on their peers and relatives for contact comfort and protection, and their bond with the mother seems much weaker than in the case of the rhesus monkey infants. The evolution of attachment theory might have been completely different if, in the 1950s and 1960s, ethologists had studied the social relationships of capuchin instead of rhesus monkey infants (Suomi 1999).

2. *Secure and Insecure Attachments*

In the development of attachment in young children four phases can be discriminated. In the first phase the baby is indiscriminately orienting and signaling to the environment, with a preference for human stimuli that seems to be most salient. Fairly soon the baby is able to fixate the eyes of caregivers, and begins to cry, smile, and grasp. It is unclear whether the baby is able to differentiate between people before 8–12 weeks of age. In the second phase the baby starts to orient and signal to a few specific caregivers for whom a preference is developed, presumably first through smell and sight. In this phase, attachment behaviors, such as crying,

can also be more easily terminated by caregivers instead of strangers. With the emergence of 'person-permanence' the infants enter into the third phase of attachment proper, in which they are able to discriminate the attachment figures from other persons, and address their attachment behaviors exclusively to these selected and preferred caregivers. They are now more actively seeking proximity and maintaining contact in stressful circumstances, and explore their environment from the safe base of the attachment figure. At around 6–8 months of age their attachment behaviors become organized in a goal-directed system, in which the set goal of proximity or 'felt security' is served by several different means of more distal or proximal behavior. In this phase, infants react to major separations in the manner that Bowlby described succinctly, with protest and anger, followed by despair and apathy, and finally detachment and the formation of new bonds. In the fourth phase the children learn to take the perspective of their attachment figures into account, and around three years of age they develop a goal-corrected partnership with their caregivers. In this phase, children construct a mental representation of their caregivers, the interactions and relationships with their attachment figures, and their expectations of caregivers' responses to their attachment signals.

Individual differences in quality of attachment relationships have been studied most intensively in the third phase of goal-directed development. In the Ainsworth Strange Situation Procedure, also termed Strange Situation (Ainsworth et al. 1987), infants in their second year of life are confronted with three stressful components, a strange environment, interaction with a stranger, and two brief separations from the caregiver. The first episode begins when the experimenter leads caregiver and child in the unfamiliar room and gives some last instructions.

The observations start when the caregiver brings the infant towards the pile of toys. The second episode is spent with the caregiver, together with the child, in the playroom. In the third episode an unfamiliar adult enters the room and, after a while, starts to play with the infant. In the fourth episode the caregiver leaves, and the infant is left with the stranger. In the fifth episode the caregiver returns after about three minutes of separation. Episode 6 starts when the caregiver leaves again and the infant is alone in the room. In the seventh episode the stranger returns, and in the eighth episode the caregiver also returns. The compound stress of this procedure has been proven to elicit attachment behaviors, and the patterning of this behavior, in particular in the reunion episodes, is taken as evidence for the quality of the attachment relationship with the caregiver.

Three organized attachment patterns have been found in several thousands of Strange Situation Procedures across the world. Infants who actively seek proximity to their caregivers upon reunion, communicate their feelings of stress and distress openly, and then readily return to exploration, are classified as secure (B) in their attachment to that caregiver. Infants who seem not to be distressed and ignore or avoid the caregiver following reunion (although physiological research shows that their arousal during separation is similar to other infants), are classified as insecure-avoidant (A). Infants who combine strong proximity seeking and contact maintaining with contact resistance, or remain inconsolable, without being able to return to play and explore the environment, are classified insecure-ambivalent (C). About two thirds of the infant–caregiver dyads are classified secure, one fifth are classified as insecure-avoidant, and about one-tenth are classified insecure-ambivalent. Caregivers of secure infants are found to respond sensitively to their infants' attachment signals, and the infants trust their availability in times of stress. Caregivers of insecure-avoidant infants have been found to reject or ignore their infants' communications of negative emotions, and the avoidant infants seem to minimize the expression of distress.

Caregivers of insecure-ambivalent infants have been found to be inconsistently sensitive to their infants' attachment signals, and the ambivalent infants appear to maximize the expression of negative emotions in order to draw their caregiver's attention. In numerous correlational and experimental studies on normal, nonclinical dyads this causal association between caregiver sensitivity and infant attachment security has been established.

During the past few decades attachment research has been broadened to include clinical groups, that is, samples with physically or psychologically impaired and disturbed children or caregivers. In particular, in abusive families, the traditional tripartite attachment classification system appeared to reach its limits, and many abused infants had to be classified secure although their parents were known to have abused the specific child. Main and her co-workers examined cases that were difficult to classify within the traditional Ainsworth system, and they developed the concept of 'disorganized' attachment, defined as the momentary breakdown of an otherwise organized attachment strategy to deal with stress. Examples of disorganized attachment behavior are contradictory behavior (e.g., at the same time seeking proximity to as well as avoiding the attachment figure), misdirected attachment behavior (e.g., seeking proximity to the stranger instead of the parent on reunion), stereotypical behavior (e.g., hair pulling with a dazed expression during stress and in presence of the caregiver), freezing and stilling (e.g., stopping all behavior as if in a trance or unable to choose between behavioral alternatives), and direct apprehension or even fear of the caregiver upon reunion. Using the disorganized attachment classification in abusive families, almost 80 percent of the dyads had to be classified as disorganized. In several studies disorganized children

have been shown to manage or regulate their physiological stress (measured by cortisol levels and heart rate) less well than children with organized (secure or insecure) attachments, and, in the long run, these infants seem to be at risk for psychopathology, in particular externalizing problems. Disorganized attachment is somewhat similar to the behavior described in the Reactive Attachment Disorders of the *DSM-IV* of the American Psychiatric Association, and similar pathogenic care is supposed to be the cause of disorganized attachment: abuse and neglect, as well as frequent changes of caregivers and, thus, major separations from attachment figures (see also *Early Childhood: Socioemotional Risks*).

Abusive parents create a paradox that their young children cannot resolve. Abusive caregivers are, at the same time, a source of fright and the only potential haven of safety in threatening situations. The combination of frightening parental behavior and the parental figure as a focus of attachment constitutes a paradox that the children respond to with contradictory, misdirected, or otherwise disorganized behaviors that bear some resemblance to dissociative states in older children and adults. In fact, some studies have found associations between disorganized attachment in infancy and elevated dissociative tendencies in adolescence. Main and her colleagues argued that frightening parental behavior does not only occur in abusive parents, but also in caregivers who suffer from unresolved loss or other trauma and cannot avoid entering into somewhat dissociative states themselves, even in presence of their children. The children would perceive this parenting as frightening and incomprehensible. In several studies with the, so-called, Adult Attachment Interview of Main and her co-workers, a rather strong association between unresolved loss or trauma and disorganized infant attachment has been found (Van IJzendoorn 1995). Furthermore, in at least three studies the hypothesis of the mechanism of frightening parental behavior linking unresolved loss to disorganized attachment has been confirmed.

3. *Continuity of Attachment Across the Life Span?*

The Adult Attachment Interview not only contributed to the investigation of antecedents of disorganized attachment, but also represented a 'move to the level of representations' and a broadening of attachment research into the domain of adolescence and adulthood (see also *Adult Psychological Development: Attachment*). Whereas the Strange Situation dominated attachment research in the 1970s and 1980s, the Adult Attachment Interview emerged as one of the most important attachment measures in the 1990s, and it facilitated the investigation of continuities and discontinuities in the development of attachment from infancy to adulthood. The Adult Attachment Interview is a semistructured, hour-long interview with open-ended questions that revolve around issues of attachment, separation, and loss during childhood and adulthood. In fact, like the Strange Situation procedure, the interview constitutes a dual task. On the one hand the participants must focus on their attachment experiences—which, in the case of bad experiences, may sometimes be rather uncomfortable. On the other hand, while contemplating their past the participants should keep focused on and follow the rules of discourse. Insecure adults, in particular, are not able to complete this dual task successfully. They remain too much focused either on the discourse context ('dismissing' subjects) or on the past experiences ('preoccupied' participants). Only the secure subjects are able to keep a balance between focus on the present discourse and the past experiences, even when they were treated badly in their childhood. The Adult Attachment Interview can be considered a stressful situation for adults in the way that the Strange Situation is for young children, and the struggle for balance between discourse context and autobiographical content runs parallel to the balance children have to strike between attachment and exploration in the Strange Situation. In fact, Main and her coworkers developed the Adult Attachment Interview coding system with the assumption that adult attachment classifications should map on corresponding Strange Situation classifications. In subsequent independent replication studies, this assumption has been confirmed (Van IJzendoorn 1995).

In several longitudinal studies continuities as well as discontinuities in the development of attachment from infancy to adulthood have been established. In stable (negative or positive) child rearing arrangements the likelihood of continuity is enhanced, and attachment security in adolescence or early adulthood appears to be almost perfectly predictable on the basis of assessment of attachment security in infancy (see, for example, Beckwith et al. 1999, Waters et al. 1995). If major life events, such as parental divorce, occur during the first seven years of life this will not only disrupt family life but also the continuity of attachment in the children. Lawful discontinuity has been established in several longitudinal studies in which disruptive life events were linked to discontinuities in attachment security. In unstable child rearing circumstances Sroufe and his colleagues were not able to detect any continuity of attachment security across the first 16 years of life, although attachment disorganisation in infancy was highly predictive of psychopathology and dissociative tendencies in adolescence (Ogawa et al. 1997). More longitudinal studies will come of age in the next few years (Grossmann and Grossmann 1991), but the available evidence suggests that attachment experiences in infancy do not leave permanent scars or give robust protection against adverse events later in life. The concept of a critical

attachment period in the first year or two has become obsolete. Attachment security seems to be environmentally labile until about the age of five. Thereafter, the development of attachment security becomes more and more stable because mental representations of earlier attachment experiences influence the perception and evaluation of later experiences and tend to become self-fulfilling prophecies. Nevertheless, environmental discontinuities may leave their traces on attachment at any major transition during the life cycle—for the better or the worse. Future, longitudinal-attachment studies should focus more carefully on repeated age-appropriate assessments of attachment, as well as on detailed descriptions of relevant environmental developments. Continuity and lawful discontinuity of attachment can only be found in the transactions between individual development and the changing environment (Sameroff 1997).

Attention and Action

1. Attention

Within information processing psychology, the term 'attention' refers to a mechanism that selects a spatially coherent subset of sensory information from among all information available. With regard to the function of attention two different theoretical camps can be distinguished: a major perception camp and a minor action camp.

2. Perception

Theorists in the perception camp, for instance Broadbent (1958) and Treisman (1988), answer the question 'What is (visual) perception for?' with the answer: 'For (visual) perception!' From this answer it immediately follows that the study of 'Visual cognition, then, deals with the processes by which a perceived, remembered, and thought-about world is brought into being from as unpromising a beginning as the retinal patterns' (Neisser 1967, p. 4). Just because perception is for perception, these are the processes the experimental research has to be concerned with.

After Broadbent (1958), the basic assumption in this line of theorizing is that the human information processing system has severe central capacity limitations. Perception is construed as a two-stage process. In the first, 'preattentive,' stage all information receives a preliminary, superficial evaluation. In the second, 'attentive,' stage, only a part of that preprocessed information is selected and subjected to a definitive, complete interrogation. Limited central capacity is regarded as the basic functional characteristic of the human information processor and attentional selection as a secondary functional consequence.

There are two basic reasons to doubt the limited capacity assumption, one theoretical and one empirical. The theoretical reason is that in this theorizing an observed phenomenon (people show overt performance limitations) is simply translated into an explanatory construct (people suffer internal capacity

limitations). The empirical reason is that behavioral experiments have not convincingly demonstrated these central capacity limitations. Moreover, also neurophysiology and neuroanatomy do not support the assumption of insufficient computational power in the brain (van der Heijden and Bem 1997).

3. Action

Theorists in the action camp, Allport (1987, 1989) and Neumann (1987, 1990) for instance, answer the question 'What is visual perception for?' with the answer: 'For (control of) action!' In their view, visual perceptual systems, just as all other '… perceptual systems have evolved in all species of animals solely as a means of guiding and controlling action … ' (Allport 1987 p. 395). Two control problems are recognized: the problem of effector recruitment (effectors can be used for different actions and one of the actions has to be selected) and the problem of parameter specification (a selected action can be executed in a number of ways and one of these has to be selected).

In correspondence with these two control problems two selection mechanisms are distinguished. The first is in charge of determining which *action* out of the total repertoire of actions is given priority at a certain moment in time (Allport 1987, p. 395). It determines which skill is allowed to recruit what effectors now (Neumann 1987, p. 376). The second, attention, is in charge of determining which *object* is acted upon (Allport 1987, p. 395). It determines from what region in space the parameters are taken that are allowed to specify a selected action in detail (Neumann 1987, p. 376). Selection for action is regarded as the basic functional characteristic of the human information processor and overt behavioral limitations as a functional consequence.

The perception for action approach presents a convincing functional analysis. Especially important is the idea that the control structures that serve to guide the selected actions, e.g., walking, throwing, or catching, have built-in selective capacities. These control structures determine and extract the parameters that specify the selected actions in detail. Therefore, besides 'action selection' and 'object selection,' no additional 'parameter selection' is required.

4. Impact

The perception for action approach has not really influenced the theorizing in information processing psychology. The prime reason for this lack of impact has to be found in the fact that the mainstream perception for perception approach is not very much helped by the *theorizing* within the perception for action approach. The perception for perception approach is not concerned with the behavior that animals and humans have in common; with how they forage for food, avoid predators, find mates, and move efficiently around. The experiments performed within this camp capitalize nearly always upon a uniquely human capability: the use of language. Subjects have to name colors or positions or to read letters or words.

5. Language

For the language behavior, used in the perception for perception camp, the analysis in terms of 'action selection' and 'object selection' of the perception for action camp still needs to be further developed. For the actions that humans share with animals the action control structures might always determine and extract the required set of action parameters from a selected object. This, however, is generally not the case with language behavior, i.e., with 'the act of speaking.' This is even not the case when in 'the act of speaking' a distinction is made between 'the act of naming' and 'the act of reading.' Two different problems have to be considered.

First, 'the act of naming' cannot select the required action parameters. When the selected object is, for instance, a small, red, triangle at the left, 'the act of naming' insufficiently constrains the verbal behavior that has to occur. The size, color, form, position and many more properties can be named. The introduction of 'size naming,' 'color naming,' 'form naming,' and 'position naming' as independent actions with devoted control structures is not a solution. That deprives the perception for action theory from its parsimony and elegance.

Second, 'the act of reading' cannot select all required action parameters. When the selected object is, for instance, the capital letter A, 'the act of reading' insufficiently constrains the verbal behavior that has to occur. Subjects need not respond with 'a.' They can refrain from responding; an adequate reaction under the instruction: say 'o' when there is an O and refrain from responding when there is an A. They can also respond with 'yes' and 'no'; adequate reactions under the instructions: say 'yes' ('no') when there is a vowel (consonant) and 'no' ('yes') when there is a consonant (vowel). Subjects can also respond with 'one'; an adequate reaction under the instruction: name the serial position of the letter in the alphabet. They can also respond with 'ape' or 'cat'; adequate reactions under the instruction: give an animal name that begins (not) with an A. Besides the selected object more than just 'the act of reading' is required for explaining a subject's task performance.

So, perception for action theorists have failed to generalize their view in such a way that also 'the act of speaking,' as encountered in the experiments of the perception for perception camp, can be dealt with.

6. Two Factors

From the perception for action approach nevertheless an important lesson follows. That lesson is that the perception for perception camp is not performing the *experiments* they think they perform and are not providing the *explanations* they have to provide. For recognizing this, it is important to see that in all experiments two experimental 'factors' are operative.

The first experimental 'factor,' that is generally acknowledged, consists of the stimuli that are presented in an experiment. The second experimental 'factor,' that is not generally acknowledged, consists of the instruction to act in a specified way. With their emphasis on 'action selection' and 'object selection,' the perception for action theorists make clear that in the laboratory experiments the instruction, for covert and overt 'action selection,' and the stimuli, for 'object selection,' are of equal importance. The instruction specifies the task to be performed and the action to be executed. The stimuli provide the objects to act upon and to specify the required action in detail. Of course, no experiment will work and produce interpretable data without one or another kind of stimuli and without one or another kind of instruction.

7. The Instruction

Within the perception for perception camp the importance of the instruction is not recognized. Reasons for this state of affairs are not too difficult to find. The perception investigators are almost exclusively interested in the bottom-up effect of the stimulus, in how it is processed and perceived despite the limited capacity. Moreover, in line with this preoccupation, in nearly all experiments, the stimulus is varied from trial to trial and produces an interesting pattern of results that invites a detailed explanation, but the instruction remains the same and can play no role in that explanation (see van der Heijden 1992).

But, recognized or not, in all experiments there is always an instruction to perform a task and to act in a specified way. So, not perception as such is investigated, but task performance involving or using perception. By failing to recognize this point and by overseeing the importance of the instruction as the factor that induces the covert and overt task performance, a discrepancy arises between the issues *explicitly addressed* (the processing of the stimulus information) and the processes *actually involved* (the instruction-induced task performance) (see Neumann 1990, p. 232).

8. The Action Plan

The important idea of the perception for action approach is that a selected action has the causal power to select the subset of parameters that is required to specify that action in detail. It is not difficult to see how that important idea can be generalized to account for the observed (language or symbolic) behavior in standard information processing experiments. Whether fixed or varied, in each information processing experiment there *is* always an instruction. The internal representation of that instruction has the causal powers that make that the subjects perform according to the instruction. That internal representation can be called an 'action plan' (Neumann 1987, p. 381). This instruction-induced 'action plan' selects its parameters in the experiments of the perception for perception camp just as the selected 'action' selects its parameters in the tasks considered in the perception for action camp.

In current theorizing in the information processing approach, the important theoretical issues with regard to 'action plans'—how they are derived from instructions, how they are structured, how they are implemented in the information processing system, and how they can exert their causal effects—are generally neglected. Therefore, the theoretical accounts are incomplete. Indeed, the internal representation of a fixed instruction cannot contribute to the explanation of the interesting *details* of the results obtained within an experiment. Without the instruction-induced action plan with its causal powers, however, the results that exhibit that interesting pattern had never been produced in the first place.

Attention-deficit/Hyperactivity Disorder (ADHD)

Attention-deficit/hyperactivity disorder (ADHD) brings to mind high energy levels, rapid reactions, and eagerness to explore novel environments. One also thinks of unfinished tasks, distractibility and disorganization, rule-breaking and risk-taking, disruptions and intrusions. Whether ADHD is considered a clinical syndrome, a cluster of behavior problems, or a dubious social construction, the characteristics are well known. Behaviors typical of ADHD are exhibited by most people on occasion, and by most children on many occasions, suggesting that people with ADHD differ more in degree than in kind from their nondiagnosed counterparts. Children are the most likely candidates for a diagnosis of ADHD, but increasing numbers of adolescents and adults are being referred for similar problems.

1. The Changing Faces of ADHD: Characterizing the Disorder

ADHD can be construed as a disorder of context, timing, and modulation. One of the biggest puzzles about children with ADHD is the number of things they can do well. They often appear to have mastered the requisite competencies, be they academic or social. Their problems emerge not as knowledge or skill deficits, but rather as application failures or mismatches between acts and settings. The appropriate time to ask the teacher what you're supposed to do is not immediately after she has given complete instructions. The optimal opportunity for practicing karate moves is not during a spelling test. The curiosity that leads a child to unwind rolls of toilet paper down the staircase is better expressed when the mother is not hosting a dinner for her employer.

1.1 Analyzing Performance: 'Can't Do' vs. 'Won't Do'

Ongoing research is identifying two focal problem areas: integrating information over time and context, and sustaining effortful problem solving. These difficulties are exacerbated when the task requires prolonged inhibitory control or the withholding of preferred actions. Children with ADHD spend less time than their peers observing task-relevant features, especially when engaging distractors are present. Tasks that require shifting from one dimension or response to another and back again on cue pose particular challenges. Also problematic are tasks that demand cognitive transformations such as integrating new data with knowledge stored in memory, or inferring causal connections between sequences of events. The metaphor presented by Milch-Reich et al. (1999) is particularly fitting. If the active processing of incoming information by most children can be likened to a cohesive, unfolding film, the mental transformations made by children with ADHD resemble a discrete and disorganized slide presentation.

These propensities have been well documented in task contexts and are also surfacing in the social arena. It seems reasonable to infer that youngsters who have difficulties organizing information over time, drawing causal connections, and shifting response sets on cue may also have problems forming accurate social impressions, understanding people's motivations, and engaging in reciprocal interactions. Children with ADHD show relatively low rates of effortful attention in social contexts; they spend little time observing how other people interact. They often seem oblivious to their impact on others and mystified when their actions provoke irritation or avoidance. Sadly, it is often the children with the strongest social interests who engender the most conflict and rejection.

Further research is required to evaluate the extent to which these information-processing differences are attributable to an impulsive response style, problems allocating attention efficiently, failures to sustain mental effort, or the pursuit of task-irrelevant goals. Distinguishing the 'can't do' from the 'won't do' facets is a continuing challenge.

1.2 Three Myths About Performance Patterns

1.2.1 Myth 1: Unpredictability. The putative unpredictability of children with ADHD is often predictable. In many situations, consistency rather than variability distinguishes them from their peers. When the task or role requirements change, when they need to stop one behavior and start another, children with ADHD often have difficulties. On cognitive tasks they tend not to slow down after an error or speed up when instructed to do so, and they have problems adjusting to a new rule or dimension (Douglas 1999). This difficulty modulating behavior has also been documented in social contexts that involve shifting from the role of leader to follower or from talk show host to guest (Whalen and Henker 1998). Thus despite the fact that spontaneous change seems to be a hallmark of ADHD, change-on-cue is problematic. These findings illustrate the hazards of interpreting

behaviors without considering contexts and task demands.

1.2.2 Myth 2: Rapid reactivity. Another counter-intuitive aspect of ADHD concerns response speed. The reputation for impulsivity is based on quick reactions that occur without reflecting on options and consequences. But on some cognitive tasks, especially those requiring sustained attention, reaction times are sluggish and variable, resulting in impaired performance. The timing problems appear to be another example of difficulties sustaining effortful control and adapting to shifting task demands rather than a global tendency to respond with undue speed.

1.2.3 Myth 3: Insensitivity to consequences. The repeated failures of children with ADHD have led many to infer a certain imperviousness to consequences. Recent studies do indeed implicate disturbed reward sensitivity, but they suggest hypersensitivity rather than a cavalier attitude toward reinforcement. It may be that children with ADHD actually care too much, becoming distracted by reinforcers and frustrated when they are delayed. Thus, the partial reinforcement schedules that so effectively maintain performance in people without ADHD may disrupt performance in those with the disorder.

1.3 A Core Deficit?

Despite extensive efforts and continuing progress in identifying a core deficit (e.g., Barkley 1998, Douglas 1999, Sergeant et al. 1999), consensus has not yet been achieved. Early conceptualizations focused on motor activity, and children with hyperactivity were described as perpetual motion machines, always on the go, acting as if driven by a motor. In the 1970s and 1980s, the focus shifted to attentional mechanisms, the abilities to focus selectively and continuously while resisting distraction. More recent formulations involve deficits in self-regulation and inhibitory competence, executive functions that involve the ability to modulate one's own responding in accord with varying cues and conventions.

1.4 Diagnostic Nomenclature, Criteria, and Subtypes

Variations in diagnostic labels and criteria have paralleled these changes in conceptualization and research emphasis. Over the second half of the twentieth century, four modifications of diagnostic labels and criteria appeared in successive versions of the *Diagnostic and Statistical Manual* (*DSM*) of the American Psychiatric Association (see *Mental and Behavioral Disorders, Diagnosis and Classification of*). In the current version (*DSM-IV*, American Psychiatric Association 1994), an ADHD diagnosis requires problems with either inattention (ADHD-I), hyperactivity and impulsivity (ADHD-HI), or the two combined (ADHD-C). ADHD-C is the most common and ADHD-HI the least common subtype. Children who meet the criteria for ADHD-I have higher rates of cognitive-academic and lower rates of social-behavioral problems and are also more likely to be girls than are those in the other two subgroups. Some specialists even question whether ADHD-I is a legitimate subtype or a distinctive disorder. The face of ADHD will probably change in subsequent revisions of *DSM-IV*. The frequent changes in diagnostic schemas attest to the continuing uncertainties about the nature and boundaries of ADHD as well as the heterogeneity of people given this label.

2. ADHD: Some Knowns and Unknowns

Of all childhood psychological dysfunctions, ADHD has been studied the most extensively and rigorously. A selection of fundamental findings that have withstood the tests of time and replication follows, laced with some remaining questions.

2.1 Nature and Nurture

Although there are no known biological markers for ADHD, multiple strands of evidence converge on the conclusion that most cases have a genetic origin. ADHD runs in families, and the behavioral characteristics as well as the clinical conditions show strong heritabilities ranging from 60 to 90 percent. Neuroimaging studies reveal subtle reductions in size and activity of several brain regions, including the prefrontal cortex, basal ganglia, and cerebellum. Neurochemical studies suggest a dysregulation of the catecholamines, especially dopamine, and genetic studies are identifying aberrant candidate genes within the dopamine system. Consistent with these findings is the fact that the most effective drugs for treating ADHD, the stimulants methylphenidate (Ritalin) and dextroamphetamine (Dexedrine), alter catecholamine functioning. Other biological systems have also been implicated, however, and inconsistencies across studies abound. Despite the complexities, rapid developments in neurobiological models and methods promise continuing elucidation of the pathophysiologies of ADHD (Castellanos 1999, Solanto 1998, Swanson et al. 1998, Tannock 1998).

The strong biological evidence does not negate the role of psychosocial and environmental contributions. Psychosocial factors influence the severity, course, and outcome of ADHD and may also modulate treatment response. In some cases, psychosocial adversity or insults such as environmental lead or maternal smoking during fetal development may also play an etiological role.

2.2 *Prevalence, Gender, and Culture*

ADHD is a common childhood disorder. The best prevalence estimate is 3–5 percent of school-age children, although rates range from less than 2 percent to over 20 percent across studies, depending on definitions and sampling. During middle childhood, boys outnumber girls at ratios of four or five to one, but the gender gap decreases with increasing age and may even reverse in adulthood. The changes in diagnostic criteria over successive versions of the DSM have been accompanied by increasing prevalence rates, especially in girls. ADHD has been found in all countries and cultures studied to date, with wide variations across geographical regions and diagnostic practices.

2.3 *Heterogeneity and Comorbidity*

People with ADHD are highly heterogeneous, showing markedly different profiles of strengths and deficiencies. Childhood ADHD typically coexists with one or more other disorders, most frequently oppositional defiant or conduct disorder. Anxiety disorders, depression, and learning problems may also accompany ADHD. In fact, a 'pure' diagnosis of ADHD tends to be the exception rather than the rule. Defining the boundaries of ADHD and identifying the subtypes continue to be controversial enterprises. Some specialists assert that there should be additional subtypes of ADHD, whereas others contend that the high rates of comorbidity raise doubts about the very validity of the syndrome.

2.4 *Pervasiveness and Severity*

Problems associated with ADHD surface across settings and affect multiple domains of everyday life. There are difficulties completing schoolwork, responding to directions, interacting harmoniously, adjusting behaviors in accord with changing settings and activities, solving the minor problems that surface during any social exchange, and managing affect, motivation, and self-esteem. The current version of the *DSM* recognizes the extensity of the problems by requiring that difficulties be observed in at least two settings and be sufficiently severe to impair functioning. Important areas for future study include a functional taxonomy of situations and delineation of settings that provoke, and those that diminish, the problems associated with ADHD.

2.5 *Developmental Course and Outcome*

ADHD is a chronic disorder. Although many children improve over the years, at least half continue to have difficulties in everyday activities and relationships, with problems changing in form if not in severity. In the transition to adolescence and adulthood, restlessness may replace hyperactivity, frequent job changes may replace frenetic shifts of activities, and argumentativeness or irritability may replace physical aggression and social disruption. Even when these problems no longer reach diagnostic thresholds, they continue to compromise overall functioning. Compared to peers and siblings, many people diagnosed with ADHD do not progress as far in school, obtain lower-ranked jobs and poorer employee evaluations, are involved in more accidents and receive more traffic citations, have more encounters with law enforcement, and show less engagement in constructive activities. Supportive and mutually gratifying social relationships continue to elude them.

The perennial search for sturdy predictors of long-term adjustment continues to yield disappointing results. Early psychosocial adversity and aggressive behavior portend a rocky developmental course, but specific prognostic indicators have not emerged. In need of systematic study is the role of intervening events in influencing outcomes. Does some of the continuity of ADHD result from avoidable consequences of problem behaviors, for example, responding to social rejection by selecting a deviant partner or peers who in turn reinforce dysfunctional responding (Taylor 1998)?

2.6 *Assessment*

There is no definitive diagnostic test of ADHD, and problem behaviors may not be observable in the doctor's office. The most useful information is obtained from parents and teachers, using standard behavioral ratings. Systematic interviews and classroom observations are also informative but often infeasible. Medical tests cannot confirm ADHD but may be useful in ruling out medical disorders that may mimic ADHD symptoms. Self-report is of limited help during the school-age years but adds an important dimension during adolescence and adulthood.

2.7 *Treatment*

The therapeutic armamentarium for ADHD is extensive, ranging from traditional behavioral, cognitive, and psychosocial therapies to unproven ap-

proaches such as biofeedback, megavitamins, exercise, sensorimotor integration, and low-sugar or additive-free diets. Parenting programs, social skills training, and educational interventions are often helpful. The most effective single treatment continues to be one that has been used since the middle of the twentieth century: stimulant pharmacotherapy (Whalen and Henker 1997). The immediate and often dramatic short-term improvements seen with stimulant medications have been documented repeatedly, and newer medications such as Adderall are dealing with some of the limitations of standard stimulants (e.g., short span of effectiveness). There is still very little evidence of enduring effects, however, either in academic/occupational or social arenas. Research is needed on modes of transforming the welcome short-term gains into long-term improvements.

2.8 The Social Ecology of ADHD and Stimulant Pharmacotherapy

ADHD affects not only individuals but also the surrounding social environment. In the presence of a child with ADHD, peers, parents, and teachers become more negative and controlling. When a child with ADHD improves on medication, other people become more positive and interactions more harmonious. These interpersonal ripple effects have significant intervention implications.

2.9 Adults with ADHD

Recent years have witnessed a surge of interest in adults with ADHD, many of whom are first diagnosed when they take their children for evaluation of ADHD. The diagnosis in adults is especially difficult to substantiate, however. Not enough is known about appropriate measures and cut-off scores, and many of the behavioral symptoms consistent with ADHD are found in other syndromes such as antisocial and substance use disorders. Concerns have been raised that some adults may actively seek a diagnosis of ADHD, perhaps because this diagnosis is more benign than other labels, or perhaps because it yields special considerations (e.g., extra time to complete certification exams; accommodations by employers) or prescriptions for controlled drugs.

2.10 Links Between ADHD and Cigarette Smoking

Mothers who smoke during pregnancy are at elevated risk for having a child who develops ADHD. Adolescents with ADHD are more likely than their peers to smoke cigarettes; they initiate these behaviors at younger ages and, as adults, have more difficulty quitting. These findings, along with indications that nicotine enhances attention and cognitive performance and reduces anger, raise important questions about whether people with ADHD may smoke as a form of self-medication. Also intriguing are converging lines of evidence implicating genes involved in dopamine regulation in both ADHD and cigarette smoking.

3. Continuing Controversies and Future Directions

Ironically, ADHD is one of the most carefully studied childhood disorders yet remains one of the most controversial. Ongoing and at times heated debates have an impact not only on how society deals with ADHD, but also on the research agenda for childhood disorders and treatments more generally. A few of the most salient controversies are:

(a) Is ADHD a socially constructed pathology imposed upon healthy children who are required to function in unsuitable environments?

(b) Are the increasing rates of ADHD diagnoses and stimulant prescriptions cause for serious concern?

(c) Are there distinctive subtypes of ADHD, with differing causes, concomitants, and courses?

(d) Does ADHD take different forms in girls than in boys? Are girls with ADHD understudied and underdiagnosed?

(e) To what extent can behavioral and psychosocial treatments obviate the need for stimulant medications, decrease the required dosage or duration, or enhance long-term outcomes?

(f) Is normalization a feasible treatment goal?

(g) Even if feasible, is normalization desirable? Or, are there contexts in which some of the characteristics of people with ADHD may prove valuable or adaptive?

There is no question that ADHD is a pervasive, perplexing, and persistent syndrome. This family of disorders has served a catalytic function, generating sophisticated procedures and instruments for studying fundamental psychobiological processes, including attentional mechanisms, self-regulation, peer interaction, developmental continuity, and risk and protective factors. Stimulant drugs have been used effectively as pharmacological probes that have yielded increased understanding of brain–behavior relationships in areas that extend far beyond ADHD. Future years should see clearer delineation of alternative developmental pathways that lead to and away from ADHD, increased understanding of how environmental factors modulate biological vulnerabilities, and systematic testing of multimodal treatment packages tailored to specific ADHD subtypes.

C. K. Whalen

Attention-deficit/Hyperactivity Disorder, Neural Basis of

Attention-deficit hyperactivity disorder (ADHD) is a clinical syndrome that was initially described in the early twentieth century in the aftermath of an encephalitis epidemic. Originally called Minimal Brain Disorder and then Minimal Brain Dysfunction, the assumption was that the disorder had a neurological etiology. More recently, the terms Hyperkinetic Syndrome, Attention Deficit Disorder (ADD) and, most recently, Attention-Deficit Hyperactivity Disorder (ADHD), replaced earlier nomenclature to capture the primary descriptive features of the disorders and avoid any commitment about etiology (Biederman 1998, Shaywitz et al. 1997). Detailed descriptions of the disorder, controversies in description and classification, prevalence and developmental course are included in the article on Attention-deficit/hyperactivity disorder (ADHD) by Carol K. Whalen (*Attention-deficit/Hyperactivity Disorder (ADHD)*). The clinical features as a prelude to a discussion of the putative psychological, neurological and biological causes of this disorder and the relationship of these causes to treatment strategies are reviewed.

1. Clinical Features

Attention-deficit/hyperactivity disorder is characterized by three core behavioral symptoms—inattention, hyperactivity, and impulsivity. The behavioral indications of inattention do not correspond to a single psychological construct, but rather combine features of sustained attention, selective attention, and active working memory (Shaywitz et al. 1997). By current definitions, inattention with or without hyperactivity and impulsivity must have persisted for a considerable amount of time—operationally since before age 7 years and at least 6 months in duration—and must characterize the child's behavior in multiple settings, operationally usually home and school (American Psychiatric Association 1994). Finally, the behaviors must lead to clinically significant functional impairments in social, academic, or occupational functioning (American Psychiatric Association 1994).

ADHD typically presents during the preschool or early school aged years. The majority of children with ADHD continue to show core symptoms in adolescence and some retain these characteristics into adulthood (Biederman 1998), although the clinical manifestations may change over time. Co-existing conditions, such as anxiety and conduct disturbance, also persist into adolescence and may predispose the teenager with ADHD to additional problems such as substance abuse and juvenile delinquency. These features—long-standing and pervasive symptoms—are suggestive but not at all conclusive that the disorder has a strong biological basis.

A debate persists as to whether ADHD should be conceptualized as a single disorder or whether inattention and hyperactivity are separate, but frequently co-occurring, deficits. Current definitions represent the middle ground: the name of the disorder includes behaviors from two dimensions and definitions allow for three different variants: ADHD-predominantly inattentive type, ADHD-predominantly hyperactive-impulsive type, and ADHD-

combined type (American Psychiatric Association 1994). The implication of this debate is that combining two overlapping syndromes into a single category may have obscured the underlying etiology. Future research will be important to determine the nosology of the condition.

ADHD frequently co-occurs with other neuropsychiatric and neurobehavioral disorders. Aggressive disorders, including oppositional defiant disorder and conduct disorder, have been reported in 15.6 to 48.3 percent of children with ADHD (Green et al. 1999). Anxiety disorder was found in 24.0 to 35.7 percent of children with ADHD (Green et al. 1999). Depression disorder was found in 14.3 percent and 18.8 percent of children with ADHD (Green et al. 1999). Learning disorders are also common in children with ADHD, though precise estimates are difficult to obtain because of the variations in the definition of learning disorders. ADHD frequently co-occurs with problems of movement and coordination. ADHD has been found to be associated with other medical and neurological disorders, including Tourette syndrome. Thus, any discussion about underlying causes must take into account the high prevalence of co-existing conditions.

2. *Underlying Psychological and Biological Mechanisms*

Some investigators conceptualize ADHD as a disorder of inhibition rather than a problem of perception or information processing (Barkley 1997, Casey et al. 1997). In this model, inattention is explained as a problem with inhibiting automatic, potent, and/or interfering responses. A major appeal of this model is that the deficits of hyperactivity/impulsivity and inattention can be unified through this single construct. Moreover, it links the core symptoms with cognitive and metacognitive deficits associated with the disorder. According to Barkley (1997), behavioral inhibition makes a fundamental contribution to other executive functions, including working memory; self-regulation of affect, motivation and arousal; and reconstitution, or the ability to analyze information and re-synthesize it into novel structures. Executive functions support the inhibition of rapid and automatic responses to immediate environmental inputs, thereby resulting in delays in responding and in control of thinking and action by internal representations rather than environmental stimuli. Together, executive functions allow prioritization, organization, and goal-directed activity. According to this model, some cases of ADHD-predominantly inattentive type may be reconceptualized as a distinct disorder. This other disorder would be characterized by slow information processing and difficulties with selective attention, rather than as impairments of inhibition, goal-directed persistence, and self-regulation. Further research is necessary to determine if the clinical condition should be reformulated into two, possibly correlated disorders.

Executive functions are the neuropsychological functions subserved by the prefrontal cortex. Children with ADHD bear a weak resemblance to patients with deficits of executive function from known causes such as frontal lobe brain injury. However, children with ADHD are typically less impaired than these patients.

A broad range of studies using multiple different methodologies support the concept that ADHD has a neurological basis. Increasing evidence from structural imaging studies comparing children with ADHD to unaffected controls find anatomic differences in prefrontal cortex and connecting networks, including in the basal ganglia, particularly in the right hemisphere and in the corpus callosum (Swanson et al. 1998, Zametkin and Liotta 1998). Functional imaging studies are also suggestive of altered functioning of the fronto-striatal circuits (Casey et al. 1997). These findings fit with the construct of ADHD as a deficit in executive functioning since these pathways originating in the prefrontal cortex are presumed to be involved in inhibition of automatic responses, planning, and organizing. Other anatomical differences have been reported, including differences in posterior regions including the parietal lobe and cerebellum, the hippocampus, and the thalamus (Zametkin and Liotta 1998).

The magnitudes of the neuroanatomical differences in all of these studies are relatively small and the distributions of the sizes of anatomic regions in the different groups overlap. Therefore, these measurements, interesting for the insights they provide regarding the neurological basis of ADHD, are currently not useful for clinical diagnostic purposes. Moreover, the association of size differences and ADHD should not be used to infer that the anatomical differences are the primary cause of the disorder. These structural and functional differences might be a reflection of a history of different neurological function rather than the cause of the disorder.

Genetic causes of ADHD are suspected because of the finding that siblings of affected children and children of affected adults are at increased risks of the disorder. Twin studies also report a higher concordance between monozygotic than dizygotic twins. Evidence is mounting that the genetic causes may relate to either abnormal dopamine receptors or dopamine transporter molecules (Biederman 1998). The role of dopamine in the etiology of ADHD has long been implicated because stimulant medications that increase dopamine concentrations in synaptic spaces have been shown in hundreds of studies to decrease the core features of ADHD. Some family studies implicate a single autosomal dominant gene (Zametkin and Liotta 1998). However, genetic heterogeneity is likely. For example, another genetic mutation in a thyroid receptor gene on chromosome 3 has been associated

with a rare disorder of ADHD plus generalized resistance to the hormone.

ADHD is also associated with a variety of prenatal and acquired medical conditions. Indeed, the disorder was initially described in the early twentieth century to characterize the behavioral problems of patients in the aftermath of encephalitis and similar neurological insults. ADHD is also associated with complications of pregnancy, labor, delivery, or infancy and also with maternal smoking or alcohol use *in utero* (Milberger et al. 1997). These data suggest that many biological conditions may give rise to ADHD, but that despite differences in etiology, all share a similar phenotypic expression. Whether all of the predisposing conditions impact the same brain regions, circuits, or neurotransmitters as those implicated in cases of familial ADHD, has yet to be determined.

It is intriguing to consider how the high prevalence of co-existing conditions with ADHD may further elucidate the underlying mechanisms. Neuropsychiatric disorders such as anxiety, depression, and learning disabilities are also thought to have a neurological basis. It is not at all clear whether co-existing conditions are based on the same underlying neural mechanisms, different but correlated disorders or secondary behavioral problems related to life difficulties with ADHD.

A dramatically different but not entirely inconsistent view of the causes of ADHD considers whether the core traits of the condition could be conceptualized as adaptive responses to certain environmental conditions over the evolution of the species or the development of the individual. The evolutionary viewpoint (Jensen et al. 1997) rests on the assumption that a disorder this prevalent in the population would not be maintained through natural selection unless it conferred some relative advantage to at least some affected individuals. High motor activity, rapid shifts of attention, and quick response might have been desirable traits in some harsh and dangerous ancestral environments. If so, the genetic basis of this response style may have been the object of natural selection, thus sustaining the high prevalence of the condition in the population. However, current conditions in the industrialized world, which emphasize universal education, literacy, and logical sequential problem solving, render these same traits as maladaptive.

The analogous argument on the developmental timetable begins with the assumption that certain conditions in the early life of the child, including the prenatal environment, infancy, and toddler years, might favor the development of a neural system that makes rapid shifts of attention and quick responses. Such environments might include excessive television watching, limited opportunities for sustained conversation, or adverse conditions in rearing, such as inconsistent and unpredictable social contact (Biederman et al. 1998). After years of such exposure, a neural system of rapid attention shifting may dominate neural functioning, even when the environment calls for different characteristics such as sustained attention and careful planning. These personal traits may interact with cultural norms and expectations, which could serve to motivate change or to encourage persistence. In such cases, the neural circuits predisposing to this condition may be present even though genetic causes might not be. This area is in need of vigorous research.

3. *Treatments*

Medications classified as stimulants, including methylphenidate hydrochloride and dextroamphetamine sulphate, are the most widely used forms of medical management for ADHD. These medications have been shown to have dramatic short-term ameliorative effects on the core systems of ADHD. A 14-month multi-center study found that about 67 percent of children treated with stimulant medications showed behavioral ratings on medication within the normal range (The MTA Cooperative Group 1999). The stimulant medications also improve some of the coexisting conditions such as anxiety and oppositional behavior.

Stimulant medications work by increasing the levels of neurotransmitters (dopamine, norepinephrine, and serotonin) at the presynaptic cleft. Thus, the utility of this treatment supports the concept of ADHD as a neurological disorder primarily in catecholamine pathways. The effects of stimulant medications on cognition, social and academic functioning and other features of the co-existing conditions remain controversial.

The other mainstay of treatment is behavior management. The goal of behavior management is to create specialized environments that provide the child with ADHD with appropriate opportunities to use motor activity and rapid attention shifts, and that offer clear contingencies for sustained on-task effort, self-paced learning, and self-monitoring. In this tailored environment, the child receives frequent feedback and reinforcement, both positive and negative, contingent on his or her behavior. Treatments are geared toward parents and teachers who are coached on how to provide frequent, consistent, appropriate, and motivating feedback to the children about desirable and unacceptable behavior. In a 14-month multicenter study, medication alone and combinations of medical and behavior management did not differ significantly in the treatment of core symptoms of ADHD, suggesting that the behavior management did not add substantially to the improvements associated with medication. However, in the treatment of oppositional/aggressive symptoms, internalizing symptoms such as anxiety, teacher-rated social skills, parent-child relations, and reading achievement, a combination of medication and behavior management

proved superior to intensive behavioral treatment alone while medication management alone was not (The MTA Cooperative Group 1999). Most clinicians recommend a combination of treatments. The use of behavior management in treatment may not have a direct effect on the underlying biological basis of ADHD. It is possible that the relearning that a child experiences through behavior management allows for modification of underlying neural networks. This topic is an important one for future research.

4. Conclusion

ADHD is a complex and prevalent neurobehavioral disorder that presents in childhood and may persist into adulthood. The condition frequently co-exists with other behavioral and cognitive disorders. Evidence of a biological basis for the disorder is mounting through the use of neural imaging studies and genetic analysis. Conceptualizing the disorder as a mismatch of the child's underlying personal characteristics and the environment does not necessarily negate the possibility of a biological basis for ADHD. Management of the disorder includes stimulant medications that operate on neural pathways putatively involved in the etiology of the disorder. Behavior management may operate at the psychosocial level but have an influence on neurological organization.

Attention: Models

'Attention' is a general term for selectivity in perception. The selectivity implies that at any instant a perceiving organism focuses on certain aspects of the stimulus situation to the exclusion of other aspects. In this article, theoretical models of attention are reviewed and their development is described.

1. Theoretical Beginnings

The first modern theory of attention was the *filter* theory of Broadbent (1958) (see Figure 1). In this theory, information flows from the senses through many parallel input channels into a short-term mem-

Figure 1
Flow diagram illustrating the filter theory of Broadbent (1958)

ory store. The short-term store can hold the information for a period of the order of seconds. Later in the system there is a *limited-capacity channel*, whose capacity for transmitting information is much smaller than the total capacity of the parallel input channels. Between the short-term memory and the limited-capacity channel is a selective filter which acts as an all-or-none switch that selects information from just one of the parallel input channels at a time.

Broadbent (1958) defined an input channel as a class of sensory events that share a simple physical feature (e.g., a position in auditory space). Except for analysis of such features, stimuli on unattended channels should not be perceived. This conjecture accounted for results of studies in the early 1950s by E. C. Cherry on the ability to attend to one speaker in the presence of others (the *cocktail party problem*). Cherry asked his subjects to repeat a prose message while they heard it, rather than waiting until it finished. When the message to be repeated (*shadowed*) was presented to one ear while a message to be ignored was presented to the other ear (*dichotic* presentation), subjects typically were unable to recall any words from the unattended message.

Later studies by Moray (1969) and others showed that subjectively important words (e.g., the subject's own name) tended to be recognized even if presented on the nonshadowed channel. To accommodate such findings, A. M. Treisman developed a variation of filter theory in which the filter operates in a graded rather than an all-or-none fashion. In Treisman's *attenuation* theory, unattended messages are weakened rather than blocked from further analyses. Both selected and attenuated messages are transmitted to a pattern recognition system with word recognition units. Because thresholds of recognition units for important words are lowered, important words tend to be recognized even if appearing in attenuated messages.

In the filter theories of Broadbent and Treisman, attentional selection occurs at an earlier stage of processing than pattern recognition. Such theories are called *early-selection* theories. In *late-selection* theories, attentional selection occurs later in processing than pattern recognition. The first late-selection theory was outlined by J. A. Deutsch and D. Deutsch in 1963. Deutsch and Deutsch argued that the early filtering mechanism in Treisman's theory was redundant. They proposed that attended and unattended messages receive the same amount of analysis by the pattern recognition system. However, after a stimulus has been recognized, the importance of the stimulus is retrieved and the stimulus with the greatest importance is selected for further processing, including conscious awareness.

The theories of Broadbent, Treisman, and Deutsch and Deutsch set the stage for the development of more specific, quantitative models of attention. Most of these models were based on experimental findings on visual processing: data on our ability to *divide* attention between multiple, simultaneous targets and data on our ability to *focus* attention on targets rather than distractors.

2. Serial Models

In serial models of attention, only one stimulus is attended at a time. This section examines the development from simple serial models to selective serial models.

2.1 Simple Serial Models

In visual *whole-report* experiments by G. Sperling in the early 1960s, subjects were instructed to report as many letters as possible from a briefly exposed array of unrelated letters followed by a pattern mask. The number of correctly reported letters depended on the stimulus-onset asynchrony (SOA) between the letter array and the mask. Corrected for guessing, the score appeared to be zero when the SOA was below a certain threshold. As the SOA exceeded the threshold, the mean score initially increased at a high rate of about one letter per 10–15 ms. The mean score leveled off as it approached a value of about four letters or the number of letters in the stimulus, whichever was smaller.

Sperling proposed a simple serial model to account for the initial strong and approximately linear increase in mean score as SOA exceeded threshold. By this model, the subject encodes one letter at a time, requiring 10–15 ms to encode a letter. The serial encoding is interrupted when the stimulus is terminated by the mask or when the number of encoded letters reaches the immediate memory span of the subject.

Simple serial models for *visual search* were developed in the 1960s by W. K. Estes, S. Sternberg, and others. In most experiments on visual search, the subject is instructed to indicate 'as quickly as possible' whether or not a certain type of target is present in a display. Positive (target present) and negative (target absent) reaction times are analyzed as functions of the number of items in the display (*display set size*).

By a simple serial model, items are scanned one by one. As each item is scanned, it is classified as a target or as a distractor. A negative response is initiated if and when all items have been scanned and classified as distractors. Thus, the number of items processed before a negative response is initiated equals the display set size, N. Accordingly, the rate of increase in mean negative reaction time as a function of display set size equals the mean time taken to process one item, Δt.

In a *self-terminating* serial search process, a positive response is initiated as soon as a target is found. As the order in which items are scanned is independent of

Figure 2
Positive and negative mean reaction times as functions of display set size in visual search for a T in one of four possible orientations among similarly rotated Ls (The observed reaction times were read from Wolfe 1994, Figure 1b. The slopes of the fitted least squares lines are 22 ms/item and 43 ms/item, respectively)

their status as targets vs. distractors, the number of items processed before a positive response is initiated varies randomly between 1 and N and averages $(1+N)/2$. Thus, the rate of increase in mean positive reaction time as a function of display set size equals one half of the mean time taken to process one time, $\Delta t/2$. A representative pair of search reaction time functions with a positive-to-negative slope ratio of about 1:2 is illustrated in Fig. 2.

A. M. Treisman has introduced a distinction between feature and conjunction search. In *feature* search, the target possesses a simple physical feature (e.g., a particular color, shape, or size) not shared by any of the distractors. For example, the target can be a red T among black Ts. In *conjunction search*, the target differs from the distractors by possessing a predesignated conjunction of physical features (e.g., both a particular color and a particular shape), but the target is not unique in any of the component features of the conjunction (i.e., in color or in shape). For example, the target can be a red T among black Ts and red Xs.

Many experiments on conjunction search have yielded positive and negative mean reaction times that are approximately linear functions of display set size with substantial slopes and positive-to-negative slope ratios of about 1:2. This pattern conforms to predictions from simple self-terminating serial models, and Treisman and co-workers have concluded that conjunction search is performed by scanning items one at a time. Experiments on feature search with low target-distractor discriminability have yielded a similar pattern of results.

2.2 Selective Serial Models

In selective serial models, items in the stimulus display are attended one at a time, but the sequential order in which items are attended depends on their status as targets vs. distractors: When a target and a distractor compete for attention, the target is more likely to win.

The first selective serial model of visual search was published by J. E. Hoffman in 1978. It was motivated by findings from C. W. Eriksen's laboratory on the time taken to shift attention in response to a visual cue. The findings cast doubt on the notion that attention can be shifted from item to item at the high rates presumed in simple (nonselective) serial models of processing.

In Hoffman's model, visual search is a two-stage process in which a parallel evaluation of the entire stimulus display guides a slow serial processor. The parallel evaluation is preattentive and quick, but error prone. For each item in the display, the outcome is an overall measure of the similarity between this item and the prespecified targets. Items are transferred one by one to the second stage of processing. The serial transfer mechanism is slow (about one item per 100 ms), but it makes search efficient by transferring items in order of decreasing overall similarity to the prespecified targets. Thus, if there is a target in the display, the target is likely to be among the first items that are transferred to the second stage of processing.

J. M. Wolfe, K. R. Cave, and S. L. Franzel have proposed a selective serial model, which they called *Guided Search* (cf. Wolfe 1994). The model combines elements of the two-stage model of Hoffman with elements of the *feature integration* theory of Treisman and co-workers (cf. Treisman 1988). As in feature integration theory, simple stimulus features such as color, size, and orientation are registered automatically, without attention, and in parallel across the visual field. Registration of objects (items defined by conjunctions of features) requires a further stage of processing at which attention is directed serially to each object. As in Hoffman's model, the outcome of the first, parallel stage of processing guides the serial processing at the second stage. The guidance works as follows.

For each feature dimension (e.g., color, size, or orientation), the parallel stage generates an array of activation values (attention values). The array forms a

map of the visual field. Each activation value is a sum of a bottom-up and a top-down component. For a particular location within a map for a given feature dimension, the bottom-up component is a measure of differences between the value of the feature at that location and values of the same feature at other locations. The top-down component for a feature dimension at a particular location is a measure of the difference between the value of the feature at that location and the target value for the feature dimension. After activations have been calculated in separate maps for each feature dimension, they are summed across feature dimensions to produce a single overall activation map. In simulations, a certain level of gaussian noise is also added at each location. The final overall activation values represent the evaluation given by the parallel stage of how likely the stimulus at each location is to be the target.

The serial stage processes the items one by one in order of decreasing activation in the overall activation map. Each item it processes gets classified as a target or as a distractor. The serial processing continues until a target is found or until all items with activations above a certain value have been processed.

The guided search model accounts for many findings from experiments on visual search. It was motivated, in particular, by demonstrations of fast conjunction search. Some demonstrations of fast conjunction search are accommodated by assuming that for some feature dimensions, top-down control is very effective. Other demonstrations are accommodated by assuming that in some subjects, the level of gaussian noise is very low.

3. *Parallel Models*

In parallel models of attention, several stimuli can be attended at the same time. This section examines the development from simple parallel (independent-channels) models to limited-capacity parallel models and race-based models of selection.

3.1 *Independent Channels Model*

The first detailed parallel model of visual processing of multi-item displays was the Independent Channels model developed by C. W. Eriksen and co-workers in the 1960s. It was based on the assumption that display items presented to separated foveal areas are processed in parallel and independently up to and including the stage of pattern recognition. The assumption implies that the way in which a display item is processed is independent of random variations in the way in which other display items are processed. It also implies that the way in which an item is processed is independent of display set size.

The notion of independent channels (*unlimited-capacity parallel processing*) is used mainly to account for cases in which visual search is highly efficient (small effects of display set size). This includes cases of feature search with high target-distractor discriminability. In a theory proposed by R. M. Shiffrin and W. Schneider in 1977, it also includes cases of search for more complex targets such as particular alphanumeric characters when subjects have been trained consistently in detecting those particular targets.

In the theory of Shiffrin and Schneider, slow, serial, *controlled search* for particular items can develop into fast, parallel *automatic detection* of the same items. Automatic detection occurs without subject control and without stressing the capacity limitations of the system. The development of automatic detection presupposes that the mapping of stimuli to responses is consistent rather than varied over trials.

3.2 *Evidence from Automatic Interference*

Empirical support for the assumption of parallel processing has come from demonstrations by Eriksen and others of *Stroop-like interference* in processing of multi-item displays. In the original task developed by J. R. Stroop in the 1930s, subjects are asked to name the color of the ink used to print a word. The *Stroop effect* denotes the fact that the task is more difficult when the word itself is the name of a different color (e.g., *red* printed in blue) than when the word does not refer to a color or refers to the color shown by the ink (*blue* printed in blue).

The original Stroop task concerns selective attention to a particular feature of an item (*featural attention*). In the *flankers task* of Eriksen, subjects are asked to focus attention on a target presented in a known spatial location (*spatial attention*). Usually, the target is a letter presented at fixation, and the subject is required to make a speeded binary classification of the letter (e.g., move a lever in one direction if the letter is a T or a K but in the opposite direction if the letter is an S or a C). The target is flanked by letters that should be ignored. However, the task is more difficult when the flankers are *response-incompatible* with the target (Ss or Cs flanking a T) than when the flankers are *neutral* (e.g., Xs flanking a T) or *response-compatible* with the target (Ts or Ks flanking a T). Eriksen suggested that the flankers are processed in parallel with the target up to and including the stage of pattern recognition.

3.3 *Limited-capacity Models*

The linear relations between mean reaction time and display set size predicted by simple serial models are hard to explain by parallel models with independent

channels (unlimited-capacity parallel models). However, the linear relations can be explained by parallel models with *limited processing capacity*. In 1969, the following example was published independently by J. T. Townsend and R. C. Atkinson, and his co-workers.

Consider a display of N items that are processed in parallel. Let the processing speed for an item (technically, the 'hazard function' for the processing time of the item; cf. Townsend and Ashby 1983) equal the amount of processing capacity devoted to that item, and suppose the total processing capacity spread across items in the display is a constant C. Then the time taken to complete processing of the first item is exponentially distributed with rate parameter C. Suppose that when the first completion occurs, the processing capacity is redistributed among the remaining N–1 items. Then the time from the first to the second completion is exponentially distributed with the same rate parameter C. Let the process repeat until all N items have been completed. If so, then the mean time taken to complete processing of the N items increases linearly with display set size N.

In 1977, M. L. Shaw and P. Shaw proposed a model for *Optimal Allocation of Cognitive Resources to Spatial Locations* that showed how limited-capacity models could be extended to situations in which the probability that a target occurs at a given location varies across display locations. In such situations, capacity was assumed to be allocated and reallocated among display items so that performance is optimized.

In the model of Shaw and Shaw, attention can be split among noncontiguous locations in the visual field. Processing capacity can be allocated to several separated locations at the same time. C. W. Eriksen and co-workers have proposed an alternative conception, a *zoom lens* model of the visual attentional field. In this conception, the attentional field can vary in size from an area subtending less than 1° of visual angle to the full size of the visual field. Because total processing capacity is limited, the amount of processing capacity allocated to a given attended location decreases as the size of the attentional field increases. However, the attentional field cannot to be split among noncontiguous locations. Direct tests of this hypothesis have been attempted, but the issue is still open.

3.4 Race Models of Selection

In race models of selection from multi-item displays, display items are processed in parallel and attentional selection is made of those items that first finish processing (the winners of the race). Thus, selection of targets rather than distractors is based on processing of targets being faster than processing of distractors.

In 1988, H. Shibuya and C. Bundesen proposed a fixed-capacity independent race model (*FIRM*). The model describes the processing of a stimulus display as follows. First, an *attentional weight* is computed for each item in the display. The weight is a measure of the strength of the sensory evidence that the item is a target. Then the available processing capacity (a total amount of C items/s) is distributed across the items in proportion to their weights. The amount of processing capacity that is allocated to an item determines how fast the item can be encoded into visual short-term memory (VSTM). Finally, the encoding race between the items takes place. The time taken to encode an item is assumed to be exponentially distributed with a rate parameter equal to the amount of processing capacity that is allocated to the item. The items that are selected (i.e., stored in VSTM) are those items whose encoding processes complete before the stimulus presentation terminates and before VSTM has been filled up.

Detailed tests of FIRM have been made in *partial-report* experiments in which subjects report as many targets as possible from a briefly exposed display showing a mixture of targets (e.g., red letters) and distractors (e.g., black letters). FIRM has provided accurate accounts of effects of selection criterion, exposure duration, and numbers of targets and distractors in the display (see Fig. 3).

3.5 Theory of Visual Attention (*TVA*)

The theory of visual attention (*TVA*) proposed by Bundesen (1990) is a generalization of FIRM. In TVA, both visual recognition and selection of items in the visual field consist in making *perceptual categorizations* (i.e., encoding categorizations into VSTM). When one makes the perceptual categorization that a given item belongs to a certain category, the item is said (a) to be selected, and (b) to be recognized as a member of the category.

Recognition and selection depend on the outcome of a biased race between possible perceptual categorizations. The rate at which a possible categorization ('item x belongs to category i') is processed increases with (a) the strength of the sensory evidence that supports the categorization, (b) the subject's bias for assigning objects to category i, and (c) the attentional weight of item x. When a possible categorization completes processing, the categorization enters VSTM if memory space is available there. The span of VSTM is limited to about four items. Competition between mutually incompatible categorizations of the same item are resolved in favor of the first-completing categorization.

TVA accounts for many findings on single-stimulus recognition, whole report, partial report, search, and detection. The theory has been extended by G. D. Logan to encompass aspects of perception and memory as well as attention.

Figure 3
Relative frequency of scores of *j* or more (correctly reported targets) as a function of exposure duration with *j*, number of targets *T*, and number of distractors *D* as parameters in partial report of digits among letters (Parameters *T* and *D* vary between panels. Parameter *j* is l (circles), 2 (downward pointing triangles), 3 (squares), 4 (diamonds), or 5 (upward pointing triangle). Smooth curves represent a theoretical fit to the data by the fixed-capacity independent race model (FIRM). For clarity, observed frequencies less than 0.02 were omitted from the figure. 4. *Neural Network Models*

Formal models like TVA are highly abstract. Neural network modeling is an attempt to theorize at a level that is closer to neurobiology. In neural network models, information processing consists in a flow of activation through a network of neuronlike units that are linked together by facilitatory and inhibitory connections.

A simple way of implementing attentional selection in a neural network is by arranging the connections so that (a) units representing mutually compatible categorizations of the same item facilitate each other but (b) units representing incompatible categorizations in-

hibit each other, and (c) units representing categorizations of different items also inhibit each other. Search for a red target, for example, can then be done by preactivating units representing redness. If a red target is present, the preactivation will directly facilitate the correct categorization of the target with respect to color. Indirectly the preactivation will facilitate categorizations of the target with respect to other properties than color but inhibit categorizations of any other items than the target (*integrated competition*; Duncan 1996).

Many neural network models of attention have appeared since the mid-1980s. Good examples are the model for selective attention and pattern recognition by K. Fukushima, the multiple object recognition and attentional selection model (MORSEL) of Mozer (1991), the selective attention model (SLAM) of R. H. Phaf, A. H. C. van der Heijden, and P. T. W. Hudson, and the search via recursive rejection model (SERR) of G. W. Humphreys and H. J. Müller.

5. *Conclusion*

Current models of attention have sprung from the theoretical framework developed by Broadbent in the 1950s. The first detailed models of visual attention were the serial scanning models of Sperling, Estes, and others and the independent channels model developed by Eriksen and co-workers. Early tests of the models brought important discoveries but no simple resolution of the serial vs. parallel processing issue. Attempts to integrate the empirical findings led to selective serial models and to parallel models with differential attentional weighting, including race models of selection. No extant model has accounted for the full range of empirical findings but substantial progress has been made.

Attention: Multiple Resources

Among the diverse conceptions of attention, a major one considers that selective attention is a consequence of the limited-capacity resources of our mental proces-

ses. Attention must be able to restrict the processing of the stream of information available from sensory and memory sources. Several questions have arisen over 50 years of research, and this article will present some related to the organization of the resources, and to the mechanisms involved when attention is focused on a piece of information.

1. Organization of Processing Resources

1.1 Limits of Processing Resources

Everyday life abounds in examples of situations in which two tasks are performed simultaneously (e.g., walking while talking). However, examples also abound of inefficient time-sharing, specifically when tasks are complex. Driving a car and talking with passengers can be relatively easy, but it becomes difficult or impossible if the demands of the driving task increase, or if the conversation requires reflection and arguments. Tasks are assumed to demand processing resources, and these resources are limited in their availability.

Many experiments have been developed to demonstrate, evaluate, and quantify the limits of mental or processing resources. In the dual-task method, subjects are required to perform two concurrent tasks simultaneously (see *Dual Task Performance*). Performance is degraded if attentional demands brought about by the tasks are high. For example, writing down a list of words heard through headphones while reading a text for meaning is extremely difficult. Subjects can be trained to carry out these two tasks simultaneously, but writing, in this case, becomes quite automatic: When subjects are asked after the experiment if there was a dominant semantic category in the list of words they had to write, results show that they did not attend to the meaning of the written words.

Other paradigms are used to explore how resources are shared when several stimuli are processed. The RSVP (rapid serial visual presentation) method consists of the fast presentation of several successive stimuli. This method shows that the identification of a first visual target disrupts the detection of a second target when the delay between both targets is too short (below 300 ms). The second target is merely not seen (a phenomenon known as the 'attentional blink') although it would have been detected if no task occurred on the first target. The identification (and/or the access to working memory) of the first target requires processing resources, which are therefore not available for the detection of another stimulus. These results are interpreted as a difficulty in sharing resources between the processing of both targets, or as the consequence of the time needed to shift attention from processing one target to processing the other.

Another type of experiment, the search task, demonstrates that several stimuli might not be processed simultaneously. In a typical search task, only one predefined target has to be detected among distracters (e.g., the target T among several Ls). Search time increases proportionally with the number of distracters (about 60 ms per additional distracter). Resources cannot easily be allocated to several stimuli in a visual display, and the search time is related to the size of the display.

1.2 Level of Selection

Because several stimuli cannot be processed simultaneously, or several concurrent tasks cannot be performed efficiently, selection has to occur. Selection allows the allocation of more processing resources to a privileged target or action. The act of attending selectively to a piece of information gives priority to more elaborate operations. The information processing flow could be considered as beginning with some parallel system followed by a serial system in which only attended information enters. The determination of the location of the bottleneck between both systems has been debated for a long time. At which level in the information processing flow is the selection performed, or which level has limited resources?

External information must undergo several successive and more or less discrete operations before an appropriate response is performed. The initial operations correspond to sensory recording: after the transduction, the different primary features are computed (e.g., color, texture, orientation, movement, etc.). A second series of operations ends with the perception of an object or event, the access to a semantic code. Then, according to the individual's goal, a strategy for action takes place (immediate motor response of different kinds, naming, access to working memory when a delayed response is required, etc.). Of course, things are more complicated, but two broad theories can be described concerning the selection level. According to the early theory of attention, the resources allowing access to the semantics are limited. In other words, only stimuli located in the focus of attention can be identified. According to the late theory of attention, the limited resources are located at the stage when a decision of response to a piece of information is taken. All the stimuli in a display can access the semantic code (provided that each stimulus is in an area of sufficient acuity), and the selection role is to choose which stimulus will provoke the response and/or which response will be performed.

In the auditory modality, the dichotic listening method (different messages delivered in each ear) has shown that, when a subject is attending to a continuous message in one ear, the identification of occasional messages in the 'ignored' ear is very poor, but not completely eliminated. This type of result is known as

the 'cocktail party' effect. At a cocktail party, people usually do not hear what is being said nearby when they are absorbed in a conversation. We are able to select a channel and filter out other channels, as predicted by the early theory. However, it might happen that a person would react, for example by turning the head, if a someone close beside them spoke their name. Consequently, an unattended piece of information can access the semantic code, as predicted by the late theory (the person's own name was identified). However, the defenders of the early theory have developed counter-arguments. First, attentional selection would be necessary to identify a piece of information unless this information was extremely familiar to the subject. Second, in the 'cocktail party' effect, as in several experiments using dichotic listening, subjects could sometimes shift their attention rapidly from the attended channel towards another channel of information. At the time of writing, the debate is still continuing, but most authors seem to agree that attentional selection can occur early *and* late in the processing of information, depending of the task, the familiarity of the information, etc.

1.3 Multiple Resources

A question which has aroused the interest of researchers working in the domain of attention concerns the unicity of the processing resources. The possibility for attention to occur at two (or more) different levels in the information flow, early and late, would indicate that the 'pool' of the mental resources may not be unique, but be composed of several 'reservoirs.' Other researches have also provided much evidence against the unicity of resources, independently of the early/late debate. For example, it is rather difficult to perform a linguistic task (repeating a text, counting in reverse order, etc.) and a spatial task (detect a target on a video screen, etc.) simultaneously. And it is still more difficult to perform two linguistic tasks simultaneously (listening and reading), or two spatial tasks, especially if these tasks concern information presented in the same modality.

Neuropsychology—the study of the performance of patients suffering from cerebral lesions—seems also in favor of such a modular organization. Lesions in different parts of the brain yield different deficits. Usually, lesions in the left hemisphere produce language disturbances, while lesions in the right hemisphere produce difficulties in visuo-spatial functions. Also, different types of language and perceptual deficits may occur, according to the exact location of the lesion. Many years ago, John Hughlings Jackson observed that cerebral lesions do not usually disrupt functioning completely, but only the most complex and propositional aspects of the function: more automatic behavior may be unimpaired. Alajouanine described the case of an anomic patient who, while not remembering the name of her daughter when asked, turned the head toward her and said 'See, my poor Jacqueline, I cannot remember even your own name.' Prosopagnosic patients cannot identify people's faces, but show different electrodermal response to familiar and unfamiliar faces.

Hemineglect patients tend to ignore the half of the visual space opposite to their lesion, but can sometimes identify information on this side when it is very familiar. Amnesic patients can demonstrate implicit learning. There are many other examples of patients who present some residual ability in their impaired function, showing that they can still process information as long as they do not need to attend to it specifically. The fact that different functional operations are linked to specific areas favors a multiple resource organization of the brain (however, no function is linked to a single area of the brain, and networks of connected areas are considered as the basis for any behavior). Neurophysiological studies (electrical cell recording, functional metabolism) also tend to show that attention is expressed 'everywhere' in the brain, and that each cortical area can have an automatic or an attentional state according to the task.

Processing resources are multiple and hierarchically organized. For example, auditory and visual resources are separated to some degree, and each of these resources can be shared by two tasks within the modality. There also exist more general resources such as verbal and spatial perception, each one able to be shared between modalities. Above all, resources can be allocated to any activity, or stage of processing, by a higher level executive program, a central processor, itself being divided into perceptual and response components. Whatever the exact organization of the hierarchy is, the role of the central processor is the command of behavior, the elaboration of strategies in allocating resources. In neuropsychology, patients suffering from frontal lesion usually have no difficulty in performing simple tasks, but are impaired considerably in complex tasks in which strategies have to be elaborated. For example, although they classify cards according to the features of the drawings on the cards quite well (i.e., color, form, number of shapes), they have great difficulty when asked to change the classification (i.e., shifting from color to form). The frontal lobe is crucial to the decision process of organizing attentional strategies.

2. Mechanisms of Attention

Research in the attention domain is not restricted to the overall organization of processing resources. Several lines of research have been developed in order to explore the mechanisms of attention (or allocation of

resources). Here, only a few examples of fundamental questions will be presented regarding (a) selection and its role in information processing, (b) preparatory attention and its components, and (c) the opposition between activation and inhibition.

2.1 Integration and Selective Attention

Selective attention enables a piece of information access to a more elaborated level of processing, in order to achieve a more accurate perceptual judgment, action, etc. In a search task, attention seems to be required when the discrimination between the target and the distracters is complex. A vertical bar can be detected easily among horizontal bars: The target will 'pop out.' Things are more complicated in the example cited above of a T among Ls, however, presumably because selection is necessary to combine or integrate specific primary features (vertical and horizontal bars), each of which being present in the distracter as well as the target. The need for a precise localization of each primary feature could explain why selection is necessary (see the work of Treisman and colleagues). Selection could be required to process attributes of objects and events as unified entities, which are the basis for the representation of knowledge in the mind.

2.2 Preparatory Attention

Another role of attention is to prepare for the processing of a stimulus or an action prior to the time when that stimulus or action is expected to occur. Attention can be maintained over a variable period of time in which some 'preprocessing' occurs, reducing the amount of processing needed when the stimulus itself appears, thus resulting in a more accurate and faster response.

A simple, noninformative signal announcing the stimulus onset can reduce the response time if the delay between the signal and the target stimulus is about 500 ms. Other types of preparation effect are even faster. Most studies in preparatory attention have used informative signals (usually called primes or cues), that is, signals sharing codes with the target. In spatial cueing experiments, a target stimulus (for example, a simple asterisk the subject has to detect by pressing a key, a letter to identify, etc.) is preceded by a spatial cue. The cue can be an arrow in the location where the subject's gaze is fixated, pointing towards one of the possible locations of the target in peripheral vision. It could also be a small signal at one of the possible locations of the target. Responses are faster and more accurate when the location indicated by the cue is congruent with the target location (valid condition) compared to when the indication is wrong (invalid condition), because preparatory attention allows the allocation of resources at the precise location of the following target. This effect occurs even if subjects do not move their eyes towards the location indicated by the cue. Preparatory attention in the visual space is usually followed by a saccade, placing the information on the fovea (area of best acuity), but both mechanisms can be dissociated, and one can attend to a location of the space without moving the eyes toward this location (covert attention).

The spatial cueing paradigm helps to dissociate between exogenous and endogenous attention. Typically, in cueing experiments, valid trials are frequent, and invalid trials rare, so the subjects' strategy is to use the information given by the cue. Endogenous attention, an active process the subject develops in order to orient voluntarily toward a location, requires a delay of 300 ms or more between the cue and the target. However, even if the subject does not elaborate strategies—for example, when the proportion of valid and invalid trials is 50/50, an effect of a peripheral spatial cue can occur with delays of 60 ms to 150 ms between the cue and the target. The cue attracts the exogenous attention automatically toward its location.

2.3 Inhibition/Activation

Another fundamental question concerns the respective contribution of inhibition and activation in the attentional mechanisms. When attention is directed toward a target stimulus in a visual display, a possibility is that inhibition would first attenuate the impact of distracters, followed by the activation of the target (although other models exist). The consequence is that the selected target stimulus can access a higher level of processing (enhancement) than nonselected stimuli.

Several components have been depicted in the cueing procedure by Posner and colleagues. In a nonvalid condition, subjects would first have to 'disengage' from the cue (inhibition) before moving and 'engaging' attention on the location of the target (activation). Behaviorally, the demonstration of inhibition or activation is not so easy, mainly because it must rest on the comparison between an attentional condition and a neutral condition, and neutral conditions are difficult to define. Nevertheless, this description of the cueing effect had the immense advantage of beginning, in the 1980s, a new era in characterizing performance of patients, as well as in understanding the cerebral mechanisms of attention. Patients who present with the syndrome of hemineglect (ignoring the part of the space controlateral to their lesion, usually in the parietal lobe) almost always have a deficit in disengaging spatial attention from the 'good' hemispace (ipsilateral to the lesion), without showing a systematic deficit in engaging attention toward the 'neglected' hemispace. According to

neuropsychological and neurophysiological data, disengagement and engagement seem related to different parts of the brain.

Finally, another important attentional operation is the 'inhibition of return.' Using the spatial cueing paradigm, it has been demonstrated that a location in the space is inhibited 500 ms or more after being activated by orienting attention to it. This operation has been generalized to other contexts and could represent some useful and adaptive device (imagine the case of an animal attending exclusively to eating, while being stalked by a predator).

3. Conclusion

Research in attention has led to the description of a hierarchical organization of processing resources allocated to information, with a central processor elaborating attentional strategies. Many experiments have been conducted to describe the operations of attention, and models developed in cognitive psychology are also helpful in explaining brain mechanisms, and in understanding the performance of patients suffering from brain lesions.

Nonetheless, the 'resource' approach has been criticized because it does not resume the concept of attention. In other words, the management of the processing resources in the brain may not be the only way for attentional operations to provide adaptive advantages within a complex environment. Attention can also be viewed as the cause of the coherence as well as the flexibility of an individual's behavior. Coherent and flexible behavior supposes the integration, comparison, and evaluation between an intention, determined by a person's motivated goals (represented in our working memory), and the actual modifications occurring in the environment. By inhibiting an immediate response to the environment, or by activating a piece of information to a higher level of processing, attention provides the time necessary for reflection. Consequently, nonroutinized strategies can be activated when someone faces a challenging problem. Also, sustaining attention may represent the condition for pleasurable activities like tasting food, listening to music, and so forth.

Attention, Neural Basis of

The flow of stimuli that is constantly available to our sense organs is far greater than our brains can handle. Studies in cognitive psychology have clearly established that our perceptual system is severely limited in its capacity to fully process and identify more than one object at a time. Moreover, our response system is limited inherently in its ability to perform concurrent actions on a large number of objects: we can only gaze at one object at a time, and reach at most to two objects. To cope with the flood of sensory inputs and achieve coordinated, purposeful behavior a powerful mechanism is available to the brain: selective attention. This term defines the mental ability to select the most important aspects of the sensory scene and filter out those that are irrelevant or potentially interfering. Perceptual experience of the sensory world critically depends on attention. Selected objects can enter awareness, guide our actions, and undergo memory storage, whereas ignored objects are often left at the margins of our consciousness.

For several decades, selective attention has been studied at the psychological level. More recently, however, behavioral research has been strengthened by a variety of neuroscience approaches as diverse as single-neuron recordings in monkeys, functional neuroimaging and event-related potentials in humans, and lesion studies in neurological patients. This interdisciplinary and convergent effort is beginning to reveal how the brain activity is regulated through attention. This article will focus mainly on selective visual attention and review some recent advances in understanding the neural underpinnings and mechanisms of this cognitive function.

1. Multiple Visual Areas

Contemporary neuroscience has revealed that the neural representations of visual objects are highly distributed. Visual inputs activate almost simultaneously a variety of cortical and subcortical regions within the brain. Among visually responsive structures are 30 or more separate cortical areas, which appear to be organised within two major parallel pathways, or streams (Ungerleider and Mishkin 1982). Each visual stream begins with the primary or striate visual cortex (area V1) and involves multiple areas beyond V1. One of the pathways, the ventral stream, leads toward the inferior temporal (IT) cortex and is crucial for object perception and recognition (the 'what' pathway). The other pathway, the dorsal stream, is directed into the posterior parietal cortex and is mostly concerned with spatial localization and action (the 'where' or 'how' pathway). Physiologically, the processing of visual information appears largely hierarchical within each cortical pathway. The latency of visual responses, the size of the receptive field, and the complexity of neuronal tuning properties increase steadily as one proceeds from one area to the next in the processing hierarchy. Anatomically, two types of connections between areas can be identified: (a) feed-forward connections that relay information from lower to higher visual areas in each pathway and (b) feed-back connections that provide recurrent signals from higher to lower levels of processing. As described below, feedback, re-entrant connections from parietal and frontal areas may form the anatomical basis of top-down attentional signals that modulate activity elsewhere in the visual system.

2. How Does Visual Selective Attention Work?

Traditionally, visual attention has been viewed as a mental spotlight or zoom lens that illuminates stimuli in selected regions of space, thus easing their access to higher processing centers (Posner 1980). According to this classical conception, visual attention is inherently spatial in nature; objects are found by rapidly shifting the attentional spotlight from one location to another. The canonical view also poses that attention is mainly controlled by a unified, topographical 'master' map located in the parietal cortex and associated spatial processing structures. However, several recent findings suggest that any effect of attention is best explained in terms of competitive interactions among the neural representations of objects present in the visual field, as outlined by the 'biased competition' model of visual attention (Desimone and Duncan 1995). According to this model, inputs compete with one another at all levels of the visual system, and different mechanisms can tip the competitive balance in favor of one stimulus' representation over others.

At the behavioral level, competition is reflected in the loss of accuracy or slowing in reaction time that result when subjects are asked to identify multiple stimuli at once, rather than a single object. At the physiological level, single-unit recording studies in monkeys have shown that responses to two stimuli in the receptive field of visual neurons are smaller than responses to either stimulus alone (Reynolds et al. 1999). This indicates that multiple stimuli in the visual field are not processed separately from each other but rather they interact in an inhibitory, suppressive fashion. In agreement with this result, a recent study using functional magnetic resonance imaging (fMRI) in humans (Kastner et al. 1998) has shown that neural responses from visual areas are lower when stimuli are presented simultaneously than when identical stimuli are presented one after the other in the same locations. The reduced activation in the simultaneous condition may reflect sensory suppression among multiple concurrent visual stimuli.

Competitive interference between stimuli has been especially observed in ventral stream areas. However, there is also evidence for sensory competition in structure associated with the dorsal stream, for example, in the frontal eye field and in areas MT and MST. Here, cells respond best to stimuli that move in a particular 'preferred' direction across the receptive field, but respond weakly or not at all to stimuli moving in the opposite or 'null' direction. Treue and Maunsell (1996) found that the response to an otherwise optimal stimulus (i.e., moving in the cell's preferred direction), placed within the receptive field of a MT neuron, was critically reduced by the addition of a second, nonpreferred stimulus at a different location in the same receptive field.

These competitive interactions between neuronal populations encoding different visual objects can be modulated by virtue of bottom-up and top-down biases, such that neurons encoding one object win out over the competition and that object receives further processing in the brain. Bottom-up factors refer to largely automatic and unconscious processes that operate early in vision and presumably contribute to perceptual pop-out phenomenon—the quick and effortless detection of a unique item on a homogeneous background. Bottom-up biases are thought to be mediated by hard-wired neural mechanisms, such as the center–surround structure of receptive fields found in many areas of the visual system. However, competition among visual neurons can also be biased by top-down cognitive influences, in which objects that meet the requirements of the current task are voluntarily selected for focal attention. For example, top-down biases allow you on one occasion to search efficiently for your mug on a desk cluttered with many objects, while on another occasion you might search the same complex visual scene for your pencil. Top-down biases, as the name implies, are imposed on low-level sensory processes by higher-level control mechanisms, and are probably mediated by extensive feedback connections from higher areas to low-level

sensory areas. It is to these processes and their contribution to resolve competition between stimuli that the article will now turn.

3. What is Selected by Attention?

In contrast to the spotlight model of visual attention, a central tenet of the biased-competition model is that the feedback bias from higher areas is not purely spatial. Depending on the context, different visual properties—spatial location, color, shape, or motion—can be used to direct attention and assign limited processing resources to a particular object. Some psychologists have arrived at the notion of attentional template, a flexible, short-term description, formed to suits the task at hand, that can be used to give a competitive advantage to visual inputs matching that description. The attentional template can specify any property of the relevant object. Spatial location is, therefore, only one among many features that can contribute to the attentional template. For example, consider a subject that is asked to search for and report numbers colored in red and to disregard numbers in other colors. Following this instruction, neurons selective for red inputs are primed or preactivated in visual areas coding colors, such that a stimulus that possesses the behaviorally relevant color is processed preferentially over others.

3.1 Space-based Selection

In the past, much research on the control of visual attention has focused on selection in space. In most behavioral studies, subjects covertly (i.e., without executing eye movement) direct their attention onto stimuli shown at a specific spatial location in the visual field, whereas distracting information is present at the other locations. Performance typically is enhanced at attended location, and impaired at the distractor locations, suggesting that competition for focal capacity is biased towards objects at the attended region of space. Single-cell recording work in monkeys has made a substantial contribution to our understanding of space-based selection mechanisms. A host of studies have reported that attention can increase the neural response to a visual stimulus when it appears at an attended location compared with when the animal attends to a different stimulus location. This selective enhancement effect, which increases with task difficulty and with the amount of visual clutter outside of the receptive field, has been demonstrated in numerous visual structures. These include primary visual cortex, areas V2 and V4, but especially in dorsal stream areas implicated in visuomotor control, such as the lateral intraparietal area, the frontal eye field, and the dorsolateral prefrontal cortex (Colby and Goldberg 1998). In humans, brain imaging and event-related potential (ERP) studies have shown similar results. In these experiments, identical stimuli were presented on either side of fixation, while normal subjects focused attention to the left or right visual field. Results showed enhanced activity in extrastriate visual areas, generally lateralized to the hemisphere contralateral to the attended stimulus, in agreement with the fact that many visual areas have a predominantly crossed representation of the visual field (Kastner and Ungerleider 2000). Overall, these findings suggest that top-down biases operate by increasing the input strength for stimuli at the attended locations. Most notably, however, these studies generally failed to find any effect of spatial attention on activity in human V1 (see below).

An alternative, not exclusive, possibility, however, is that spatial attention filters out distracting information when multiple stimuli appear simultaneously within the cell's receptive field. Studies in extrastriate ventral areas V2 and V4, but also in dorsal areas MT and MST, have shown that when monkeys attend to a stimulus at one location within the RF, competitive interference from stimuli at ignored locations within the RF is greatly attenuated or suppressed (Moran and Desimone 1985). Apparently, the cell receptive field 'shrinks' around the attended location, with unattended stimuli being filtered out. In addition, the effects of attention are much weaker when either the target or the distractor is placed outside the RF. Indeed, in such a configuration stimuli are no longer competing for the cell's response, thus reducing the need of attentional biases. The suppressive mechanism of attention may explain why we have little awareness of unattended stimuli, and is highly consistent with the idea that spatial attention biases the sensory interactions among neurons, causing them to respond primarily to the attended stimulus.

In accordance with monkey neurophysiology, one fMRI study in humans showed that directing attention to one object in a cluttered visual scene reduces the sensory interference exerted by distracting stimuli at nearby locations (Kastner et al. 1998). Although attention can suppress irrelevant stimuli, it does not imply that it always does. According to one theory of attention, the extent to which spatial attention inhibits irrelevant information depends on the processing load imposed by the primary task, with stronger inhibition occurring when processing load is high. Consistent with this, an fMRI study by Rees et al. (1997) showed that neural responses to irrelevant moving stimuli, as registered in the motion-processing visual areas MT and MST, are much weaker when the primary task is difficult than when it is easy.

3.2 Object-based Selection

Although spatially directed attention has proven to be an excellent model system for investigating attentional

mechanism, objects can be also selected by attention based on nonspatial properties. For example, color can be used efficiently to control attention, particularly when there is a large hue difference between target and distractors. Neurophysiological studies in monkeys have considerably extended our understanding of feature-based processes for directing visual attention. In a single-neuron study in IT cortex, monkeys were instructed to perform a simple visual search task (Chelazzi et al. 1993). On each trial, a central cue was presented, followed by a blank delay period. At the end of the delay, an array of stimuli was presented and the monkey was rewarded to make a saccadic eye movement toward the stimulus matching the cue (target). The location of the target was not known in advance and thus selection could not be based on spatial information. Just like attention to location, attention to an object (non-spatial) feature was found to inhibit neuronal responses to irrelevant stimuli. Neurons in IT cortex showed an initial response if the choice array contained their preferred stimulus, without regard of the target identity. When the preferred stimulus was the eye movement target, the initial response remained high. However, when the preferred stimulus was an irrelevant, distracting stimulus in the array, the initial response was rapidly inhibited, long in advance of the onset of the saccade. Interestingly, neurons selective for the cue showed higher sustained activity during the delay. It has been argued that this tonic activity during the interval represents the neural correlate of the attentional template, which can be used to bias competition in favor of cells representing the target. Other neurophysiological studies also reported attentional modulation based on object features. Interestingly, studies that have used a single stimulus within the cell receptive field found facilitation of attended stimuli as well as inhibition of unattended stimuli.

Functional neuroimaging studies provided additional insight into feature selection. In a classic PET study (Corbetta et al. 1991), subjects compared two successive visual displays, with reference to the color, shape, or speed of motion. Depending on the relevant visual feature, different extrastriate areas were active: attention to color led to enhanced visual response in area MT, whereas attention to shape and motion color induced response enhancement in area V4.

Similar results have been reported using ERPs and fMRI. Together, these studies argue that selective attention to a particular visual feature enhances neural activity in areas selectively specialised for that attribute. Attention selection can also occur from whole object representations. In a recent fMRI study (O'Craven et al. 1999), two stimuli, a face and a house, were superimposed transparently in the same location. In each trial, either the face or the house oscillated back and forth. Subjects' attention was directed in different conditions to the face, the house, the direction of motion, or the spatial location of the stationary stimulus. As expected, different brain regions were activated depending on whether the relevant feature was the face (fusiform face area), the house (parahippocampal place area), or the direction of motion (areas MT and MST). Importantly, however, results showed that attention to one feature of an object enhanced the representation of other features of the same object, even when these features were completely irrelevant for the task. These findings strongly suggest that attention selects entire objects, rather than selecting simple visual attributes.

4. *The Anatomical Locus of Attentional Selection*

Historically, the parietal lobe has been viewed as central in visual selection. Damage to this region commonly produces unilateral neglect, a deficit in perceiving and interacting with events on the contralesional side of space, which has often been explained as a difficulty in directing attention to that side. Patients with left neglect, for example, fail to complete the left half drawings, or to read the left side of words or passages of text. The attentional nature of neglect is well shown by the observation that the deficit is greatly exaggerated by competing inputs on the intact, ipsilesional side, a phenomenon termed extinction. In fact, recent evidence based on large series studies indicates that neglect and extinction may follow a wide variety of unilateral lesions, both cortical and subcortical. This indicates a multiplicity of competitive systems modulated by attention and behavioral relevance, rather than a single anatomical level at which attention affects processing.

Data from lesion studies in monkeys are consistent with this conclusion. Indeed, different methodologies, such as single-unit recording, ERPs, functional imaging, and lesion studies provide converging evidence that attention can affect neuronal activity in most of the extrastriate visual areas where such modulation has been investigated. Paradoxically, many electrophysiological reports suggested that the processing of attended and unattended items does not differ in primary visual cortex. Monkey physiology in the past yielded conflicting results in this regard. In some studies approximately 30 percent of V1 neurons revealed some form of attentional modulation. More recently, however, Roelfsema et al. (1998) trained monkeys on an ingenious task in which animals had to trace one of two curves—the attended curve—while maintaining fixation. They found that the firing rate of V1 neurons was significantly higher when the receptive field was on the curve that needed to be traced, than on the distracting curve. The long latency of the enhancement (about 200 ms) suggested that this effect might be mediated by feedback processing.

Recent functional magnetic resonance imaging studies in humans have also shown that spatial attention is indeed capable of modulating neuronal

activity in V1. One study compared the magnetic resonance signals in central and peripheral parts of V1 while subjects were either attending to a rapidly presented series of letters in the center of the visual field or performing a direction-of-rotation discrimination task on a peripheral rotating disk (Somers et al. 1999). In striking contrast with previous imaging studies, substantial increases in activity were found in V1 regions corresponding to the attended stimulus and decreases in regions representing the nonattended stimulus. Together these studies demonstrated that, depending on the visual task, attentional modulation of responses does indeed occur in the primary visual cortex. For the region of V1 representing the attended part of the visual field, neuronal responsiveness increases; conversely, when attention is directed away from a particular location there appears to be a consequent decrease in responsiveness in the retinotopically corresponding V1 region.

How can these recent findings be reconciled with previous failure to find attentional modulation in V1? One explanation is that, in the earlier studies, the tasks were not sufficiently demanding. In the new studies, stimulus parameters were chosen so that tasks were difficult and only 70–90 percent correct responses were achieved. Alternatively, it is possible that some techniques, like ERP recordings, may reflect only initial, feed-forward processing in V1. Apparently, the early part of the visual response of V1 neurons is unaffected by attention, as single-unit studies have shown. In contrast, the relatively poor time resolution of fMRI measurements would capture both early feed-forward processing and later top-down attentional influences from higher visual areas.

5. *The Neural Mechanisms of Selection*

Do attentional signals affect visual processing by facilitation of attended stimuli or by inhibition of irrelevant distractors, or both? One view suggests that attention exerts its influence by inhibiting unwanted stimuli early in visual processing, and by enhancing relevant information later on. The assumption underlying this view is that neurons in early visual areas respond at close to maximal rates to visual stimuli even during passive viewing, and therefore there is little room for response enhancement in early stages. In contrast, in higher visual areas, cells become less stimulus-driven and more sensitive to behavioral relevance. Overall, recent single-unit and neuroimaging data do not support such a suggestion, and argue instead for a close interplay between suppressive and enhancing mechanisms at all levels of the visual system. For example, one recent fMRI study reported that attention to a particular spatial location, in addition to an enhanced response to the attended visual stimulus, results in a widespread suppression of activity at all other locations (Smith et al. 2000). However, ERP studies have shown that the 'costs' of spatial cueing are associated with suppression of unattended inputs at an early stage, whereas the 'benefits' of cueing are associated with enhancement of attended stimuli at a later stage (Hillyard and Anllo-Vento 1998). Thus, there is at least some suggestive evidence that suppression and enhancement may entail qualitatively different mechanisms, which operate at different levels of the visual pathways.

Top-down attentional signals may also affect visual processing by increasing the spontaneous (baseline) level of neural activity in the absence of any visual stimulation. Single-cell recording studies have clearly shown a substantial elevation of baseline activity for neurons in area V2 and V4, when the monkey was instructed to attend covertly to a location within the receptive field, even before the stimulus was presented there (Luck et al. 1997). The shift in baseline activity during spatial attention closely resembles the sustained, tonic activation found in IT neurons during visual search experiments. This increase in spontaneous firing rate is consistent with the idea of top-down feedback signals priming neurons coding the attended location of space. In a similar vein, several fMRI studies in humans have shown that during the expectation period preceding the arrival of a stimulus at an attended location, baseline activity increased in numerous extrastriate visual areas. The effect is spatially selective, as it occurs only in subregions of visual areas with a representation of the attended location; thus, it cannot be due to nonspecific arousal. Remarkably, an increase in baseline activity has been found even in the primary visual cortex during a demanding threshold detection task, and its magnitude was highly predictive of the subject's behavioral performance (Ress et al. 2000).

6. *The Control of Visual Attention*

A central issue in the current debate on selective visual attention concerns the brain sources of the top-down attentional signals to extrastriate and striate visual areas. Studies of brain-damaged patients, single-neuron recordings in primates and more recently blood-flow neuroimaging methods have identified a network of interconnected cortical and subcortical areas that play a key role in the control of selective visual attention. These areas include the dorsolateral prefrontal and posterior parietal cortex, the anterior cingulated gyrus, and the pulvinar nucleus of the thalamus. It has been proposed that in this circuitry, the prefrontal cortex would initiate and maintain the selective sensory bias in working memory, whereas the parietal cortex would direct and shift attention to specific objects and locations in space. In turn, this control network would enhance or suppress stimulus

representations in the extrastriate visual areas according to current concern. Parietal and prefrontal cortex have anatomical and functional properties ideal for providing attentional templates. Both regions are extensively and reciprocally interconnected with virtually all visual cortical areas, and are therefore in a position to influence visual processing at multiple levels of the visual system. Neurons in the prefrontal and parietal cortex are capable of encoding the behavioral relevance or saliency of a visual stimulus. Furthermore, they display a pattern of activity that is well suited to form and maintain on line a representation of an object or of a location for as long as that representation is relevant to behavior. In the past years, several functional neuroimaging studies in humans have shown frontal and parietal activations during visual attention tasks (see Kastner and Ungerleider 2000, for a recent review). However, only recently top-down control signals for allocating attention have been distinguished from the modulatory effects that these signals have on the processing of incoming visual stimuli. For example, Hopfinger et al. (2000) asked which brain regions were activated in response to cues instructing shift or attention, and which were activated by the subsequent visual target presentation. A number of different visual areas were active; the surprising finding was that there was relatively little overlap between the two sets of visual responses. Importantly, posterior parietal and prefrontal areas were selectively engaged by attention-directing cues, thus suggesting that these two structures play a fundamental role in top-down attentional control. It should be noted, however, that the fronto-parietal network is not exclusively related to visual attention, but may coincide or overlap with cortical regions involved in oculomotor processing. This overlap supports the hypothesis that the neuronal signals used to direct attention correspond to the premotor signals that drive the eyes. One way to disentangle attentional and oculomotor processes would be an attentional task that does not require eye movements. In one study, for instance, subjects performed rapid attention shifting between the shape and color of stimuli presented at fixation, so that the need for eye movements was eliminated (Le et al. 1998). Nevertheless, significant activations were observed in superior parietal lobule and other occipital visual areas, as well as the lateral cerebellum. Thus, it seems that at least some activity in the parietal and frontal cortex reflects attentional signals that are independent of eye movement. The frontoparietal circuit may therefore play a very general role in visual attention, governing the access of competing visual representations to higher brain centers and ultimately to perceptual consciousness.

Attitude Change: Psychological

Attitudes refer to people's global and relatively enduring (i.e., stored in long-term memory) evaluations of objects, issues, or persons (e.g., I dislike chocolate; I'm opposed to the governor's tax policy). Numerous procedures have been developed to modify these evaluations with some change techniques involving considerable thinking about the attitude object and some requiring little. Attitudes are one of the most studied and important constructs in psychology because of the critical role of attitudes in guiding behavior (see *Attitudes and Behavior*).

1. Overview of Attitudes and Attitude Change

Attitudes are based on some combination of cognitive, behavioral, and affective influences, and are typically measured by self-report scales such as the 'semantic differential,' where a person rates the target on bipolar evaluative dimensions such as how good/bad or favorable/unfavorable it is. Increasingly, researchers have appreciated that it is also useful to assess attitudes on dimensions other than their valence, such as their accessibility (how quickly the attitude comes to mind) and ambivalence (how consistent the basis of the attitude is). These indicators of attitude 'strength' are useful in determining which attitudes are consequential and which are not. Strong attitudes are those that persist over time, are resistant to change, and predict other judgments and actions (Petty and Krosnick 1995). At any given moment, one's expressed evaluation can be influenced by a variety of contextual factors, but the common assumption is that one's core 'attitude' is the underlying evaluation that is capable of guiding behavior (one's actions), cognition (one's thoughts and memories), and affect (emotional reactions).

Attitude change occurs when one's core evaluation shifts from one meaningful value to another, and is typically inferred from a change in a person's scale rating, although behavioral and other indirect or implicit procedures for assessing change are sometimes used. Most studies of attitude change involve exposing individuals to a persuasive communication of some sort but, as noted below, some attitude change techniques do not involve exposure to any message. The earliest work on attitude change attempted to examine which variables and procedures increased and which decreased the likelihood of change (e.g., did more change occur when the message source was described as an expert than when the source lacked expertise even though the message was the same?).

2. Two Routes to Attitude Change

After numerous studies, the accumulated evidence suggests that even the simplest variables (e.g., being in a positive mood) sometimes increase, sometimes decrease, and sometimes have no impact on the likelihood that a person's attitude will change. Numerous theories and psychological processes have been proposed to account for these divergent results. Even though the many different theories of attitude change have different names, postulates, and particular effects and variables that they specialize in explaining, the many different theories of attitude change can be thought of as emphasizing just two relatively distinct 'routes to persuasion' (Petty and Cacioppo 1981). The first change technique, persuasion via the central route, focuses on the information that a person has about the central merits of the object under consideration. Some of the central route approaches postulate that comprehending and learning the information presented is critical for attitude change, whereas others focus more on the evaluation, elaboration, and integration of this information. In contrast, the peripheral route approaches emphasize attitude changes that are brought about without much thinking about information central to the merits of the attitude issue. Thus, the peripheral approaches deal with changes resulting from rewards, punishments, and affective experiences that are associated directly with the attitude object, or simple inferences that people draw about the appropriate attitude to adopt based on their own behavior or other simple cues in the persuasion environment. For example, a person might be more persuaded by a message containing nine rather than three arguments because each of the arguments is evaluated and determined to be compelling (central route), or because the person simply counts the arguments and reasons, 'the more the better' (peripheral route). Before integrating these approaches, it is useful to describe the major central and peripheral processes responsible for persuasion.

3. Central Route Approaches to Attitude Change

3.1 Message Learning Approach

One of the most influential programs of research on attitude change was that undertaken by Carl Hovland

and his colleagues at Yale University in the years following World War II (e.g., Hovland et al. 1953). The Yale group studied how source, message, recipient, and channel factors affected the comprehension, acceptance, and retention of the arguments in a persuasive communication. Although no formal theory tied together the many experiments conducted by this group, they often attempted to explain the results obtained in terms of general learning principles such as the more message content you learned, the more your attitudes should change (see McGuire 1985). Contemporary research shows that people can be persuaded without learning or remembering any of the message content. That is, people are sometimes persuaded solely by the 'cues' associated with the message (e.g., the source is expert; Petty and Cacioppo 1986). Or, the message might elicit a favorable thought that persists in the absence of memory for the information that provoked it (Greenwald 1968). Message learning appears to be most important when people are not engaged in an on-line evaluation of the information presented to them, such as when they do not think they have to form an opinion at the time of information exposure. In such cases, subsequent attitudes may be dependent on the valence of information they have learned and can recall (Hastie and Park 1986).

3.2 Self-persuasion Approach

Self-persuasion theories hold that people's attitudes can change in the absence of any new external information. This is because people can self-generate reasons to favor or disfavor any position. The powerful and persisting effects of completely self-generated messages were shown in early research on 'role-playing' where people were asked to generate messages on certain topics (e.g., the dangers of smoking). The subsequent attitudes of these people were compared to those who had either passively listened to the communication or who had received no message. A consistent result was that active generation of a message was a successful strategy for producing attitude change, and these changes persisted longer than changes based on passive exposure to a communication. Finally, merely asking someone to think about an issue, object, or person can lead to attitude change as a result of the evaluative thoughts generated. Cognitive response theorists hold that just as one's thoughts can produce change in the absence of a message, so too are one's own thoughts responsible for attitude change even when a persuasive message is presented. That is, to the extent that a person's thoughts in response to the message are favorable, persuasion should result, but to the extent that they are unfavorable (e.g., counterarguments), resistance or even boomerang are more likely. These theorists hold that persistence of persuasion depends upon the decay function for cognitive responses rather than message arguments *per se* (see Petty et al. 1981, for review).

3.3 Expectancy-value Approach

The message learning and self-persuasion approaches focus on the information (either externally or internally generated) that is responsible for persuasion. Neither approach has much to say about the particular features of the information that are critical for influencing attitudes. In contrast, expectancy-value theorists analyze attitudes by focusing on the extent to which people expect the attitude issue to be related to important values or produce positive and negative consequences. In one influential expectancy-value model, Fishbein and Ajzen's theory of reasoned action (1975) holds that the attributes (or consequences) associated with an attitude object are evaluated along two dimensions—the likelihood that an attribute or consequence is associated with the object, and the desirability of that attribute or consequence. If a persuasive message says that raising taxes will lead to reduced crime, the effectiveness of this argument should depend on how likely people think it is that crime will be reduced if taxes are increased (likelihood), and how favorably they view the outcome of reducing crime (desirability). Although some questions have been raised about the necessity of one or the other of these components, a large body of research supports the idea that attitudes are more favorable the more that likely–desirable consequences (or attributes) and unlikely–undesirable consequences are associated with them. The major implication of this theory for persuasion is that a message will produce attitude change to the extent that it introduces new attributes of an object, or produces a change in the likelihood and/or the desirability components of an already accepted attribute. Another proposition of this theory is that the items of information constituting an attitude are combined in an additive fashion. Other theorists, however, have contended that an averaging mechanism is more appropriate (see Anderson 1971).

3.4 Functional Approach

In their expectancy-value theory, Fishbein and Ajzen speculate that five to seven attributes or consequences are critical in determining a person's overall attitude. It is not clear, however, which particular attributes will be the most important (i.e., how the attributes are weighted). Functional theories of persuasion focus on the specific needs or functions that attitudes serve for a person and are therefore relevant for understanding the underlying dimensions of the attitude that are

most important to influence (e.g., Smith et al. 1956). For example, some attitudes are postulated to protect people from threatening truths about themselves or to enhance their own self-image ('ego-defensive function'), others give expression to important values ('value-expressive function'), or help people to understand the world around them ('knowledge function') or facilitate achieving rewards and avoiding punishments ('utilitarian function'). According to these theories, change depends on challenging the underlying functional basis of the attitude. Thus, if a person dislikes lowering taxes because of concern about social inequality (value expressive function), an argument about the amount of money the taxpayer will save (utilitarian function) will be ineffective.

3.5 Consistency Approach

Just as functional theories hold that attitudes serve important needs for individuals, dissonance and related theories hold that attitudes are often in the service of maintaining a need for consistency among the elements in a cognitive system (Festinger 1957). In Festinger's original formulation of dissonance theory, two elements in a cognitive system (e.g., a belief and an attitude; an attitude and a behavior) were said to be consonant if one followed from the other, and dissonant if one implied the opposite of the other. Two elements could also be irrelevant to each other. One of the more interesting dissonance situations occurs when a person's behavior is in conflict with his or her attitudes or beliefs because behavior is usually difficult to undo. According to the theory, dissonance, experienced as an aversive tension, may be reduced by changing beliefs and attitudes to bring them into line with the behavior. Thus, if you were opposed to the election of Candidate Smith, it would be inconsistent to sign a petition in favor of this candidate. According to dissonance theory, signing such a petition would produce discomfort that could result in a more favorable evaluation of the candidate in an effort to restore consistency.

Although early dissonance research was generally supportive of the theory, several competing formulations were proposed. Although it is now clear that many of the behaviors described by Festinger induce in people an 'unpleasant tension,' just as the theory predicts, current research has begun to focus more on understanding the precise cause of that tension. For example, some have questioned Festinger's view that inconsistency *per se* produces tension in many people. Rather, some argue that people must believe that by their behavior they have freely chosen to bring about some foreseeable negative consequence, or that the inconsistency involves a critical aspect of oneself or a threat to one's positive self-concept (see Harmon-Jones and Mills 1999).

4. Peripheral Route Approaches

Each of the central route approaches described above assumes that attitude change results from people actively considering the merits of some position either in a fairly objective manner, or in a biased way (such as when seeking to restore consistency). The next group of theories does not share this assumption. Instead, these theories suggest that people often prefer to conserve their cognitive resources and form or change attitudes with relatively little cognitive effort.

4.1 Inference Approaches

Rather than effortfully examining all of the issue-relevant information available, people can make an evaluative inference based on some meaningful subset of information. One popular inference approach is based on 'attribution theory' and holds that people come to infer underlying characteristics about themselves and others from the behaviors that they observe and the situational constraints imposed on these behaviors (e.g., Kelley 1967). Bem (1965) suggested that people sometimes have no special knowledge of their own internal states and simply infer their attitudes in a manner similar to that by which they infer the attitudes of others. In his self-perception theory, Bem reasoned that just as people assume that the behavior of others and the context in which it occurs provides information about the presumed attitudes of these people, so too would a person's own behavior provide information about the person's own attitude. Thus, a person might reason, 'since I signed Candidate Smith's petition, I must be in favor of her election.'

The attribution approach has also been useful in understanding the persuasion consequences of making inferences about relatively simple cues. For example, when external incentives (e.g., money) provide a salient explanation for a speaker's advocacy ('he was paid to say it'), the message is less effective than when a discounting external attribution is not possible. Research indicates that these simple attribution processes are most likely to influence attitudes when people are relatively unmotivated or unable to think carefully about the issue, such as when they have relatively little knowledge on the topic and the issue has few anticipated personal consequences.

Like the attributional framework, the heuristic–systematic model of persuasion postulates that when people are not motivated or able to process all of the relevant information available, attitude change can result from the use of certain heuristics or rules of thumb that people have learned on the basis of past experience and observation (see Eagly and Chaiken 1993). To the extent that various persuasion heuristics are available in memory, they may be invoked to evaluate persuasive communications. For example,

either because of prior personal experience or explicit training, people may evaluate a message with many arguments by invoking the heuristic 'the more arguments, the more valid it is.' If so, no effortful learning or evaluation of the actual arguments presented is necessary for influence to occur.

4.2 Approaches Emphasizing Affect

The attribution and heuristic models focus on simple cognitive inferences that can modify attitudes. Other peripheral route theories emphasize the role of affective processes in attitude change. One of the most direct means of associating 'affect' with objects, issues, or people is through classical conditioning (e.g., see Staats and Staats 1958). In brief, conditioning occurs when an initially neutral stimulus (the conditioned stimulus; CS) is associated with another stimulus (the unconditioned stimulus; UCS) that is connected directly or through prior conditioning to some response (the unconditioned response; UCR). By pairing the UCS with the CS, the CS becomes able to elicit a conditioned response (CR) that is similar to the UCR (Pavlov 1927). So, when food is paired over and over again with a bell, eventually the bell elicits salivation in the absence of food.

Considerable research has shown that attitudes can be influenced by pairing initially neutral objects with stimuli about which people already feel positively or negatively. For example, peoples' evaluations of words, other people, political slogans, consumer products, and persuasive communications have been modified by pairing them with such affect-producing stimuli as unpleasant odors and temperatures, the onset and offset of electric shock, harsh sounds, and elating and depressing films. People are especially susceptible to the simple transfer of affect from one stimulus to another when the likelihood of object-relevant thinking is rather low.

Another procedure for modifying attitudes through simple affective means was identified by Zajonc (1968) in his work on mere exposure. In this research, Zajonc and his colleagues showed consistently that when objects are presented to an individual on repeated occasions, the mere exposure is capable of making the individuals' attitudes toward these objects more positive. Recent work on this phenomenon indicates that simple repetition of objects can lead to more positive evaluations even when people do not recognize that the objects are familiar. Mere exposure effects have been shown in a number of studies using a variety of stimuli such as polygons, tones, nonsense syllables, Chinese ideograms, photographs of faces, and foreign words. Interestingly, what these stimuli have in common is that they tend to be meaningless and are relatively unlikely to elicit spontaneous thought. In fact, the simple affective process induced by mere exposure appears to be more successful in influencing attitudes when processing of the repeated stimuli is minimal. When more meaningful stimuli have been repeated such as words or sentences, mere exposure effects have been less common. Instead, when processing occurs with repetition, the increased exposures enhance the dominant cognitive response to the stimulus. Thus, repeating strong arguments tends to lead to more persuasion (at least to the point of tedium), and repeating weak arguments tends to lead to less persuasion (Petty and Cacioppo 1986).

5. A Dual Process Approach to Understanding Attitude Change

Although the theories just described continue to be useful in accounting for a variety of persuasion phenomena, much of the contemporary literature on attitude change is guided by one of the available 'dual process' models of judgment. For example, one of the earliest approaches of this type, the elaboration likelihood model (ELM) represents an attempt to integrate the many seemingly conflicting findings in the persuasion literature under one conceptual umbrella by specifying a finite number of ways in which source, message, recipient, and contextual variables have an impact on attitude change (see Petty and Cacioppo 1986, Petty and Wegener 1998; for reviews of the ELM, the related heuristic–systematic model, and other dual process approaches, see Chaiken and Trope 1999). The ELM is based on the notion that people want to form correct attitudes (i.e., those that will prove useful in functioning in the environment) as a result of exposure to a persuasive communication, but there are a variety of ways in which a reasonable position can be adopted.

The most effortful procedure for evaluating an advocacy involves drawing upon prior experience and knowledge to scrutinize carefully and think about all of the issue-relevant information available in the current environment, along the dimensions that are perceived central to the merits of the attitude object. According to the ELM, attitudes formed or changed by this central route are postulated to be relatively persistent, predictive of behavior, and resistant to change until they are challenged by cogent contrary information along the dimension or dimensions perceived central to the merits of the object. However, it is neither adaptive nor possible for people to exert considerable mental effort in processing all of the persuasive information to which they are exposed. This does not mean that people never form attitudes when motivation and/or ability to think are low, but rather that attitudes are more likely to be changed as a result of relatively simple associations, on-line inferences, and well-learned heuristics in these situations. Attitudes formed or changed by these peripheral

route processes are postulated to be relatively less persistent, resistant, and predictive of long-term behavior than those based on central route processes. Thus, the ELM holds that both central and peripheral processes are important for understanding attitude change, but their influence varies depending on the likelihood of thinking.

The ELM holds that there are many variables capable of affecting elaboration and influencing the route to persuasion. Some variables affect a person's motivation to process issue-relevant information (e.g., the personal relevance of the issue; personal accountability for a decision), whereas others affect their ability or opportunity to think about a message (e.g., the extent of distraction present; the number of times the information is repeated). Some variables affect processing in a relatively objective manner (e.g., distraction disrupts both favorable and unfavorable thinking) whereas others influence elaboration in a biased fashion (e.g., a positive mood makes positive thoughts more likely than negative thoughts when people are motivated and able to think). Biases can stem from both ability factors (e.g., a biased knowledge store), or motivational factors (e.g., when a desire to maintain one's current attitude is more salient than one's desire to consider new information objectively).

Research on the ELM has shown that when the elaboration likelihood is high (e.g., high personal relevance, high knowledge of topic, simple message in print, no distractions, etc.), people typically know that they want and are able to evaluate the merits of the information presented, and they do so. Sometimes this effortful evaluation is relatively objective, but sometimes it is biased. On the other hand, when the elaboration likelihood is low, people know that they do not want and/or are not able to carefully evaluate the merits of the information presented (or they do not even consider exerting effort). Thus, if any evaluation is formed, it is likely to be the result of relatively simple associations or inferences (e.g., agreement with an expert source; counting the number of arguments presented). When the elaboration likelihood is moderate (e.g., uncertain personal relevance, moderate knowledge, moderate complexity, etc.), however, people may be unsure as to whether the message warrants or needs scrutiny, and whether or not they are capable of providing this analysis. In these situations, they may examine the persuasion context for indications (e.g., is the source credible?) as to whether or not they should attempt to process the message.

There are at least two important implications of the ELM. First, the model holds that any one variable can produce persuasion by different processes in different situations. For example, putting people in a positive mood can influence attitudes because of a simple inference process when the likelihood of thinking is low (e.g., 'I feel good so I must like it'), bias thinking when the likelihood of thinking is high (i.e., making positive interpretations more likely than negative ones), and influence the extent of thinking when it is not already constrained to be high or low (e.g., thinking about an unpleasant message less when happy than when sad). Second, as explained next, the model holds that not all attitude changes of the same magnitude are equal. Specifically, thoughtful attitude changes (central route) tend to be more consequential than nonthoughtful changes (peripheral route).

6. *Consequences of Attitude Changes Produced by Different Processes*

It is now clear that there are a variety of processes by which attitudes can be changed, and that the different processes dominate in different situations. That is, some change processes dominate when motivation and ability to think are high, but other change processes dominate when motivation and ability to think are low. Research suggests that attitudes formed by different processes often have different characteristics (Petty and Cacioppo 1986). For example, persistence of persuasion refers to the extent to which attitude changes endure over time. When attitude change is based on extensive issue-relevant thinking, it tends to persist longer than when it is not. However, multiple exposures to positive cues can also produce relatively persistent attitudes.

Resistance refers to the extent to which attitude change is capable of surviving an attack from contrary information. Attitudes are more resistant the stronger the attack they can withstand. Although attitude persistence and resistance tend to co-occur, their potential independence is shown conclusively in work on cultural truisms (McGuire 1964). Truisms such as 'you should brush your teeth after every meal,' tend to be highly persistent in a vacuum, but very susceptible to influence when challenged. People have very little practice in defending truisms because they have never been attacked. These beliefs were likely formed with little issue-relevant thinking at a time during childhood when extensive thinking was relatively unlikely. Instead, the truisms were probably presented repeatedly by powerful, likable, and expert sources. As noted above, the continual pairing of an attitude with positive cues may produce a relatively persistent opinion, but it may not prove resistant when attacked. The resistance of cultural truisms and other attitudes can be improved by motivating and enabling people to defend their positions in advance of a challenging communication. One such 'inoculation' treatment involves exposing people to a few pieces of counter-attitudinal information prior to the threatening communication and showing them how to refute it. The inoculation procedures do not change the valence of a person's initial attitude, but it makes it stronger. Other persuasion treatments that seem ineffective in changing the valence of attitudes might nonetheless be

effective in modifying the strength of the attitude—making it more or less enduring, resistant, or predictive of behavior than it was initially.

7. Summary

In sum, contemporary persuasion theories hold that changes in attitudes can come about through a variety of processes which imbue them with a multiplicity of characteristics and render them capable of inducing a diversity of consequences. According to the popular dual process logic, the processes emphasized by the central route theories should be largely responsible for attitude change when a person's motivation and ability to scrutinize issue-relevant information is high. In contrast, the peripheral route processes should become more dominant as either motivation or ability to think is attenuated. This framework allows understanding and prediction of what variables affect attitudes and in what general situations. It also permits understanding and prediction of the consequences of attitude change. It is now accepted that all attitudes can be based on cognitive, affective, and behavioral information, and that any one variable can have an impact on persuasion by invoking different processes in different situations. Finally, attitudes that appear identical when measured can be quite different in their underlying basis or structure and thus can be quite different in their temporal persistence, resistance, or in their ability to predict behavior. Work on attitude change to the present has focused on the intrapsychic processes responsible for change in adult populations mostly in Western cultures. Future research is needed on the interpersonal processes responsible for attitude change, and the potentially different mechanisms that produce change in different population groups (e.g., children versus elderly individuals, those in individualistic versus collectivist cultures). In addition, as the field matures, current theories are ripe for exportation to important applied domains such as health promotion (e.g., AIDS education), political participation (e.g., determinants of voter choice), and others.

Attitude Formation: Function and Structure

Attitude is a psychological tendency that is expressed by evaluating a particular object or entity with some degree of favor or disfavor. In this definition, an object or entity can be virtually any 'thing' in a person's

internal or external social environment. Thus, people hold attitudes, or evaluations, toward an endless variety of objects, including the self, another person or groups of persons, social and political policies, goals, and behaviors. Specific terms are sometimes applied to certain classes of attitudes. For example, attitudes toward minority groups are often called *prejudice*, and an attitude toward one's self is often called *self-esteem*. Attitudes have two basic components at the level of abstract evaluation, direction (positive vs. negative) and intensity—one may, for example, be extremely positive or only moderately positive toward 'Democrats.' This definition of attitude is consensual within social psychology, the discipline that has generated most basic theory and research on this concept. From a very early point in social psychology, attitude has been regarded as a fundamental construct (Allport 1935). This high status in social psychology, and throughout the social sciences, has endured and shows no signs of abating.

1. Attitude and Other Constructs

For many years attitude was viewed solely as a hypothetical construct. Like intelligence and other hypothetical constructs, attitude was considered a theoretically and empirically useful construct capable of explaining certain regularities in social thought and behavior. In this S-O-R (stimulus-organism-response) approach, attitude could be inferred from overt cognitive, affective, or behavioral responding. But attitude itself was considered neither directly observable nor likely to have a genuine physical or neural reality. At the beginning of the twenty-first century, attitude remains largely a hypothetical construct. Nonetheless, there is widespread agreement that attitudes are represented in memory, and increased understanding that as measurement technology in psychological science progresses, attitudes will eventually be shown to have more directly observable physiological, especially neural, underpinnings.

Before considering the formation, functions, and structure of attitudes, it is important to differentiate attitudes from other, seemingly related individual difference constructs. While attitudes do differ from person to person, they are always held in relation to a specific object, unlike broader personality dimensions such as extraversion–introversion, and unlike the relatively temporary evaluative states known as moods. Also, while personality differences like extraversion are usually thought to be chronic and thus relatively stable—and despite early treatments of attitudes as *enduring* dispositions—attitudes may in fact be either stable or unstable. Stability has become a theoretical and empirical issue, with stability, or persistence, dependent on factors such as attitudinal structure and people's exposure to new direct or indirect experience with attitude objects (Eagly and Chaiken 1993).

Habits, opinions, beliefs, and values have often been confused with attitudes. Habits refer more to regularities in behavior, are considered relatively automatic, and do not necessarily imply evaluation. Opinions and beliefs are interchangeable in contemporary usage. While beliefs do often imply evaluation, the hallmark of attitude, they are best viewed as likelihoods, or subjective probabilities; for example, the belief that attitude object X (e.g., African-Americans) possesses or is associated with certain attributes (e.g., athleticism). Beliefs may contribute to the formation of attitudes and are best viewed as part of an attitude's structure (see Sect. 3). Finally, attitudes and values are typically distinguished, though they need not be. Strictly speaking, values are 'just' attitudes in the sense that they convey people's evaluations of 'objects' (e.g., one values freedom). Yet researchers continue to use both terms because the objects toward which we hold values are broader than the objects toward which we hold attitudes. We hold values toward very broad and, at least within cultures, consensually held personal or social goals (e.g., being responsible) and desired end-states of existence (e.g., equality). The objects toward which we hold attitudes are typically narrower (e.g., health care reform).

2. Attitude Formation

How are attitudes, our abstract evaluations of objects in our environment, formed? Traditional accounts of attitude formation have emphasized that attitudes are *learned*. Indeed, early definitions of attitudes emphasized that attitudes are 'learned' predispositions to respond favorably or unfavorably toward objects in the environment (e.g., Allport 1935). That many, if not most, attitudes are learned is theoretically and empirically uncontroversial. Nonetheless, it should be noted that some scholars have argued that at least some attitudes are unlearned in the sense that people may have predispositions to react positively or negatively to novel attitude objects. Such predispositions may reflect evolutionary adaptations and/or biological substrates that are inherited (e.g., Tesser 1993). Predispositions to evaluate, however, are not the same thing as attitudes because attitudes arise from *evaluative responding* to an attitude object. Thus, people do not have an attitude until they first encounter the attitude object and respond evaluatively to it on an affective, cognitive, or behavioral basis. For example, although humans may be predisposed to react negatively to sour tastes, a person would not have a negative attitude toward a sour-tasting fruit until he or she had some first- or second-hand experience with it (e.g., tasting it, hearing another describe its taste).

Cognitive learning theories have been especially prominent in explaining how attitudes are formed (and modified). In the most widely accepted cognitive learning model of attitude formation, Fishbein and Ajzen (e.g., 1975) proposed that people's evaluations

of objects are based on the beliefs that they form about these objects, whether through direct or indirect experience. In this expectancy-value approach, attitudes are viewed as the sum of the evaluative implications of a person's beliefs about the attitude object. Beliefs about an object (e.g., Democrats care about the poor) represent the expectancy (or subjective probability) component, and evaluations of the attributes of beliefs (e.g., 'caring for the poor') represent the value component. This general theory has obvious implications for how attitudes are formed and modified (see also *Attitudes and Behavior*; *Attitude Change: Psychological*). Beliefs may be acquired directly, through firsthand experience with attitude objects (e.g., playing with a dog), and also indirectly, via socialization agents such as parents, teachers, peers, and the mass media. The large literature on designing persuasive messages attests to the popularity of attempting to change attitudes by instilling new beliefs (or refuting old beliefs) about attitude objects (see also *Sexual Attitudes and Behavior*). By these various means we form beliefs about, and therefore attitudes toward, a vast array of socially significant (and insignificant) objects in our environment.

Fishbein and Ajzen's approach stressed beliefs, or cognitions, as the foundation of attitudes. In contrast, other models of attitude formation have emphasized *affective* experience. Traditional affective approaches included both operant and classical conditioning explanations of attitude formation. Most notably, classical conditioning studies paired neutral ('conditioned') attitude–object stimuli (e.g., 'George') with evaluative ('unconditioned') stimuli (e.g., 'friendly,' or 'naughty') guaranteed to elicit positive or negative ('unconditioned') responses. These studies showed that after repeated pairings, previously neutral stimuli came to elicit positive or negative evaluations, depending upon the positive/negative nature of the unconditioned stimuli they were paired with.

Empirical evidence for classical (as well as operant) conditioning of attitudes was criticized during the 'demand characteristics' crisis in social psychology, in the 1960s. Critics argued that the simplicity of these experimental paradigms made clear to participants the purposes of the research enterprise, and argued that experimental outcomes were simply the result of 'good subjects' providing 'respected' researchers their hoped-for results. Yet, more recent analysis of the conditioning literature and these critiques suggest that the fundamental proposition that attitudes can be formed through simple affective conditioning mechanisms remains plausible (Eagly and Chaiken 1993).

Research on mere exposure also gives importance to affective experience in attitude formation. The mere exposure effect, demonstrated initially by Zajonc (see Zajonc 1980) and subsequently by numerous others, is that the more frequently people are minimally, or 'merely,' exposed to stimuli—ranging from other persons to simple geometric figures—the more positive their attitudes toward such stimuli become. Some commentators dismissed this work as the product of demand characteristics, or as demonstrating little more than cognitive learning (e.g., Fishbein and Ajzen 1975). Yet more recent research has bolstered Zajonc's (e.g., 1980) contention that mere exposure is the result of a simple, and *automatic*, affective conditioning process.

In current usage, an automatic process is fast, consumes little if any cognitive capacity, and is largely unconscious in the sense that it occurs without awareness and is neither intentional nor controllable (e.g., Bargh 1997). Automatic attitude formation is therefore of great importance insofar as it challenges traditional cognitive theorizing that attitudes (and numerous other types of judgments) are the product of deliberative cognitive processing of information in one's environment. Deliberative, or controlled, processing is everything that automatic processing is not: It is relatively slow, demands cognitive resources, and proceeds with intentionality and awareness. A theoretical possibility in the 1980s, automatic attitude formation has now been demonstrated in a variety of experimental paradigms. Most notably, mere exposure effects have been found even when research participants cannot consciously recognize the stimuli to which they are (more or less frequently) exposed. In much of this work, participants have been exposed to stimuli subliminally. Despite the phenomenological fact that participants have no idea which stimuli are 'old' (i.e., those that have been presented subliminally) and which stimuli are 'new' (i.e., those that have never been presented) they nevertheless exhibit a strong evaluative preference for 'old' stimuli (see Zajonc 1980). In related work, researchers have shown affective priming effects (e.g., Murphy et al. 1995). In such studies, participants' attitudes toward novel stimuli (e.g., geometric figures) are more positive (or more negative) when these stimuli are presented just after (a single) subliminal exposure to an emotionally evocative positive (or negative) picture.

Complementing this work has been research demonstrating that people may automatically evaluate virtually everything in their environment (see Bargh 1997). In this research paradigm, participants are briefly exposed to an 'attitude object prime' of positive or negative valence (e.g., 'summer' or 'snake') and, a fraction of a second later, to a target adjective of positive or negative valence (e.g., 'beautiful' or 'ugly'). Participants' task is to respond in some manner to the target word (e.g., to pronounce it) while ignoring the prime word. Results across a variety of instructional sets and stimuli (including familiar as well as novel stimuli) indicate that participants are engaged in automatic evaluation of the prime word. This is demonstrated by the fact that participants are, for example, faster to pronounce a target word (e.g., 'ugly') if it has been preceded by a prime of like valence (e.g., 'snake' vs. 'summer').

In addition to attitudes arising out of cognitive and affective responding to attitude objects, attitudes can of course also arise from behavioral responding. In most such direct experience situations, behavior's impact on attitude is probably mediated by a combination of affective and cognitive responding; in other words, behavior vis-à-vis an attitude object elicits both beliefs and feelings in perceivers which, in turn, give rise to an overall attitude, or evaluation. There are, however, other mechanisms by which behavior creates attitudes. In classic dissonance research, participants induced to engage in a behavior assumed to be at odds with their (often unmeasured) initial attitudes subsequently report attitudes that are congruent with their induced behavior, presumably out of a desire to reduce the dissonance, or discomfort, caused by an attitude–behavior discrepancy. A more purely cognitive account of the same phenomenon is provided in self-perception theory. In this account, people are assumed to have little access to their interior feelings and beliefs. Hence, when induced to perform a certain behavior (e.g., signing a petition) they simply infer that they possess an attitude congruent with that behavior, perhaps using the simple heuristic that 'behavior x implies disposition or attitude y' (see Chaiken et al. 1996).

This section has emphasized how attitudes are formed in an experiential way based on direct or indirect cognitive, affective, or behavioral responding to an attitude object. Contemporary scholarship holds that this responding is represented in memory as attitude object–response associations. As evaluative meaning is abstracted from these associations, an attitude is formed as a generalization from more elementary associations. In contrast to this intra-attitudinal mode of attitude formation, people may also form attitudes by forging linkages between an attitude object and other attitude objects. Such linkages, or associations, are represented in memory along with the target attitude itself. Often this interattitudinal mode of attitude formation entails an inference by which a new attitude (e.g., toward recycling) is deduced from a more abstract or general attitude that has already been formed (e.g., the value of 'a world of beauty').

3. *Attitude Structure*

Attitudes have most often been measured by self-report. Paralleling the automatic-controlled processing distinction, contemporary researchers have begun to label such measures *explicit*, because respondents are usually well aware that their attitudes are the target of measurement. For decades researchers have explored various 'unobtrusive' attitude measures, including physiological assessments such as heart rate, pupil size and, more recently, facial muscle patterns. These have been newly labeled *implicit*, insofar as respondents are usually unaware of the purpose of these measurements. Promising new implicit measures rely on response-time methods such as those featured in the automatic evaluation paradigm described earlier, and dissociations between explicit and implicit measures are attracting a great deal of empirical attention (e.g., Fazio 1995; see also *Attitude Measurement*).

Regardless of their explicit or implicit nature, measures of attitude have traditionally been used to locate individuals along a bipolar dimension running from highly positive to highly negative toward the attitude object. If theorists assumed that attitude structure reflected this operational definition (though generally they do not), attitudes would have, at best, rather simple structural properties. Although some such properties have been ascribed to attitudes, most researchers have focused on (a) attitude's relation to other attitudes, as in Heider's classic balance theory and some ideological conceptions of structure; and even more so on (b) attitude's associations with attitude-relevant beliefs, affects, and behaviors (see Eagly and Chaiken 1993, 1998). This discussion focuses on the latter, more extensively researched issue, namely intra-attitudinal structure. Critical to work on this topic is the assumption that attitudinal responding is better understood when attitudes' internal structure is taken into account along with the sheer positive vs. negative nature of overall attitude.

Considering that attitudes are formed through affective as well as cognitive (and behavioral) responding, and that attitudes and associated beliefs and affects are represented in memory, it is unsurprising that questions regarding the nature of such associations would be of interest to investigators. Most work has concentrated on attitude-relevant beliefs, and structural properties such as the amount, complexity, and consistency of beliefs have been examined. For example, how many beliefs a person holds about an attitude object is important for understanding the processing of new attitude-relevant information; more knowledgeable people tend to process information deeply, or systematically, whereas less knowledgeable people tend to process information superficially, or heuristically (e.g., Wood et al. 1995). As a second example, belief complexity is predictive of either attitudinal extremity or attitudinal moderation, depending on other conditions such as the extent to which beliefs are evaluatively redundant (e.g., Judd and Lusk 1984). Finally, the extent to which beliefs are themselves more or less evaluatively congruent has also yielded interesting insights. Inconsistency among beliefs, often termed *ambivalence*, is associated with attitude instability and heightened susceptibility to social influence. Similar structural properties no doubt exist with respect to affective associations to attitude objects but have to date not been well researched.

A particularly interesting structural property is evaluative-cognitive consistency—the extent to which

the evaluative implications of a person's stored (or accessible) beliefs match the evaluation implied by overall attitude. Research on this property has, for example, shown that high consistency attitudes are better predictors of behavior and are also more resistant to social influence attempts (see also *Attitudes and Behavior*; *Attitude Change*: *Psychological*). More recent work has also demonstrated the importance of evaluative-affective consistency—the extent to which the evaluative implications of affective associations match the evaluation implied by overall attitude. For example, research on selective memory has shown that higher evaluative-affective consistency produces a memory bias favoring attitude-congruent information; in contrast, higher evaluative-cognitive consistency produces a memory bias favoring attitude-incongruent information (see Eagly and Chaiken 1998). This research reflects another recent structural distinction, whether affect-based attitudes behave differently from cognitively based attitudes. In these terms, the selective memory research just described could be restated as showing that affective attitudes produce a congeniality bias, whereas cognitive attitudes produce an incongruency bias. Additional issues regarding attitude basis are sure to receive increased empirical attention in the future.

One of the most important reasons for examining attitude structure is its relation to the concept of attitude *strength*. Although traditional treatments of attitude held that they are important to study because attitudes guide thought, judgment, and behavior, contemporary investigators know well that not all attitudes are equally predictive of such outcomes. Hence the concept of attitude strength; 'strong' attitudes are highly predictive of thought, judgment, and behavior while 'weaker' attitudes are not. But what, exactly, constitutes a strong attitude? There have been numerous conceptions of attitude strength; for example, that such attitudes are 'personally important,' or 'ego-involving,' or 'intense,' or 'come easily to mind,' and so on. Yet there is not yet consensus on strength's conceptual definition or its specific properties or, for that matter, whether there are multiple aspects of strength. Research on attitude structure, however, presents a promising and relatively integrative way of examining the nature of attitude strength (see Eagly and Chaiken 1995). For example, some strength research suggests that affective attitudes may be stronger than cognitive attitudes; such attitudes come to mind more easily (i.e., are more accessible) and may well be more predictive of behavior (e.g., Fazio 1995). Other work suggests that regardless of whether attitudinal associations in memory are mostly affective, mostly cognitive, or some combination, attitudes are stronger to the extent that their internal structure consists of many (vs. few) affective and/or cognitive associations, especially when such associations possess greater *evaluative consistency* (see Eagly and Chaiken 1995, 1998).

Although issues of attitude structure have been addressed throughout the history of attitude theorizing and research, there has been a renaissance of sorts on this topic since the early 1990s. Because of its importance to a large number of attitudinal phenomena (e.g., attitude strength, selective information processing, attitudinal persistence and resistance to change), it is likely to be a prominent area of research for many years to come.

4. *Attitude Functions*

Why do people hold attitudes? Like other broad questions, this one can be answered on several levels. Yet the assumption underlying all such answers is the usual functionalist premise that attitudes enable individuals to adapt to their environment. The most profound sense in which attitudes help people adapt emerges readily from their definition. To evaluate—to assess the degree of goodness vs. badness inherent in features of one's world—is absolutely fundamental to the task of survival. If people were unable to identify 'good' stimuli, those that enable survival and enhance well-being, and to identify 'bad' stimuli, those that threaten survival and lessen well-being, they would fail to thrive.

Consistent with this view, the seminal work of Osgood et al. (1957) argued that evaluation is primary, and offered as their main evidence numerous factor analyses of meaning in which an evaluative factor accounted for more variability than any other factor (in particular, potency and activity). Although always influential in attitude theory, the strongest evidence for the primacy of evaluation has come only recently, in research on evaluative primacy and the automatic nature of attitude formation. As cited earlier, for example, Bargh and colleagues (see Bargh 1997) have shown that people immediately (i.e., within a fraction of a second) evaluate as good or as bad any stimulus object presented to them—regardless of whether the object is a word or a picture, regardless of the strength of one's stored evaluation of the object, and regardless of whether the object is familiar or novel.

Smith and colleagues (e.g., Smith et al. 1956) captured this essential function of attitudes in their conception of *object appraisal*, a function by which attitudes allow people to appraise stimuli in terms of their goals and concerns. Shortly thereafter, Katz (1960) essentially partitioned the object appraisal function into two components. Whereas Katz's *knowledge* function emphasized the cognitive function of facilitating people's ability to interpret and make sense of otherwise disorganized perceptions, his *instrumental* function emphasized the motivational function of facilitating people's ability to maximize rewards and minimize punishments. Object appraisal, which joins the knowledge and instrumental aspects of attitudes, should be regarded as attitudes' universal function.

Indeed, many contemporary discussions emphasize that attitudes allow people to categorize objects, persons, and events and to differentiate between things they should approach and things they should avoid (Eagly and Chaiken 1998).

The universal, object appraisal function of attitudes implies a very general view of the kinds of rewards and punishments with which attitudes are associated. These positive and negative outcomes may reflect both narrow self-interest and more abstract benefits such as the affirmation of one's values or self-concept. To stabilize terminology with respect to attitudes' facilitation of rewarding outcomes, Eagly and Chaiken (1998) have proposed that object appraisal should indeed encompass all classes of positive and negative outcomes. In contrast, a narrower *utilitarian* function should encompass only those concrete rewards and punishments (e.g., money, opportunities) that the attitude object provides directly. This narrower function is useful for contrast with an *expressive* function of attitudes wherein psychological gains and losses follow from holding or expressing an attitude. For example, in discussions of *symbolic politics*, researchers have tried to determine whether people's attitudes toward policies such as affirmative action are better predicted by narrow self-interest or by internalized social values such as fairness and equality (see Sears and Funk 1991).

Three additional functions of attitudes have frequently been identified. The *value-expressive* function assumes that people find it inherently rewarding to hold and express attitudes that affirm their core values and self-concepts. The *social adjustive* function assumes that there are inherent rewards in holding and expressing attitudes that are pleasing to others or that coincide with the norms and values of important reference groups. Finally, the *ego-defensive* function assumes that holding or expressing attitudes can also serve to defend the self (and one's important reference groups) from potentially threatening events. Because these functions are not inherent in the nature of all attitudes, they, along with the utilitarian function, coexist with the universal object appraisal function. Moreover, these more specific functions are assumed to be more important for some individuals, for some attitude objects, and under some circumstances. Identifying when attitudes serve these particular functions, and how attitude functions map on to structural issues has been and will remain a key issue for researchers (see Eagly and Chaiken 1998).

5. *Future Directions*

The purpose of this article has been to inform readers outside the area of attitudes about classic and contemporary theoretical and empirical issues. As noted earlier, attitude theory and research has been central to the discipline of social psychology since its inception. While this area of inquiry has been highly programmatic and remains vigorous and rigorous in its theorizing and methodologies, there are ample issues for future research. Some have already been mentioned. For example, future directions should include achieving a better understanding of distinctions such as automatic vs. controlled processing in attitude formation (and change), implicit vs. explicit measures of attitude, and the relation between attitude structure and attitude strength and between attitude structure and attitude function. In addition, future research would benefit greatly from greater attention to other psychological disciplines as well as other social science disciplines. For example, little social psychological work on attitudes has considered developmental issues such as how attitudes develop over time or across the lifespan. Finally, although attitude is an important construct throughout the social sciences, there has been too little scholarly contact between social psychological and other social science treatments of attitudes. Greater attention to integrating knowledge across relevant disciplines should ensure the continuing fundamental importance of the attitude construct.

Attitude Measurement

The term *attitude* refers to a hypothetical construct, namely a predisposition to evaluate some object in a favorable or unfavorable manner. This predisposition cannot be directly observed and is inferred from individuals' responses to the attitude object, which can run from overt behavior (such as approaching or avoiding the object) and explicit verbal statements to covert responses, which may be outside of the individual's awareness (such as minute facial expressions). This article reviews diverse measurement procedures that draw on these different manifestations of attitudes (see Oskamp 1991, for a history).

1. *Explicit Self-reports*

Most attitude researchers rely on respondents' answers to questions, such as 'Do you approve or disapprove of how President Clinton is handling his job?' Direct questions are the most feasible procedure for assessing the attitudes of the population at large, e.g., in representative sample surveys. Unfortunately, self-reports of attitudes are highly context dependent and minor changes in question wording, question format, and question order can dramatically alter the obtained results (for reviews see Schuman and Presser 1981, Schwarz and Sudman 1992, Tourangeau et al. 2000). This section addresses the underlying processes and their implications for the measurement and conceptualization of attitudes.

1.1 *The Question Answering Process*

To answer an attitude question, respondents need to: (a) understand the meaning of the question; (b) retrieve relevant information from memory to; and (c) form an attitude judgment. In most cases, they also need to: (e) map their judgment onto the response alternatives provided by the researcher; and they (f) may want to edit their response before they report it, due to reasons of social desirability and self-presentation. Respondents' performance at each of these steps is highly context dependent (see Sudman et al. 1996 for a comprehensive treatment). The cognitive and communicative processes involved in these tasks are reviewed in *Data Collection: Interviewing*, *Questionnaires: Assessing Subjective Expectations*, and this material applies directly to attitude questions. The following discussion is restricted to specific aspects of the judgment stage and the use of different response formats.

1.2 *The Construction of Attitude Judgments*

Once respondents determined what the question refers to, they need to recall relevant information from memory. In some cases, they may have direct access to a previously formed relevant judgment that they can offer as an answer. In most cases, however, they will not find an appropriate answer readily stored in memory and will need to compute a judgment on the spot. To do so, they need to form a mental representation of the attitude object and of a standard, against which the object is evaluated. The resulting judgment depends on which information happens to come to mind at that point in time and on how this information is used.

As a large body of research demonstrated, individuals rarely retrieve all information that may bear on an attitude object but truncate the search process as soon as enough information has been retrieved to form a judgment with sufficient subjective certainty (Wyer and Srull 1989). Hence, the judgment depends on the first few pieces of information that come to mind. Whereas some information may always come to mind when the person thinks of this object (and is therefore called *chronically accessible*), other information may be only *temporarily accessible*, for example, because it

has been brought to mind by preceding questions. Changes in what is temporarily accessible are at the heart of many context effects in attitude measurement, whereas chronically accessible information contributes some stability to attitude judgments.

How accessible information influences the attitude judgment depends on how it is used. Information that is included in the mental representation formed of the attitude object results in assimilation effects, i.e., the judgment becomes more positive (negative) when information with positive (negative) implications comes to mind. In contrast, information that is used in forming a mental representation of the standard against which the attitude object is evaluated results in contrast effect. In this case, the judgment becomes more negative (positive) when information with positive (negative) implications comes to mind and is used as a positive (negative) standard of comparison. Suppose, for example, that a preceding question brings a politician to mind who was involved in a scandal (say, Richard Nixon). When a subsequent question pertains to the trustworthiness of American politicians in general (a superordinate category), Richard Nixon is likely to be included in the representation formed of 'politicians' as a group, resulting in judgments of decreased trustworthiness (an *assimilation effect*). Suppose, however, that the question pertains to the trustworthiness of Bill Clinton (a lateral category), rather than to politicians in general. In this case, Richard Nixon cannot be included in the representation formed of the attitude object 'Bill Clinton'; instead, he is likely to serve as a (rather negative) standard of comparison, relative to which Bill Clinton will be evaluated as more trustworthy than would otherwise be the case (a *contrast effect*). As this example illustrates, the same context question can have profoundly different effects on superficially similar subsequent questions, resulting in many apparent inconsistencies: in the present case, a researcher might conclude that political scandals decrease trust in politicians when judgments of the group are used as the dependent variable, but increase trust in politicians when judgments of individual politicians are used as the dependent variable.

If a given piece of information is used in constructing a representation of the attitude object (resulting in assimilation effects), or of a standard of comparison (resulting in contrast effects), depends on a host of different variables. Sudman et al. (1996, Chap. 5) review these variables and summarize a theoretical model that predicts the direction, size, and generalization of context effects in attitude measurement.

1.3 Some Attitude Scale Formats

Textbooks consistently advise researchers to use multi-item scales. Yet, the classic examples of multi-item attitude scales—namely, *Thurstone scales, Guttman scales*, and *Likert scales* (see Eagly and Chaiken 1993, Chap. 2)—are rarely used in practice, primarily because they require extensive, topic-specific development work. An exception is Osgood and colleagues' *Semantic Differential Scale*(see Eagly and Chaiken 1993, Chap. 2), which is a ready-to-use scale that can be applied to any topic, making it considerably more popular. Respondents are asked to rate the attitude object (e.g., 'welfare') on a set of seven-point bipolar adjective scales. The adjectives used as endpoint labels reflect three general factors, namely evaluation (e.g., good–bad; pleasant–unpleasant), potency (e.g., strong–weak; small–large), and activity (e.g., active–passive; fast–slow). Of these factors, evaluation is considered the primary indicator of respondents' attitude towards the object, as reflected in the objects' (relatively global) connotative meaning.

However, in most studies respondents' attitudes are assessed by only one or two questions, presented either with multiple-choice response alternatives or a rating scale. When the question offers several distinct opinions in a *multiple-choice format*, it is important to ensure that the set of response alternatives offered covers the whole range of plausible positions. Any option omitted from the set is unlikely to be reported at all, even when respondents are offered a general 'other' response option, which they rarely endorse. Similarly, few respondents report not having an opinion on an issue when this option is not explicitly provided—yet, they may be happy to report so when 'don't know' is offered as an alternative (see Schuman and Presser 1981, Schwarz and Hippler 1991, for reviews).

When *rating scales* are used, respondents are presented with a numerical scale with verbally labeled endpoints (e.g., -3 = 'strongly disagree,' $+3$ = 'strongly agree') and asked to check the number that best represents their opinion. Alternatively, each point of the rating scale may be labeled, a format that is common in telephone interviews. In general, the retest-reliability of fully labeled scales is somewhat higher than that of partially labeled scales and retest reliability decreases as the number of scale points increases beyond seven, reflecting the difficulty of making many fine-grained distinctions (Krosnick and Fabrigar in press). What is often overlooked is that the numeric values of the scale may influence respondents' substantive interpretation of the question. For example, when asked to report how highly they think of a politician along a scale from 'not so highly' to 'very highly,' respondents need to determine if 'not so highly' pertains to the absence of positive thoughts or to the presence of negative thoughts. When the numeric values run from 0 to 10, respondents interpret 0 = 'not so highly' as reflecting the absence of positive thoughts; but when the scale runs from -5 to $+5$, they interpret -5 = 'not so highly' as pertaining to the presence of negative thoughts. In general, scales that

range from negative to positive numbers suggest that the researcher has a bipolar dimension in mind, implying that one endpoint label refers to the *opposite* of the other; in contrast, scales that present only positive numbers suggest a unipolar dimension, implying that different scale values pertain to different degrees of the *same* attribute. Such shifts in question meaning result in markedly different responses (see Sudman et al. 1996, Chap. 3, for what respondents learn from scales).

1.4 Implications

The emergence of context effects in attitude measurement raises important theoretical issues. Traditionally, attitudes have been conceptualized as enduring dispositions, implying that context effects represent undesirable noise. In fact, some researchers suggested that context effects may only emerge when respondents have not yet formed an opinion about the object, but not when respondents have formed strong, or crystallized, attitudes. Empirically, however, this *attitude strength* hypothesis has received little support (see Krosnick and Abelson 1992, for a review). Alternatively, we may conceptualize attitudes as evaluative judgments that are formed on the spot, when needed, based on whatever information is accessible at the time. These diverging perspectives have differential implications for the conditions under which we can expect attitude stability over time, or close attitude-behavior relationships, and suggest different research and measurement strategies (see Schwarz and Bohner 2001).

2. Implicit Attitude Measures

Complementing direct attitude questions, researchers have developed a number of indirect measures, often intended to assess attitudes that respondents may not be willing to report or of which they may themselves be unaware. Such measures include projective procedures, such as the *Thematic Apperception Test*, as well as more recent developments that rely on response time measurement, such as lexical decision or pronunciation tasks. These measures are commonly referred to as *implicit measures* and their hallmark is that respondents are not aware that their attitude is being assessed.

The use of *lexical decision tasks* is based on the observation that a letter string (e.g., 'doctor') is more quickly recognized as a meaningful word when preceded by a closely related concept (e.g., 'nurse') rather than an unrelated one (e.g., 'butter'). In applications of this method, meaningful words as well as meaningless letter strings are presented for a very short time and respondents are asked to say, as quickly as possible, if what they see is a word or a nonword; alternatively, they may be asked to *pronounce* the word as fast as possible. Of interest is how fast they can recognize a given evaluatively laden word when it is, or is not, preceded by the attitude object (for reviews see Bassili 2001, Dovidio and Fazio 1992). Using this procedure to assess racial attitudes in the United States, researchers observed, for example, that words describing positive personality traits were recognized faster than words describing negative personality traits when preceded by 'Whites,' whereas the reverse held true when the same traits were preceded by 'Blacks.' These findings indicate that positive traits are more closely associated with the attitude object 'Whites' than negative traits, whereas the reverse holds for the attitude object 'Blacks.' More complex variants of this general approach include the *Implicit Associations Test*(*IAT*), which draws on the observation that a given response, like pressing a key with one's left index finger, is easier (and hence faster) when all objects associated with this response share the same valence (see Bassili 2001, Banaji et al. 2001, for reviews).

In most studies, the results obtained with these implicit procedures are only weakly related to explicit self-reports of attitudes or overt behavior. Some researchers concluded that this observation demonstrates the power of implicit measures: presumably, the weak relationships indicate that these procedures assess attitudes that respondents do not want to admit or may not even be aware of. In contrast, others wondered what weak relationships imply for the validity of implicit measures: do they really assess evaluative dispositions or do the results merely reflect the structure of semantic knowledge with limited behavioral implications? Recent research further suggests that implicit measures are as likely to show context effects as explicit measures, potentially thwarting the hope that they may provide an unbiased window on individuals' attitudes (see Banaji et al. 2001). Future work in this very active area will need to settle these issues.

3. Observational and Psychophysiological Measures

In principle, an individual's attitude towards some object may be inferred from his or her behavior towards it. Unfortunately, however, individuals' behavior is influenced by many variables other than their attitudes and the attitude-behavior relationship is typically weak. Hence, direct *behavioral observation* is rarely used in attitude measurement.

As an alternative observational approach, researchers may assess individuals' physiological responses to the attitude object (for reviews see Cacioppo et al. 1994, Winkielman et al. 2001). If an attitude object evokes strong feelings, exposure to it should be

associated with increased activation of the sympathetic nervous system. Increased sympathetic activation results in increased sweat glands activity, which can be measured by assessing the resistance of the skin to low level electric currents. This *electrodermal measurement*, however, has the disadvantage that sweat glands activity only reflects the intensity but not the direction (favorable or unfavorable) of the evaluative response, thus limiting its usefulness.

More promising are attempts to assess changes in individuals' facial expression in response to an attitude object. Overt facial expressions (like smiling or frowning) may often be observed in response to attitude objects that elicit strong reactions. Yet, these expressions may be intentionally concealed and many evaluative reactions may be too subtle to evoke overt expressive behaviors. Even subtle evaluative reactions, however, are associated with low-level activation of facial muscles that can be detected by *electromyography* (EMG). These muscle reactions reflect the direction (favorable vs. unfavorable) as well as the intensity of the evaluative response. Unfortunately, the obtained measures can be distorted by facial movements that are unrelated to the evaluative reaction, rendering their interpretation ambiguous in the absence of additional evidence.

Another potentially promising development involves the measurement of brain activity through *electroencephalography* (EEG), the assessment of small electric signals recorded from the scalp. This procedure, however, does not lend itself to a direct assessment of positive or negative responses. Instead, it capitalizes on the observation that unexpected stimuli evoke brain wave activity that differs from the activity evoked by expected stimuli. Hence, one may detect if a target object is evaluated positively or negatively by embedding its presentation in a long series of other objects with a known evaluation. The brain activity evoked by the target object will then indicate if its evaluation is consistent or inconsistent with the evaluation of the context objects.

4. Future Directions

Different attitude measures may suggest different conclusions, giving rise to debates over which one best reflects respondents' 'true' attitude. Subliminal exposure to 'cod liver oil,' for example, may facilitate your identification of 'disgusting' as a 'bad' word and may elicit a negative physiological response, yet you report that you think cod liver oil is good for you and you take it regularly. Which of these diverging responses should we consider an unbiased indicator of your 'true' attitude? Each measure reflects a different aspect of a complex phenomenon, rendering the designation of any single one as the only 'true' window on individuals' attitudes counterproductive. Understanding the interplay between cognitive, affective, physiological, and behavioral responses presents the most challenging issue for future research.

Attitudes and Behavior

Although there is no single, universally accepted definition of 'attitude', social psychologists use the term to refer to a relatively enduring tendency to respond to someone or something in a way that reflects a positive or a negative evaluation of that person or thing. Eagly and Chaiken (1993, p. 155) define attitudes as 'tendencies to evaluate an entity with some degree of favor or disfavor, ordinarily expressed in cognitive, affective, and behavioral responses.' This immediately raises the issue of the relationship between attitude and behavior, since 'behavioral responses' are given as one of the ways in which an individual can express evaluation of the attitude object. If cognitive, affective, and behavioral measures of evaluative responses to an object are all indices of the same underlying construct, attitude, there should be some consistency between them. If measures of cognitive and affective responses to an attitude object fail to correlate with measures of behavioral responses, the widespread assumption that attitudes consist of these three components is called into question.

This 'three-component' view of attitudes is one theoretical basis for expecting attitudes to be correlated with behavior. Another is Festinger's (1957) theory of cognitive dissonance. Festinger argued that humans are characterized by a need to maintain consistency between their cognitions. These cognitions can be about one's behavior ('I told somebody else that I really enjoyed the meal') and about one's attitudes ('At the time I ate the food I did not like it very much'). If individuals become aware of inconsistencies between cognitions, they are said to experience 'cognitive dissonance,' an unpleasant state that they will be motivated to reduce or eliminate. Thus where an individual has had some behavioral experience with the attitude object, there should be a positive correlation between attitudes and behavior.

1. *Early Empirical Evidence*

There are various reasons, then, for expecting attitudes and behavior to be correlated. However, early empirical studies yielded evidence of a weak relation between these constructs. In 1969 Wicker published an influential review of 45 studies on the attitude–behavior relation. He found that the correlation between measures of attitude and measures of behavior rarely exceeded 0.30 and was often closer to zero. The mean correlation was 0.15. Wicker (1969, p. 65) concluded that 'it is considerably more likely that attitudes will be unrelated or only slightly related to overt behaviors than that attitudes will be strongly related to actions.' This led Wicker and others to suggest that the attitude concept should be abandoned. Although there was a crisis in confidence in the attitude–behavior relationship in the early 1970s, the attitude concept has not been abandoned; indeed, research on the attitude–behavior relationship has flourished.

2. *The Principles of Aggregation and Compatibility*

The field was transformed by Ajzen and Fishbein's (1977) paper, in which the authors developed two principles—the principle of aggregation, and the principle of compatibility. The principle of aggregation is a straightforward application to the attitude–behavior relation of ideas well known to psychometricians. A standard notion in psychological measurement is that one should not try to measure anything but the simplest of constructs using a single item. Precisely the same point applies to the measurement of attitudes and of behavior. In attitude measurement the logic of this argument is generally recognized, and present-day researchers would not attempt to assess attitudes using a single item. However, researchers have not always been as careful to apply these elementary principles to the assessment of behavior. Take DeFleur and Westie's (1958) study. They used a multiple-item measure of white persons' attitudes to black persons, but a single-item measure of behavior, namely whether or not a white participant was willing to be photographed with a black person of the opposite sex. How validly does this measure reflect a dispositional tendency to behave favorably or unfavorably towards black persons? Someone with nonracist attitudes might refuse to have his or her photograph taken because of a reluctance about being photographed. The solution is to use more than one item to assess the behavioral disposition to act positively or negatively towards black persons. This is the principle of aggregation: by aggregating across different measures of behavior toward the entity in question, one arrives at a more valid and reliable index of an evaluative tendency expressed in behavior. Thus it should be easier to find strong attitude–behavior correlations where both attitudes and behavior are measured using multiple items, and there is empirical evidence to support this (see Eagly and Chaiken 1993).

The principle of aggregation leads to the conclusion that general measures of attitude should be better predictors of general measures of behavior than of specific measures of behavior. The principle of compatibility is a logical extension of this argument, being more precise about what is meant by 'general' and 'specific.' Ajzen and Fishbein (1977) noted that a behavior varies not only with respect to the action performed; other elements are the target at which the action is directed, the context in which the action takes place, and the time at which it takes place. The principle of compatibility states that measures of attitudes and behavior are more likely to be correlated with each other if they are compatible with respect to

action, target, context, and time. Thus if your attitudinal measure is a general one, not tied to any specific action, target, context, or time, it should not be surprising to find that behavioral measures that are tied to specific actions, objects, contexts, and times correlate poorly with the attitudinal measure. The corollary is that if the behavior one seeks to predict is specific with respect to action, object, context, and time, then the attitudinal measure employed should be compatible with the behavioral measure in these respects. There is also empirical evidence to support this (see Eagly and Chaiken 1993).

Armed with these principles, we can account for the early failures to find substantial correlations between attitudes and behavior. DeFleur and Westie (1958), along with many others, used general measures of attitude to predict quite specific measures of behavior, usually involving a specific action toward designated objects in a certain context and at a particular time. Ajzen and Fishbein (1977) reviewed previous studies of the attitude–behavior relation in terms of whether or not the attitudinal and behavioral measures had been compatible. Where the measures were not compatible, the correlation was typically nonsignificant; but in all 26 studies in which the measures were compatible, the correlation was significant.

3. *The Theory of Reasoned Action*

These methodological analyses of the attitude–behavior relation were not the only responses to Wicker's (1969) conclusions. Social psychologists also began developing theoretical frameworks in which the attitude–behavior relation was nested within a broader causal model. The central point of these models is that thinking of behaviors as being determined exclusively or even principally by attitudes is an oversimplification. Moreover, this sits rather strangely in a discipline—social psychology—whose primary focus of concern can be regarded as the impact of social factors on behavior. Although attitudes are implicitly regarded as 'social products' by most attitude researches, in practice they are treated as attributes of the individual. Thus, much of the research effort on the attitude–behavior relation can be seen as focusing on the way in which an individual's behavior is shaped by personal attributes. Yet many of the classic studies in social psychology (e.g., Asch 1951, Milgram 1963) testify to the powerful effects that the implicit and explicit expectations of others can have on behavior. The best known of the theoretical frameworks in which the attitude–behavior relation was set in a broader causal model, incorporating the impact of social factors, is what came to be known as the theory of reasoned action (TRA) (Fishbein and Ajzen 1975).

The TRA has two key attributes. First, consistent with the principle of compatibility, it holds that strong relations between attitudes and behavior will only be found where attitudinal measures and behavioral measures are compatible with each other. Second, attitude is construed as just one determinant of behavior. The model is represented diagrammatically in Fig. 1.

Figure 1
The theory of reasoned action (after Fishbein and Ajzen 1975)

The immediate determinant of behavior in this model is behavioral intention, or how the individual intends to act. This reflects an important assumption of the TRA, namely that most of the behaviors that social psychologists are interested in studying are 'volitional' in nature, in the sense that they can be performed (or not performed) at will.

Intention, in turn, is determined by the individual's attitude to the behavior in question, and by his or her subjective norm. Attitude to behavior is, of course, the individual's evaluation of the behavior. Subjective norm refers to the individual's belief that important others expect him or her to perform (or not to perform) the behavior. The relative contributions of attitude to behavior and subjective norm in determining behavioral intentions is left open; which of these factors is more important in shaping intentions is thought to depend on the behavior and the individual in question.

The TRA unfolds further by specifying the determinants of attitudes to behavior and of subjective norms. In the case of attitudes, the determinants are said to be behavioral beliefs, that is, beliefs about the consequences of performing the behavior; and outcome evaluations, or the individual's evaluation of each of those consequences. Thus attitude to behavior is treated as an evaluation of performing the behavior, based on the perceived likelihood that carrying out the behavior leads to outcomes of which one approves or disapproves. In the case of subjective norms, the determinants are said to be normative beliefs, or the individual's beliefs that each of a number of significant others expects him or her to act in a certain way; and motivations to comply, or the individual's inclination to conform to these other people's expectations. Thus

subjective norm is based on the perceived expectations of others, weighted by the extent to which one is inclined to fulfil those others' expectations.

The TRA has in many respects been highly successful. It has been widely used by social psychologists and other social scientists, and it has generally performed quite well in terms of the ability of the constructs in the model to predict behavior and behavioral intentions. The performance of the TRA has been assessed in various meta-analytic studies. In a widely cited meta-analysis of 87 separate studies, Sheppard et al. (1988) found a weighted average multiple correlation of 0.66 for the relationship between attitude and subjective norm, on the one hand, and behavioral intention, on the other. The average correlation between behavioral intention and behavior was 0.53. It is clear, then, that behavioral prediction can be achieved with reasonable accuracy if one assesses behavioral intentions, rather than attitudes; and that behavioral intentions, in turn, can be predicted with acceptable accuracy if one assesses attitude to behavior and subjective norm.

However, the TRA is concerned with more than simply the prediction of intentions and behaviors. It also attempts to provide an explanation for behavior, by specifying the determinants of intentions (i.e., attitude to behavior and subjective norm), as well as the factors that underlie these determinants (i.e., behavioral beliefs, outcome evaluations, normative beliefs, and motivations to comply). How does this help to explain behavior? Fishbein and Ajzen (1975) assume that the basic building blocks of volitional behavior are beliefs, values, and motives. Attitudes to behavior are built up through experience (direct and indirect) of the behavior in question, in the course of which individuals form and change beliefs about the consequences of the behavior. They may also form or change their evaluations of these consequences. If behavioral beliefs and outcome evaluations together determine an individual's attitude to a given behavior, and attitude to behavior in turn shapes behavioral intentions, identifying which behavioral beliefs and outcome evaluations distinguish people with positive intentions from those with negative intentions helps us to understand and explain behavior.

Exactly the same reasoning applies to the role of normative beliefs and motivations to comply in shaping subjective norms. To the extent that those who engage in a behavior (or who intend to engage in that behavior) differ significantly on these variables from those who do not, it can be argued that key determinants of the behavior in question have been identified. From an applied perspective, the importance of this process of identifying at the level of behavioral beliefs, outcome evaluations, normative beliefs, and motivations to comply which factors discriminate 'intenders' from 'nonintenders', or those who do perform the behavior from those who do not, resides in the enhanced potential for designing effective interventions. In devising such interventions (e.g., to quit smoking, engage in regular exercise, drive within the speed limit, use condoms), it clearly makes sense to focus the communication on those factors that are known to determine the behavior you are trying to change.

Successful though the TRA has undoubtedly been, it has certain limitations. One objection is that it is better suited to the prediction and understanding of challenging behavioral decisions that require the individual to deliberate the pros and cons of alternative courses of action than to the prediction and understanding of everyday, routine behaviors, of behaviors that have a strong habitual component. Much of our everyday behavior, according to this argument, is engaged in rather spontaneously and unthinkingly: It is more a matter of habit than of careful consideration. Consistent with this, various investigators have reported a significant direct link between previous behavior and current behavior, unmediated by the constructs of the TRA. This is inconsistent with the theory of reasoned action, which holds that the influence of past behavior on present behavior is mediated by constructs within the model. One explanation for this sort of finding is that both past and present behaviors are influenced by essentially noncognitive factors, such as habit, conditioning, or addiction (see Ouellette and Wood 1998).

One way in which Fishbein and Ajzen (1975) could respond to the challenge presented by the notions of habit, conditioning, and addiction would be to point out that the TRA was developed in order to predict and understand behaviors that are engaged in voluntarily by the individual. Habitual, conditioned, and addictive behaviors therefore lie outside the model's explanatory scope. However, the restriction to volitional behaviors also excludes any behaviors that require skills, resources, or the cooperation of others, a point made by Liska (1984). In other words, only the simplest and most trivial of behaviors are entirely under volitional control, in the sense that performance of such behaviors is dependent only on the individual's motivation to perform the behavior. This issue of the role played by control over behavior was a major reason for the development of a successor to the TRA, in the form of the theory of planned behavior.

4. *The Theory of Planned Behavior*

Ajzen (1985) proposed the theory of planned behavior (TPB) with the explicit goal of extending the explanatory scope of the TRA. Recognizing that at least some of the behaviors that social psychologists want to explain and understand are not under complete volitional control, Ajzen added a new construct, which he called perceived behavioral control. This construct represents the individual's perception of how easy or difficult it is to perform the behavior in question. A

Figure 2
Theory of planned behavior (after Ajzen 1991)

behavior that is seen as easy to perform is high in perceived behavioral control; one that is seen as difficult to perform is low in perceived behavioral control. The TPB argues that an individual who has high perceived behavioral control with respect to a particular behavior is more likely to form the intention to perform that behavior, and is more likely to act on that intention in the face of obstacles and setbacks, than someone who is low in perceived behavioral control.

Just as attitudes to behavior and subjective norms are seen within the TRA as being founded on beliefs, so perceived control is regarded within the TPB as being founded on control beliefs. These are expected to reflect direct, observed, and related experiences of the behavior and 'other factors that may increase or reduce the perceived difficulty of performing the behavior in question' (Ajzen 1988, p. 135).

The TPB is shown in Fig. 2. It can be seen that perceived behavioral control determines both intentions (together with attitudes to behavior and subjective norms) and behavior (together with intentions). The joint determination of intentions is straightforward: it is assumed that when individuals form intentions they take into account how much control they have over the behavior. The joint determination of behavior (together with intention) can be understood in two ways. The first relates to motivation: an individual who has high perceived behavioral control and who has formed the intention to do something will simply try harder to carry out that action than someone with an equally strong intention but who has lower perceived behavioral control. The second explanation assumes that when someone has the intention to perform a behavior and fails to act on that intention, this failure is attributable to his or her lack of control over the behavior. The role of perceived behavioral control here is 'nonpsychological' in the sense that it is not the perception of control that causes the failure to act in accordance with intentions; rather, it is a lack of actual control. However, to the extent that perceived control is accurate thereby reflecting lack of actual control, a measure of perceived behavioral control should help to predict behavior. This is why the direct link between perceived behavioral control and behavior is depicted in Fig. 2 as a broken line, rather than a solid one: perceived behavioral control only helps to predict behavior if the individual has sufficient experience with the behavior to be able to make a reasonably accurate estimate of his or her control over the behavior.

Ajzen (1991) reviewed the findings of more than a dozen empirical tests of the TPB. In most of these studies the addition of perceived behavioral control to the TRA resulted in a significant improvement in the prediction of intentions and/or behavior. More recently, Godin and Kok (1996) reviewed the results of 54 empirical tests of the TPB within the domain of health behavior, and came to broadly similar conclusions. It is safe to assume that for most behaviors that are likely to be of interest to social scientists, it is worth using the TPB rather than the TRA.

5. *Direct Experience of the Attitude Object*

As we have just seen, direct experience of the attitude object can have an impact on the extent to which a dispositional construct (such as perceived behavioral control) is predictive of behavior. Fazio (1990) has developed a theoretical model in which the influence of direct experience on attitudes to an object is of central importance. His argument is that attitudes formed on the basis of direct behavioral experience with an object are more predictive of future behavior towards that object than are attitudes based on indirect experience. The rationale for this argument is that attitudes based on direct experience are stronger (they have greater clarity and they are held with greater certainty and confidence) and more accessible.

Attitude strength is seen as the strength of the association between an attitude object and the perceiver's evaluation of that object. The more experience one has with the object, the stronger will be this associative link. One's attitude will also be more accessible, in the sense that it will be more easily and quickly retrieved from memory. This is why attitudes based on direct behavioral experience are more predictive of future behavior, according to Fazio. Attitudes that are retrieved from memory easily and quickly are more likely to be activated whenever the attitude object is present. Frequent interaction with another person whom you like should lead to a highly accessible positive attitude to this person. The result is that whenever one is responding to the actual or symbolic presence of that person, whether this is in the context of a questionnaire assessing attitudes or in the context of an assessment of behavior toward that person, the same positive attitude should be elicited rapidly and automatically, and this attitude should guide both questionnaire responses and behavior. Attitudes and behavior should therefore be strongly correlated when the attitude is highly accessible.

Fazio operationalizes attitude accessibility as the time taken to respond to a question about that attitude. If an attitude is highly accessible it should take less time for people to retrieve their evaluation of the object in question from memory, and they should therefore be quicker to answer questions about attitudes to that object. Thus attitudes based on direct behavioral experience with an object should be (a) more accessible, in the sense that reaction times to questions about these attitudes should be faster; and (b) more predictive of behavior toward that object. There is empirical support for both these predictions (see Fazio 1990).

The significance of Fazio's work is that it shows that there are conditions under which reasonably strong attitude–behavior relations can be found even when one measures attitudes to the targets of behavior, rather than attitudes to behavior towards those targets. Thus the principle of compatibility can be violated without necessarily weakening the relationship between attitudinal and behavioral measures. For this to apply the respondent has to have a highly accessible attitude towards the target of the behavior.

6. Conclusion

Social psychologists' understanding of the attitude–behavior relation has developed considerably since early studies such as the one by DeFleur and Westie (1958). Wicker (1969) and others regarded these studies as evidence of a worrying inconsistency between what people say and what they do. The crisis that ensued has to a large extent been resolved, partly by a careful conceptual and methodological analysis of the problem, and partly by locating the attitude–behavior relation within more general theoretical frameworks.

Attributional Processes: Psychological

1. Background

Psychological research on attribution was inspired by Heider (1958), who developed models of attribution for object perception as well as person perception. Heider assumed, following the philosophical tradition of phenomenology, that a perceiver faced with observational data tries to attribute these data to their underlying cause—to an object in the case of sensory data, and to characteristics of the agent or the environment in the case of human behavioral data.

Heider recognized, however, that person perception is more complex than object perception—due to the manifold observational data available and the manifold causes (e.g., beliefs, desires, emotions, traits) to which these data can be attributed. Heider believed that people master this complexity by means of a sophisticated conceptual framework that he labeled 'commonsense psychology'—nowadays also called 'folk psychology' or 'theory of mind.' Using this conceptual framework, perceivers bring order to the massive stream of behavioral data by classifying them and attributing them to mental categories—including

motives, obligations, sentiments, and personality traits. For example, certain behaviors are classified as 'intentional actions', and the perceiver looks for the specific intention underlying each action (what the agent was trying to do).

Heider's research method was philosophical. He relied on conceptual analysis complemented by linguistic examples and thought experiments, but he provided no empirical experiments to test his model. The impact of Heider's work, then, was largely mediated by other researchers, who turned some of his ideas into empirical research programs. The evolution of attribution research can therefore be seen as a selective exegesis of Heider—with different scholars picking up different ideas and developing them in more detail.

This survey begins with a brief sketch of Heider's charismatic work, then turns to the two main strands of post-Heiderian attribution research: trait attribution work and causal explanation work. Finally, recent theoretical developments are addressed that return to some of Heider's original concerns and link attribution research to developmental research on children's theory of mind (see *Theory of Mind*) and philosophical work on folk psychology.

2. Heider

Despite his early focus on object perception, Heider's deepest concern was always with the topics of person perception and social interaction. Just like Lewin and Asch before him, Heider recognized that a psychology of social interaction must chart out people's *subjective* conceptions of the social world. At first Heider tried to develop a general theoretical framework to describe these conceptions, but then he realized that such a powerful framework already existed—it was commonsense psychology, the system of concepts ordinary people use to describe and understand human behavior. In his 1958 book, Heider thoroughly explored this framework, analyzing such commonsense concepts as *can*, *want*, *try*, and *ought*. Heider's blend of empirical observation with conceptual and linguistic analysis was visionary and unlike anything psychology had seen before—resembling more the tradition of ordinary language philosophy or contemporary cognitive linguistics.

Two major insights stand out from Heider's analysis of social perception. The first is that social perception is a process of reconstructing invariance out of variance. According to Heider, the social perceiver is presented with streams of behavior, and the cognitive system conceptualizes these streams in terms of a network of fundamental concepts, trying to reconstruct the invariances underlying behavior. Heider's notion of invariances encompassed perceptions, intentions, motives, abilities, and sentiments, which are all relatively invariant against the stream of ongoing behavior. Among these invariances, the agent's motives occupied a special role: 'The underlying causes of events, especially the motives of other persons, are the invariances of the environment that are relevant to [the perceiver]; they give meaning to what he experiences' (Heider 1958, p. 81). Heider's second major insight was that the reconstructive process of identifying invariances is a form of causal (i.e., attributional) analysis, rendering judgments of causality one of the primary elements in social perception. According to Heider, the commonsense conception of causality breaks down into two separate models. For one, there is *impersonal causality*, applied to unintentional human behaviors (such as sneezing or feeling pain) as well as physical events (such as stones rolling or leaves falling). For another, there is *personal causality*, applied only to human agents who perform an intentional action (such as cleaning the kitchen or inviting someone to dinner): 'Personal causality refers to instances in which p causes x intentionally. That is to say, the action is purposive' (Heider 1958, p. 100). For Heider, this distinction between unintentional and intentional behavior was central to commonsense psychology because it guides how people predict, evaluate, and influence social behavior.

In the literature, Heider's distinction between personal (intentional) and impersonal (unintentional) causality is typically portrayed as a distinction between internal (or person) causes and external (or situation) causes of behavior. But Heider did not subsume all internal attributions under the label 'personal causality'; only the attribution of purposive behavior to intentions and motives was characterized that way. The remaining internal causes fall under the 'impersonal' label, because they bring about behavior in a mechanical, nonintentional way. Thus, Heider drew a line between intentional and unintentional events, whereby intentional events are based on a special class of person causes (intentions and motives) and unintentional events can be based on person or situation causes.

3. Attribution Research After Heider

The rise of empirical attribution research in the 1960s and 1970s was sparked by a focusing and narrowing of Heider's broad model of social perception. Two main strands of research can be identified, each of which used Heider's ideas as a starting point and then developed them in more detail.

3.1 Attribution as Trait Inference

Heider theorized about the conditions under which people infer intentions from behavior. In their classic

paper, Jones and Davis (1965) took this idea a step further by developing a model of 'correspondent inferences' from a given intentional behavior ('he acted friendly') not just to a corresponding intention ('he tried to be friendly') but to a corresponding trait ('he is friendly'). The model identified conditions that increase the likelihood of such correspondent trait inferences. For example, the social perceiver will be more likely to infer a trait the more the action in question deviates from what is normally seen as desirable, and the more unique (positive) effects it has compared to alternative courses of action. If none of these conditions hold, the perceiver will not infer a correspondent trait but instead attribute the agent's behavior to forces of the situation.

The initial model was limited to intentional behaviors and predicted that people do not infer traits from unintentional behaviors or from behaviors performed under strong constraints (e.g., upon request by an authority). However, subsequent research found that people infer traits even from unintentional behaviors such as mistakes and accidents (e.g., 'he's clumsy') and even when the agent acted under strong constraints. This tendency to make correspondent trait inferences, even from single behaviors, and the parallel reluctance to attribute behavior to situational forces, was later dubbed the 'correspondence bias' or fundamental attribution error' (Ross 1977).

Researchers became increasingly interested in the question as to why people are so ready to infer traits from behavior and what conditions would moderate this bias. The currently dominant models of trait inference postulate a multistage process in which a behavior is identified as a certain type of action, a corresponding trait is then inferred by default, and only subsequent corrections take situational influences into account (Gilbert and Malone 1995). However, this default trait inference does not occur, for example, when the situational influence is salient or when the perceiver suspects that the agent acted out of ulterior motives. A potential limitation of trait attribution work is the scarcity of studies that examine the frequency and conditions of trait inferences in naturalistic social contexts.

3.2 Attribution as Causal Judgment

The second major strand of attribution research was inspired by Kelley's (1967) model of causal attribution. Focusing on Heider's insight that causal judgments are pivotal in social perception, Kelley proposed that such judgments are based on a simple information-processing rule: people infer those causes that covary with the event in question. Specifically, when an agent *A* behaves toward object *O*, the cause of the behavior is perceived to lie in *A* (internal attribution) if few other people behave as *A* does (low consensus), if *A* behaves the same way toward *O* over time (high consistency), and if *A* behaves the same way toward other objects (low distinctiveness). By contrast, the cause of the behavior is perceived to lie in *O* (external attribution) if most other people behave as *A* does (high consensus), if *A* behaves the same way toward *O* over time (high consistency), and if *A* behaves differently toward other objects (high distinctiveness). For Kelley, the principles of covariation applied equally to behaviors (whether intentional or unintentional) and physical events. His model was therefore embraced by causal reasoning researchers in both social and cognitive psychology.

Empirical tests of the covariation model tended to support it, although this support was limited to experimental settings in which explicitly presented covariation information had an effect on judgments. At the turn of the twenty-first century, no studies had demonstrated that people spontaneously, in everyday situations, seek out covariation information before answering a why question. Moreover, the covariation model makes no predictions about situations in which people lack covariation information (e.g., single observations) or in which they are not motivated to make use of the information (e.g., under time pressure). For those instances, Kelley later proposed additional rules of causal reasoning ('causal schemata'). One of them is the discounting principle, which states that, under certain circumstances, a second cause weakens the plausibility of a first cause. For example, if a student aces a difficult exam, we might explain it by assuming that he studied hard; but upon hearing that he cheated we may no longer believe that he studied hard, thereby discounting the previous explanation.

The problem that Kelley's causal attribution models tried to address was the 'causal selection problem'—how perceivers select particular causes for explaining a given behavior or event. Even though Kelley's models themselves did not completely solve this problem (alternative models were developed later), Kelley's work profoundly influenced attribution research by assuming that (a) people break down causes into internal ones (something about the agent) and external ones (something about the situation) and (b) that the internal–external dichotomy generally applies to all behaviors and events alike. This dichotomy proved to be a compellingly simple dependent variable that allowed researchers to explore a variety of interesting phenomena. One of these phenomena is the self-serving bias in explanations (see Miller and Ross 1975)—the tendency for people to explain their own positive and negative outcomes so as to maintain favorable self-perceptions or public impressions. For example, students would be expected to explain a good grade by citing internal causes (e.g., ability or hard work) and a bad grade by citing external causes (e.g., bad luck or an unreasonable teacher). Another important phenomenon is the actor–observer asymmetry, which is the tendency for people to explain their

own behaviors and other people's behaviors in systematically different ways. Specifically, Jones and Nisbett (1972) argued, and later studies confirmed, that people tend to explain their own behaviors by reference to external factors (e.g., 'I chose psychology as my major because *it's interesting*') but explain other people's behavior by reference to internal attributes (e.g., 'He chose psychology as his major because *he wants to help people*').

Some researchers proposed alternatives to the internal–external dichotomy of causes. For example, Weiner introduced two additional distinctions—one between stable and unstable causes and one between controllable and uncontrollable causes—and thereby improved predictions for people's emotions and motivations in the wake of explaining achievement outcomes, health outcomes, and deviant social conduct (see Weiner 1995). Abramson et al. (1978) introduced another distinction, between global and specific causes, to describe a hopeless explanatory style in depression (see *Depression*). However, most attribution work at the beginning of the twenty-first century still uses a single internal–external (or sometimes trait–situation) distinction.

The focus on internal vs. external causal attributions to all behaviors and events alike can be contrasted with Heider's claim that ordinary people sharply distinguish between (a) attributing *intentional actions* to the actor's motivation and (b) attributing *unintentional behaviors* (e.g., failure, depression) to causal factors internal or external to the agent. Heider felt, as an interview in 1976 reveals, that people's attributions of events were adequately depicted in Weiner's model, but that attributions of actions to motives were inadequately treated by contemporary research (Ickes 1976). A second limitation of contemporary research is that it developed primarily cognitive models of the attribution process, whereas Heider demanded careful attention to the communicative functions of attributions and the language of causality. Theoretical developments of the 1990s tried to address both of these potential limitations.

4. *Theoretical Developments of the 1990s*

4.1 *Attribution as Folk Theory of Mind*

Over the decades, attribution research has offered increasingly sophisticated information-processing models for the basic internal–external distinction, but it has not examined the distinctions that actually guide people's explanations within folk psychology—an omission that Kelley and Michela (1980) called the central irony of attribution research. The study of people's own concepts and distinctions has recently gained force among researchers who endorse what may be called a folk-theoretical approach to explanations. This approach considers behavior explanations an integral part of people's folk theory of mind and assigns the concept of *intentionality* a central role in these explanations, because people reliably distinguish between intentional and unintentional human behaviors and use distinct modes of explanation for each type of behavior (Buss 1978, Malle 1999).

In particular, unintentional behavior is explained by *causes*, perceived as simply bringing about the behavior in a mechanical way (e.g., 'She cried because *she was sad*'; 'He fell because *the floor was slippery*'). By contrast, intentional behavior is primarily explained by *reasons*, conceptualized as the beliefs and desires an agent considers when forming an intention to act (e.g., 'She quit her job because *she felt the pay was too low*'; 'They worked extra hours because *they needed to finish the project*'). Thus, when people offer reason explanations, they presume the agent's awareness of the reason content and a more or less rational process of forming an intention to act in light of those reasons. According to the folk-theoretical approach, the traditional internal–external dichotomy applies well to people's cause explanations of unintentional behavior but not to reason explanations of intentional behavior. For example, the above reason explanation, 'she felt the pay was too low,' refers to the agent's own belief ('she felt'), but the belief itself has a content that refers to the situation ('the pay was too low'), so it is unclear how this reason should be classified within an internal–external scheme. To analyze adequately people's reason explanations of intentional behavior, new theoretical categories have been developed that take into account the complex conceptual and linguistic nature of reasons (Malle 1999).

One advantage of the folk-theoretical approach lies in its compatibility with work on responsibility attribution. For example, Shaver (1985) argued that assignments of responsibility and blame are critically dependent on the intentionality of the behavior in question, and so the choice of explanations (e.g., causes vs. reasons) often manages assignments of blame. Another advantage of this approach lies in the integration of social-psychological work on explanations with developmental research on children's emerging theory of mind and philosophical analysis of the properties and evolution of folk psychology (Malle et al. 2001). These disciplines have highlighted people's unique conception and explanation of intentional action, and the next generation of attribution research will have to flesh out in detail the conceptual, linguistic, and social nature of these unique explanations.

4.2 *Attribution as Communication*

Heider examined the concepts of commonsense psychology in their everyday conversational context because he was convinced that tools of social perception help people to accomplish their goals in social communication and interaction. Along these lines,

innovative work by Hilton (1990) and Antaki (1994) suggests that attributions are not just cognitive processes but rather communicative acts that obey the rules of conversation; that is, behavior explanations are altered for impression-management purposes (e.g., to appear rational or fend off blame). Explanations are also responsive to an interlocutor's concerns and questions (e.g., 'How was this possible?' elicits different modes of explanation than 'For what reason?'). Finally, explanations have an immediate impact on others' perceptions and evaluations of the explainer and the agent whose behavior is being explained.

5. *Future Directions*

Promising new directions of attribution research may arise from a merging of the folk-theoretical and communicative approaches. By recognizing people's fine-grained theory of mind and their distinctions between various modes of explanation, researchers can more effectively trace the cognitive as well as communicative functions that explanations serve in social interaction. Classic phenomena such as the self-serving bias, the fundamental attribution error, and the actor–observer asymmetry may then be fruitfully re-examined, not just under laboratory constraints, but within their natural contexts of occurrence. Greater attention to the social context and functional roles of attribution processes may perhaps be the most important desideratum for future research. As a result, attribution theory might lead to powerful applications in the domain of social relations (e.g., conflict resolution, relationship dynamics) and would contribute to the scientific knowledge of both social perception and social interaction, reverberating Heider's (1958) timeless goal of providing a psychology of interpersonal relations.

Auctions

1. *Introduction*

The use of auctions to allocate goods is quite common and has been known for centuries. Numerous and quite different goods are sold by auctions, that is, antiques, fish, flowers, real estate, gold, securities, and oil exploration rights. Cassady (1967) gives a complete list of goods sold by auction. The literature on auctions is enormous, and it is increasing rapidly. It is concerned mainly with revenue and efficiency considerations, namely to find the auction that yields the greatest expected revenues to the auctioneer and that allocates the goods to the bidders which value them most highly. Further issues, like the robustness of auctions, transactions costs, bid preparation costs, and the vulnerability to cheating are addressed rarely.

2. Definitions

According to Cassady (1967, p. 8), auctioning is

> a unique system of allocating … property based on price making by competition of buyers for the right to purchase.

More formally, Myerson (1981) defines an auction mechanism by (a) a pair of outcome functions, which gives the allocation of the goods and the bidders' fees in dependence of the bidders' strategies, and (b) a description of bidders' strategic plans. According to those definitions, there is a plethora of different auctions. To fix ideas, assume that there are N units of a homogenous good for sale and that each bidder is restricted to one unit of the goods. First of all, open and sealed-bid auctions can be distinguished. An auction is open, if the bids become known to all participants of the auction when submitted. In contrast to this, an auction is sealed-bid, if bidders submit their bids privately. Thus, bidders have no knowledge of the bids of their competitors.

The best known open auctions are the English and the Dutch auction (cf. Milgrom and Weber (1982)). In the English auction, the auctioneer raises the price up to the point, where N bidders remain, with the understanding that the N units of the good are sold to the remaining bidders at the last called-out price. In the Dutch auction the auctioneer lowers the price interrupted only by bidders accepting the last called-out price for one unit of the good. The auction ends when all units are sold or a lower price limit is reached.

The best known sealed-bid auctions are the discriminatory and the uniform-price (competitive) auction (cf. Smith 1966, Harris and Raviv 1981). In the discriminatory auction the N units are allocated to the bidders with the highest price bids in descending order. Successful bidders are charged an amount equal to their bids. Thus, for more than one unit for sale, different bidders pay different unit prices in a discriminatory auction. If there is only one unit for sale, the discriminatory auction is called first-price auction. The rules of the uniform-price auction are the same as those of the discriminatory auction, except for the prices paid by successful bidders. In the uniform-price auction all successful bidders are charged the same price, which equals the highest unsuccessful bid. If there is only one unit for sale, the uniform-price auction is called second-price auction or Vickrey auction. Vickrey (1961) introduced this type of auction.

Allowing for more than one seller, a double auction results. In a double auction sellers submit bids to sell and buyers submit bids to buy. The sellers' (buyers') bids are ranked in ascending (descending) order. The price in a nondiscriminatory double auction is determined by the intersection of the obtained supply and demand schedule. This auction as well as other types may be performed as a discrete-time auction at predetermined times during a trading period, or as a continuous-time auction at any moment during a trading period (cf. Friedman 1991).

The goods sold by auction can be classified with respect to the monetary value that bidders attach to them. Milgrom and Weber (1982) distinguish between goods with private value, goods with common value, and goods with general value. Goods are of the private value type (or of preference uncertainty (cf. Myerson (1981)), if its value to a bidder is a purely personal matter. A painting bought for purely personal reasons provides an example. Goods are of the common value type (or of quality uncertainty); (cf. Myerson 1981), if the monetary value bidders attach to it is the same for all bidders. This value, however, generally will be unknown at the time the auction takes place. Typically, securities have a future uncertain monetary value. Thus, they are of common value. A good is called to be of the general value type, if its value to a bidder is a combination of private and common values. A painting bought for both personal reasons and later resale could be considered being of the general value type.

3. Analyzing Auctions

The auction literature can be divided into three groups: *decision-theoretic auction models*, *game-theoretic auction models*, and *empirical studies*. Decision-theoretic auction models deal with the bidder's decision problem in a way which ignores her strategic response to the bidding behavior of her competitor. The game-theoretic approach, on the contrary, is based on this strategic aspect of the bidding process. Empirical studies make use of either the decision-theoretic or the game-theoretic approach when examing data sets resulting from real-life auctions or controlled laboratory experiments.

The earliest auction models are of the decision-theoretic type. They are motivated by real-world auction design problems concerning the sale of oil exploration rights (Hughart 1975) and US Treasury bills (Smith 1966, Scott and Wolf 1979). Formal in nature, they assume that bidders are expected utility maximizers, where the expectation is with respect to a subjective probability density function for the lowest accepted bid (cp., e.g., Smith 1966). In particular, it is assumed that a bidder's action does not affect the realization of the lowest successful bid (cp., e.g., Scott and Wolf 1979). Despite obvious modeling deficiencies, those early models already succeed in identifying certain effects, which later are proved rigorously within the game-theoretic approach to auction theory.

The earliest game-theoretic auction studies primarily are concerned with the determination of Bayes–Nash equilibrium bidding strategies. The models are quite simple in that they assume symmetric bidders with independent value estimates. Those results are generalized in different directions in order to account

for bidders with correlated value estimates, for goods of the general value type (Milgrom and Weber 1982), and for goods with a resale market (Bikhchandani and Huang 1989).

Empirical studies of auctions are concerned with the analysis of real-life auction data sets or controlled laboratory experiments. Examples are auctions of Federal leases on the Outer Continental Shelf (Hendricks and Porter 1988), US Treasury bills (Cammack 1991), wine (Ashenfelter 1989), and collectible trading cards over the Internet (Lucking-Reiley 1999).

4. *A Game-theoretic Auction Model*

For ease of exposition there is only one unit of goods to be sold in an auction. The *auctioneer*, who for simplicity is assumed to be the owner of the goods, sets the auction rules and makes them known to all participants. The auction rules are binding even though it might be in the auctioneer's interest to change them after the bids have been submitted. The auctioneer is risk-neutral, that is, interested in maximizing the expected revenues resulting from the sale of the goods. There are n risk-neutral bidders competing with each other in the auction. When preparing their bids, they do not cooperate. Every bidder i has some private information x_i, a realization of her information variable. Bidders are distinguished solely by their private information; otherwise they are identical. It is assumed that the number of bidders and the joint distribution of all information variables is common knowledge.

In an auction a rational bidder takes the bidding behavior of the competitors into account and behaves strategically. However, a bidder has only incomplete information about the relevant features of the bidding situation. Thus, an auction is to be considered a non-cooperative game with incomplete information among the bidders. To analyze this game the Bayes–Nash equilibrium concept (Harsanyi (1967/68) is employed. For that purpose, a bidder's strategy is defined as a real-valued function mapping possible realizations of her information variable into bids. A Bayes–Nash equilibrium $(B_1, \ldots, B_n)$ of bidders' strategies is described by the following properties. B_i maximizes bidder i's expected gains assuming bidding strategies $B_1, \ldots, B_{i-1}, B_{i+1}, \ldots, B_n$ of her competitors and the assumed bidding behavior is correct.

5. *Theoretical Results*

Fundamental to the theory of auctions is the bidding behavior under varying assumptions. This naturally includes alternative auction rules. In what follows the Dutch, English, first-price, and second-price auctions will be considered and compared.

The simplest set-up is the one where the good to be auctioned is of private value and the values that different bidders attach to it are independent. This assumption is well suited for goods without resale, but it excludes cases like the painting of an artist whose work has some prestige among collectors.

5.1 *The Private Value Model*

5.1.1 Independent private values. Although the rules of the standard open and sealed-bid auctions are quite different, Vickrey (1961) found an astonishing similarity. When comparing the Dutch and the first-price auction, he noted that a bidder would follow the same strategy in both auctions. In either auction, a bidder has to determine a price at which she is willing to accept the good. In the first-price auction this would correspond to her bid; in the Dutch auction this would be the lowest called-out price at which she would claim the good. Thus, the Dutch and the first-price auction are strategically equivalent. A similar argument applies to the English and the second-price auction. In either auction, a bidder would bid her private value. This ensures that she will accept all prices below and no price above her private value of the good.

To be more specific in the first-price auction, consider the decision problem of bidder i. Her expected gains are given by

$$x_i \times \text{probability of winning} - \text{expected payments} \quad (1)$$

where x_i denotes her private value. Note that lowering the bid has two opposing effects on expected gains. The probability of winning decreases and the gains from the bid increase. Intuitively, the optimal bid will be such that it balances those two effects, thus maximizing Eqn. (1).

Since bidders differ only by their private information, bidding behavior can be described by a common bidding strategy B. The resulting bidding strategies in the standard sealed-bid auctions are as follows, where F is the distribution function of X_i:

(a) *Bidding strategies* (Vickrey 1961, Harris and Raviv 1981).

(i) In the second-price auction the symmetric bidding strategy is given by

$$B(x) = x$$

(ii) In the first-price auction the symmetric bidding strategy is given by

$$B(x) = x - \frac{\int_0^x (F(y))^{n-1}\,\mathrm{d}y}{(F(x))^{n-1}} \quad (2)$$

From this a number of conclusions follow that are subject to empirical testing. Both in the first- and second-price auction, bidding strategies are increasing

in bidders' private values. In a first-price auction, bidding becomes more aggressive with an increasing number of bidders. A comparison of first- and second-price auctions yields that a bidder submits a lower bid in the first than in the later auction. This difference in bids is represented by the second term of Eqn. (2).

Uniqueness of symmetric equilibria can be established (cp. Milgrom and Weber 1982). Furthermore, efficiency is guaranteed in both types of auction, that is the bidder with the highest private value is the one who wins the good.

From the described bidding behavior, bidders' expected gains and the auctioneer's expected revenues can be derived. Both coincide in the case of first-price and second-price auction. This is a special case of the revenue equivalence theorem (Vickrey 1961, Harris and Raviv 1981, Myerson 1981, Riley and Samuelson 1981).

(b) *Revenue equivalence*. The auctioneer's expected revenues are the same in the single-unit English, single-unit Dutch, first-price, and second-price auction.

Similarly, a bidder's expected gains coincide in the above mentioned auction types.

5.1.2 Strictly affiliated private values. Suppose that bidders' private values are strictly affiliated, that is, large values of one variable are more likely, when the other variables are large as well. Milgrom and Weber (1982) introduced this generalization of nonnegative correlation. This concept allows for goods of private value, where bidders have some common liking.

Although Dutch and first-price auction are still strategically equivalent, this is no longer true for English and second-price auction. In particular, Milgrom and Weber (1982) established the following ranking of auctions.

(a) *Auction ranking*. The auctioneer's expected revenues in the first-price auction are never higher than those in the second-price auction. The auctioneer's expected revenues in the second-price auction are never higher than those in the single-unit English auction. The single-unit Dutch auction yields the same expected revenues as the first-price auction.

Similarly, in the second-price auction a bidder's expected gains are smaller or equal to those in the first-price auction.

5.2 The Common Value Model

In the common value model the unknown value of the good and bidders' information (about the unknown value) are affiliated. Auctions of financial securities like US Treasury bills and of Federal leases on the Outer Continental Shelf can be analyzed within this framework. The informational effect, however, makes bidding quite complicated and gives rise to the following phenomenon.

5.2.1 Winner's curse. Common value models suffer from an effect called the winner's curse.

> learning that others have bid less than [his own bid]… is bad news about the value of the item being acquired (Milgrom 1987, p. 18).

Unsophisticated bidding leads to the effect that the successful bidder tends to be the one who overvalued the goods. Substantial losses in common value auctions are quite often attributed to this effect. Thus rational bidders take account of the winner's curse effect, when preparing their bids. The 'winner's curse' was the subject of a lot of controversy (cf., e.g., Kagel and Levin (1986). Milgrom (1987) formalizes the winner's curse effect for a sealed-bid common value auction for one unit of the good, where the highest bid wins the auction. A bidder's expected unit value of the goods, when she has won with her bid, is smaller than her expected unit value. Thus, the winner's curse effect can be measured by this difference.

Any information on the unknown common value will weaken the winner's curse effect. In particular, linking the price in an auction to affiliated information of the common value reduces the winner's curse. This is the essence of the linkage principle (Milgrom and Weber 1982). Reducing the winner's curse effect leads to more aggressive bidding and higher auction prices. Also competition matters, that is, the winner's curse effect gets stronger with an increasing number of bidders.

5.2.2 Independent information variables. If the bidders' information variables are independent, the results of the common value model resemble those of the independent private value model. In particular, the auctioneer's expected revenues in the first-price and second-price auction coincide. Similarly, the same is true for a bidder's expected gains in both auctions.

5.2.3 Strictly affiliated information variables. The bidding behavior in the common value set up can be described in the same way as in the private value model. Again, Dutch and first-price auction are strategically equivalent. This, however, is not the case for the English and second-price auction. Fundamental to the analysis is a bidder's expected value of the good given her information and the fact of winning the auction with her bid. This way she takes care of the winner's curse effect. Taking this into account, existence and uniqueness of symmetric equilibria can be established (cf. Milgrom and Weber 1982).

The central results of the common value auction literature concern the ranking of auctions, the auctioneer's information policy and the information aggregation property of auctions. All those results rely on

the comparison of symmetric equilibria of the respective auctions. The basic results are as follows:

(a) *Auction ranking* (Milgrom and Weber 1982). The auctioneer's expected revenues in the first-price auction are never higher than those in the second-price auction. The auctioneer's expected revenues in the second-price auction are never higher than those in the single-unit English auction.

If the auctioneer has private information about the unknown common value, she may use this fact to influence the outcome of the auction. She may commit to supplying information publicly in order to increase revenues. There is a whole range of possible information policies. Milgrom and Weber (1982) mention complete revelation (fully reporting of all information), censoring (reporting of favorable information only), randomizing (reporting after having added noise to the information), and concealment (no reporting of private information).

(b) *Information revelation* (Milgrom and Weber 1982). The auctioneer's policy of revealing any affiliated information publicly and completely raises her expected revenues in the first-price auction, the second-price auction and the single-unit English auction.

There has always been the question of whether the price of a good of unknown value reflects (aggregates) the dispersed information of market participants. Under certain assumptions this could be answered in the affirmative in the case of auctions.

(c) *Information aggregation* (Wilson 1977). The winning bid in a first-price auction converges almost surely to the common value V as the number of bidders n goes to infinity.

5.3 The General Value Model

The general value model gives results in much the same way as the common value model. In particular, the auction ranking and the information revelation results hold true. However, the information aggregation property relies on the simple structure of the pure common value model and thus does not generalize.

6. Empirical Results

There is an increasing number of studies which provide tests of auction market behavior by means of experimental methods or real-life auction data sets (field data). Whereas the experimental approach allows for controlling a specific auction model including informational assumptions, the field approach provides a test of auction theory in situations where most theoretical assumptions are unobservable.

Quite often, experimental studies are concerned with the independent private values model, which predictions are being tested. The results obtained are mixed (cf. Smith 1991, Kagel 1995, and their citations for the following). Bidding behavior is characterized by deviations from the strategic equivalence of first-price and Dutch auctions and second-price and English auctions, respectively. In particular, in first-price (second-price) auctions bidders submit higher bids than in the corresponding Dutch (English) auctions. Consequently, revenue equivalence does not hold. However, as predicted by theory, individual bids are strictly increasing in bidders' private values. As concerns comparative statics, increasing the number of bidders leads to more aggressive bidding on the bidders' part in first-price auctions. When introducing affiliated private values in experiments, the resulting bids could be better explained by Bayes–Nash bidding behavior than by alternative ad hoc bidding models.

Fundamental to experimental work in the common value set-up is the study of Smith (1967), who examines individual bidding behavior in discriminatory and uniform-price auctions. His results are consistent with the predictions of auction theory. He establishes that bids in the discriminatory auction are lower than those in the uniform-price auction and that the same is true for the auctioneer's revenues. Other results are less supportive of auction theory (cf. Kagel and Levin 1986, Kagel 1995, and his citations for the following). As predicted by theory, individual bids are strictly increasing in bidders' information. However, comparative statics might fail. This is the case in second-price auctions, where increasing the number of bidders leaves bids unaffected.

In general, Bayes–Nash bidding behavior in sealed-bid auctions is questioned by strong winner's curse effects especially for inexperienced bidders. Furthermore, the common value auction rankings could not be confirmed in experiments. Due to the winner's curse effect, sealed-bid auctions yield higher revenues than English auctions. Even information revelation can be affected by the winner's curse effect. Kagel and Levin (1986) find that information revelation reduces average revenues, when the number of bidders is high. Only for smaller numbers of bidders, the theoretical predictions of information revelation could be confirmed. This effect applies to sealed-bid as well as English auctions. Thus, in first- and second-price auctions theoretical predictions are valid only when the winner's curse effect is weak.

Early results of field data support auction theory. For example, Tenorio (1993) establishes that in the Zambian foreign exchange uniform-price auction average revenues are higher than in the corresponding discriminatory auction. Lucking-Reiley (1999), on the contrary, reports a failure of revenue equivalence for auctions of collectible trading cards over the Internet. He finds that revenues in the Dutch auction are higher than those in the first-price auction. With respect to English and second-price auctions, however, the data

support revenue equivalence. This contrasts sharply with the results of independent private values experiments.

7. Double Auctions

Since the nineteenth century, trade at organized exchanges to a large extent was conducted by means of double auctions. Nowadays, double auctions are important tools for computerized trade. They also serve well for the organization of markets for natural gas as well as for electric power networks. The theoretical analysis concerning double auctions is much more involved than that of one-sided auctions. Determination of Bayes–Nash equilibrium is complicated, if at all feasible. Often the analysis gives rise to a multiplicity problem. For that reason, the theoretical analysis centers around the independent private values model for a single indivisible unit. Satterthwaite and Williams (1993) give results for particular sealed-bid nondiscriminatory double auctions. For m risk-neutral sellers and m risk-neutral buyers symmetric Bayes–Nash equilibria are determined. Convergence of equilibria to ex post efficiency as both the number of sellers and buyers increase is shown to hold.

However, due to the abovementioned technical problems, the analysis of double auctions is done almost always by means of empirical or experimental studies (cf., e.g. Friedman and Rust 1993, Sect. 3).

8. Application to Financial Markets

Interest in the market institutions that govern the trade of financial securities grew rapidly during the last decades of the twentieth century. Along with the successful introduction of new exchanges, the trading rules at existing exchanges were examined more closely. Common to all those activities is an interest in the price formation process under alternative trading rules. An important example of this approach is the discussion of the design of the US Treasury bill auction, one of the most important auctions of financial securities. Every Monday the US Treasury auctions a previously announced quantity of Treasury bills maturing in 91 and 182 days, respectively.

Since the late 1950s there has been quite a controversy concerning the design of this auction. This controversy started with a proposal from Milton Friedman to change the Treasury bill auction from discriminatory to uniform-pricing. The reasons given in favor of this proposal were quite different in nature. They ranged from revelation of bidders' true demand curves and an increase in the number of bidders to discouragement of collusion under uniform-pricing. They did not, however, include an increase in the Treasury's average revenues from a sale under uniform-pricing. In fact, the early opponents to this proposal argued by a reduction in revenues through a change from discriminatory to uniform-pricing. Several years later, models of the decision- and the game-theoretic type lent additional support to the Friedman proposal.

In that respect, the results of Smith (1966) and Milgrom and Weber (1982) on the superiority of uniform over discriminatory pricing in terms of auctioneer's expected revenues were especially successful. Despite the fact that a completely satisfactory theoretical model of the Treasury bill auction is not available yet, those results made the Treasury reconsider the Friedman proposal. Those considerations led to experimentation with a uniform-price auction in the 1970s. However, the Treasury retained the discriminatory rules. Only after the Salomon Brothers Inc admission of violating the US Treasury auction rules, the experiments were taken up again in September 1992 for the two-year and five-year note auctions (cf. Bikhchandani and Huang (1993)). Experimentation ended in a decision effective with the February 11, 1998 auction to auctioning all bills using the uniform-pricing rules.

9. Conclusion

The basic game-theoretic auction model gives rise to a number of strong results which have been subject to empirical and/or experimental tests. Naturally, the question arises as to whether those results are robust with respect to a relaxation of assumptions. Unfortunately, there are several assumptions which, when relaxed, give rise to different results. There are a number of factors which have to be dealt with. First, risk neutrality matters. When allowing for risk aversion on the bidders' part, the expected revenue comparison will yield different results. For example, in models with both risk-aversion and strictly affiliated information variables, the established ranking of first- and second-price auctions with respect to expected revenues fails to hold. Only in special cases (e.g., independently and identically distributed (i.i.d) information variables) general results can be established (cf. Milgrom and Weber 1982).

Second, multiunit demand by bidders changes results dramatically. Endogenizing quantity, for example, as in the case of a share auction, might result in a multiplicity of equilibria and a substantial lower expected sale price than in comparable unit auctions (cp. Wilson 1979). Third, in auctions of financial securities bidders usually meet more than once. The introduction of this phenomenon produces all effects that apply to repeated noncooperative games. Finally, a number of features cannot be solved in the outlined theoretical auction model due to mathematical complexities. It is in those cases that one has to rely on controlled laboratory experiments in order to draw conclusions.

Audience Measurement

Audience measurement, as the term is commonly used, refers to regular assessments of the size and composition of media audiences. It is based on survey research wherein individual attributes (e.g., age, gender, etc.) are quantified to produce statistical summaries of various audience aggregates. These numbers, which include broadcast audience ratings, are sold in the form of syndicated reports that are indispensable to advertiser-supported media.

1. Uses of Audience Measurement

The major impetus for audience measurement is advertising. By the late nineteenth century most newspapers and mass circulation magazines had begun to sell space to advertisers. The value of space was determined largely by the number of readers who would see each publication, and by extension each ad. Paid circulation served as a reasonable surrogate for the size of the readership. Many publishers, however, made inflated claims about their circulation, undermining the confidence of advertisers. To make print media credible, in 1914 the industry created the Audit Bureau of Circulations, an independent organization that verified circulation (Beniger 1986). To this day, such audits continue in the USA and many other countries around the world.

The growth of radio in the 1920s presented new problems for those who would use it as an advertising medium. Unlike print, there were few traces of the radio audience save for fan mail or the sheer number of receivers being sold. For all intents and purposes,

the radio audience was invisible. To provide reliable estimates of the number of people listening to specific programs, the industry sponsored audience surveys. By the 1930s independent research firms had begun to produce what were called 'ratings' (i.e., percentages of the population tuned to a particular program or station). These made the audience visible and allowed advertisers to buy spot announcements in radio with a degree of certainty. When television and other forms of electronic media emerged in the latter half of the century, similar mechanisms for measuring the size and composition of audiences were quickly put in place (Beville 1988).

Today, advertising is a multi-billion dollar business. Audiences are bought and sold like commodities. Advertising expenditures are typically guided by audience measurement and the cost of reaching various audience segments. In a business world increasingly interested in target marketing, research firms have been called upon to produce ever finer demographic distinctions, as well as data on lifestyles and product purchases. Curiously, all published audience measurements describe something that has already happened, while all advertising expenditures are made in anticipation of audiences that have yet to materialize. This odd system works because, in the aggregate, media audiences are quite predictable. For example, advertisers and networks know the total number of people who are likely to watch television at any time during the year, and negotiate ad prices on that basis. The stability of audience behavior has also allowed researchers to identify various 'law-like' features of the mass audience (Comstock and Scharrer 1999, Goodhardt et al. 1987, Webster and Phalen1997).

The fact that advertising is the major source of revenue for several forms of media (including broadcasting, newspapers, and magazines) has embedded audience measurement in the operation of these industries. Obviously, the system places a premium on audiences that will be attractive to advertisers, either by virtue of their sheer size or desirable composition. Content, therefore, is evaluated with an eye toward its audience-making potential. Moreover, broadcasters pay careful attention to how audiences 'flow' across an entire schedule of programming, relying on established patterns of media use to deliver people to their program offerings. In all of these endeavors, audience measurement is crucial. In fact, a good case can be made that audience measurement is a necessary condition for the emergence of any form of advertiser-supported media (Ettema and Whitney 1994).

Even in social systems not fully committed to advertising, audience measurement can become a fixture. Public service broadcasting around the world must often justify its existence by demonstrating that it has an audience (Ang 1991). Here the techniques of audience measurement are similar to those in commercial systems, though they may involve the use of more 'qualitative' measures, such as the appeal or usefulness of media materials (Beville 1988, Lindlof 1995). Similarly, government officials concerned with good or bad media effects often relate these to the audience and the magnitude of exposure to good or bad content (Webster and Phalen 1997).

2. *Methods of Audience Measurement*

As a type of survey research, audience measurement confronts issues common in sampling and statistical inference. Its distinctiveness comes from the methods it uses to measure the behavior of audience members. One of three techniques is typically employed: interviews, diaries, and meters.

The first regular surveys of radio audiences were conducted using telephones. Respondents were called at home and asked either what they were currently listening to (i.e., telephone coincidental method) or what they had listened to in the recent past (i.e., telephone recall method). Both techniques are used today. In fact, telephone coincidentals are generally regarded as the most accurate way to measure broadcast audiences and are, therefore, the standard against which other methods are judged (Beville 1988).

The advent of radio audience measurement forced print media to go beyond circulation as the sole indication of readership. Since a single copy of a magazine or paper might well be read by more that one person, circulation alone seemed to understate the audience for print. The industry eventually adopted survey research to better estimate readership. Personal interviews were conducted in which respondents were shown stripped down copies of various magazines and asked if they recalled reading them (i.e., through-the-book method). Alternatively, to economize on time and increase the number of publications that could be assessed, respondents were asked to sort through cards containing magazine logos and indicate which of these were read (i.e., recent reading method). Today, the recent reading method remains the standard of magazine audience measurement (Bogart 1996). Between the 1940s and 1970s local radio audiences were also measured using personal interview techniques. Respondents were presented with a list of radio stations and asked which they listened to (i.e., the roster recall method). Eventually the roster recall technique gave way to the use of diaries (Beville 1988).

Diaries are small booklets in which respondents keep a log of their radio or television usage throughout the day. Typically, diaries are kept for a week, though time periods of different durations are possible. Diaries are a relatively inexpensive data collection technique and, properly filled out, contain a wealth of information. However, many people are reluctant to accept a diary, or are unwilling or unable to make accurate entries. In a world of push-button radios, multichannel television, and remote control devices, completing a diary can be a burdensome task. Nonetheless,

diaries are a common measurement technique for producing local radio and television audience reports (Webster and Wakshlag 1985).

Many of the problems associated with diaries can be solved by the use of meters. These devices attach to a receiver and automatically record the source to which the set is tuned. By the early 1940s Arthur Nielsen had developed such a device and had placed it in a panel of American households to produce national radio network ratings. Household meters were eventually adapted to the new medium of television. While household meters eliminate various problems of response, they are expensive and offer no information about who is actually using the set. With advertisers increasingly concerned about demographics, the latter is a serious shortcoming. To address it, meters were adapted so that people could identify themselves by pressing a button. This so-called 'peoplemeter' is the technique now used to produce network television ratings in the United States and several countries around the world (Webster et al. 2000).

The fact that respondents need to actively signal their presence before the set by pressing a button reintroduced response errors. Children, for example, are not particularly diligent button pushers. From the industry's point of view, the ideal measurement device would be a passive peoplemeter, one that would somehow register who was watching the set without requiring any action on the part of viewers. Experiments have been conducted using infrared sensing and image recognition technology, but at the time of writing no such system has been put into commercial operation. Pilot studies have also been conducted on wireless devices that sense an inaudible code placed in a radio or television signal. In one manifestation, a pager-like device worn by a respondent picks up and identifies all radio programming within earshot of the listener.

The rapid growth of the Internet in the 1990s and the prospect of using the World Wide Web as an advertising medium motivated a number of companies to measure Internet use. While individual web sites could track people who visited their pages, what was needed was a 'user-centric' form of measurement to track people from site to site. Firms providing this type of measurement typically create a panel of computer users who agree to have monitoring software loaded on their machines. These programs record the various web pages the user visits. Data are then aggregated to produce web site ratings not unlike television ratings (Webster et al. 2000).

3. *Sources of Error in Audience Measurement*

There are four sources of error in audience measurement: sampling, nonresponse, response, and processing. The first three are, again, problems commonly associated with survey research. The last includes a variety of issues that have to do with bringing a saleable research product to market.

Most syndicated audience measurement is based on some form of probability sampling. Compounding considerations of sampling error is the tension between sample size and the growing complexity of the media environment. Virtually all forms of mass media are becoming more diversified: there are dozens of television networks available on broadband distribution systems, there are hundreds of special interest magazines, and there are an untold number of web sites. This, in combination with the need to estimate ever narrower audience segments, constantly presses sample sizes to the limit. In fact, samples for estimating magazine readership and Internet use already number in the tens of thousands. Unfortunately, the high cost of some measurement devices (e.g., meters) and the diminishing marginal returns associated with increases in sample size have forced difficult compromises on sample size and allowable levels of sampling error. Moreover, individual subscribers who manipulate databases to suit themselves are under no restrictions as to how they 'crunch the numbers' or the sampling error attendant to the estimates they produce.

There are also potential problems of response. Written forms of feedback (e.g., self-administered questionnaires, diaries, etc.) often suffer from low rates of response. Further, as people become increasingly leery of telemarketers, telephone survey completion rates are threatened. All these lead to concerns about non-response (i.e., the people being studied are systematically different from those who don't respond). Even among those who agree to cooperate, there may be problems with the quality of their responses (e.g., response error). There is anecdotal evidence that people, increasingly aware of the impact of audience ratings, can deliberately misrepresent their behaviors (Beville 1988). More likely, the flood of modern media simply overwhelms the reporting capabilities of even the most conscientious respondent.

The information collected by interviews, diaries and meters can be thought of as raw material that must be processed into a saleable product. Data must be coded and checked for obvious errors. Missing values are occasionally imputed using a process called ascription. New information, like program schedules, must be added. Responses from under-represented or over-represented groups are sometimes assigned a mathematical weight in a process called sample balancing. Responses generated by one method may be adjusted to parameters set by another method in a controversial process called calibration. Finally, data must be aggregated and projected to form the population estimates in published reports. In all of these matters, errors of fact or judgment may creep into the process (Bogart 1996, Webster et al. 2000).

4. Institutional Aspects of Audience Measurement

In most developed countries, audience measurement is a business that sells research reports or data to multiple subscribers. Rarely do more than two firms compete for any given market. Sometimes only one firm provides the measurements for an entire medium. As such, their reports take on the air of quasi-public, official documents. Though various errors in the data mean the numbers are not nearly as 'hard' as they appear, the organizations that use them have little alternative but to treat them as such. And an enormous amount rides on those numbers. The process of allocating billions of dollars in advertising and programming resources is informed, some would say tyrannized, by audience measurement (Ang 1991, Bogart 1995).

The institutional significance of audience measurement has not gone unnoticed. In the 1960s the United States Congress held hearings into the quality and consequences of the American broadcast ratings industry. Public scrutiny induced the industry to create an ongoing council to audit and accredit ratings research methods, as well as sponsor industry-wide methodological research (Beville 1988). For these reasons, and because audience measurements are used by powerful institutions with competing interests, it is probably the case that no research firm can drift too far from truthful reporting without sowing the seeds of its own destruction.

Even so, much about audience measurement is negotiable and left to industry consensus. Like any self-interested business, research firms try to adapt their products to client needs. This has led to charges that traditional audience measurement fails to address factors that others find important (i.e., people's attentiveness, preferences, needs, or understandings). It has also given rise to a more cynical view that research companies simply adopt whatever methods and produce whatever results serve dominant institutional interests (Meehan 1990).

The matter of turning the audience into a commodity has also drawn critics. Audience measurement essentially lumps people into categories, with one person being the functional equivalent of all others in the group. These groups are then sold to advertisers at some 'cost-per-thousand.' At best, the business is dehumanizing. At worst, it has been argued, the entire enterprise serves to colonize, manipulate, and ultimately victimize audiences (Ang 1991).

Alternatively, audience measurement can be seen as exercising a democratizing influence on popular culture. Material that is successful in the marketplace proliferates, while content that is unpopular fades away. While this notion of cultural democracy is oversimplified, a case can be made that measurement empowers audiences by casting them in a form to which institutions can and do respond (Webster and Phalen 1997). One way or another, it can certainly be said that audience measurement helps shape mass culture.

Audiences

The notion of audience in social research has been largely derived from the image media producers have of the actual, or the intended, people or groups of people that they imagine as the main recipients of their products. Media products—newspapers, television shows, films, radio broadcasts—are for the most part

manufactured with the aim of capturing the attention of certain of these people, the audience members. Often this interest is commercial: When media can capture the attention of particular audiences, their producers can sell this attention to various advertisers who may profit from this exposure.

While a long tradition of scholarship has accepted this idea of the audience, other thinkers have been rancorous in their disapproval of the commercial nature of the very concept. According to Ang, the '"television audience" only exists as an imaginary entity, an abstraction constructed from the vantage point of the institutions, in the interest of the institutions' (Ang 1991, p. 2). Nevertheless, scholars as well as market researchers study these groups of people that media products assemble. Audience research has been partitioned according to the type of media consumed. Different media have inspired different methods of primary research, as media differ in how they are received, and in the type of access scholars have to studying their modes of reception. The film audience has been analyzed most often from a historical or a psychoanalytic perspective, for example, while the television audience has been studied from a wide variety of perspectives, humanistic as well as social-scientific. Recent studies of the audiences for television, popular fiction, and popular music have used ethnographic methods. The trend toward ethnography attempts to recognize that the media 'audience' cannot be entirely separated from the role that media play in the everyday lives of the people who are medias' users, spectators, and viewers.

1. *Changes in Focus Over Time*

Audience research grew out of theoretical debates about the nature of public opinion and knowledge, and concern about the influence of the mass media on it. Early theories posited a 'hypodermic needle' model of media influence on its audience (sometimes called the 'magic bullet' theory), whereby audience members were powerfully influenced directly by media exposure ('injected' with ideas by the media, so the metaphor goes). This model of powerful media influence over a passive audience was supplanted by the work of Paul Lazarsfeld in the 1940s and 1950s. Directing a research program at the Bureau of Applied Social Research, affiliated loosely with Columbia University, Lazarsfeld had strong ties to industry and private money to finance targeted studies of the media audience.

Along with Elihu Katz, Lazarsfeld elaborated a 'limited effects' model in the work *Personal Influence* (Katz and Lazarsfeld 1955). This became famous for elaborating the 'two-step' flow model of the influence of the media on the audience. Instead of directly and powerfully influencing people, Katz and Lazarsfeld argued, media influence was mediated by influential people whom they called 'opinion leaders,' to whom audience members attended more strongly than they did directly to media itself. In this work, Katz and Lazarsfeld integrated the insights of social-psychological small-group theory into their approach to media influence. In general, the study confirmed the idea that media effects, rather than being powerful and evil, were actually for the most part rather minor and noninvasive, and that the media audience, as a social entity, was more powerful and resistant to them than previously thought. The limited effects model was influential in audience research throughout the 1960s. While limited effects research does not necessarily argue that mass media have no impact, this body of research generally asserts that its effect is primarily to reinforce existing opinions.

One critical response to the limited effects model was 'agenda setting' research (see *Agenda-setting*). This work argues that the mass media don't tell people what to think, but they do tell people what to think about. In particular, agenda-setting research has focused on the impact and meaning of news, and often argues that news has a structuring impact on the way both viewers and social policy makers prioritize society's social and political issues. Many of the insights of agenda-setting research have informed the cultural approaches to audience analysis discussed below.

Another response came in a direct, vitriolic critique of limited effects theory by Todd Gitlin (1978), widely read and cited, and having an important influence on audience research since the early 1980s. Gitlin accuses Lazarsfeld and his followers of misconceiving the problem of media effects. By conceptualizing an 'effect' too narrowly and concretely, they miss the many less measurable ways the mass media influence their audience. Much of this influence, Gitlin asserts, is not particularly amenable to the kind of 'scientific' study that Lazarsfeld championed. When media effects on their audience are too broad and diffuse, they can be theorized, described, and analyzed, but not necessarily measured, and this, Gitlin argued, was the nature of the modern mass medias' impact on their audience.

Other audience scholars working simultaneously to Gitlin developed what has come to be known as the 'uses and gratifications' tradition of audience research. Uses and gratifications research emerged from the functionalist perspective in US sociology, which was ascendant in the 1950s and 1960s. It focused on the active processes by which audiences 'used' the media they consumed, in an instrumental fashion, to gratify a variety of needs researchers identified to be present in audience members. This shift in emphasis from a discussion of 'effects' to 'uses' highlighted and elaborated the nature of active audience involvement in media reception. However, the emphasis upon an active audience was limited by its rather instrumental concept of audience members' orientation toward media, as one of purely satisfying particular 'needs' that individuals had (for instance, a need for in-

formation, for escape, for status enhancement), the nature of which remained merely taken for granted and unquestioned by researchers. It remained for scholars in the critical tradition to push the active audience notion further, while questioning the 'uses'–'needs' paradigm of this perspective.

2. *Emphases in Current Theory and Research*

While earlier studies tended to build audience theory as though the experiences of all types of media audiences could be analyzed and understood with one set of concepts, audience theory since the 1970s has tended to be more segmented. Partly this is a result of scholars questioning the uniform, aggregate vision of the audience which emerges from broad theories of media 'effects' or the lack thereof. Current approaches to media audience research tend to draw in part from the uses and gratifications tradition to emphasize the active engagement of the audience with the mass media, rather than focusing on the passivity of audiences in the face of media exposure. Yet active audience research tends to eschew the cognitive dimension of this research, instead combining the focus on activity with a critical perspective on media and their uses often deriving from the Marxist tradition and from theories of democracy, which both criticize and herald the role of media in a democratic society. Particularly important for current audience research has been the cultural studies tradition, both the British (see *British Cultural Studies*) and the US versions.

British cultural studies has been associated with the work of those at the Centre for Contemporary Cultural Studies in Birmingham. Stuart Hall, David Morley, Angela McRobbie, Paul Willis, Dick Hebdige, and Roger Silverstone have all done work that looks at media audiences not as isolated phenomena, but as individuals and groups of individuals who must be studied in the context of the rest of their lives, and whose nature as a part of the media audience is only one segment of an overall set of cultural practices that characterize their identities.

Also emphasized in cultural audience work has been the multilayered nature of texts as well as the complexity of how they are received. Cultural audience researchers have drawn from semiotic and hermeneutic approaches to text analysis to make clear the multitextured nature of media 'messages.' Formerly treated as fixed and transparent, media messages themselves are now understood as complex and multitextured.

Perhaps the first work to bring together textual and audience analysis from these new, critical perspectives was Stuart Hall's (1973) essay about television reception, entitled 'Encoding/Decoding in the Media Discourse.' In this work, Hall theorizes both the complex nature of the meanings 'encoded' primarily in the television text, and the necessarily separate, but equally complex nature of the process by which viewers decode these messages. This seminal article paved the way for the more empirical audience studies which were produced in its wake by cultural audience researchers. Audience research carried out in this tradition emphasizes overall the ways in which the media are part of culture, and concomitantly, the way in which audience reception of media is only one facet of the way an entire cultural system influences those who live within it.

David Morley's work has been particularly influential in current audience study. He has authored two famous studies, *The Nationwide Audience* and *Family Television* (Morley 1980, 1986). In *Nationwide Audience*, he looked at the way people of different occupations, social class statuses, and ethnicities interpreted a television news program differently. Even a supposedly 'objective' news show, he found, was open to different interpretations, made by different types of audiences. In *Family Television*, Morley took the family locale of the television audience seriously. He and his research team went into the homes of families and both interviewed them about television, and observed them watching it. Through this research Morley was able to talk about the gender dynamics of the family audience for television. He observed how husbands rather than wives often commandeered the remote control, enabling them to make many of the family viewing decisions.

Morley's work, and the work of others in cultural studies, helped to shift research from a scientific paradigm which attempted to measure audience exposure and effects, to a more holistic one which looks at audiences in the context of their everyday lives. Rather than searching for more narrow, measurable influences of media, cultural researchers examine the narratives embedded within media, and look at how these are interpreted and indeed adopted by audience members in the course of many activities in their lives. Audience research is less focused only on 'audiences' *per se*, and has expanded to include the many uses people make of culture and media in postmodern society.

Many studies now emphasize active audience interpretation in a broad cultural context. Among the most important of these are Liebes and Katz' (1990) work, *The Export of Meaning*. In their research, Liebes and Katz looked cross-culturally at the ways audiences in different countries, and members of different ethnic and religious groups within each country, interpreted the same episodes of the prime-time soap opera *Dallas*, which had become a global phenomenon, being broadcast worldwide and achieving an avid following in many different national and cultural contexts. They found striking ethnic and religious group differences in how these audiences read the very same episodes of this popular television show. For example, Israeli Arabs and Russian immigrants were defensive about the US way of life pictured in the show, and attempted

to shield their children from it, while others in cultures closer to that pictured in the show read it more as nonthreatening, simple entertainment.

Other cultural studies work often chooses locales rather than particular media as the frame for audience study. Willis (1978), for example, studied bars and looked at the types of audiences for different sorts of music assembled there. More contemporary work focuses on theme parks like Disneyland, and charts the activities of audiences there, or focuses on formal as well as informal types of museums or other audience gatherings.

Simultaneous to the cultural studies productions of Morley, Willis, and other members of the Birmingham School, scholars primarily located in literature, humanities, and film departments have produced an enormous body of work theorizing the film audience. This work has drawn on different theoretical traditions from most of the television-focused work discussed so far, which was produced primarily in social science and communication departments. Drawing on psychoanalytic theory, film scholars have theorized the way filmic texts structure and position what they call the 'spectator' of film. They theorize what is in many ways an asocial type of audience for this medium, best illustrated by early scholars' discussions of how the situation of the film audience closely approximates the dream state, a resemblance underscored by the darkened movie theater, which makes acknowledgment of audience members, and discussion with them, difficult. Much of the early film theorizing was published in the British journal *Screen* (originally named *Screen Education*). Screen theory elaborated the contours of what was termed the 'filmic spectator.' This universalized 'spectator' was constructed with the aid of Freudian concepts of the family, which were applied to the way Hollywood cinema inserts—or 'sutures'—the viewer as an individual into the family setting and other family-like relationships set up by films. Such theory was based largely on psychoanalytically informed text analyses, rather than the study of actual viewers.

While retaining some of the insights of each of these traditions, current audience work has introduced new emphases: the increasing globalization of the media (Ang 1991); the historical specificity of the audience; the segmentation and diversity of the media audience; and recent and historical changes in media such as television, film, radio, newspapers, and magazines since the early 1990s, and the implications this has had for the media audience.

For example, Levine (1988) looks historically at the development of the distinction between 'high' and 'low' culture by studying theater audiences in the eighteenth and nineteenth centuries, emphasizing their often lower-class composition and their appreciation of authors like Shakespeare, whom modern audiences consider only for intellectuals interested in high culture. Film historians like Hansen (1991) continue this tradition by studying the informal ethnic and class organization among film audiences in the early twentieth century. She shows how film was received in a social and communal way by women in New York's immigrant communities in the early 1900s, and highlights the role film played in the development of ethnic identities. Scholars like Dayan and Katz (1992) analyze the audience for particular national media events, like the coronation of Queen Elizabeth in the UK, or Rabin's assassination in Israel, and find a political meaning and potential for mobilization in this type of event-oriented audience which may not exist in more day-to-day media audiences. Their study raises questions about many conventional approaches to audience study, which often perhaps falsely individualize reception and ignore its social functions and political impact.

2.1 Feminist Audience Study

Feminist study of the audience has grown auspiciously over the past several decades. It now constitutes a sizeable body of work with its own history, subfields, criticism, and problems. In film, Mulvey's (1975) seminal article put forth the idea that the female spectator must assume what is essentially a male identity in order to derive pleasure from classical Hollywood cinema. Others responded to this claim with extensive discussions of the melodrama and other allegedly 'female' genres of the classical cinema, asserting that these genres opened a space for an essentially female spectatorial identity. Perhaps, too, because gender was already so central a concept for psychoanalytic theory generally, the entire field of spectator theory was reframed by these feminist debates, which now often revolve around gender-related issues.

Many feminist audience researchers have employed what is often called 'feminist methodology' to study the media audience. Generally, feminist methodology employs interpretive, intersubjective techniques to probe the creative responses to oppression that women and members of other oppressed groups make. Topically, feminist audience researchers seek to look at the particular uses women and others make of our culture in response to their oppression.

Janice Radway (1984), for example, in *Reading the Romance*, interviewed female members of a Midwestern community who were fans of romance novel reading. Feminist communication researchers of the time had deemed romance literature sexist, oppressive to women, trashy, and of little literary value. Radway illustrated how, contrary to these dicta, women fans found great value in this literature, and admired it for its portrayal of strong and independent heroines. In addition, many used their reading time aggressively, to claim time away from family duties and household chores. Her interpretive methodology, which consisted

of speaking to the women on their own terms, and in their own language and spaces, helped her to elicit these findings, which were surprising at the time. This book was innovative and influential in its focused, qualitative study of readers rather than texts, and its focus on a popular 'woman's' genre, the romance, which had never before been taken seriously enough to be the object of scholarly study.

Press (1991) continued in Radway's tradition with the study *Women Watching Television*, an interviewing study of working-class and middle-class women of different ages in which she discusses the role of television in their lives. In this book, Press documents the role television plays for women of different social classes and age groups in reinforcing the culture's hegemonic values. She found that television seemed to reinforce different values and beliefs for different groups of women. For middle-class women, television's hegemony operated around issues concerning gender, often reinforcing stereotypical notions of proper feminine and masculine behavior. For working-class women, television hegemony operated along a class dimension, reinforcing the normality of a middle-class or often an upper-middle-class way of life in the USA, and underscoring the notion that poor or working-class people are abnormal and somehow individually inadequate.

Television soap opera in particular, traditionally considered a 'woman's genre' (although this is changing, particularly with an increasingly flexible workforce), has inspired researchers worldwide to study its audience. Often these studies assess the impact of US television soaps, which have been exported to many cultures around the globe, and are heavily consumed in a variety of contexts. Gripsrud (1995) studied the notable success of the prime-time soap opera *Dynasty* in Norway, and documented the enormous public debate over its broadcast in a television system that was tightly state-controlled and concerned that US shows would erode traditional culture. In the end, the show's widespread popularity, and public expression of this accolade in the mass media, swayed officials to permit its continued broadcast. Liebes and Katz (1990) document the failure of another prime-time soap opera, *Dallas*, phenomenally popular worldwide, to capture the popular audience in Japan. The unconventional family and gender relationships on the show were incomprehensible to the Japanese audience, they conclude. Other scholars have documented the continuing widespread popularity of telenovelas on Brazilian television (see *Soap Opera/Telenovela*).

3. *Probable Future Directions of Theory and Research*

Possible future trends of audience research will undoubtedly continue current insights into the nature of the media audience as increasingly fragmented into specific cultural 'segments' separated by race, nationality, ethnicity, sexuality, religion, and 'lifestyle.' Audience researchers are being challenged to refine their notion of the 'audience' to accommodate increasing recognition on the part of media, new media, and advertisers of its specialized and segmented nature. For example, the decline of viewership for nightly television news and of readership for the major national newspapers, and the concomitant rise of unconventional news sources such as MTV news and on-line news forms, have led to a level of fragmentation and specialization among news audiences inconceivable even at the start of the 1990s. These developments have spawned new types of local audience research which focus on the processes of reception and appropriation of media specific to particular groups of people, in particular locations, at particular moments in time. New media such as computers and the Internet pose particular challenges in this regard for current audience researchers. Often this research looks at the social, interactive, and consequently the often political media audience in a way ignored by earlier researchers, as in the work of Dayan and Katz (1992) discussed above.

In particular, the proliferation of new media, and the concomitant changing face of the old media since the 1980s have pushed audience research in new and ever-changing directions. Many researchers are interested in studying the impact of electronic media, both on children and adults. Some are discussing the way in which virtual communities have changed identities. Turkle (1995), for example, discusses the intriguing issue of how writing on computers, and communicating with others through computers, changes the sense of self (see *Virtual Reality, Psychology of*). She argues that a new sense of identity, decentered and multiple, is emerging as more and more people spend more and more of their daily lives communicating by computer. In a sense, Turkle asserts, computers bring the concepts of postmodernism 'down to earth,' concretizing the decentered sense of identity that scholars have been theorizing since the 1980s. Others discuss how digital technologies have transformed the very notion of interaction and dialog, or the particular implications of these changes for women and members of various minority groups in contemporary societies.

Certainly such observations transform the concept of 'audience.' As electronic media have become more participatory and dialogical, our notion of audience has transformed to become a more participatory concepts itself. Similarly, the notion of community that undergirded the conventional concept of audience has also been radically challenged. Virtual communities have some of the characteristics of communities in the traditional sense, but not others. The global nature of new communication technologies is fundamentally transforming the sense of space, and of what collectivity means. As notions of community develop along-

side rapidly changing electronic media, so will new dimensions of the term audience continue to unfold.

Audition and Hearing

Hearing, like most senses, allows an organism to determine objects in its environment. Objects can vibrate, producing sound that provides information about the object. However, sounds from the many sound sources in one's environment are combined into one complex sound field, and therefore sounds from individual sources do not reach the listener as separate events. This complex sound field is the frequency components of the sound's spectrum, the level of the spectral components, and the timing relationships among the components. The auditory periphery codes for the frequency, level, and timing parameters of the components of the entire complex sound field and not for sound sources *per se*. The spectral–temporal code generated by the auditory periphery contains information that is processed by brainstem and cortical auditory centers to help determine the originating sound sources (Yost et al. 1993).

1. Outer and Middle Ears

The head and torso transform sound spectrally as it travels from its source to the outer ear canal. Resonances of the outer ear canal provide further modifications (increases in pressure in the 2,000–6,000 Hz frequency region) before sound vibrates the tympanic membrane and ossicular bones (see *Auditory System* for a description of auditory anatomy). The vibrations of the ossicular chain cause the fluids and membranes of the inner ear to move, which begins the biomechanical and neural transduction of vibration into neural discharges. The fluids and membranes of the inner ear offer a significant impedance to the vibratory motion established by the incoming pressure wave. The resonance of the outer ear canal and, most important, the lever action and pressure transformations provided by the ossicular chain, compensate for this impedance mismatch, providing an efficient transfer of pressure from air to the fluids of the inner ear (Dallos 1973).

2. The Inner Ear

The coiled cochlea constitutes the auditory part of the inner ear with the cochlear partition, lying within the middle segment (scala media) of the three-part cochlea, housing the major structures (e.g., inner and outer haircells) responsible for the biomechanical and neural sound transduction. As shown in Fig. 1, the stapes vibrates the fluids of the cochlea in a piston-like manner (Dallos et al. 1996). The resulting pressure wave develops a pressure gradient across the cochlear partition, setting it in motion such that it moves from the base of the cochlea toward its apex. The stiffness gradient of the cochlear partition; the widening of the cochlear partition toward the apex; and the opening (the habenula perforata) between the cochlear partition and the cochlear end lead to a traveling motion of the cochlear partition. For high-frequency sounds, the traveling wave produces maximal displacement at the base and the wave does not propagate to the apex. For low-frequency sounds, the traveling wave propagates toward the apex where maximal displacement occurs. Cochlear partition vibration follows the vibratory pattern of the incoming sound, but maximal

Figure 1
A schematic diagram of the uncoiled cochlea and the middle ear ossicles with the moving stapes initiating a pressure gradient across the cochlear partition which vibrates with a traveling wave motion from base (near the stapes) to apex. The envelope of the traveling wave (the dotted curve) shows that the point of maximal cochlear partition displacement is frequency dependent (reproduced by permission from Yost, 2000)

displacement varies from base to apex depending on the frequency of the originating sound: maximal displacement toward the base for high frequencies and toward the apex for low frequencies. Cochlear partition motion is in phase with stapes movement near the cochlear base but, due largely to traveling wave travel times, there is a phase lag between cochlear partition and stapes vibrations toward the apex.

The vibratory pattern of cochlear partition displacement can be estimated using laser interferometry or the Mossbauer technique to measure basilar membrane displacement (the basilar membrane forms one boundary of the cochlear partition). Figure 2 shows an iso-displacement plot for one location along the basilar membrane for tones of different frequencies, indicating the sound level required to displace the basilar membrane by a threshold amount. For this location near the base of the cochlea, sounds with frequency components near 8,000 Hz require the lowest level for threshold displacement (8.3 kHz is the best frequency (BF) for this basilar membrane location).

Figure 2
The level of tones of different frequencies required to displace the basilar membrane 19 angstroms using the Mossbauer technique. The BF for this function is 8.3 kHz (reproduced by permission of from Yost (2000), adapted from Ruggero and Rich, 1986)

Each point along the basilar membrane produces a function similar to that shown in Fig. 2, but with a different BF for each point: maximal displacement at the base for high frequencies, and toward the apex for low frequencies. The amount of basilar membrane displacement is proportional to stimulus level, but for tones with frequencies near BF displacement, it is a nonlinear compressive function of sound level. At all points along the membrane, the temporal pattern of displacement follows the sound's pressure waveform, except that displacement magnitude depends on interactions between basilar membrane location and frequency, and there is a time delay for displacement at apical locations.

Cochlear partition motion causes the stereocilla of the inner and outer haircells to bend (shear), triggering an ion exchange across the haircell membrane wall, most likely near the base of the stereocilla, that produces a neural generator potential propagating to auditory nerve fibers innervating the haircells (Dallos et al. 1996). Shearing of stereocillia is due to differential motion of the basilar membrane on which the haircells sit, and the tectorial membrane that lies at the top of the haircells' stereocilla. The generator potential creates neural discharges within the auditory nerve, which carries this neural information about the incoming sound to the cochlear nucleus, the first auditory brainstem nucleus.

Inner and outer haircells serve two different functions in the transduction process (Dallos et al. 1996). Inner haircells are the actual biological transducers that convert stereocillia shearing into neural generator potentials. Approximately 90 percent of the afferent auditory nerve fibers innervate inner haircells, with

only a few auditory nerve fibers innervating any one inner haircell. The outer haircells most likely modify the mechanical coupling within the cochlear partition that provides the high sensitivity and frequency selectivity of the biomechanical traveling wave. The outer haircells are motile in that they change length in response to electrical stimulation in vitro, and most likely also change length in response to cochlear partition vibrations in vivo (Dallos et al. 1996). Since the outer haircells are connected to basilar and tectorial membranes, the change in outer haircell confirmation can alter the coupling between these two membranes that is crucial for stereocilla shearing. Outer haircell motility is also most likely under some efferent control from the olivocochlea bundle coming from the cochlear nucleus. Direct outer haircell motility operates on a cycle by cycle basis as the cochlear partition vibrates (as fast as fractions of a millisecond), whereas efferent control of outer haircell function operates on a longer timescale (many milliseconds). Outer haircell changes are consistent with a system that feeds energy back into the cochlea as it is stimulated. This feedback system is referred to as the cochlear amplifier, in that the function of the outer haircells may be to 'amplify' the sensitivity of the biomechanical system. When outer haircells are damaged and inner haircells remain functional, the sensitivity of the inner ear is significantly reduced, frequency selectivity is poor, and the system becomes nearly linear—no longer displaying a compressive nonlinearity. These alterations in cochlear function demonstrate the significant role of outer hair cells in auditory processing.

Hearing loss due to overexposure to sound, exposure to some ototoxic drugs, and aging results from deterioration of haircells, both inner and outer. The haircells are either destroyed or their ciliary structures become malformed. In mammals, haircells do not regenerate once they are destroyed (Rubel et al. 1999). However, haircells do appear to regenerate in many birds and fish. In birds, there is strong anatomical evidence for haircell regeneration, and mounting evidence that the physiological properties of regenerated haircells are the same as for normal haircells. In addition, it does not appear that birds suffer permanent hearing loss following intense sound exposure as mammals do. It is not clear what causes haircells to regenerate in birds and fish and not in mammals. Several hypotheses concerning genetic triggers are currently being investigated.

3. *Auditory Nerve*

Activity within the inner haircells triggers neural responses in auditory nerve fibers lying in the VIIIth cranial nerve bundle. Figure 3 displays tuning curves for different auditory nerve fibers in the VIIIth nerve. Each tuning curve displays the sound level required to increase neural firing rate a threshold amount above spontaneous rate as a function of frequency. Each auditory nerve fiber has a different BF; fibers with high-frequency BFs innervate haircells near the base of the cochlear partition, and fibers with low-frequency BFs innervate apical locations (note the similarity between Fig. 1 displaying tuning at the level of basilar membrane displacement and Fig. 2 displaying neural tuning). Due to the refractory properties of neuronal firing, auditory nerve fibers discharge in synchrony with the temporal pattern of the sound waveform up to approximately 5 kHz. Any one auditory neuron responds over a 30–50 decibel (dB) range of sound level. Thus, the auditory nerve carries a code for sound to the auditory brainstem. Frequency is coded primarily by the differential sensitivity of each nerve to frequency (tonotopic organization); sound level is coded by overall neural discharge rate; and timing information is coded by the temporal pattern of neural discharges (Geisler 1998). This spectral–temporal code has limitations in its ability to represent faithfully the originating sound. While each auditory nerve fiber is most sensitive to one frequency, it does respond to a range of frequencies. Any one auditory neuron only responds with a change in discharge rate to a stimulus change of 30 to 50 dB, which is a small part of the 120 dB dynamic range of hearing. Each nerve can only code for temporal structure up to approximately a rate of 5 kHz (or a timing difference of 0.2 ms), whereas the auditory system is sensitive to frequencies as high as 20,000 Hz. However, this peripheral code accounts for much of auditory perception. And the peripheral code is refined in many ways as neural information ascends through the auditory brainstem toward the cortex.

4. *Auditory Brainstem and Cortex*

The auditory pathway from the auditory nerve to the auditory cortex is a complex system of afferent and efferent subpathways (see *Auditory System*). The varying morphological cell types within the various brainstem nuclei and auditory cortex appear to have corresponding physiological function (Fay and Popper 1992). For instance, fusiform cells in the dorsal cochlear nucleus produce neural firing patterns with an excitatory tuning curve as well as inhibitory areas. These inhibitory areas reveal cases in which tones of one frequency inhibit the firing rate of the cell caused by tones of a different frequency (two-tone inhibition; Geisler 1998). Such two-tone inhibition exists at the level of the auditory nerve and throughout the auditory brainstem. Some of these inhibitory cells may be part of lateral inhibitory networks that could sharpen the neural response to sounds with complex spectral patterns (Shamma 1985). The behavioral significance of the function of central neural circuits in several species of bats and song birds is better understood than those of most other animals (see *Birdsong and Vocal Learning during Development*).

Figure 3
Neural tuning curves from six auditory nerve fibers showing the level of tones of different frequencies required to increase the firing rate a threshold amount above spontaneous activity (reproduced by permission from Yost (2000), adapted from Liberman and Kiang, 1978)

The peripheral neural code contains information about the individual sound sources of a complex sound field that can be processed by higher auditory centers. One form of processing is binaural processing, which makes possible sound source location in the horizontal or azimuth plane (Yost and Gourevitch 1987). Sound from a horizontally located source reaches the ear closest to the source sooner and with a greater level than that reaching the other ear. Differences in interaural (between the ears) time and level are cues used for azimuthal sound localization. There are only a few bilateral neural connections between the two ears within the cochlear nucleus, but there are strong bilateral connections at the next brainstem nucleus, the olivary complex. Neural units within the medial superior olive (MSO) respond to interaural time differences, while the lateral superior olive (LSO) processes interaural level differences. MSO and LSO outputs are sent to the inferior colliculus and then to the auditory cortex, where additional binaural processing takes place. While there is some evidence for auditory neural spatial maps (Yin et al. 1997), determining azimuthal spatial location depends on neural computations of interaural time and level differences.

Animal models such as the barn owl, which may be adapted specially to use sound to locate prey, have provided valuable information about binaural hearing. In several animal species, interaural time differences are likely processed by a coincidence network of bilateral cells (Yin et al. 1997). In the barn owl these cells are located in the nucleus laminaris, which is a homolog to the MSO. Such coincidence networks perform a form of cross-correlation on the signals reaching the two ears, providing a spatial map for processing interaural time as a cue for azimuthal sound localization. Bats (Popper and Fay 1995) and dolphins (Au 1993), which use echolocation for navigation and feeding, are also valuable animal models for studying sound localization.

Location in the vertical plane most likely depends on spectral information contained in the Head Related Transfer Function (HRTF), which describes the spectral changes sound undergoes as it passes over the torso and head on its way from the source to the outer ear canal (Wightman and Kistler 1993). Parts of the torso and head (e.g., pinna) alter the spectral information reaching the outer ear canals, especially in the high frequencies where the spectral locus of deep spectral valleys in the amplitude spectrum of the HRTF covaries with vertical stimulus location. Thus, the spectral location of these valleys is the likely cue for vertical sound localization. The complex neural circuitry of the cochlear nucleus (e.g., the dorsal cochlear nucleus) is a candidate for initially processing complex spectral structure, such as that associated with the HRTF (Young et al. 1997).

Segregating one sound source from others in a complex sound field may be aided by the fact that an independent, slow temporal amplitude modulation of the sound can be imparted by each source (Yost et al. 1993). Neurons at several brainstem levels (cochlear nucleus and inferior colliculus) and in the auditory cortex are differentially sensitive to sounds with different rates of amplitude modulation. These neural units display a modulation transfer function suggesting that they may be tuned to a particular rate or pattern of amplitude modulation. There is evidence that inferior colliculus units in the central nucleus are organized according to their preferred amplitude modulation rate (Langner et al. 1998). Thus, these circuits may subserve modulation processing as one means of segregating sound sources in complex, multisource environments.

The periodic envelope of amplitude-modulated sounds often provides a complex periodicity pitch cue that can be used for sound source determination and segregation. The same central auditory system circuits described above that process amplitude modulation have also been suggested as circuits for complex periodicity pitch processing (Langner et al. 1998). Other sounds have a similar complex pitch. Some of these sounds do not have the periodic envelopes of amplitude modulated sounds, but they do have a temporal regularity in their waveform fine structure (Yost et al. 1996). One such sound, iterated rippled noise, is formed by a sound and its added delayed reflections. The amplitude envelope of such sounds is flat, but there is a temporal regularity in the fine structure equal to the delay, the reciprocal of which is the perceived pitch. Studies of the anteroventral cochlear nucleus have shown that the neuronal discharge pattern of these units preserves this temporal regularity (Shofner 1991). Autocorrelation of the neural spike trains reveals a strong temporal regularity associated with iterated ripple noise stimuli that might be the basis for the perceived complex pitch. While autocorrelation of neural spike trains has been a useful analysis tool (Cariani and Delgutte 1996), there is little evidence for neural coincidence networks that might form an autocorrelator. Auditory science is learning more about the functional properties of the auditory brainstem nuclei and cortex as a means of understanding the neural basis for sound source determination and segregation.

Auditory Models

For more than one hundred years models of hearing have played a significant role in the development of auditory theories. Modeling efforts in hearing can be divided into three categories: models of the inner ear (cochlear models), models of auditory detection and discrimination, and auditory computational models.

In the last part of the nineteenth century several 'theories of hearing' were proposed (Boring 1942). In reality these were theories of frequency coding by the cochlea. The bases for these theories were actual physical models, descriptions of such models, or mathematical realizations of the biomechanical vibratory patterns that might exist within the cochlea and how those patterns code for the frequency content (the spectrum) of sound. Cochlear modeling is still an extremely active and important effort. Following World War II a group of psychologists and engineers at the University of Michigan developed Signal Detection Theory (SDT, e.g., see *Signal Detection Theory, History of*) and adapted it as a model of hearing for predicting the detection and discrimination of tonal signals in noisy backgrounds. Models based on SDT still provide a fundamental base for many models of auditory perception. With the advent of fast computers, computational models of hearing have been developed for both neural and perceptual data including those describing auditory neurons and neural circuits, spatial localization, pitch perception, speech perception, amplitude modulation processing, and, recently, auditory scene analysis (e.g., see *Auditory Scene Analysis: Computational Models*).

1. Cochlear Modeling

Sound enters the ear canal and vibrates the eardrum (tympanic membrane) and the middle ear bones (ossicular chain). The stapes, the ossicular bone nearest the inner ear, transmits this vibration to the fluids of the cochlea (part of the inner ear). The moving fluids vibrate a set of structures within the cochlea called the cochlear partition, such that cochlear partition vibrations are sorted into a frequency-selective pattern. The inner haircells lying within the cochlear partition, which serve as the biological transducers, produce neural activity in proportion to cochlear partition vibratory displacement. The auditory nerve relays the neural activity to the central nervous system such that each auditory nerve fiber has a preferred (or best) frequency to which it discharges due to the location of the inner haircells along the cochlear partition. Thus, frequency is place coded in that each nerve fiber carries information about a particular frequency region of the auditory spectrum. This place code is the basis for all theories of hearing (see Yost 2000 for an introduction to hearing).

Due to the difficulty of measuring cochlear-partition vibrations, cochlear models have played a major role in understanding cochlear-partition vibrations. George von Bekesy, who won the Nobel prize in 1959, built real models made of wood, metal, rubber, and fluids scaled to the actual dimensions of the cochlea to understand the frequency selectivity of cochlear-

Figure 1
A schematic depiction of the uncoiled cochlea and the middle ear ossicles with the stapes shown. A predicted instantaneous traveling wave motion of the cochlear partition is shown indicating that the area of maximal displacement (dotted curve) is about two-thirds of the way toward the cochlear apex for this low-frequency stimulus

Figure 2
Simulation of the vibration pattern in the cochlea based on the output of a bank of 64 gammatone filters to the vowel /a/

partition wave motion (von Bekesy 1960). Modern models are based on hydrodynamic or equivalent electrical circuits (Hawkins et al. 1996). The key prediction of these models is that cochlear-partition wave motion produces a traveling wave that travels from the cochlear base toward its apical end. Figure 1 is a schematic depiction of the cochlea and an instantaneous traveling-wave. The place of the traveling wave's maximal displacement is frequency dependent, with high frequencies generating a traveling wave that travels partway toward the cochlear apex and having its maximal place of displacement near the cochlear base. Low frequencies generate a traveling wave that travels to the apex, with its maximal place of displacement near the apex. These wave-propagation models are based on longwave and shortwave hydromechanical assumptions (Dallos et al. 1996). They do a good job of describing classic measures of cochlear vibration and indirect measures of these vibrations, and thus they account for frequency coding by the auditory periphery.

The classic measures of cochlear vibrations were based on cochleas that were severely compromised by the surgery required to make the measurements, and, thus, do not represent the true biological state of the cochlea. The earlier wave-propagation models cannot account for the high sensitivity and acute frequency selectivity measured for biologically vital cochleas. In addition, the healthy cochlea produces vibration patterns that are nonlinear and the earlier models are linear. The role of the outer haircells must be included in an improved cochlear model. The function of outer haircells is minimized in damaged cochleas. It is now known that outer haircells are motile, acting like motors that probably modify the cochlear-partition vibrations. Outer haircells may feed energy back into the cochlear partition vibration process providing an active mechanism that increases the partition's vibratory sensitivity and improves its frequency selectivity. Such feedback mechanisms are nonlinear. The difficulty of measuring outer haircell function, especially in vivo, has made cochlear models critically important (Dallos et al. 1996). The active process is often modeled as a form of 'negative damping' that counteracts the inherent damping (friction) provided by the cochlear partition membranes and fluids (Dallos et al. 1996). Modern laser-interferometry techniques allow accurate measures of cochlear-partition vibrations, and several current models can account for the sensitivity, frequency selectivity, and nonlinear properties of these vibrations. However, knowledge about the details of cochlear biomechanics is changing rapidly, and the modeling efforts are, therefore, dynamic ones.

As described above the biomechanics of the cochlea generate a spectral-temporal pattern of neural discharges within the auditory nerve bundle providing the neural code for the stimulus' spectrum. This spectral-temporal pattern can also be modeled as if the stimulus were filtered by a bank of narrow band filters. A filterbank can also account for the perception of the interactions that takes place when sounds of different frequencies coexist in an acoustic environment. The sound of one frequency (masking sound) can interfere with the detection of a sound of a different frequency (signal frequency) only if the masker frequency is in the spectral region of the signal frequency. This result can be explained by assuming that the masker is filtered by a bandpass filter whose center frequency is

that of the signal, and the total power of the masker at the output of this hypothetical filter determines signal thresholds (Moore 1986).

Thus, it is not surprising that several models of these 'internal filters' have been proposed to model physiological and psychoacoustical data. One such filter is based on a gammatone impulse function (an impulse function with a gamma-function envelope of a cosinusoidal fine structure) which is derived from direct neural measurements of auditory nerve tuning (Patterson et al. 1995). Figure 2 depicts the filtered output of the vowel /a/ provided by a gammatone filterbank. Each line is the filtered output of a gammatone filter with center frequencies ranging from low frequencies at the bottom to high frequencies at the top. By looking across frequency at any one point in time, an estimate of an instantaneous measure of the traveling wave can be established. The display also reveals the spectral-temporal code provided by the cochlea. The time delay seen in low-frequency channels result from the impulse time of low-frequency filters and corresponds to the traveling wave delay toward the cochlear apex (where low frequencies are coded). The gammatone filter bank has provided a good fit to many psychoacoustical and auditory nerve data.

2. *Models of Auditory Detection and Discrimination*

Auditory models based on Signal Detection Theory have played a major role in psychoacoustically based theories of hearing (e.g., see *Signal Detection Theory*). The classic auditory stimulus condition for these models involves the detection of a tonal signal in a background of Gaussian noise. The energy-detection model, as developed by Dave Green and colleagues in the 1960s, was derived from SDT (Green and Swets 1974). It assumes that the listener uses the distribution of instantaneous amplitudes of the two sounds (signal-plus-noise and noise alone) for a decision as to whether or not a tone was added to the noise. The instantaneous amplitudes of Gaussian noise are normally distributed with zero mean and a standard deviation equal to the root-mean-square (rms) amplitude of the noise. When a sinusoidal tone is added to the noise, the distribution remains normal with a mean equal to the energy of the signal and the same standard deviation. The decision is assumed to be based on the likelihood that a sampled instantaneous amplitude would come from the signal-plus-noise distribution as opposed to the noise distribution. The distributions of the likelihood ratios remain normal and the distance (d') between the two distribution means normalized to the common standard deviation takes the form: $d' = \sqrt{(2E/N_o)}$, where E is signal energy and N_o is noise spectrum level. Thus, as the energy of the signal increases relative to the level of the noise, d' increases, suggesting higher signal detectability.

A d' measure of performance can be derived from a masking task. In the single-interval psychophysical task the signal-plus-noise is presented randomly on half of the trials and the noise on the other half. The listener indicates either 'Yes' the tone-plus-noise was presented or 'No' only the noise was presented. The hits (proportion of Yes responses given signal-plus-noise) and false alarms (proportion of No responses given signal-plus-noise) are converted to normal standard scores (z-scores) and $d' = z_{hit} - z_{fa}$, where z_{hit} is the hit z-score and z_{fa} is the false alarm z-score.

According to the model's assumptions the listener establishes a criterion likelihood ratio for making the Yes/No decision. If the obtained likelihood ratio is greater than the criterion value, the decision is 'Yes' the signal-plus-noise was presented, otherwise the decision is 'No.' Because of the normal form of the underlying distributions as explained above, z_{hit} and z_{fa} represent the appropriate response outcomes given the model's assumptions. Thus, the obtained d' values can be compared with the predicted values. The predictions are close to the obtained data, but miss in both slope and intercept. Better fits can be obtained, but the model adjustments usually miss fitting the proper slope (Green and Swets 1974). The general energy-detection model has been applied to a wide range of stimulus conditions (Swets 1964) such as different stimulus durations and different frequency content for the signal and masker, and to tasks involving discrimination stimulus changes (e.g., in signal level). The energy-detection models are most accurate for limited data sets.

The energy-detection model is used less today, but several aspects of the SDT approach remain as powerful components of many current auditory models. The energy model is often termed an 'ideal detector' in that the model's prediction represents the maximal use of all available information, and given this information no other decision process is more accurate in determining the presence or absence of the signal. Many current models use such an 'ideal detector' approach. The result of $d' = \sqrt{(2E/N_o)}$ can be equivalently derived by assuming that the observer cross correlates a sample of the instantaneous amplitude to a known template of the signal-plus-noise distribution. As such this template matching calculation is an ideal detector. Current auditory models often include such template matching operations (Dau et al. 1996). Many current models contain a decision-processing stage. The concepts of SDT, in which the decision process is divided into two classes of variables, those controlling the sensitivity of the observer to the stimulus conditions and those that control the observer's response bias, have been used extensively in many current auditory models. Other models have assumed other divisions of the variables that might

control a decision, such as the stimulus context in which a signal exists (Durlach and Braida 1969).

3. Auditory Computational Models

Most computational models of hearing have a modular approach, with each module representing a different stage of auditory processing. The 'front-end' to many models contain an outer and middle ear module, a cochlear module, and a haircell module (Patterson et al. 1995). The outer and middle ear module is usually based on a simple bandpass-filter model to represent the filtering of the middle ear and its relationship to the thresholds of hearing (Patterson et al. 1995). Recent work has shown that the spectral transformations that sounds undergo as they travel from the source across the body and head (especially the pinna) before reaching the outer ear are extremely important in providing sound localization cues, especially in the vertical plane. These head related transfer functions (HRTFs) are crucial characterizations of the acoustic input to the outer ear for which modeling efforts have been important for understanding sound localization and providing realistic virtual auditory environments (Gilkey and Anderson 1996).

The gammatone filter bank (see Fig. 2) is a common cochlear model. An often used neural transduction model is the Meddis haircell, which is a computational model of inner haircell function (Meddis 1986). The parameters governing neurotransmitter release in the Meddis haircell have been tailored to the unique physiology of auditory haircells. Figure 3 displays the output of the Meddis haircell for the same /a/ vowel used in Fig. 2. The display reveals the spectral-temporal code provided by the auditory periphery.

Figure 3
Simulation of the neural spectral-temporal pattern in the auditory nerve based on the neural output of the Meddis haircell model for the 64 tuned channels shown in Fig. 2

Figure 4
Top: The correlogram for 64 neural channels (as in Fig. 3) formed by autocorrelation. The stimulus was an iterated rippled noise that produces a 125-Hz pitch. Bottom: The summary correlogram formed by adding the correlogram across channels, showing the clear peak at 8 ms

In most computational models additional modules process the information provided by these 'front-end' modules. Often these higher modules are based on pattern recognizing models derived from neural network technology. These models attempt to find appropriate patterns of information in displays such as those shown in Figs. 2 and 3. Sometimes, especially for models of auditory scene analysis (e.g., see *Auditory Scene Analysis*), the neural network requires some prior knowledge about the acoustic or listening situation in order for accurate predictions to emerge. In other models a decision module is provided (Dau et al. 1996), and if so, they use models following those from SDT as described above.

Figure 4 displays the output of a model used to predict the pitch of complex sounds (Yost et al. 1996). The front end to this model is a middle-ear filter, the gammatone filterbank, and Meddis haircell. Following the earlier suggestions of Licklider (Licklider 1951), the final module is based on autocorrelation performed on the neural spike trains of each frequency channel (such as shown in Fig. 3). Such a display is

called a correlogram. At the bottom of the figure is a summary correlogram generated by summing across frequency channels for each autocorrelation lag. The stimulus for this display is a regular-interval noise stimulus generated by delaying a noise by 8 ms and adding it back to itself several times (iterated rippled noise, Yost et al. 1996). This stimulus has a flat amplitude envelope and a spectrum with noisy spectral peaks and valleys, and it produces a salient pitch of 125 Hz. The summary correlogram shows a clear peak at a lag of 8 ms suggesting an 8-ms temporal regularity. The model predicts that this iterated rippled noise stimulus should have a pitch of 125 Hz (the reciprocal of 8 ms), and that the pitch should be relatively strong given the prominence of the summary correlogram peak. Both predictions are in excellent agreement with psychoacoustical data.

A similar approach has been proposed to account for interaural time differences as a major cue for horizontal-plane sound localization. Jeffress (1948) proposed a model for processing interaural time differences in which the neural activity at the output of each cochlea was cross correlated. Several versions of such cross-correlation models have been successful in accounting for a wide range of binaural and spatial hearing data (Colburn and Durlach 1978, Hawkins et al. 1996). Such a cross-correlation process could be realized by a coincidence network of bilateral cells receiving inputs from each cochlea (Jeffress 1948).

The modeling efforts described in this chapter and many other models have provided valuable links between empirical research on hearing and the development of theories of auditory processing. Occasionally, as with cochlear models, the models provide a close approximation to nature. The recent advances in computational power and in our understanding of hearing suggest that many more models will be soon be available which will provide useful descriptions of the hearing process.

Auditory Scene Analysis

Sounds are created by acoustic sources (sound-producing activities) such as a horse galloping or a person talking. The typical source generates complex sounds, having many frequency components. [Its *spectrum* (pl. *spectra*) consists of the frequency and amplitude of every pure-tone component in it.] In a typical listening situation, different acoustic sources are active at the same time. Therefore, only the sum of their spectra will reach the listener's ear. For individual sound patterns to be recognized—such as those arriving from the human voice in a mixture—the incoming auditory information has to be partitioned, and the correct subset allocated to individual sounds, so that an accurate description may be formed for each. This process of grouping and segregating sensory data into separate mental representations, called *auditory streams*, has been named 'auditory scene analysis' (ASA) by Bregman (1990).

The formation of auditory streams is the result of processes of sequential and simultaneous grouping. Sequential grouping connects sense data over time,

Auditory Scene Analysis: Computational Models

1. Introduction

Human listeners have a remarkable ability to separate a complex mixture of sounds into discrete sources. The processes underlying this ability have been termed 'auditory scene analysis' (Bregman 1990) (see also *Auditory Scene Analysis*). Recently, an interdisciplinary field known as 'computational auditory scene analysis' (CASA) has emerged which aims to develop computer systems that mimic this aspect of hearing (Rosenthal and Okuno 1998).

Work in CASA is motivated both by a desire to understand the mechanisms of auditory perceptual organization and by a demand for practical sound separation devices. Currently, automatic speech recognizers perform badly in noisy acoustic environments. It is likely that their performance could be improved by integrating CASA with speech recognition technology. Other applications of CASA include hearing prostheses and music analysis.

This article considers three general classes of CASA system and discusses their relative merits. Evaluation techniques for CASA are described and outstanding challenges in the field are identified.

2. Theoretical Influences

CASA has been motivated principally by Bregman's (1990) account of auditory organization. However, it has also drawn inspiration from Marr's (1982) work in the field of machine vision. Marr regarded visual processing as a series of representational transforms, each of which makes explicit some aspect of the preceding representation. Starting with Cooke (1993), several workers in the field of CASA have acknowledged Marr's influence and have developed systems in which representational transforms of the acoustic signal play a key role.

3. Three Classes of CASA System

The stages of processing in a CASA system mirror the conceptual stages of auditory scene analysis (Fig. 1). The input to a CASA system is a digitally recorded mixture of sound sources; following feature extraction, this acoustic mixture is decomposed into parts (segmentation). Subsequently, a grouping mechanism identifies segments that are likely to have arisen from the same sound source, and combines them to form a structure that corresponds to a perceptual stream. A final evaluation stage appraises the quality of sound separation.

Figure 1
Characteristics of frame-based, symbolic, and neural oscillator approaches to computational auditory scene analysis

Approaches to CASA can be separated broadly into three categories, which differ both in their motivation and in their implementation of the four processing stages identified above. Symbolic systems (e.g., Cooke 1993) adopt a Marrian approach: the segmentation stage derives intermediate representations that characterize properties of the acoustic input. In particular, symbolic systems tend to employ representations of the auditory scene in which temporal continuity has been made explicit. In contrast, frame-based systems (e.g., Denbigh and Zhao 1992) do not use such 'rich' representations; they make grouping decisions within short overlapping time windows ('frames'). Neural oscillator systems (e.g., Wang and Brown 1999) are based more firmly on neurobiological principles than the other types of CASA system. Motivated by reports of neural oscillations in sensory cortex, they achieve segmentation and grouping of acoustic components by forming blocks of synchronized activity in networks of neurons with oscillatory firing responses.

The following sections review the four processing stages of CASA from the perspective of symbolic, frame-based, and neural oscillator systems.

4. Feature Extraction

4.1 Peripheral Auditory Function

The frequency analysis performed by the peripheral auditory system can be modeled by a bank of bandpass filters with overlapping passbands. Each 'auditory filter' channel simulates the frequency response associated with a particular point on the basilar membrane.

Neuromechanical transduction in the cochlea can be modeled by a detailed simulation of inner hair cell function (Brown 1992) or may be approximated by half-wave rectifying the auditory filter outputs and applying a static nonlinearity to compress the dynamic range. CASA approaches which are motivated less strongly by mechanisms of auditory function employ conventional methods of spectral analysis, such as the short-time Fourier transform or discrete wavelet transform (Nakatani and Okuno 1999).

4.2 Auditory Representations of Acoustic Features

Most CASA systems process the peripheral auditory representation in order to derive further representations that make aspects of the acoustic signal explicit. Symbolic and neural oscillator approaches place greater emphasis on these intermediate representations than do frame-based systems.

Human listeners tend to group acoustic components that have the same fundamental frequency (F0). The periodicity of auditory nerve firings provides a cue to F0 and this can be extracted by a running autocorrelation of the activity arising from each auditory filter channel (Brown 1992). Amplitude modulation (AM) in high frequency channels of the auditory filterbank provides another cue to F0 and is used by some CASA systems (Cooke 1993).

Many CASA systems identify the times at which appreciable onsets and offsets of energy occur in the auditory spectrum, since acoustic components which start and stop at the same time are likely to have arisen from the same sound source (Brown 1992). The movement of resonances in the time-frequency plane may also provide information that can be used to track harmonics and formants over time or to identify acoustic components that have a common pattern of frequency modulation (FM) (Mellinger 1992).

Human listeners are also able to separate sounds on the basis of their spatial locations. Phase and intensity differences between the two ears are important cues for spatial location; accordingly, some CASA systems estimate these parameters from a binaural peripheral model (Denbigh and Zhao 1992).

5. Segmentation

The segmentation stage of CASA aims to represent the auditory scene in a manner that is amenable to grouping. Frame-based systems omit this stage of processing: they operate directly on the acoustic features described above.

In many CASA systems, the segmentation stage makes temporal continuity explicit. Typical is the approach of Cooke (1993), which tracks changes in instantaneous frequency and instantaneous amplitude in each channel of an auditory filterbank to create 'synchrony strands' (Fig. 2). Each strand traces the evolution of an acoustic component (such as an harmonic or formant) in the time-frequency plane. This approach offers advantages over frame-based processing: because frame-based schemes make

Figure 2
Segregation of speech from an interfering telephone ring in the 'symbolic' CASA system described by Cooke (1993). The utterance is 'why were you all weary?' spoken by a male speaker. A group of harmonically related synchrony strands belonging to the speech source are highlighted in gray. The remaining strands (shown in black) predominantly belong to the telephone sound

Figure 3
Behavior of the Wang and Brown (1999) system for the sound mixture shown in Fig. 2. Two groups of synchronized oscillators are shown, corresponding to the speech (white) and telephone (gray)

grouping decisions locally in time, they must resolve ambiguities which would have an obvious solution if temporal continuity were taken into account.

Neural oscillator models of CASA also exploit temporal continuity in the time-frequency plane. In this approach, groups of features that belong to the same acoustic source are represented by a population of neural oscillators whose firing is synchronized. Other groups of features are also represented by synchronized populations but oscillators coding different sound sources are desynchronized. The model of Wang and Brown (1999) employs an architecture consisting of a 'segmentation layer' and a 'grouping layer.' Each layer is a two-dimensional network of oscillators with respect to time and frequency. In the segmentation layer, lateral connections are formed between oscillators on the basis of local similarities in energy and periodicity. Synchronized populations of oscillators emerge that represent contiguous regions in the time-frequency plane (Fig. 3).

6. *Grouping*

The grouping stage of CASA identifies acoustic components that are likely to have arisen from the same sound source. This is achieved by implementing Gestalt-like grouping principles that underlie auditory organisation in human listeners (Bregman 1990).

A number of CASA systems apply grouping principles using a simple search engine. For example, Cooke's (1993) system initiates search from a 'seed' synchrony strand, and identifies other overlapping strands which match the seed according to some principle of organization. Figure 2 shows a group of synchrony strands that have been identified as harmonically related in this way. A higher-level grouping stage then integrates groups that have been formed by different organizational principles (such as common AM, common FM, onset and offset synchrony).

This approach to grouping is entirely data-driven (i.e., information flows strictly from top to bottom in Fig. 1). However, it is clear that human listeners are able to predict the behavior of acoustic sources (such as speech) in order to disambiguate an acoustic mixture. A more flexible computational framework is needed to combine this top-down information flow with data-driven grouping mechanisms.

Ellis (1999) describes such a 'prediction-driven' architecture. In his system, a world model is updated in response to errors between observed and predicted signals. Context-sensitive behavior emerges as a result of the interaction between model predictions for (possibly overlapping) segments in the auditory scene. For instance, consider a tone that is interrupted by a burst of noise. The observed acoustic evidence may be compatible with both the predictions made for the noise burst and the predictions made for the tone; since the tone is assumed to be continuous rather than intermittent, it is 'perceived' as continuing through the noise. Hence, Ellis's architecture is able to account for the occurrence of perceptual restoration phenomena (Bregman 1990). A similar 'residue-driven' system is described by Nakatani and Okuno (1999).

In the neural oscillator architecture of Wang and Brown (1999), grouping arises from the dynamics of their oscillator network. In the second layer of the network, excitatory connections are made between segments if the segments are related to the same fundamental frequency and inhibitory connections are made otherwise. As a result, synchronized groups of oscillators emerge which define sound streams (Fig. 3).

7. *Evaluation*

Most CASA systems allow a time-domain waveform to be resynthesized for each separated 'stream.' Hence, sound separation performance can be judged by listening tests or can be quantified as a change in signal-to-noise ratio (Brown 1992).

A number of workers have evaluated CASA systems as components of automatic speech recognition systems. Early approaches treated CASA as a separate preprocessor; resynthesized speech was presented to an unmodified speech recognition algorithm (Weintraub 1985). However, the performance of this approach was disappointing: although interfering sounds were rejected, the speech was distorted and hence little improvement in recognition rate was obtained. Recent efforts to integrate CASA and speech recognition more tightly have produced encouraging results (Ellis 1999).

8. *Future Challenges*

Although the CASA systems described here show promise as useful sound separation devices, their performance is still far below that of human listeners. Some workers claim that improved performance can be obtained by an approach which is based more closely on the neurobiology of hearing (Wang and Brown 1999). Equally, however, 'blind' statistical techniques are able to achieve near-perfect sound separation when certain constraints are placed on the statistical properties of the sound sources and the number of sound sensors (Bell and Sejnowski 1995). It remains to be shown, therefore, whether sound separation systems which are strongly motivated by an auditory account have an advantage over engineering approaches.

Another challenge for CASA systems is real-time performance; currently, they tend to be computationally expensive and nonreal-time. The neural oscillator approach may offer some advantage here, since parallel and distributed architectures are easier to implement in hardware than are the complex algorithms associated with symbolic CASA approaches.

Auditory System

We perceive an acoustic landscape through a system of exquisite microarchitectures along the auditory pathway to the brain. These structures range from the biomechanical at the periphery to topographical organizations more centrally. Rarely stationary, the acoustic landscape is transformed ultimately into our familiar objects of auditory perception such as speech and music. The ocean of sound waves surrounding us encounters two small points of sensory transduction on both sides of the head—leading remarkably to our perception of a full three-dimensional world of sound. The acoustic medium is often viewed as a complementary source of information; after all, higher order primates for the most part are highly visual beings. However, the physical characteristics of sound offer certain advantages in the detection of an object regardless of its location relative to the animal, such as the ability to detect the location and movement of a sound source in darkness or when the line of sight is occluded. In this article the serial and parallel processing pathways of the auditory system are described briefly, together with observations on the neural coding of auditory information. The term 'neural code' refers to a precise language—inferred by experimental observation—that reliably conveys information along neural pathways. Whether the code is actually used by the animal can only be evaluated with respect to the code's causal impact on the behavior of the animal.

The auditory system, like other sensory systems, consists of a series of connected nuclei that process acoustic information via a complex neural code that necessarily must exist in time and anatomical space (or place). Neural activity in the auditory system is capable of preserving the temporal fine structure of acoustic waveforms, up to a certain degree. Consequently, the timing of individual action potentials likely serves as a major channel of auditory information, particularly at the early levels of the auditory pathway. Centuries ago Jean Baptiste Joseph Fourier (1768–1830) defined the reciprocal relationship between time and frequency of sinusoidal waveforms that form a composite known as the spectrum. A single sinusoidal waveform can be represented as a periodic function in the time domain, but also represented as a single component among others in the composite spectrum of frequencies. This dual relationship plays a prominent role in the representation of acoustic information in the auditory system, beginning with the anatomical frequency mapping on the basilar membrane of the cochlea. The majority of nuclei in the auditory system reflect this frequency mapping, an observation that is commonly referred to as cochleotopic or tonotopic organization.

Acoustic vibrations are initially transferred to the tympanic membrane through the external ear, which causes an increase in sound pressure due to resonance formed in the ear canal. The familiar fleshy appendages we commonly refer to as 'ears' are called pinnae. Pinnae play an important role in our ability to locate sounds in space. Next, the middle ear couples acoustic energy from the external ear via three small bones called the malleus, incus, and stapes to the oval window of the cochlea in the inner ear.

1. Cochlea

The cochlea forms the foundation for signal processing in the auditory periphery (see Geisler 1998). It is embedded deep in the temporal bone and contains a coiled basilar membrane that is shown unwrapped in Fig. 1. Three fluid-filled ducts can be observed (scala vestibuli, scala media, and scala tympani), divided by a stiff cochlear partition composed of the basilar membrane and associated structures. The organ of Corti sits atop the basilar membrane and contains the

Figure 1
Schematic of the uncoiled mammalian cochlea showing a resonant vibration in the cochlear partition tuned to a particular frequency. The oscillation shows a broadness of tuning that accounts for a broad representation of a single pure tone; this coarse tuning in turn is reflected at subsequent stages in the auditory pathway (source: Geisler, 1998. *From Sound to Synapse: Physiology of the Mammalian Ear*, © Oxford University Press. Reproduced with permission).

Figure 2
A more detailed cross-section of the cochlea showing the mechanical structures of the cochlear partition (source: Fawcett, 1994. *A Textbook of Histology*, © Chapman and Hall. Reproduced with permission).

transducing hair cells, together with various supporting structures shown in Fig. 2. The uncoiled human cochlea is approximately 35 mm in length and innervated by some 30,000 nerve fibers (Pickles 1988). The basilar membrane partition becomes wider and less stiff with distance from the base. A traveling wave

initiated by the incoming sound travels rapidly from the base towards the apex. The amplitude of the wave increases at first and then decreases quite abruptly, due to the dispersive nature of the basilar membrane as shown in Fig. 1. As a result of these mechanical properties, complex sounds composed of multiple frequencies produce maximum displacement at different places along the basilar membrane, resonating to higher frequencies at the base and lower frequencies at the apex. In effect, the cochlea acts as a spectrum or frequency analyzer, although with limited resolving power.

2. *Auditory Nerve* (*AN*)

Auditory nerve fibers are ideally suited to take advantage of the cochlea's spatial frequency analysis due to nearly uniform innervations along the basilar membrane partition. Between the basilar membrane and the tectorial membrane are hair cells that together form the organ of Corti. Hair cells on the inner side of the organ of Corti are known as inner hair cells. Hair cells nearer the opposite side of the organ of Corti are known as outer hair cells that may actively influence the mechanics of the cochlea. Most auditory nerve fibers connect to inner hair cells that transduce displacements of the basilar membrane partition through shearing motion. A small minority of auditory nerve fibers innervates the outer hair cells.

As a consequence of the mechanical properties of the organ of Corti, complex sounds are decomposed into a spectral series of signals distributed along the cochlear partition. At low sound pressure levels the basilar membrane responds most vigorously to low frequencies at its apex and to high frequencies at the base. This place coding of frequency is translated into discrete populations of AN fibers responding to individual frequencies shown in Fig. 3. A distinctive property of AN fibers is their ability to temporally synchronize (phase-lock) their discharge to a restricted portion of the stimulus cycle. Fibers are capable of encoding information concerning stimulus frequency in terms of the temporal properties of the discharge, in addition to the cochlear place identity of the fiber. In response to a complex signal, with a broad range of frequencies the temporal information could, in principle, provide better resolution of the stimulus spectrum than possible through place information alone.

AN fibers vary in terms of their spontaneous discharge activity. Approximately 60 percent are highly active in the absence of sound. About a quarter show moderate rates of background activity, while the remainder (15 percent) are spontaneously inactive or nearly so.

3. *Brainstem Auditory Pathways*

3.1 *Cochlear Nuclei* (*CN*)

The auditory nerve fibers project to the cochlear nuclear complex made up of the posteroventral (PVCN) and dorsal (DCN) cochlear nuclei and the anteroventral cochlear nucleus (AVCN) (refer to Fig. 4). A complete tonotopic organization is main-

Figure 3

Schematic of the auditory pathway. See text for definitions. Parallel processing streams are denoted A, B, and C (source: adapted from Aitkin, 1990. *The Auditory Cortex*, © Chapman & Hall. Reproduced with permission).

tained in each subdivision. There is a varied taxonomy of cell types in the cochlear nuclei. The branch of the auditory nerve fiber that innervates the AVCN usually has a large, specialized calyceal ending, also known as an end bulb that more or less engulfs the cell body of bushy cells (Rhode and Greenberg 1992). Because of this secure connection, bushy cells faithfully convey timing information from the auditory nerve and therefore the cochlea. Stellate cells, found in both the AVCN and PVCN, receive their input from auditory nerve fibers spatially distributed on their dendrites. Octopus cells, found in the PVCN, possess long dendrites that serve to integrate information across neighboring frequencies—perhaps serving to bring neighboring spectral information into a common temporal register (Oertel 1999). The form and structure of these different cells is reflected in the individual firing patterns—bushy cells evidence firing patterns that are similar to that of auditory nerve fibers, stellate cells typically show a 'chopping' pattern, and octopus cells respond primarily to the onset of a tone whose frequency is within the response region of the cell.

3.2 Superior Olivary Complex (SOC)

The SOC is made up of many nuclei, but the main nuclei associated with the ascending auditory pathway are the lateral superior olive (LSO), the medial superior olive (MSO), and the medial nucleus of the trapezoid body (MTB). Other nuclei in the SOC are descending efferents involved in controlling the stiffness of the basilar membrane and the middle ear reflex. The primary afferents projecting to the LSO, MSO, and MTB are from the AVCN and the PVCN (Aitkin 1986). Neural computation in the SOC nuclei is inherently based on the physics of the relative acoustic delays resulting from the spatial separation of the two ears.

The difference in the interaural time-of-arrival of sound pressure waves at the two ears is an important source of information for the degree of 'leftness' or 'rightness' of a sound source, or in common spherical (astronomical) coordinates, its azimuthal position. Based on early anatomical evidence, Lloyd Jeffress speculated on a coincidence detection mechanism for operating on interaural time differences that has become known as the Jeffress model (1948). Interestingly, there is now considerable anatomical and physiological evidence for such a mechanism in the auditory brainstem, as well as psychophysical support. This is perhaps one of the rare examples where an abstract mathematical model predicted future anatomical and physiological observations so well. Electrophysiological observations have implicated the medial superior olive (MSO) in mammals (nucleus laminaris in birds) as the anatomical site of cross-correlation of sound synchronized responses from the two ears (see Oertel 1999). However, the inference that the MSO serves only as a simple coincidence detector of excitatory inputs from the two ears underestimates the full functionality of the circuit. Neurons in the MSO also respond to sounds presented in just one ear, so coincidence from the two sides is not exclusively required for responding. Also, neurons in the MSO receive inhibitory inputs from the MTB, which may serve to improve the temporal resolution of the circuit. The MSO receives tonotopically organized input from both ears, directly and indirectly from the AVCN, where the frequencies are systematically mapped on the MSO. The map is biased toward the lower frequencies, likely due to the low-frequency restriction of useful interaural time and phase differences resulting from the acoustic delay between the two ears. Electrophysiological evidence suggests that the LSO is the site where sound level differences between the two ears are computed. Neurons of the LSO also detect the

timing of excitation from one ear and inhibition from the other ear, so LSO neurons are sensitive not only to interaural level but also interaural time differences (Oertel 1999). The ability to detect rapid timing changes in interaural level differences may have implications for the perception of moving sounds.

3.3 *Inferior Colliculus* (*IC*)

The central nucleus of the inferior colliculus (CNIC) is the target for the vast majority of terminals from the CN and SOC and therefore represents a common point of convergence serving as a relay to higher cortical processing (Aitkin 1990). The ascending fibers run in a tract called the lateral lemniscus, and send collaterals to the nuclei of the lateral lemniscus (NLL). A tonotopic representation can again be found in the CNIC. There is a precise arrangement of neurons in the CNIC, with a continuum of frequency selectivity, with isofrequencies represented as planes in a three-dimensional structure. The LSO projects to the CNIC on both sides of the brainstem, and the MSO projects primarily to the ipsilateral (or same) side of the CNIC. There are also projections from the contralateral (or opposite) side DCN that terminate in the CNIC. Hence, the CNIC serves as an important site of convergence for several parallel paths of acoustic information. Interaural phase sensitive neurons in the SOC that converge on the lateral lemniscus and the CNIC likely account for the sound localization properties of IC neurons. Neurons sensitive to higher frequencies are less able to follow the temporal fine structure of complex sounds such as speech at the level of the CNIC compared to that of neurons lower in the pathway (AN and CN). Consequently, it is likely that periodic sounds such as speech, that were previously coded in time, may be recoded at some level into a place code for periodicity in the CNIC. Neurons in the external nucleus (EN) and dorsal cortex (DC) tend to respond to the stimulus onset and have lost their frequency selectivity. This absence of frequency selectivity is sometimes referred to as being 'diffuse' in contrast to tonotopic. The EN is not modality specific and represents a possible motor pathway in the auditory pathway.

Figure 5
Left cerebral hemisphere of the cat showing the locations and boundaries of auditory cortical fields. The lower diagram shows the cortex unfolded revealing the auditory cortex hidden within the fissures. Four of the fields have a known tonotopic organization—primary auditory (AI) cortex, anterior auditory field (A), posterior field (P), ventral posterior field (VP). *High* and *Low* denote the highest and lowest frequencies represented in each field. Surrounding fields include secondary auditory (AII) cortex, temporal field (T), dorsal posterior field (DP) are likely to be more diffuse (source: Imig and Reale 1980. *Journal of Comparative Neurology* © Reproduced with permission).

4. *Thalamocortical System*

The auditory thalamus and cortex can best be thought of as an integrated system with feedback (see Aitkin 1990, Clarey et al. 1992, de Ribaupierre 1997, Rouiller 1997). Projections from the thalamus to cortex are reciprocated to afford feedback control of the cortex, producing a powerful information processing system.

4.1 *Medial Geniculate Body* (*MGB*)

The MGB is the major auditory nucleus of the thalamus and can be divided into ventral, dorsal, and medial divisions. The major ascending auditory pathway from the CNIC is through a bulge in the lateral surface of the brainstem of the IC to the ventral division of the MGB. The ventral division projects to the primary auditory cortex (AI), as well as the adjacent cortical fields, anterior (A), posterior (P), and ventral posterior (VP). The medial division is less specifically auditory, projecting diffusely to auditory cortex, and the dorsal division projects to the more diffuse secondary cortex (AII) and temporal field (T) (see Fig. 5).

4.2 Auditory Cortex

The primary auditory cortex, as in other sensory cortices, has systematic columnal organization that exists within a three-dimensional volume. The organization of the auditory cortex has largely been explored in the cat, but other species, including primates, have been investigated as well. A faithful tonotopic map can be observed along one surface dimension of AI in nearly all mammalian species. In some cases, such as the mustache bat, the organization, although systematic, can be quite complex (Suga 1982). The dimension orthogonal to the tonotopic axis shows no change in frequency and hence reflects bands of isofrequency. Several functional organizations other than frequency have been shown. First, there is evidence of periodic patches of binaural interactions along the isofrequency bands. In addition, systematic gradients of frequency tuning, response latency, and best intensity have also been observed (Schreiner 1998). Although the tonotopic dimension is fairly well structured, the organizations orthogonal to the frequency axis are less so, and highly individualized across different animals.

Auditory cortex is generally consistent with the classical six-layer architecture of other cortical areas (Winer 1992). There are specific relationships among the interconnections between the six layers (see Fig. 6). Within a cortical column, which descends through the cortical layers, there is a distribution of processing that begins with input from the thalamus (MGB) to layer IV. Information is then sent to other layers of the same column where it is integrated with other sources of information and then broadcast to other columns, subdivisions, and brainstem nuclei. Cortical projections back to the thalamus originate in the deep cortical layers V and VI. These descending projections return to the same tonotopic regions of the MGB that projected originally to the cortex. The functional role of the corticothalamic feedback is likely that of adaptive filtering of the acoustic information specific to each of the subdivisions, since the parallel streams remain segregated in the feedback pathways as well. Layers II and III are involved in local cortical interconnections. Various areas of auditory cortex also have connections between hemispheres via the corpus callosum.

The overlay of several dimensions of functionality (i.e., frequency, intensity, broadness of tuning, and so on), onto essentially two surface dimensions, means that the acoustic landscape must be represented by a multivariate pattern of action potential firings across the cortical expanse. Decoding these patterns into particular speech sounds or sound locations in space is a classical example of the perceptual inverse problem in neural computation. The precise and orderly thalamocortical feedback circuits, although computationally powerful, make interpretation of cortical firing patterns very difficult. However, advances in computational neuroscience (Rieke et al. 1997), particularly the analysis of timing patterns across ensembles of cortical neurons, are just beginning to shed light onto the possible neural codes for our objects of auditory perception.

Australia and New Guinea, Archaeology of

1. Dating the Arrival of Humans

Although today Australia and New Guinea comprise three nations on two landmasses, during times of lowered sea levels in the late Pleistocene they formed a single continent, commonly called *Sahul* or *Greater Australia*. There is general consensus that the first human colonizers were both anatomically and behaviorally modern humans; indeed the necessary crossing of a minimum water barrier of c. 90 km to reach New Guinea or Australia in the late Pleistocene constitutes one measure of that modernity.

Beyond that, there is little consensus for the date of earliest arrival. Oldest claims, in the 100–200 ka (thousands of years) range, all depend upon ecological evidence—usually charcoal counts in pollen cores interpreted as anthropogenic rather than natural fires—and are claimed in both the north and south of the Pleistocene continent, as well as Eastern Indonesia. The second group of claims consists of analyses of mtDNA diversity which put humans in New Guinea and Australia c. 70–100 ka. A third group of claims associate direct archaeological evidence with uranium series, luminescence, and electron spin resonance dates in the 50–70 ka range. The fourth category includes those sites which form the beginning of a continuous sequence of occupation in the Pleistocene continent which may extend to 43–45 ka sidereal years ago. Certainly by c. 35 ka all the major ecological zones of Australia and New Guinea had been colonized by humans.

Claims in the first group have little support because they lack direct artefactual evidence and because it is difficult to accept that humans in Greater Australia before 100 ka could have been anatomically and behaviorally modern. *Homo erectus* probably reached Java one million years ago but was apparently prevented from moving further east by the water barrier known as Wallace's Line.

Three specifically archaeological claims put humans in Australia before or at 50 ka. The western New South Wales burial known as Mungo 3 has recently been redated to c. 56–68 ka using uranium series and ESR (electron spin resonance) techniques on the skeletal elements and OSL to date the surrounding deposits. This is particularly dramatic because the Mungo 3 human was ritually buried, covered in red ocher. Such burial is seen as a marker of modern behavior, and if as old as this, would be the oldest unambiguous ritual burial of *H. sapiens* presently known. The second claim is for two rockshelter sites in the Northern Territory, Nauwalabila and Malakunanja, where the lowest stone artifacts are associated with TL and OSL dates having central tendencies between 50 ka and 60 ka. Here critics question the *in situ* nature of the lowest artifacts being dated rather than the dating techniques themselves (see *Chronology, Stratigraphy, and Dating Methods in Archaeology*). Similar criticisms have been leveled at the third example, the recent AMS dating of the Devil's Lair cave in southwest Western Australia to c. 48–50 ka, where the lowest levels of the site which produced this date are water-scoured and contain only a few stone flakes, some not clearly of human manufacture.

Defenders of the longer chronologies criticize the shorter chronology on the grounds that the great majority of dates are based on older radiocarbon dating which was unreliable for ages much over 40 ka, so that this age for earliest arrival might easily be a product of the technique. However, modern radiocarbon techniques now produce accurate dates in the

range 35–45 ka and have done so regularly in Australia in the 1990s for nonarchaeological samples, but only on a very few occasions for archaeological sites.

The resolution of this debate is needed to understand the rate at which Greater Australia was colonized, and the adaptive strategies used to occupy a wide range of new environments. Equally important are the implications of this debate for understanding the spread of modern humans elsewhere in the world, since behaviorally modern humans are unknown before c. 50 ka anywhere in Eurasia.

1.1 Routes of Entry

The Sunda shelf of Southeast Asia is separated from the Sahul shelf of Australia and New Guinea, and this break forms a significant biogeographical boundary first recognized by Alfred Russell Wallace. Wallace's Line separates an Asian fauna which includes primates, carnivores, elephants, and ungulates from the marsupial fauna of Australia and New Guinea. However, the widespread elements of Asian flora in Indonesia, New Guinea, and into northern Australia indicate that this boundary still permitted the natural transfer of this flora.

Two routes of entry from Southeast Asia seem possible, the first and more northern route through the Indonesian Moluccan archipelago to New Guinea and a second more southern route along the Flores chain to Timor and thence to northern Australia. Any of the subroutes which might form the northern route had two sailing advantages which the southern route lacked—intervisibility between departure point and target landfall on all legs and the ability to return to the departure point on existing winds and currents. Sea craft could journey blind from Timor to Australia on the summer monsoon, but not return. Interestingly, altered heights of islands because of sea level fluctuations had no appreciable effect on either intervisibility or distance between landfalls.

The earliest coastal site in New Guinea is at its extreme eastern end, emphasizing the absence of systematic archaeological exploration of the western half of the island. This site, an open site on uplifted coralline terraces on the Huon Peninsula, has yielded dates of c. 40,000 or a little older for large tanged and waisted flaked axes which must have been hafted.

1.2 New Guinea Highlands

New Guinea is dominated by a steep central cordillera rising to 4,000 m in places. Because of rainfall patterns and cloud cover, Pleistocene colonists likely settled the series of intermontane valleys ranging between 1,200 m and 2,400 m. Currently the oldest dates for humans in the highlands are c. 30,000 ka, the time lag from the coast perhaps indicating the significant adaptations required to settle this region. The subsistence patterns reflected in excavated sites like the Nombe rockshelter reflect a strategy of hunting and collecting across these altitudinal zones. While forests and grasslands contained mainly small game, Pleistocene New Guinea was also home to a small number of large mammals, all now extinct. At Nombe, four species—all forest browsers—occur between c. 25,000 and c. 14,000 ka, but it is uncertain whether these constitute human prey remains. The general paucity of game animals in New Guinea is, however, offset by the huge array of plants, of which more than 200 are used for food. While little direct evidence exists for the development of plant processing and plant storage, it is likely that these processes developed from the beginning. The Huon axes also occur at Nombe, Kosipe and other early sites, where they have been identified as tools used to thin forest patches by trimming and ring-barking so as to promote the growth of useful plants. The burning of forests at this time is reflected in the pollen records and supports this interpretation.

If accurate, these data suggest a long evolution of plant management which culminates in a distinctive highlands agriculture at 9–6000 BP at Kuk in the Wahgi Valley. Here evolutionary stages of garden technology have been identified, which include hydraulic practices involving both drainage and irrigation. The most recent phases reflect the familiar root crop/arboriculture/pig-husbandry systems present in the highlands today. Pigs, not indigenous to New Guinea, appear in the archaeological record 5–6,000 ka with some claims back to 10,000 ka.

1.3 Island Melanesia Before Lapita

Moving into the nearer islands of Melanesia required adapting to the simplified terrestrial ecology of an oceanic world. The initial colonists adopted strategies which compensated for this reduced range of edible plants and terrestrial animals by high mobility across large territories. This, in turn, depended on safe, if simple, watercraft. Initially it appears such craft took people to scattered resources, but over time, as populations and specialized resource knowledge increased, moving resources to people increasingly replaced the first strategy.

Because of tectonic uplift and deep submarine contours along the north coast of New Ireland, Pleistocene sites now normally flooded by later rising seas have been preserved. The oldest known of these, Buang Merebak, recently redated to 40–41,000 ka, and Matenkupkum (c. 35,000 ka) are about 140 km apart, and both contain marine shell middens which are very similar. Both contain marine fish bones indicating some form of fishing at this age, and both reflect strategies of shellfish collecting and processing the

shells for food and tools. People also moved inland, quarrying chert outcrops near Yombon in New Britain at c. 36,000 ka. At Kilu Cave in the northern Solomons, stone tools dated between 29,000 ka and 20,000 ka carry residues of *Colocasia* and *Alocasia* taro, in quantities sufficient to suggest that successful selection had already taken place for starch-rich tubers.

Getting to Kilu required a sea journey about twice that of any prior necessary crossing between mainland Southeast Asia and the Bismarcks, a voyage without the aid of two-way intervisibility. But by 21,000 ka people had reached the Admiralties Group, a voyage of over 200 km which required that 60–90 km be traversed totally out of the sight of any land; this is the earliest known example of true seafaring anywhere.

By 20,000 ka, moving resources to people is reflected in New Ireland in the appearance of obsidian from a New Britain source 300–350 km distant and the introduction of *Phalanger orientalis*, a marsupial which became an important food source. It is the first of a series of animal translocations in the region and flags the possibility that useful plants and nut bearing trees were also moved about well before the end of the Pleistocene.

A reduction in cave use in the region during the early Holocene raises the question of whether these islanders were more dependent on cultivated plants than previously. While the evidence is piecemeal, gradual economic intensification is reflected in aspects of the archaeology such as intensive and extensive trade in obsidian, plant residues on tools, domesticated and transported nut remains in sites, elaborate stemmed and hafted obsidian and chert tools, stone and shell ground axes, open site settlement patterns and expansion onto smaller offshore islands, all aspects which seemingly demand more substantial food productive systems than those provided solely by hunting and gathering.

Maritime trading systems with their genesis in the Pleistocene elaborated during the later Holocene, as horticulture underwrote village development both in the near islands and around the New Guinea coast. The growth of these systems, particularly after the spread of Lapita-introduced pottery technology, has been a major research concern of archaeologists in the region (see *Pacific Islands, Archaeology of*).

2. *Australia*

Regardless of where first landfall occurred, the move south was into environments more foreign in their floras and faunas and in increasing contrast to presumed tropical humid homelands. Although more than 160 Pleistocene age sites are known in the region, they occupy a diverse range of environments and are frequently hundreds of km apart, such that no neat synthesis of past human behaviors is yet possible. A few short generalizations will provide some background. (a) With some glaring exceptions, such as edge-ground axes in Arnhem Land at c. 20 ka, Pleistocene flaked stone tools across Australia are mostly amorphous, showing little of the development which characterizes the Upper Palaeolithic in Europe or the Later Stone Age in Africa. (b) A host of larger marsupials, collectively dubbed megafauna, appear to have become extinct around the time of human arrival, although the dating of the extinction event(s) is poor. While it is difficult not to implicate humans in this extinction, the processes are unclear. Direct extinction by hunting appears unlikely, given the range of species, the size of the continent and its varieties of environments, the presumed low numbers of humans, and the conspicuous absence of kill sites. Many commentators appeal to less direct effects, particularly habitat modification by the human use of fire, but not even this effect is universally endorsed. Arguments of climate change are still advanced to counter human involvement, but these are also widely criticized. (c) A tradition of small blade tools and points appears c. 4 ka throughout Australia, but not in Tasmania, with clearer stylistic differences between them identified at the regional level. (d) Despite the example of New Guinea to the north, Aborigines did not adopt or develop agriculture, remaining a continent of hunter–gatherers until European arrival. Even so, the successful colonization of even marginal areas of the continent reflects the adaptability of these humans, while the widely documented development of art and engraving on rocks and cave walls, now demonstrated from earliest arrival, reflects an intellectuality and social awareness among Aborigines previously only documented ethnographically.

2.1 *The Arid Zone*

The arid zone occupies an area of c. five million square km—about 70 percent of Australia's land surface—and during the Pleistocene this area was even larger. In this region occupation and movement has always been constrained by the distribution of food and water. Areas of relatively high relief, the ranges of the central desert and the Kimberly and the Pilbara in particular, concentrate run-off in stream channels and waterholes; similarly, riverine floodplains contain perennial and seasonal streams which contain surface water in some seasons and store accessible subsurface reserves. The riverine floodplains, particularly those along the Darling system in New South Wales, offer a range of aquatic resources, including fish, shellfish, hydrophytic plants, and water birds.

Before 25 ka, conditions were perhaps wetter but cool to cold, but between 25 ka and 12 ka conditions

were much colder and drier, especially at the last glacial maximum. Much of this zone would have been inimical to human settlement at this time. Although people were on its fringes by 40 ka and occupying the 'dead heart' before 30 ka, many sites were abandoned at the height of the ice age.

People were at Mandu rockshelter on the arid Western Australian coast c. 34 ka and left behind shell beads apparently used for personal adornment, as well as ochre carried there from the Pilbara area. As the sea dropped, offshore islands were incorporated into coastal territories as people followed the receding coastline. Today the bare rocks of the Montebello islands contain small rockshelter sites which reveal human presence at c. 27 ka, with both terrestrial and coastal resources represented in the deposits, and again between 7 ka and 10 ka, when the prograding sea was again near. These sites were not used between times and were abandoned when they again became offshore islands.

Thus models of changing land-use patterns put forward by arid-region scholars all emphasize mobility and adaptation to changing environmental conditions and suggest small populations thinly spread across the arid zone. Diets may not have been greatly different from those recorded ethnographically in these regions. They are generally similar and broadly based and included, in addition to marsupials, reptiles, birds, larvae, tubers, fruits, seeds, and aquatic resources where available. Recent claims that grass and tree seeds might have been gathered and processed in the Pleistocene and particularly before the last glacial maximum is notable because although seeds are nutritious, their gathering and processing is laborious. For this reason, seed processing elsewhere in the world is seen as a key indicator of changes in human behavior connected to the appearance of new technologies, larger and more settled populations and in places the establishment of agriculture. Its presence in an Australian form in preglacial arid Australia has significant theoretical relevance. Traces of seeds and other plant food remains from Pleistocene levels in Carpenters Gap in the northwest is complemented by pieces of grinding stones dating to c. 30 ka at Cuddie Springs some thousands of kilometers to the east. These carry usewear and residue traces suggesting the processing of starchy and siliceous plants, evidence coincident with a local change to grasslands seen in the pollen record at this time.

Data from the Mungo region of western New South Wales indicate how favorable these lake systems were when lacustral conditions ensued. A range of resources—fish, shellfish, crustaceans, and birds—were taken. Fish may have been taken using nets and spears and possibly traps. A range of mainly small terrestrial game was also captured and again in this region unspecialized grinding tools suggest at least generalized processing of plant foods and seeds during the Pleistocene.

2.2 *Tasmania*

Today, and for the last 12 ka, humans have occupied the north and east of Tasmania. In the southwest, temperate rainforest continues to exclude settlement. During the late Pleistocene, however, this situation was reversed. At times glacial deserts made the east inhospitable, while colder and drier conditions forced the rainforests in the southwest into refugia at lower altitudes, opening up the montane valleys to open forest with patches of grassland on limestone substrates in the valley bottoms. Since 1980 c. 30 sites, predominantly limestone caves have been located in the rainforest and c. 12 tested by excavation. The oldest, Warreen, was occupied c. 35 ka and all were abandoned by 12 ka, when warmer and wetter conditions encouraged the return of the forests, which drove out game animals and their human hunters. At the height of the last glacial maximum the mountains had glaciers extending as low as perhaps 700 m above sea level, only a few hundred meters above some of the occupied caves. With temperature reductions of c. 7 °C and winds reducing temperatures sometimes tens of degrees it was indeed an extreme climatic place, some 40 degrees of latitude south of their ancestors' equatorial point of departure.

The cluster of known sites provides a rare glimpse at a regional pattern of Pleistocene behavior extremely different to that depicted for arid Australia. Here the subsistence strategy was the opposite of broad spectrum. There are no obvious vegetable staples which might have supported even small transient groups and the plentiful faunal remains repeat the same pattern from site to site. Up to 80 percent of bones from humanly consumed animals were from the single species *Macropus rufogriseus*—the Bennetts wallaby, supplemented in small amounts by wombat and platypus. In more than 630,000 animal bones processed from eight sites, there is not a single extinct megafaunal species represented, although some are present in nonarchaeological deposits in caves in the same region, suggesting that those species known from Tasmania had become locally extinct before human arrival, or that they were not hunted or scavenged.

3. *Holocene Continuities and Changes*

As the forests drove Tasmanians from the southwest, rising sea levels at the end of the Pleistocene cut off Tasmanian access to the Australian continent and for 8 ka the Tasmanians were deprived of human contact beyond their island. When reunited with the world at the end of the eighteenth century, they no longer made bone points, caught fish, or made fire, and were obliged to keep fire burning or rekindle flame from neighboring groups. Their technology comprised no composite or hafted tools, and consisted only of single piece wooden spears, clubs, digging sticks, kangaroo

skin capes, skin and kelp water containers, string, and small baskets. A simple stone tool technology was compared by Europeans to Mousterian industries. While the loss of fish in the diet c. 4 ka may reflect some established island-wide taboo, this dietary loss was offset by the continued capture of seals and terrestrial mammals and an expanded range of shellfish species. In the recent Holocene more use seems to have been made of the less hospitable south and west coasts and people also used nearby offshore islands. Bundles of reeds tied in the shape of small canoes are known ethnographically where they were used as flotation devices.

In contrast, the end point of Holocene changes on the mainland differentiated Tasmanians and mainland Australians so distinctly that early explorers and anthropologists considered them different races. But while the Tasmanian devil and marsupial tiger or thylacine—both extant in Tasmania when Europeans arrived—had disappeared from the mainland when the dingo was introduced there from Southeast Asia or New Guinea c. 4 ka, few other Holocene changes can clearly be attributed to external influences. In particular, the temporal and distributional evidence for the appearances of small points, geometric microliths, and other tools of the 'Australian Small Tool Phase' during the mid and late Holocene suggest different and regional origins within the country. While some of these tool types disappeared perhaps 1–2 ka in some regions, in the north larger bifacially points and other macroblade tools appeared more recently.

This proliferation of regional tool types, increases in site numbers, site types, and the range of organic and inorganic artifacts to be found in them, together with the appearance of cemeteries, evidence for exchange networks and labor-intensive specialized food procurement activities like constructing artificial channels to capture migrating eels has been taken as a package by some Australian archaeologists to promote a model of socioeconomic intensification in the late Holocene. Even though stationary sea level and the relatively young ages of these sites clearly promotes better preservation and higher visibility, this package is contrasted with the Pleistocene and early Holocene, where population densities were lower, territories larger, people were less sedentary, there was less social ranking and less complex food procurement strategies. Critics of this model question its testability in the archaeology and some prefer to continue seeking environmental explanations for the changes seen in the archaeological record.

The unsurpassed heritage of Australian rock art has been recorded, classified, and interpreted for more than a century. The ability to now date many of the varied styles directly is a recent revolution which is enabling the integration of art with other aspects of the archaeological record. Many new and ingenious techniques, such as luminescence dating of sand grains in mudwasp nests overlying painted surfaces, or dates that use carbon in oxalate salts to indicate the time when such encrustations covered the art, are now demonstrating a long Pleistocene history for many paintings, providing a further window on the nature of hunter–gatherer intellectuality.

Australian Aborigines: Sociocultural Aspects

Australian Aborigines are surely the most famous of indigenous peoples, due to their place in western evolutionary thought. In the nineteenth and early twentieth centuries they were studied as living evidence of the earliest, most primitive form of a universal human past. All of us, it was asserted, were once hunter-gatherers like these. The nineteenth-century anthropologist Lewis Henry Morgan exemplified primitive forms of kinship from descriptions of the Kamilaroi and Kurnai of South-eastern Australia (Fison and Howitt 1880/1991). Aborigines were central characters in the origin myths of Freud and Durkheim. Such erudite studies occupied elite scholarship, but theories of primitivity and evolution also formed the foundation of public understanding and government policies.

Controversies about Australian Aborigines in the first half of the twentieth century concerned their antiquity and the proper way to describe their social traditions. Today, there is intense public dissension about the category Aboriginal itself, as well as about political and symbolic representation, rights to land, and rights to compensation for past wrongs. Since about 1970 many Aboriginal people have participated vigorously in these controversies, marking a major shift in the place of indigenous peoples in the West's academic canon. At the same time radical changes have occurred in Aborigines' conditions in relation to the Australian nation and state in law, scholarship, political activism, and public perception.

Archaeologists and physical anthropologists have found evidence of human habitation in Australia from 50,000 years ago, though prehistorical anomalies and mysteries are still being unraveled. The search for the 'racial origins' of Aborigines began to be muted in the 1950s because its language was that of scientific racism. More recently, such research has had to face Aborigines' assertions that the skeletons in Australian soil

are the ancestors of contemporary Aborigines and should be left undisturbed. Yet recoil at the racial connotations of past scholarship has been ameliorated by the value Aboriginal people, poets as well as political activists, have recognized in the legitimacy which expert evidence of great antiquity confers on them. Fifty thousand years of undisputed possession has immense symbolic power. Further, the kind of evidence archaeologists produce is valuable when land claims are mounted. Thus, Aborigines have often inverted the connotations of being the most primitive peoples in the world by emphasizing the spiritual wisdom and rights to land conferred by antiquity.

1. *The Reign of Social Anthropology*

Aborigines are now also questioning social anthropology's representations. When Australian anthropology was established at the University of Sydney in 1928, it claimed expertise in managing indigenous populations. As 'culture' became privileged over 'race,' social anthropology displaced prehistory as the pre-eminent science in relation to Aborigines. These 'hunter-gatherers' were defined by their artefacts and rituals, languages, religious beliefs, and kinship systems. Those who had 'retained their culture' were in the northern and central parts of Australia where the invading British had only lately and sparsely occupied the land.

From the 1930s, systematic field workers such as Lloyd Warner, Phyllis Kaberry, Donald Thomson, and T. G. H. Strehlow and in the 1950s and 1960s W. E. H. Stanner, Catherine and Ronald Berndt, Mervyn Meggitt, and Lester Hiatt traveled north to conduct careful studies of remote Aboriginal communities. All assumed that the authentic culture of Aborigines was disappearing. Writings about social change were premised mostly on a dichotomy between 'full-bloods' who were 'traditional' and those who had 'lost the essential elements of that heritage, that living link with their cultural past' (Elkin 1938/1974).

'Their cultural past' was depicted as static by structural-functional social anthropology established by Radcliffe-Brown's seminal study of *The Social Organisation of Australian Tribes* (1931). In fact, these traditions were under extreme pressure from the colonisers. Anthropologists were far behind the frontier where the first and most fundamental social disruption, the removal from land, took place gradually from the late eighteenth to the twentieth century. The invaders' access to the land was assured as Aborigines were variously massacred, removed to reserves and missions, and re/formed through a vast plethora of legislation and regulation which reached its height in the 1950s (Rowley 1970). By the time Australia began to recognize Aboriginal traditional ownership of land in the Northern Territory in the 1970s there was a solid body of ethnographic documentation of Aboriginal traditions in relationship to the social significance of country. Since the High Court (1991) affirmed that native title exists in Australia, research in this field has burgeoned.

2. *'Country' or 'Native Title'*

The seminomadic groups of 'hunter-gatherers' were not understood to be deeply attached to particular areas of land until proto-anthropologists such as Spencer and Gillen (1899) began to document totemic affiliations and dreaming tracks. There emerged detailed ethnographic accounts of the classic Aboriginal traditions, kinship and genealogical ties, clan organization, conception and birth sites, and historical associations which give individuals authority and responsibility in relation to various sites. These are now understood to involve flexible principles rather than fixed rules, and debate over rights and obligations under ancestral law are understood as the stuff of everyday life.

Ceremonies are arranged and authorized by mutually dependent clans and lineages involving large networks of intricately related individuals who negotiate endlessly about their authority. For instance in the Arnhem Land area, the senior 'boss' (djungkayi) and 'owner' (gidjan) share responsibility as manager and performer of the Yappaduruwa ceremony; these responsibilities are reversed for the Gunappipi ceremony (Maddock 1982). Sophisticated negotiations take place constantly as democracy is practiced; no rights are taken for granted but certain underlying principles are called upon to settle disputes in ever changing circumstances (Myers 1991, Sansom 1988).

Such complex, flexible sets of rights and responsibilities to country are incommensurable with the Australian law which typically recognizes particular individuals as exclusive owners of specific, bounded areas. Further, the commercial exploitation which renders land the passive object of human agency is incommensurable with Aboriginal understanding of the productive interdependence between people and land. Sitting in country and walking through country are actions which generate meanings and events as the sentient country responds to people and people respond back (Povinelli 1993). Aboriginal people assert endlessly to government officials that the interactive, ceremonial, and productive relationship with country is necessary for the continuation of social life.

3. *Kinship and Religion*

Aboriginal kinship was long a major focus of anthropologists' research. They recorded the system of moieties, clans and lineages, sections and subsections

which identified people as nodes in a web of intricate affiliations. The meaning and corporate power of the clan and its reproduction over time were the subject of many ethnographic and theoretical studies (Hiatt 1965, Meggitt 1962).

Aboriginal religion has always attracted both scholarly and popular interest. Variously designated as 'the law' and 'the dreaming' (Stanner 1979), the body of beliefs saturates all facets of the classic traditions. Kinship, totemism, rights to land, dance, song and body art, and hunting and gathering practices, are all ways to 'follow up the dreaming.' Each of these terms is but a crude reference to a precisely integrated cosmology and ontology based in concepts that are at odds with Western traditions of thought. It was probably inevitable that attempts by ethnographers to grasp and convey the significant themes of this system with its specific epistemology have tended to represent it as given, rather than as an arena in which its participants are engaged creatively with their own reproduction over time.

Perhaps the contemporary irrelevance of much of the body of ethnography stems from the fact that, while the centrality of kinship and land to social relations among Aborigines was being documented, governments were systematically breaking up family groups, taking half-cast children, removing 'tribal remnants' from their country, and trying to break down the system of exchange partly by instigating a system of rationing (Rowse 1998). This is well known, yet only lately have researchers begun to be examine the social conditions in which the body of ethnography was produced.

4. *Anthropology's Legacy*

In the middle of the twentieth century three comprehensive anthropological textbooks summarized existing knowledge. Elkin's *The Australian Aborigines* was published in 1938/1974, with several later editions and reprints. In 1964, Ronald and Catherine Berndt published *The World of the First Australians*, and this was superseded in 1972 by a shorter, more sophisticated work by Maddock which reverted to Elkin's title, *The Australian Aborigines*. Each of these texts defined the classical Aboriginal traditions as the 'real object' of Australian anthropology. The provision of accurate and profound knowledge of Aboriginal cultures accrued intellectual and moral worth because it would both provide the basis of appropriate policies and lead to sympathetic understanding from other Australians. However, the many specialized ethnographic studies not only failed to protect the fundamental institutions of Aboriginal society, but also failed to make much public impression. Knowledge of even basic elements of traditional Aboriginal cultural life is absent from the intellectual baggage of educated nonindigenous Australians, as has become clear during recent indigenous struggles concerning sacred sites, native title, and colonial history. Also, these studies largely left out what are now the majority of people who are known and who know themselves as Aborigines, those whose social lives were disrupted to the extent that they no longer recognize moieties, practice ceremonies, or speak traditional languages and whose ancestors include white or other immigrant Australians.

5. *'The Aboriginal Race' or 'Traditional Culture'*

In much of the older ethnographic work, Aboriginal cultural characteristics appeared as fixed as those of race, though in fact both racial and cultural characteristics were changing. Though racial classifications and racial explanations were eschewed, a submerged or implied definition of Aborigines as a race was retained. That race was identified with an unsullied tradition known as 'Aboriginal culture' which remained a discrete *a priori* category. Australian anthropology continued to be associated with the study of 'traditional Aborigines' whose definitive characteristics were formed before colonization. Such studies reinforce the popular judgment that only remote 'full-bloods' are real Aborigines. The metaphor of destruction became entrenched, fixing the complex, ongoing events of colonization into a one way process of collapse. No explanation replaced that of race for the social inequality which separated Aborigines from Europeans throughout Australia. The boundaries of racial categories had been smudged, but they were not re-examined or redrawn, and until the 1970s no serious cultural analysis was undertaken of the relationship between the two populations.

The few studies of what were known as 'mixed bloods' or 'detribalized remnants' usually sought 'traditional' features rather than an understanding of the forces that had transformed them. The actual social lives of these groups were judged depressing and deprived, rather than sites where transformations of cultural forms were taking place. While Aboriginal activists in the 1970s acquired the power to give authoritative expression to a counterdiscourse and to modern Aboriginal culture, there is still a heavy burden of inauthenticity associated with those who display no elements or echoes of an autochthonous past.

With the emergence of Aboriginal voices in the public arena, the ethnographic legacy came under widespread and intense though contradictory criticism, both for complicity in the colonial management of Aborigines and for ignoring their plight. In the 1980s, however, ethnographies began to branch out in several directions. The politics of representation is now firmly on the academic agenda, with articles and

books deconstructing the 'construction of Aboriginality' (Beckett 1988) and an insistence that the study of 'Us' is part of the study of 'Them' (Collmann 1988). Detailed cultural analysis of colonial relations in Australia has showed the complex, creative responses to the distinctive forms of governance Aborigines were subjected to (Morris 1989). Anthropological writings now vie with cultural studies, history, sociology, and law faculties for authority in this domain. Aboriginal intellectuals and academics provide powerful and varied challenges to the writings of the old 'experts.' Some social scientists fear the inevitable political struggles that constitute the realm of Aboriginal studies. However, as the intellectual and ethnographic boundaries have been breached, different kinds of research, such as ethnography on the racial borderlands, can flower (Cowlishaw and Morris 1997).

While critiques of anthropology's essentialism and primitivism have become popular, the moral authority of the old ethnographies has also been revived, as they provide evidence concerning native title claims, both in those few areas where Aborigines have unbroken connections with their traditional land and for groups who were displaced in an earlier era.

6. *Cultural Conundrums*

Aboriginality today is varied and complex. There are fringe dwellers and intellectuals, remote speakers of Aboriginal languages and urban sophisticates, jail birds and film makers, politicians and lawyers. This 2 percent of Australia's population (386,000 people) is the focus of much dispute and debate. A dominant image of distress is supported by statistical evidence that Aborigines are vastly over-represented among those who die young or are in jail.

The Australian constitution of 1901 decreed that Aborigines, meaning those known as 'full-bloods,' would not be counted in the population census, and gave the federal government no jurisdiction over Aborigines residing in the various states. In 1967, a referendum removed these two items from the constitution. The official definition of an Aboriginal person now has three elements, descent, self-identification, and acceptance by an Aboriginal community. But two centuries of categorization as 'full-bloods,' 'mixed bloods,' 'half-castes,' and 'quadroons' have left a complicating racial legacy, for instance, for those who, by force or under legal or social pressure, were removed from family and community, and ceased to identify as Aboriginal. Now individuals can be denigrated for belatedly claiming inclusion in the category 'Aboriginal' when not sufficiently dark, or for trying to remain outside it when a shade too dark. In remote rural communities family histories are well known, but for an increasingly urban, anonymous population the necessity to have one's Aboriginality authorized by a community can be a source of conflict. Another source of conflict is created by the recognition of native title and official protection of sacred or significant Aboriginal sites.

7. *Contrasting Epistemologies*

The problem of legitimizing Aboriginal culture was typified in the events surrounding one much publicized disputed claim for the protection of an Aboriginal sacred site (Bell 1998). Aborigines and anthropologists were accused of conniving in fabricating cultural material. 'Secret women's business' became a widely used term of derision. The dispute itself and the publicity it received revealed the threat posed by contrasting epistemologies. In the classic Aboriginal tradition, knowledge does not circulate freely. Elements of cosmology are the responsibility of particular people (men or women, certain clans, those related to particular places). That is, knowledge is both localized and 'owned.' But if knowledge is secret, how can indigenous people prove their claims, and how can sites be recognized and protected by the state? In fact, a series of answers to this problem have emerged. Land tribunals have accepted the performance of a dance, a song, or a design as supporting a claim and have agreed to restricting the circulation of evidence. But in some cases the insensitivity of authorities to secrecy and sacredness has led to the abandoning of claims (McRae et al. 1997).

Attempts to legitimize the knowledge of dispossessed Aborigines have given rise to sophisticated arguments about the legitimacy of cultural transformation and the interweaving of historical experience with cultural identities. There is a bitter irony here, for it is commonly the fixed tradition, the given culture, the ancestor's true knowledge that is appealed to by Aborigines as the basis of claim. Scholars who want to assert the fictional basis of all culture can appear to undermine those claiming authority over their own cultural knowledge and history. The notion of culture has powerful public meanings. The policy of indigenous self-determination has registered 'Aboriginal culture' with formal respect, but has given it no systematic place in the state funded structure of organizations or enterprises. 'Culture' is the icing on the cake of 'social' matters, with 'viable projects' to be run by Aborigines. The myth of a fragile Aboriginal tradition has been replaced with its opposite; now Aborigines can become part of capitalist culture without tarnishing their own cultural identity which is rendered as an indigenous version of elite culture, with ritual and ceremony severed from social conditions and everyday meanings.

Aboriginal culture is also called upon to play a redemptive role for the white nation. Its symbols are used routinely to construct a unique imagery for

Australia. The fear of being complicit in this appropriation and the constricting traditionalism leads to ambivalence about, for instance, hanging bark paintings on the wall. Continuing controversy over the status of modern Aboriginal art (Michaels 1994), and continuing celebrations of the primitive, confuse the interpretations and the intentions of scholarship in this field.

8. History

Historians began, in the 1970s, to document the horrific atrocities and the accompanying savage rhetoric of British settlers in the eighteenth and nineteenth centuries. Some conservative scholars and politicians deplore the emergence of what they call the 'black armband' view of history, making Australians ashamed of their forebears. But the opposite problem is that the racism of the past is not seen to be an organic and ongoing part of colonialism. As Australian readers recoil in horror from the bloody history, the obsession with color and race is attributed to some deranged, long-gone strangers rather than to our own grandparents. But these violent and racist people certainly left us something, if not the land they took or the wealth they made from it, then the culture they were developing. As we position ourselves against the invaders, we obscure the way a racialized society has been reproduced over time and the cultural source of contemporary events is lost. Where before anthropologists' writings offered no access to the contemporary experiences of the timeless Aborigines, now historical discourse immerses readers in an awful past and distracts them from contemporary forms of violence and racism.

The destructive effects of well intentioned government policies are now receiving attention. From the early twentieth century successive governments have attempted to ameliorate the conditions of Aborigines through varied policies of protection, assimilation, integration, and self-determination. In each case there have been assimilative forces which have led to a degree of empowerment of a minority of people, and communities have had to adjust to new relationships with the state's institutions (Cowlishaw 1999).

Australian Settler Society: Sociocultural Aspects

Australia ranks among the more affluent and stable of Western societies. It has also experienced major changes since the 1970s. The more significant material and cultural transformations have been accompanied by a marked uncertainty over the country's cultural standing and its collective identity.

1. Prosperity and Paradox

Two properties of contemporary Australia distinguish it from other nation-states with a comparable pattern of settlement. One is that a clear majority shares a high standard of living, a predominantly middle-class life

style. Australians enjoy one of the highest rates of private property ownership in the Western world: household ownership of a second or third car is commonplace: a wide range of costly consumer goods is customary; even the possession of a second dwelling for vacation purposes is nothing untoward. There is a strong emphasis too on costly hedonistic activities, notably multiple forms of gambling.

The other distinguishing feature is political stability. Unlike South Africa or Israel, for example, the political process is strikingly free from outright conflict. Constitutional crises are rare, elections are routine, and changes in government are uncomplicated. This it not to suggest the political arena is free from major lines of cleavage, nor that public confrontations are unknown: the divide between Aboriginal and non-Aboriginal interests is profound and open dispute is recurrent. But the absorption of major conflict is undoubtedly among the more pronounced qualities of the political system.

Yet despite affluence and order, a distinct disquiet prevails over Australia's cultural and national identity. It repeatedly surfaces in debate about how 'We' differ from significant 'Others,' whether 'Our' culture is the equal of 'Theirs.' Australia's most renowned author writes: 'Identity can be experienced in two ways. Either as a confident being-in-the-world or as anxiety about our-place-in-the-world; as something we live for ourselves, or as something that demands for its confirmation the approval of others.' Malouf (1998) argues that the latter condition prevails in Australia, so he suggests: 'Perhaps it is time to stop asking what our Asian neighbours will think of us, or the Americans, or the British, and try living free of all the watchers but our own better and freer and more adventurous selves.'

This, then, is the paradox at the core of Australian society: a prosperity and stability that are the envy of others, coupled with a profound concern about cultural worth and collective identity. The roots of the paradox lie in recent economic and political developments.

2. *Rural Change*

Australia's small, peripheral economy (the population is 18.5 million) has long been integrated into the global marketplace, mostly to distinct economic advantage. Throughout the first half of the twentieth century, the export of agricultural produce and minerals to Britain and mainland Europe generated a prosperity from which only particular minorities were categorically excluded.

This affluence was sustained after World War II as new international markets were added to traditional ones. By the early 1970s, however, this export dependent economy proved vulnerable to changed global conditions (Bell 1997), and the major impact fell on the small-to-moderate sized family farms. Declining commodity prices, increased interest rates, price hikes in key inputs, and rising transport costs, impacted most severely on the bottom 25 per cent of the rural hierarchy; and their problems have been compounded by the loss of wage-earning opportunities, as well as cutbacks to the infrastructure and welfare services. The result has been the loss of young people to the cities, the annual closure of between 2,000 and 3,000 production units, and increased dependence on minimal welfare by the already marginal, along with a deepening of the divide between prosperous and poor.

Lawrence (1987) has made it clear that these changes to the rural class structure are inseparable from transnational corporations' increased hegemony over agriculture, especially through control over the supply of critical inputs to the rural sector (mechanical equipment, seeds, building materials) as well as its major outputs (canning, packaging, shipping). The larger units of rural production that are contractually integrated into transnational structures realize higher rates of profit than ever before, but smaller ones find it increasingly difficult to survive.

In these circumstances, the independence of farm family producers, so integral in the past to the culture of rural Australia, becomes illusory. But the significance of these material changes is more wide-ranging. The bush has always provided the more powerful symbols from which cultural specialists forged narratives about the distinctiveness of the Australian character (Ward 1966). Self-reliance, egalitarianism, and mateship are all idealizations drawn from outback experience, and all have been part of distinguishing Australian culture and the nation from their European origins. Where the realities of rural experience are characterized by increasing inequalities of class, destruction of community life, and transnational domination, the bush inevitably loses its symbolic worth in the process of constructing Australia as a distinct cultural space.

3. *Urban Transformation*

These changes have also compounded rural–urban differentials: by the 1990s, the average urban income was half as much again as the rural one. But it has been class inequalities that have become most conspicuous in the major metropolises, where well over two-thirds of Australians reside. The most powerful members of the country's dominant class are from the transnational capitalist class: their major allies are drawn from the Anglo-Celtic power bloc of business, political, and media institutions that are all similarly wedded to a narrow ideology of late capitalist development. The life style of this class is cosmopolitan and ostentatious; since it attracts extensive media coverage, it contrasts all the more objectionably with the circumstances of urban residents who are 'doing it

hard,' especially the one-third of the population reliant on some form of welfare. The long-hallowed ethos of Australia as an open, 'fair go' society, rooted in individual achievement rather than ascribed status, thus has increasingly limited relevance.

It is, however, changes in ethnic composition that have generated the most telling questions as to how Australians imagine themselves to be as a nation. With the exception of Israel, no other modern society has relied so heavily on immigration to build up its settled population. Between 1947 (when the population stood at 7.5 million) and 1987, some 4 million immigrants entered the country. Since the UK and Ireland were no longer able to meet Australia's demand for labor, substantial numbers were recruited from southern Europe and the Levantine by the 1960s. Regardless of place of origin, these new immigrants were offered citizenship to encourage permanent residence.

The result was an exponential increase in cultural heterogeneity. Inner city areas were transformed from predominantly Anglo-Celtic working-class neighborhoods into multiethnic lower-class suburbs. These were not destined to become ethnic ghettoes, however, because a pattern of modest clustering was sufficient to establish residential stability, gain employment, and bring other family members from Italy, Greece, Yugoslavia, and elsewhere. Then again, as these migrants accumulated capital and became small business owners, they moved into more prestigious suburbs. Finally, second and third generations have displayed even less inclination to being restricted by ethnic considerations in their choice of spouses, personal friendships, and business associates (Price 1988).

It would be more than appropriate to utilize such concepts as creolization and hybridization (Hannerz 1996) to detail the innovative cultural relationships and associations that have so transformed Australia's urban areas. The monochromatic mould of Anglo-Celtic dominance is, at this level, a thing of the past. But not only have urban social analysts generally opted for more conventional analytic categories, successive governments have worked hard to obscure the rich character of these creolizing, hybrid processes, with a stultifying rhetoric of multiculturalism.

4. *Multiculturalism*

Multiculturalism was adopted as state policy in the early 1970s, by which time it was more than evident that immigrants from southern Europe had no intention of assimilating into the Anglo-Celtic ethnic majority as the previous policy had (unsuccessfully) dictated (Jakubowicz 1984). The following decade saw the establishment of numerous governmental organizations whose function was to implement different facets of multiculturalism, even though what was meant by the term proved difficult to establish (Jupp 1991). Two considerations, however, were returned to time and again in policy statements. First, multiculturalism entailed unqualified respect for those cultures imported into Australia by successive immigrant waves. Second, certain core values had to be honoured by all in order that the stability of society could be maintained.

Notwithstanding the liberal rhetoric of tolerance and coexistence woven around the ideal of a multicultural society, this proved not only a remorselessly conservative set of ideas but also a discourse of control from which many came to feel alienated. For in political practice, multiculturalism entailed the privileging of the Anglo-Celtic core culture already enshrined in the dominant institutions of Australian society, and this monocultural core was to be surrounded by the diverse range of ethnic cultures to which 'Non-English-Speaking-Migrants' were assumed to be still committed. The Anglo-Celtic core was not acknowledged as the preserve of a particular ethnic category; it was represented instead as a naturalized Australian culture. Those not fortunate enough to have been born into this cultural mainstream could now couple it with the culture which was their inheritance—and thus become 'Greek–Australian,' 'Chinese–Australian,' and so on.

It was this arbitrary privileging of Anglo-Celtic culture that alienated many people. Multiculturalism proved to be a state policy that discriminated against cultural difference rather than celebrating it. More problematic still, the policy subsequently endorsed a new, emergent form of racism which also equated an Anglo-Celtic heritage with the supposedly national culture, while stridently claiming also that other particular cultures (those of Asian immigrants, for example) were quite incompatible with the latter (Stratton 1998). All things considered, it was hardly surprising that for many immigrants multicultural policy raised contentious questions about how those in power evaluated their position and their worth in Australian society. Notwithstanding their formal citizenship, at least in cultural terms they were being considered less than full and equal members of a rapidly evolving and increasingly complex nation-state.

5. *Globalization*

The final development that transformed the social and political landscape has been the globalization of culture, especially in its popular mass forms. The expansion of a middle-class prosperity and life style, including extended leisure time, has coincided with the ready availability of popular cultural commodities, and at least the superficial impact has been wide-ranging. Especially among the young, but by no means exclusive to them, the appeal of American fashion is pronounced: the major US corporations dominate the lucrative fast food market; and films, videos, CDs, and other forms of entertainment are predominantly im-

ported, along with spectacular mega-events. As with the exceptional growth of tourism into Australia from south east and east Asia, not only has the expansion of popular culture compounded levels of economic growth; it too has been constitutive of newly hybrid, cultural developments. Imported commodities spawn not only imitations but also equally lucrative innovations. There is also a wide-ranging reverse flow, including the export of Aboriginal art, soap operas, and films.

In the judgment of some social analysts, however, the impact has been much more than superficial: mass produced commodities from the US are considered a substantial threat to the already fragile and uncertain status of Australian culture (see Bell and Bell 1998). There are always difficult questions to be asked about the multiple meanings which consumers glean from, or invest in, these predominantly ephemeral cultural forms. But whether these justify such newspaper headlines as 'Australia—the 51st State' and turns of phrase like 'the Trojan horse of American culture' remains a moot point, not least because it is rarely made clear which aspects of Australian culture are most at hazard, and why this culture is considered especially fragile and threatened in the first place. At the very least, analysis of the impact of global culture needs to be coupled with, rather than separated from, exploration of the national fervour so conspicuously generated by sporting achievements.

6. *Conclusion*

In sum, the paradox of prosperity and stability on the one hand, and concern about cultural worth and collective identity on the other, is in substantial part indicative of the varied ways in which Australia is articulated within the global system. Increased affluence and social order have been sustained by such processes as the continued export of agricultural and mineral commodities, the recruitment of skilled and educated immigrant labor, and engagement in the extensive (albeit uneven) exchange of global culture in its multiple forms, as well as a general commitment to important principles of conduct such as the search for consensus through sustained negotiation.

But the course of rapid and fragmenting social change has seen an undermining of the potency of key symbols, the appeal of significant icons, and the interpretive power of unifying narratives, all of which were indispensable sources of meaning and comprehension in more stable, less complex times. This is not to suggest that other cultural constructs have not taken their place, only that—as is more widely the case in the postmodern era—these do not have, and most likely cannot take on, the broadly-based appeal and influence which could be effected in the past.

A small but significant illustration must suffice. In the final days of the twentieth century it was determined by the political elite that the Australian constitution demanded a preamble. In its draft form, co-authored by the Prime Minister and the country's leading poet, the term 'mateship' was used in order to capture some quintessential quality of how the Australian people relate to one another. For much of the twentieth century this claim would have been beyond contention. Yet no sooner did the draft document enter the public arena than the inclusion of 'mateship' was subject to derision, derogatory comment, and dismissal from many different quarters. It was an ignominious incident, yet—again paradoxically—it had a wealth of meaning inscribed within it.

A. Peace

Authenticity, Anthropology of

Within anthropology, there are two principal approaches to the question of authenticity. The first presupposes that authenticity is an attribute or prop-

erty inherent in cultural objects, and that the role of anthropology is to determine, using scientifically appropriate evidence and methods, whether particular objects are or are not authentic. The second locates authenticity not in objects but in discourses about them. This approach holds that the authenticity of phenomena is never a matter of objectively determinable fact, but is always socially constructed and, as such, subject to change.

Presently, the second approach is in the ascendance. It would, however, be short-sighted to view this trend as the culmination of a unilineal historical development in which the second approach has eclipsed the first. Rather, these opposed approaches endure because they replicate a fundamental epistemological opposition within modern societies, that between objectivism, realism or positivism, on the one hand, and constructionism or hermeneutics, on the other. Despite the recent persuasiveness of constructionism in social science, objectivist notions of authenticity remain hegemonic in many late-capitalist institutions, such as the art market, museums and courts of law.

1. *Authenticity and Reality*

Questions about authenticity should be distinguished from questions about reality and its representation. To ask whether an object is real, or an event occurred, is to ask about its existence relative to the empirical world. To declare an object or event 'unreal' or 'illusory' is to claim that it never existed or occurred. Note that such 'unreal' phenomena can exist in imagination. At least since Durkheim, anthropologists have argued that representations of objects are real-world phenomena with real-world effects, whether or not the objects of such representations can be shown (according to some sets of criteria) to exist in the world beyond those representations.

In contrast, to ask whether an object is authentic is to ask not about its existence but about its relationship to a posited social or cultural identity. The opposite of 'authentic' is not 'unreal' but 'inauthentic.' To deem an object inauthentic is to assert that it is not, despite claims to the contrary, an example of an identified class of objects, or not the creation of an identified person or group.

It is easy to confuse questions of reality and those of authenticity due to the commonsense use of the word 'real' to mean 'authentic,' as in the phrase 'this is a real Native American medicine bundle.' Such claims are not intended as predications of existence as such, but as evaluations of what is understood to be the essential nature, or the identity, of the phenomenon in question. Thus, assertions of authenticity always have embedded within them assertions of identity.

Throughout the history of their discipline, anthropologists have been asked to authenticate artifacts, customs, legends, texts, and other cultural objects, as well as the racial, ethnic, or cultural affiliation of persons. Depending on subdisciplinary and areal expertise, anthropologists might offer authoritative answers to such questions as: 'Are these stone weapons Clovis points, from Western North America and 12,000 years old, or are they modern reproductions?' 'Can this narrative be attributed to precolonial Native Americans, is it the result of European influence on Native American traditions, or is it a recent creation, and if the latter, what is the cultural identity of its author?' And most bluntly: 'Are these people Indians with unbroken ties to precolonial America, or have generations of racial mixing and cultural borrowing erased that identity?' Such assessments of the authenticity of particular objects and persons are similar to those required in fields like art history and museology, where it is often important to be able to identify objects by attributing them to named artists, historical periods, or cultural groups.

2. *Authenticity and Modern Individualism*

The commonsense notion that authenticity is an expression of the essential identity of an object stems from modern (in the sense of post-fifteenth-century) individualism. In this worldview, ultimate reality is understood to be lodged, not in a hierarchically interrelated divine cosmos, but in individuals, from the smallest particles to persons to delineated groups of persons (cultures). To quote the philosopher Cassirer on the modern ontology of nature: 'Nature … implies the individuality, the independence and particularity of objects. And from this characteristic force, which radiates from every object as a special center of activity, is derived also the inalienable worth which belongs to it in the totality of being … The part not only exists within the whole but asserts itself against it, constituting a specific element of individuality and necessity' (1965, p. 41). From such an outlook the notion of authenticity derives: each object, each individuality is itself a center of reality with a unique essence or identity that distinguishes it from all other objects.

2.1 *Authenticity and Sincerity*

In *Sincerity and Authenticity*, Trilling (1972) drew out the implications of this worldview for modern conceptions of sociality and personhood. With the emergence of modern individualism, persons were no longer defined by their position in a social hierarchy (as in medieval European realms). Instead, social positions came to be understood as 'roles' to be filled by persons whose essence, or individuality, precedes and transcends those roles. In this perspective, the inner realm

of individual character or personality is more real than the outer world of social relations.

The importance of sincerity in the early modern period, Trilling argued, derived from concerns about whether a person's social actions matched or masked inner attitudes. Indeed, it was insincerity that was at issue. As Rousseau put it, humans in the 'state of nature,' prelingual and presocial 'savages,' had no means to dissemble; their actions could be nothing other than the direct expression of their inner or essential being. But with the emergence of human language and society, 'it ... became the interest of men to appear what they really were not' (1972, p. 86). Inner authenticity diverged from outer sociality, and the 'rise' of civilization, as Rousseau saw it, entailed a process of moral corruption.

In Trilling's account, concern for sincerity, with its questioning of the relationship between society and the individual, began to cede place in the Romantic period to concern for authenticity, which privileges inner essences without relating them to an outer world of other people. The Romantics' quest for authenticity was a quest for 'essential identity,' a longing for knowledge of true inner being irrespective of any accidents of social history or circumstance. Artists, in particular, were understood to be individuals possessed of powerfully unique inner realities, uncorrupted and undiminished by social conventions. At the same time, the growing middle classes of the new mass democracies were coming to see their lives or identities as increasingly 'unreal' or 'inauthentic.'

2.2 *Authenticity and Collectivities*

In social philosophy, and later the social sciences, these concerns for individual realities were applied to human collectivities. The leap from the individual to the collective is not as great as it seems, for, as Dumont (1970) has insisted, modern ideology understands groups as 'collective individuals.' From the eighteenth century onward, folklorists and anthropologists assumed that groups of people could be characterized by unique cultural, historical, religious, linguistic or otherwise traditional features that set them off from all other groups. These models of the group were often naturalistic, using analogies to biological organisms or species: it was assumed that a group was a bounded natural unit or object, that members of the group shared its defining features, and that it was possible objectively to evaluate the cultural identities of individual persons, based on the cultural attributes they 'possessed.'

2.3 *Authenticity Endangered*

A noteworthy accompaniment of this conception of cultural authenticity is a fear of its demise. Authenticity is seen to be perpetually threatened. The authenticity of nonmodern ('savage,' 'primitive,' 'native,' 'indigenous,' 'folk,' 'peasant,' or 'traditional') cultures is imagined to depend on their pristine existence beyond the reach of advancing 'civilization.' Throughout the epoch of European colonial expansion, down to the present day, metropolitan authorities—scholars, travelers, missionaries, colonial officials, collectors—took it upon themselves to delineate unique groups in terms of their 'possession' of specific racial, linguistic and cultural attributes. The impingement of European culture on such groups, or even the influence of non-European but purportedly more 'complex' cultures, was thought to alter their unique identities and thus to destroy their cultural authenticity. Such conceptions were applied at the level of the individual as well, such that in colonial social orders, the 'half-breed' (to use a racial term) or the culturally bastardized colonial subject was often scorned as the embodiment of the worst of both the 'primitive' and 'civilized' worlds.

In sum, the European 'discovery' of 'Others' followed by ongoing 'contact' made them, almost by definition, inauthentic. Authenticity as a quality of cultures, artifacts and persons was projected by metropolitan authorities into the past, a past they might be able to document, but only just before its destruction.

3. *Constructionist Accounts of Authenticity*

Despite the pervasiveness of such assumptions about groups as bounded objects, there have been recurring social-scientific trends (historical diffusionism, for example) that privileged intergroup connections, contacts, borrowings, and syncretisms. In Anglo-American anthropology since the 1970s, there has been growing rejection of the notion that cultures, societies, and groups in general are naturally bounded and internally homogeneous. Indeed, it is now commonplace to assert the opposite, and to claim that groups are historically and situationally contingent; that the relative rigidity (or porousness) of group boundaries is a function of semiotic, not natural, factors; that collective identities salient in contemporary institutions, politics and scholarship ought not to be projected into the past; that individual persons have multiple identities that can shift according to social context, although not without regard to institutional and cultural constraints; and that the products of human creativity cannot unproblematically be assigned cultural, racial or ethnic identities. In addition, recent historical scholarship has argued that the work of colonial cultural classification was carried out in areas of the world where European notions of objective social boundaries encompassing homogeneous, authentic cultural identities made little sense in relation to local people's understanding of sociality.

3.1 Negotiating Authenticity

Constructionist approaches to authenticity question whether it's useful to specify the 'essential' identity of groups, artifacts and persons. Since human beings are historically and socially situated, they are always connected to other people. Culture exists not simply *in* them but *between* them. Any understanding of a particular person's or group's authentic identity will be a function of specific social encounters, and particular evaluations of authenticity are open to negotiation and dispute. An 'expert' (colonial administrator, art collector, anthropologist) may claim that a person is not a 'real' or 'pure' member of a posited culture, or that an artifact is not an authentic product of it, but others may reject such evaluations based on differing definitions of cultural boundaries and essences.

This does not mean it is impossible or unhelpful to describe and classify cultures. Rather, it means that the terms used to do so must be understood in relation to the discursive project of the classifiers. At any historical moment, some such terms will be relatively unproblematic. For example, given our present technology and understanding of time, we can expect the carbon 14 dating of archaeological artifacts to yield valid information. We need not question the empirical validity of the description to recognize that such data become useful, or meaningful, only in terms of more general hypotheses concerning culture history, hypotheses that can never be reduced merely to facts derived from carbon 14 dating. Moreover, terms of cultural classification that are unproblematic in one context might become contested in another, for example, present-day descendants of precolonial Native Americans might dispute carbon 14 results, claiming a greater antiquity for artifacts than anthropological methods can demonstrate.

3.2 The Politics of Authenticity

Assertions of cultural authenticity can have political consequences. Among the most serious are governmental recognition of 'tribal' or 'aboriginal' status, a status that often entitles group members to government subsidies and services, and to government (mis)management. In settler societies such as the US, Canada, and Australia, some 'indigenous' groups have governmental recognition based on treaties, some of which date to the late eighteenth century; other groups claiming to be authentically indigenous may turn to the courts to gain such recognition. In the courts, authenticity is defined in terms of temporal continuity, cultural homogeneity and distinctiveness, and geographical stability. It may or may not be possible for people who have lived for generations in a situation of 'contact' to demonstrate possession of cultural authenticity defined in such terms. Indeed, there is a cruel irony inherent in the relationship of 'native' authenticity to nation-state citizenship. On the one hand, 'indigenous' peoples are asked to assimilate, through education and economic mobility, into modern society; on the other hand, to do so is to be seen as having become inauthentic and to be scorned on that basis. In practice, both racist barriers and modern fantasies of authenticity fence people in, making it difficult for them to enjoy full citizenship.

Claims concerning the authenticity of individuals and objects can also have political (and economic) consequences. Government criteria to evaluate the affiliation of individuals to recognized tribal groups are often based on quantifications of 'blood,' that is, proportion of 'native' descent. Such criteria usually do not match those that defined social inclusion before the imposition of modern definitions of authentic personhood. Individuals' access to government benefits nonetheless depends upon satisfying the imposed criteria.

The authenticity of cultural objects is negotiated in the markets for art, museum artifacts, and touristic souvenirs. Objects deemed culturally authentic command higher prices and can claim space in more prestigious venues, such as museums and the homes of wealthy collectors, than those considered culturally 'mixed' or 'commercial.' Over time, however, objects can gain authenticity as scholars and collectors objectify and historicize what were once seen as debased cultural forms. 'Indigenous' artists and craftworkers, too, can influence standards of authenticity as they position themselves vis-à-vis the art market and museum world.

3.3 Anthropologists and Authenticity

Some anthropologists continue to approach authenticity as an objectively verifiable property of cultural objects. Others admit the validity of constructionist arguments, but worry that they undermine the claims of marginalized people to the possession of authentic culture and the accompanying political benefits. Although these anthropologists may reject objectivism in principle, they want to be able to deploy an objectivist notion of authenticity 'strategically' to support politically embattled minorities. Other anthropologists argue that recourse to concepts of authenticity inevitably reproduces the hegemonic ideology of identities that led to racial, ethnic and cultural minoritization in the first place. The fact that anthropological expertise based on any of these positions can influence the social status of objects and people is if nothing else evidence that supports a constructionist account of authenticity.

Authoritarian Personality: History of the Concept

Around 1930 Wilhelm Reich and Erich Fromm, two Marxian psychoanalysts, developed similar psychodynamic models to account for the attraction of Germans to Nazism. Subsequent development by the exiled Frankfurt Institute linked up with empirical research on antisemitism by psychologists at Berkeley. Adorno et al. (1950) published *The Authoritarian Personality*. It presented a three-level theory: an ethnocentric, power-oriented surface ideology, undergirded by a conflicted personality structure, in turn generated by authoritarian child-rearing practices. Highly praised, the tome spawned hundreds of research reports in America and, later, abroad. But gradually the theory succumbed to methodological criticism, spotty empirical confirmation, and a changed political climate. Recent attempts to revive the theory had little impact. After promising an understanding of major historical-political developments, the idea's empirical applications failed to convince. Only the pejorative label 'authoritarian' appears to have survived.

1. *Emerging Conceptions of the Authoritarian Character*

1.1 *Reich's* Massenpsychologie des Faschismus

In the years after World War One, the core problem for leftist politicians and intellectuals in Europe was the failure of the proletarian revolution in the industrial countries. This apparent failure of Marx's theory preoccupied the young Wilhelm Reich, a Marxist activist as well as rising star of Freud's psychoanalytic circle. Combining the two revolutionary doctrines, and changing focus from capitalism to patriarchy, he diagnosed sexual repression by society as the main cause of political passivity. He called this, by 1930, '*autoritäre Unterordnung*' (authoritarian submission), personified in the *Feldwebelnatur* (sergeant-major nature), 'groveling upwards and bullying downwards.' Discussing Nazi psychology and its race theory, he proclaimed that German Fascism would be the inevitable outcome of the patriarchal-authoritarian family system. Without the label '*Autoritärer Charakter*,' Reich had assembled most elements of Authoritarianism theory by 1932.

Reich's lack of respect for orthodoxy landed him in trouble with both Communists and psychoanalysts. Soon the Nazis' rise to power, confirming his prediction, forced him to emigrate and eventually settle in America. He also elaborated his ideas of the appeals of National Socialism in his *Massenpsychologie des Faschismus* (1933). Discounting Hitler's charisma and propaganda as shallow explanations, he found the roots of the catastrophe in the character structure of lower-middle class Germans. In patriarchal society the family, as 'factory of bourgeois ideologies,' molded the child's character by implanting sexual inhibition and fear. Sexual repression and economic exploitation produced conservatism and not only submission but active support for the authoritarian order and its propaganda. The repressed sexuality turned into yearnings for mystical ideal: nation, honor, motherhood, symbols exploited eagerly by Nazi propaganda. Race theory, militarism, and anti-Bolshevism were allied themes, sadistic aggression their derivative. Sexual politics—a term apparently coined by Reich—was the key to understanding and combating Fascism.

Published on the run, the book had little effect. Its English edition (eliminating Reich's original Marxist language) was delayed until 1946. By then, Nazism was defeated, and Reich's new 'orgone' theory had made him an outcast. Earlier, Fromm had criticized Reich's overemphasis on genital sexuality in his essay

in the Frankfurt Institute's 1936 volume on *Studien über Autorität und Familie* (Horkheimer 1936)—the next development of the idea.

1.2 Fromm's Social Psychology and the Frankfurt Institute

Like Reich, Erich Fromm was a young Freudian analyst and a Marxist. In 1930, he joined the Frankfurt Institute, to provide social psychological expertise to Horkheimer's group. Fromm, too, tried to integrate Freud and Marx but still focused on the 'spirit' of capitalism, mentioning Fascism only in footnotes. Generally, Fromm's emphasis on the family as agent of authoritarian society in character formation, his references to patriarchy, sex morality, and the role of women were similar to Reich, whom he had met in Berlin and later in Switzerland. How much their ideas developed independently is unclear, although Fromm denied any influence. Reich may have been some steps ahead chronologically.

Four years later, the Frankfurt Institute, exiled to New York and renamed the International Institute for Social Research, published its *Autorität und Familie*. Horkheimer's foreword defined 'autoritär' as *autoritätsbejahend* (authority affirming). His lead essay, mentioning the 'authoritarian character' (here making its first appearance in print) as a submissive, masochistic type, dealt with freedom, reason, and authority; it invoked Hegel much more often than Marx. The Institute was moving away from historical materialism to Critical Theory. Fromm's chapter expanded his ideas into a detailed analysis of the psychology of submission to authority. He described, still in mostly orthodox terms, the anal character, which in authoritarian society metamorphoses into the 'autorite—masochistische' character—without mentioning antisemitism so important to Reich and later in Berkeley.

1.3 The Institute's Questionnaire Survey and 'Escape from Freedom'

The volume's empirical part drew a thumbnail sketch of revolutionary and authoritarian types in a summary of the Institute's survey of German workers and employees begun in 1929—years before anyone in the Institute had anticipated a Nazi takeover and before Fromm had joined the Frankfurt Institute (see Samelson in Stone et al. 1993). A complete report had to wait 50 years (Fromm 1983).

Fromm left the Institute in 1939, partly because of a quarrel with Horkheimer about scientific weaknesses in the study. He reformulated his theories in his 1941 book *Escape from Freedom*. Since the Reformation, modern man (sic) had acquired freedom from many constraints and developed several mechanisms of escape from his ensuing isolation, among them the authoritarianism of the sadomasochistic character. Fromm's 'neo-Freudian' ego psychology was responding to his new American environment as well as returning to his initial concern with capitalism. Transforming democracy's lonely citizens into more spontaneous and loving personalities, not the threat of Fascism, was now the greater challenge. Having moved away from the negations of the Critical Theorists, Fromm's more popular social psychology was shifting, like the field as a whole, toward 'interpersonal relations,' although Fromm personally remained politically engaged.

2. Empirical Research on the Fascist Character

Realizing the need for empirical data, the Critical Theorists themselves began a research project on antisemitism, a topic absent from their earlier work. In 1943, Horkheimer made contact with Nevitt Sanford, a young psychology professor at Berkeley, interested in problems of personality structure and ideology. Sanford and his graduate student Levinson were then constructing an attitude scale to measure antisemitism.

2.1 The Authoritarian Personality in Berkeley

Expanding their project, they linked up with ideas formulated in Germany a decade earlier. With Adorno representing the Critical Theory group, they developed a cooperative research plan to study what was initially called the 'Fascist character,' then 'Antidemocratic,' and finally *The Authoritarian Personality* (Adorno et al. 1950). Over five years in the making, the hefty volume described—in Horkheimer's words—a 'new anthropological species': the potential Fascist who, in contrast to the old-style bigot, combined the skills of industrial man with irrational beliefs. A cluster of ethnocentric attitudes and power orientation on the surface reflected an underlying personality structure characterized by conflict between submission and aggression, intolerance of ambiguity, and related dynamics, in their turn produced by authoritarian upbringing.

The book became an 'instant classic' (Jay 1973), praised as a model of imaginative and integrative social science research. It brought together sophisticated attitude scaling, opinion research, projective testing, and clinical interviews; it combined hard-headed empirical methods, clinical sensitivity, and original theoretical insights; and it dealt with a problem of major social significance. For two decades it produced a veritable flood of empirical follow-up studies. But a two-pronged counterattack on *The Authoritarian Personality* had also developed, the first one involving politics directly. Adapting Arendt's new

'Totalitarianism' theory of Fascism, it charged that the Berkeley group had concentrated exclusively on 'right-wing' authoritarians, while ignoring the 'authoritarians of the left': the Communists. Although differing, for doctrinal reasons, on surface attitudes such as antisemitism or ethnocentrism, fascists and communists were basically similar types. Complaining about the Berkeley group's naive left–right scheme, the critics denied any possibility of a real threat from American nativist–authoritarians.

These charges were not purely academic. At the height of the Cold War, the Berkeley group was accused of completely ignoring the authoritarianism of the left, that is, Communism, although it was the much greater threat. Such political attacks, at a time of difficulties for psychologists with real or alleged left-wing involvements, put some 'chill' on further work on this and related issues.

2.2 *The End of Ideology?*

The other line of criticism, more indigenous to psychology, tried in effect to drain the phenomenon of all political meaning. The dominant positivist-empiricist research style had already reduced the complex 'Berkeley project to the "California F Scale,"' a questionnaire handy for generating reams of data, while ignoring the rest of the theory. Whereas the outsiders had faulted the F Scale for capturing the wrong kind of political extremist, the insiders' professional consensus declared the F Scale invalid for the opposite reason. Due to a technical flaw, it identified not genuine protofascists, but only a 'response-set to agree,' that is, some very agreeable persons without strong opinions, or in one variant of this depoliticization process, only dogmatists of all stripes. Fixated on the paper-and-pencil F scale's real and alleged defects, investigators gradually abandoned this research, except for isolated individuals mostly in other countries. Repairing the scale's alleged defect proved as problematical as the original. Even Altemeyer's balanced Right-Wing Authoritarianism scale, laboriously constructed long after the F scale had fallen out of favor, tapped a much more restricted set of personality characteristics than those postulated by the original theory. Reich's original Freudo–Marxist idea of the interplay between societal organization and individual character mediated by the family had been fitted into an American empiricist, individual-psychology framework.

3. *Epilogue: Authoritarianism and the Dialectics of History*

Soon liberal, and by then staunchly anti-Communist, social science found it more appealing to attack, contrary to Horkheimer's claim, the old-style bigots from the moral high ground of antiracism. And as society changed, the predominant liberalism gave way to an apolitical scramble for practical applications capable of generating grants. Value-free empiricism had won the day—but only by reducing a genuine and important problem to a meaningless artifact, a 'response set,' drained of interest to any one except methodologists. The nuclear idea had moved from the Left to the Right until it ended in the mass media, which skillfully personalized it in the bigoted but basically harmless Archie Bunker—an utterly different, American version of the German *Feldwebel*. In the meantime, neoconservatives, in the 1950s insisting on the similarity of right- and left-wing authoritarianism, now stressed the differences between the authoritarian Right, who were possible allies, and the totalitarian Marxist–Leninists who only understood force. The psychological argument had turned into polemic and the label had become an epithet.

Recent attempts to revive the Authoritarian Personality failed to have much impact, though supporting some of the original findings (Altemeyer 1988). Whatever interesting results may be produced by tracking F scale means over time and space (Meloen, in Stone et al. 1993), they add little to our understanding of the theory. Social psychological textbooks of the 1990s usually devote only a few—respectful—paragraphs to it. Although it had been an intriguing idea, promising some understanding of major historical-political developments, a problematic initial assumption (that Hitler's main support had come from the lower middle class), the theory's erratic applications, and a changed political climate led to a shift in researchers' interests. What survived best is the pejorative label 'authoritarian,' widely used for persons or institutions considered—as in Horkheimer's original meaning—to be '*autoritätsbejahend*' (authority affirming), but stripped of the theory's complex personality dynamics and its antecedents.

Authoritarianism

The construct of authoritarianism grew out of attempts by psychologists to understand the mass appeal of fascism in the first half of the twentieth century. As a result of a large body of empirical research, authoritarianism has become one of the major psychological explanations for the persisting finding of generalized prejudice and intolerance: the tendency for negative attitudes toward out-groups to correlate across different targets. It remains one of the most important approaches in the political psychology literature.

1. *Origins*

Research on authoritarianism was influenced by the attempts of European psychologists in the psychoanalytic tradition to understand mass support for fascism (Fromm 1941, Reich 1946). The major defining work was the publication in 1950 of *The Authoritarian Personality* by Adorno et al. (1950). This book of almost 1,000 pages combined psychoanalytic and personality theory with empirical research from in-depth interviews and questionnaires. While the project began as a study of antisemitism, the researchers quickly discovered that antisemitism appeared to be a part of a broader ethnocentrism. They located the origins of this ethnocentrism in basic personality processes as seen from a Freudian perspective.

Adorno et al. argued that punitive child-rearing practices and inconsistent parental affection produce a severe conflict within the young child. The repression of hostility toward the parents is, in adulthood, displaced onto groups perceived to be weak or inferior while authority figures (a generalization from the parents) are deferred to. Another consequence of this psychological conflict is a weak ego, which in turn leads to characteristics such as an unusual adherence to conventional social values, intolerance of ambiguity, and attraction to superstitions. From this perspective, prejudice has little to do with the actions or attributes of the target group but is a consequence of the psychological needs of those high in authoritarianism to direct repressed hostility toward subordinate groups.

Along with their explanation, Adorno et al. developed a paper and pencil measure of authoritarianism. It was labeled the F-scale because it was considered to be an indicator of susceptibility to fascist appeals. Introduced just as quantitative social science research was gaining momentum, an enormous literature soon developed that examined the correlates of authoritarianism, as measured by the F-scale or similar measure. As of 1989 there were well over 2,000 publications on authoritarianism and related constructs (Meloen 1993). Studies cataloged the relationship between the F-scale and social background characteristics, various measures of personality, and a wide range of social and political attitudes (see Kirscht and Dillehay 1967 for a typical review of this research).

2. *Criticisms*

The Authoritarian Personality was subjected to close scrutiny and criticism almost immediately after it was published (see Christie and Jahoda 1954). Methodologically, problems with the F-scale measure of authoritarianism cast doubt on much of the empirical research. Since all of the questions in this scale were worded so that an agree response indicated authoritarian characteristics, a tendency to agree with questions like this regardless of content (agreement response set) could produce high authoritarianism scores independent of any individual differences in personality. And while the questions in the F-scale were developed to tap the various syndromes hypothesized to make up authoritarianism, it is not clear that the measure reflects the underlying conceptualization. Factor analyses of the F-scale always show the measure to be multidimensional but the factors are always difficult to interpret and never cleanly correspond to the hypothesized components (see Altemeyer 1981).

Critics also argued that the authoritarianism measure, and possibly the construct itself, was ideologically biased. Although Adorno et al. were clearly responding to the history of fascism in Europe, the growing threat of communism in the 1950s led to concerns about an authoritarianism of the left (Shills 1954). However, despite observations that communists appeared to possess traits characteristic of authoritarians, there is little empirical evidence to support these claims (Stone 1980).

Perhaps most importantly, the Freudian-based theory underlying *The Authoritarian Personality* proved far less useful than the authors thought and as a result research become increasingly divorced from the theory. In addition to the general loss of status of Freudian explanations in empirical social science research, Adorno et al.'s specific explanation of authoritarianism has not fared well. Although quantitative research established relationships between the F-scale, social background characteristics, and social

attitudes, evidence on the dynamics and origins of authoritarianism consistent with the Adorno et al. theory proved elusive (see Altemeyer 1981, 1988, Duckitt 1989). The bulk of research based on *The Authoritarian Personality* thus consists of short empirical studies with only limited guidance from the original theory. Most of these studies report correlations between measures of authoritarianism and a small number of other individual level characteristics: social background, personality, values, and attitudes.

3. *More Recent Approaches*

Several attempts have been made since the publication of *The Authoritarian Personality* to develop alternative explanations for individual differences in prejudice and intolerance. Perhaps the best known of these is Rokeach's research on dogmatism reported in *The Open and Closed Mind* (1960). Rokeach moved from the Freudian perspective of Adorno et al. to a more cognitive explanation based on the structure and function of belief systems. He argued that prejudice and intolerance are a result of closed belief systems that ward off threats by limiting the scope of accepted beliefs and rejecting all challenges. Like Adorno et al., Rokeach developed a measure of dogmatism based on the same methodology of agree–disagree attitude statements. His dogmatism measure was also constructed of a diverse range of statements designed to reflect the various elements of open and closed belief systems.

While research has utilized Rokeach's dogmatism scale, most of it, like research using the F-scale, consists of narrow empirical studies that examine the correlates of the measure. There has been little reported work that has examined Rokeach's conceptualization of open and closed belief systems despite his own detailed and novel explorations reported in the book. In addition, the measurement properties of the dogmatism measure have proved to be no improvement on the F-scale. It too has items that are worded in only the agree direction and the interitem correlations and dimensionality of the measure may be even worse than the F-scale (Altemeyer 1981).

The most significant new contribution to the authoritarianism literature has been a recent body of research reported by Altemeyer (1981, 1988, 1996). From years of studies using undergraduate students, Altemeyer has both developed a new and more reliable measure of the construct and advanced a new conceptualization based on social learning theory. Rejecting the Adorno et al.'s Freudian explanation, Altemeyer (1988) prefers a simpler conceptualization that sees authoritarianism as a social attitude (or cluster of attitudes) that is learned through interactions with parents, peers, schools, the media, and through experiences with people who hold conventional and unconventional beliefs and lifestyles. His measure of right-wing authoritarianism (RWA) is more reliable and unidimensional than previous scales and has items balanced for agreement response set.

There have been several other attempts to reconceptualize the authoritarianism phenomenon. Kelman and Barkley (1963) argued that high authoritarianism reflects a limited breadth of perspective. Lipset (1960), Selznick and Steinberg (1969), and others have suggested that authoritarianism is a function of social learning associated with lower social class and less educated environments. More recently, Duckitt (1989) has developed a model in which authoritarianism reflects the desire to maintain strong in-group identifications.

4. *Limitations and Problems*

In addition to the measurement and theoretical problems discussed above, there are other significant shortcomings of the authoritarianism approach.

How do factors in the social environment exacerbate or moderate predispositions toward prejudice and intolerance? Some researchers have hypothesized that social threats or anxiety will arouse prejudice and punitiveness and encourage support for extreme right-wing parties and even mass violence (Staub 1989). There is also some evidence from archival and individual level studies that levels of authoritarianism, or the strength of the connection between authoritarianism, prejudice, and intolerance, increase during periods of threat (Sales 1973, Doty et al. 1991, Feldman and Stenner 1997). Although there appears to be strong impressionistic evidence that prejudice, intolerance, and support for right-wing groups wax and wane over time, there is nothing obvious in the present conceptualizations of authoritarianism that would help to explain this phenomenon.

More generally, authoritarianism is generally treated as a purely dispositional construct; researchers almost always examine simple additive relationships between measures of authoritarianism and indicators of prejudice and intolerance. This type of approach provides no understanding of how the reality of social and political conflicts—or any other environmental factors—interact with authoritarian predispositions. This leaves authoritarianism a purely 'personality' explanation, with only weak connections to other explanations of prejudice and intolerance.

It is also necessary to make progress on the relationship between authoritarianism and ideology, particularly since the authoritarianism construct is beginning to be used in studies of countries with a history of communist governments. Studies in the USA and Canada consistently find negative relationships between measures of authoritarianism and attitudes toward communism. In Russia, however, researchers have shown that 'right-wing authoritarianism' has been associated with support for communism (McFarland et al. 1992). This relationship can be understood if support for communism in countries

like this represents a commitment to the established, authoritarian order. Even so, a positive correlation between 'right-wing' values and communism strongly suggests that the construct of authoritarianism must be defined and measured in a way that allows it to be used in cross-national research.

5. Conclusions

Despite all of the problems that have been raised with the authoritarianism construct since the 1950s, it continues to be used in research on prejudice and intolerance. Its longevity is, in part, a function of the repeated findings of consistency in expressions of prejudice and intolerance across a wide range of targets. Individual differences account for a significant proportion of the variance in these attitudes and authoritarianism remains one of the major explanations of those individual differences.

Authority: Delegation

Authority is a relationship between a superior or overseer and a subordinate, whereby the subordinate relies upon the superior for specific direction. The concept and practice of authority has a position of prominence in the history of human society as well as the academic fields of public policy, public administration, political science, sociology, economics, and psychology. Considerations of authority are particularly important in the policy sciences, because politics is fundamentally about who gets what, when, and how, and, perhaps most importantly, *who decides*. Since people generally would like to maximize their own decision-making authority, to promote their own interests and causes, while simultaneously minimizing the authority to which they themselves are subject, determinations of authority of necessity play a crucial role in moderating such conflicting impulses so as to organize cooperative human activity and civil society. However, authority relationships and delegations of authority are rarely self-executing, unambiguous, or nonproblematic. Often, authority is not merely granted but must be earned, and authority relationships must be negotiated and renegotiated.

1. Definition of Authority

Authority is nearly as difficult as it is important to define clearly. At a minimum, authority can be thought of as either a possession, as in claiming that someone 'speaks with authority' on a matter, or as a relationship, as in the fact that a superior exercises authority over a subordinate. The very use of the term 'exercise' in tandem with 'authority' signals the sense in which authority can be likened to a muscle, which can increase in mass and tone with use, as opposed to a

checking account balance, which inevitably decreases with use.

Flathman (1980) cuts the matter slightly differently with his distinction between 'an' authority and 'in' authority. *An authority* is a person who is generally thought of as possessing specialized knowledge regarding a topic. *In authority* is drawn from occupying an office or holding a formal title. A criminologist might be described as 'an authority on crime,' whereas one would contact a police officer if one sought 'help from the authorities.' Many contemporary normative debates over authority structures and practices highlight this difference, with the general trend in most industrialized nations being towards shifting from a reliance on 'in authority' to a reliance on 'an authority,' with the judgment regarding whether or not someone *is* an authority in relationship to another person being left increasingly to the potential subject of that authority.

1.1 Distinctions Between Authority and Power or Influence

Authority is primarily and increasingly considered to be a relationship between a superior or overseer and a subordinate, whereby the subordinate relies upon the superior for specific direction, whether it be in the form of expert advice or operational commands. A respected dictionary definition of authority is 'power to influence or command thought, opinion, or behavior' (*Webster's Ninth Collegiate Dictionary* 1983). This definition suggests that authority is related to, but distinct from, the concepts of *power* and *influence*. A widely accepted definition of *power* is that person A has power over person B when A can get B to do what A wants B to do, which is something that B would not have done on B's own (Dahl 1957). The existence of power in a relationship depends upon B's behavior actually being altered from the course that it otherwise would have taken, specifically as a result of A's intervention. *Influence* is closely related to power in that it concerns itself with an external force (e.g., a person) acting upon an object (e.g., another person) to change the object's status or behavior in some way. Influence can be distinguished from power in the sense that the outcome it produces tends to be less specifically and directly intended (e.g., the influence that a mentor has on a student) than does the outcome of the exercise of power. However, both power and influence are contingent upon outcomes.

Authority is less teleological, or outcome-focused, than power. Someone can be an authority or in a position of authority over another person before, and even without, altering the other person's behavior in any meaningful way. They may or may not influence the other person, yet remain in a position or relationship of authority over that person. The existence of authority depends more on what is brought to the situation, in terms of reputations, titles, offices, and positions, than on what actions (if any) are taken as a result of the exercise of authority.

1.2 Anticipatory Reactions

Since outcomes do not determine authority, we ought to focus our attention on the process of exercising authority in order to identify when authority does and does not exist. However, such an approach is potentially limited by the problem of anticipatory reactions. A subordinate might anticipate the preferences of a superior so perfectly that the subordinate acts in exactly the way that the authority wishes the subordinate to act without the superior needing to command the action explicitly. Anticipatory reactions to authorities can occur because a subordinate has fully internalized the preferences and values of the superior, or because the subordinate knows what the authority prefers and fears punishment if the preferred behavior is not forthcoming. For example, motorists who approach traffic lights that are changing to red choose either to speed through the light or to stop. Motorists know, at least subconsciously, that the authorities would like them to stop. Motorists might stop because they fear the possible physical consequences of not stopping, in which case authority has not affected their decision. However, motorists also might stop because they have internalized the value of orderly and predictable driving behavior, because they fear that a police officer might ticket them for running the red light, or because a traffic cop explicitly holds up a hand, ordering them to stop. All three of these responses would be reactions to authority, although the first two could be considered cases of anticipatory reactions.

2. Legitimacy

The concept of legitimacy is central to the exercise of authority. Regardless of the source of authority, if it is not perceived as legitimate by the object of authority, then there is little chance of the authority being exercised effectively. Authority is considered to be legitimate if the object of authority accepts the appropriateness of its exercise and therefore submits to its dictates (Barnard 1968). Legitimacy renders authority *authoritative* in a given case.

2.1 Weber's Ideal Types

Although Max Weber was not the first scholar to inform thinking on legitimacy as it concerns authority, his contribution to our understanding on this topic is profound. Weber (1947) argues that the legitimacy which is attached to authority stems primarily from

one of three general sources, which he characterizes as *ideal types*. The three Weberian ideal types of legitimate authority systems are traditional, charismatic, and rational-legal in design.

Under a traditional system of authority, legitimacy adheres in the station of the person who is exercising authority, and is largely unearned. The roots of traditional authority systems lie in early pagan religions and the traditional structure of authority relationships in the family. Most early religions and mythologies identified gods with forces of nature that were mysterious to, and more powerful than, the people and societies who were regularly subjected to their apparent dictates. Thor, the Norse God of Thunder, was thought to rule the sky, and the Greek god Poseidon to rule the sea. The founding event of the Jewish religious faith was a supernatural event, Abraham's witness to the burning bush that was not consumed, and from which God announced 'I am who am,' generally interpreted to mean 'I am existence itself,' something both superior to and essential to human beings. Thus began the traditional understanding of the legitimacy of God's dominion over the Jewish people and, by extension, all of creation. God neither sought nor needed to earn authority over human beings. All God had to do was declare that authority. The authority was considered to be legitimate simply because God is God.

Traditional sources of legitimate authority have also been evidenced in the power relationships of family structures ('obey me because I am your father') as well as the feudal and caste systems employed by various premodern cultures. Perhaps the clearest example of a traditional basis for the legitimacy of authority was the principle of the Divine Right of Kings. Kings were to be obeyed because they were kings, regardless of the prudence or benevolence of their commands. Kings, in particular, were thought to be appointed by God, with subsequent succession usually determined by birth or kinship, though occasionally also influenced by human schemes. Aquinas (1953, p. 160) captures the essence of the traditional source of legitimate authority when he says: 'In natural things it behooved the higher to move the lower to their actions by the excellence of the natural power bestowed on them by God; and so in human affairs also the higher must move the lower by their will in virtue of a divinely established authority.' Under a traditional system of authority, one is born into one's natural station in life, and the position of that station, from prince to slave, determines over whom one exercises legitimate authority, and to whose authority one is subject.

Weber's second ideal type of legitimate authority is termed charismatic. Under a charismatic system of authority, the legitimacy of the authority is tied to the person and is in some sense earned. Mahatma Gandhi exercised legitimate authority over the actions of many people in India, not because of any offices he held, nor due to his natural station in life, but because of who he was and what he advocated. The roots of scholarly thinking about charismatic authority go at least as far back in time as ancient Greece, when Plato argued that philosophers deserve to be kings because they possess the greatest wisdom, and Aristotle reasoned about the authority merited by effective leaders. Weber argues that charismatic authority is perceived to be legitimate because the charismatic leader binds the wills of subjects to the leader and the leader's causes. Once a leader has persuaded followers that the cause to be pursued is worthy, the followers suspend their personal judgment and follow that leader. Because the commitment to the leader and cause is both personal and complete, few if any formal systems or rules for ensuring compliance are necessary. Charismatic leaders employ the force of their personality and the power of their ideology to meld the wills of subordinates to them and their cause. As such, Weber's charismatic authority system closely resembles the prescription of Rousseau (1986) that citizens must always submit to the legitimacy of the General Will once it has been formulated.

The third and most modern of Weber's ideal types of authority systems is termed rational-legal. Under a rational-legal system, authority adheres in the office that is occupied by the person who exercises authority, a system that Oakshott (1975) has termed 'formal-procedural' or 'F-P' authority. One obeys a police officer not because of cultural tradition or the officer's charisma, but because the officer occupies a position of authority. The police officer's exercise of authority is considered to be legitimate because a rational system of training and selection places qualified officers in such positions, and clarifies and delimits their authority. Because authority adheres in the office and not the person, transitions and successions can be seamless under a rational-legal system. When the chief of police retires, a successor is appointed, often by promoting the next-highest-ranking officer in the organization. Subordinate officers and citizens continue to submit to the authority of the new chief, just as they did to the old one, because the new chief now holds the office of chief of police. Weber reasons that the rational-legal system of legitimating authority is both highly efficient and conducive to promoting the industrial and organizational development of societies, though he also fears the capacity of such systems to dehumanize workers and to assume dangerous degrees of autonomy from political and social control.

Administrative hierarchy is a central yet oft maligned feature of a rational-legal authority system. Official offices are arranged in a pyramid-shaped hierarchy to formalize and systematize authority relationships within organizations as well as to provide for a rational system for training and promoting workers. However, along with excessive formalization, a condition that is often referred to as 'red tape,' hierarchy has been a flashpoint for criticisms of

rational-legal systems of authority. Parkinson (1957) reasons that hierarchies have a self-perpetuating logic to them, as officials in a hierarchy will seek to increase the number of their subordinates, and thus enhance their relative status in the hierarchy, far beyond the number of people required to do the work of the organization. More recently, Light (1995) observes that modern governmental organizations in the USA are becoming 'thick' in the sense that their hierarchies are as wide in the middle as they are at the bottom. Contrary to Parkinson's claim, managers in thick organizations supervise few if any direct subordinates but gain great status and authority from their formal titles, such as Principal Deputy Assistant Undersecretary for Regulatory Affairs.

2.2 Legitimacy Hybrids

Another important consideration regarding Weber's ideal-type systems of authority is the existence of hybrids. Weber never claimed that his ideal-types would describe exactly the empirical reality of authority systems, so we should not be surprised that few, if any, systems reach the purity of any of his types. Nevertheless, it is strikingly common for organizational systems to employ multiple systems for legitimating authority. This reality suggests that the legitimacy of authority is so vitally important to a government, society, or organization, that no single source is trusted entirely to ensure it.

The Westminster governing system employed by the United Kingdom as well as other countries is a case in point. The most influential body of government, the House of Commons, is organized and operates based on a rational-legal model of formal rules and hierarchy that extends from the Prime Minister (PM) through the various cabinet ministers (elected Members of Parliament who are appointed to the cabinet by the PM) and down through the executive branch of government, which is staffed exclusively by career civil servants. The PM is elected to that office by fellow party members, and remains in office as long as he or she avoids a parliamentary vote of no confidence, or the electoral defeat of the majority party. Thus, the PM tends to draw upon charismatic foundations for his or her legitimacy. When the charismatic luster of a PM's standing wanes, as it did for Margaret Thatcher in 1990, the PM's authority is questioned and he or she may be replaced (as Thatcher was by John Major) in order to avoid the fall of the government due to a successful vote of no confidence.

At the same time, the UK government includes a number of institutions that draw upon traditional authority for their legitimacy. The most obvious one is the sitting Monarch, who serves as formal head of state as well as in less formal roles as a social and moral leader of the country. The second body of Parliament, the House of Lords, has traditionally drawn its membership from the titled aristocracy and retains a limited, though occasionally pivotal, role in the approval or disapproval of initiatives passed by the House of Commons. The Judiciary exercises its authority largely based on respect for the body of precedents and practices referred to as 'Common Law,' or the traditional content and practice of law in the country. Additional examples of governments that employ interesting hybrids of traditional, charismatic, and rational-legal authority systems include contemporary Russia, North Korea, Syria, Canada, and the USA, among others.

Hybrids of legitimate authority systems are also common in individual organizations, especially due to the distinction between the formal and the informal features of an organization. Formal structures, practices, and relationships are those that are contained within the official design of the organization and its written operational rules. Informal structures, practices, and relationships are those that exist outside of these official bounds, in what has been called the *culture* of an organization (Schein 1985). After acknowledging this critical differentiation, Bennis et al. (1958) proceed to argue that authority only resides in the formal aspects of an organization. Influence that is exerted through informal organizational channels, such as personal relationships, is the exercise of power, not authority. Other prominent scholars of organizations claim that informal structures can be as well developed and predictable as formal structures in organizations, and that authority relationships exist simultaneously within both of them (Crozier 1963, Downs 1967). For example, the employee at a company who is in charge of Information Technology (IT) is likely to hold a subordinate position in the formal structure of the firm. However, because IT is critical to the work of all the other employees in the organization, including the boss, and most of those other workers are not *authorities on* IT, tasks such as computer programming and Internet trouble-shooting, as is the IT professional, in practice the IT manager at a company possesses a level of informal authority that may at times exceed the formal authority even of the firm's leader.

3. Extensions of and Alternatives to Weberian Legitimacy

3.1 Procedural Legitimacy

Weber's articulation of the ideal type rational-legal bureaucracy is merely a focal point in a long tradition of thinking about *procedural legitimacy*. According to procedural legitimacy, commands are authoritative regardless of their content, as long as proper procedures were followed in developing and issuing the commands. An early example of argumentation in the procedural legitimacy tradition is the trial of Socrates, where the great Greek philosopher was found guilty

and sentenced to death for allegedly corrupting the youth of Athens. As recounted by Plato, Socrates rebuffed the entreaties of his friends to escape the harsh sentence issued by the state, claiming that he was properly tried by his peers in a court of law based on sound procedures. Since the procedures that were followed in the trial were legitimate, Socrates argued that he had no choice but to abide by the result. The role of procedural legitimacy in rendering authority authoritative is also emphasized in more recent philosophical works such as Rawls's *A Theory of Justice* (Rawls 1971), where justice is equated with fairness, and fairness is largely determined procedurally.

3.2 The Authoritarian vs. the Authoritative

More recent scholars have developed further the concept of legitimate authority. First, they have dealt with the important distinction between the authoritarian and the authoritative. Generally, an *authoritarian* approach to authority involves the issuance of commands that are expected to be obeyed automatically; whereas, an *authoritative* style of oversight relies upon explanations for rules and justifications for orders, to help render the orders and rules themselves authoritative. Along these lines, Flathman (1980) criticizes the assumption of formal-procedural theories that F-P legitimacy guarantees obedience. Drawing from Tocqueville (1842), Flathman claims that shared social values and beliefs are required to make formal rules authoritative. Absent such shared values and norms, effective authority is all but impossible. Flathman's critique leaves open the question of whether shared norms regarding the legitimacy of authority must emerge naturally from the grassroots, or can essentially be imposed on a society by the political leadership. Nevertheless, his point is bolstered by the related claim of Simon (1957) that subordinates in a hierarchical organization will only obey orders if the substance of those orders fall within a *zone of acceptability* that is bounded by the personal values and belief system of the subordinates.

Modern and postmodern commentators on authority and superior/subordinate relationships have confronted the important question of how to shape the zone of acceptability of workers so that it includes the actions that are necessary to advance the interests of an organization. Barnard (1968) writes of the exchange relationship that surrounds employment relationships, whereby the organization's executive provides material and purposive incentives to workers in exchange for their cooperation in the necessary activities of the firm.

3.3 Horizontality and Team-based Organization

Recently, public-administration theorists have promoted the idea of horizontality and team-based organization as both an incentive to induce worker cooperation, and a more efficient and effective administrative structure for organizing work activities (Osborne and Gaebler 1992). Under the principle of *horizontality*, steep rational-legal style administrative hierarchies are flattened by eliminating many middle-management positions and by establishing working relationships horizontally across functional or geographic divisions of an agency (Ostroff 1999). Under team-based systems, such as those called for by Total Quality Management, new working groups are organized to complete specific projects, comprising workers of various formal ranks and with varying skills and expertise (Cohen and Brand 1993). A team leader is appointed, who may or may not hold the highest formal rank in the group, although all team members are expected to collaborate as equals. The authority ambiguity that is a signature characteristic of team-based organization, and perhaps its most alluring feature as a management reform, also appears to be its greatest weakness. A common complaint of participants in team-based administrative operations that fail is that no one took charge of the operation, thus leading it to founder. Also, because many team-based organizations are matrix organizations that retain the formal structure of a rational-legal bureaucracy on paper, at any stage of a project a manager might reimpose the formal structure of authority on a team, thus quashing the organization's horizontality.

4. Delegation

Horizontal organization and team-based management reforms are specific manifestation of a concept that is closely associated with considerations of authority, namely, delegation. Delegation involves the transfer of authority from a superior to a subordinate. The transfer can be permanent, but often it is temporary, and the superior retains the ability to reclaim the authority if necessary. The authority that is delegated can be general, as in when a deputy secretary of a cabinet department is authorized to make all necessary decisions in the absence of the secretary, or specific, as when a subordinate is assigned the authority to review a set of contract bids and select the winner. Delegations of authority are explicit and tend to be formally documented through general rules or specific memoranda, as when a family member or friend is granted the legal 'power of attorney' to make health care or financial decisions on behalf of an incapacitated person.

4.1 Distinction Between Delegation and Discretion

Delegated authority is similar to, but distinct from, discretion. Discretion generally refers to decision-making authority within specified bounds or parameters that officials have by virtue of their position or office. Grants of discretion tend to be more informal and more implicit than delegations of authority.

Discretion often refers to the decision as to whether or not to use delegated authority in a particular situation. For example, police officers in most societies are authorized (e.g., granted the authority) to use deadly force to defend themselves and other citizens from serious threats of violence. They are then instructed to use their discretion (i.e., judgment within certain reasonable bounds) in deciding when are appropriate or inappropriate times to use the authority that has been delegated to them. Such circumstances are referred to commonly in the public administration literature as situational imperatives in which it is either impossible or unwise for superiors (at headquarters) to explicitly issue real-time commands to their subordinates in the field.

4.2 The Principle of Subsidiarity

An important question regarding delegation is where authority best lies in a given organization and for a given decision. The principle of subsidiarit*y* holds that decision-making authority is best placed (a) where responsibility for outcomes will occur; and (b) in the closest appropriate proximity to where the actions will be taken that will produce the outcomes. Authority ought to be matched with responsibility, because one tends to use authority more judiciously if one knows that one will be held accountable for the results. Moreover, once so matched, both authority and responsibility ought to be situated as closely as possible to operations, so that decisions might be well-informed by the context of real situations. A classic example of the application of the principle of subsidiarity is the position of the Roman Catholic Church that parents should have the maximum reasonable amount of authority over, and responsibility for, the raising of their children. The nature and effectiveness with which children develop into responsible adults affects the lives and interests of parents more directly and profoundly than it does the state, which the Church advises should only become directly involved in child rearing when and if individual families have clearly failed to discharge their responsibilities.

In the field of public administration more specifically, it is generally held that strategic decisions requiring a broad perspective are best made by executives near the top of an administrative hierarchy. Such top-level managers tend to have the generalist training, experience, and political sensibilities that are necessary in order to balance competing claims in light of the overall mission and goals of the agency. Tactical decisions regarding exactly how a task is to be performed on the ground are thought to be best left to the subordinates on the scene (Wilson 1989). For example, the director of a law enforcement agency confronted with an armed standoff with a suspected criminal might instruct a sharpshooter to 'shoot the suspect if he threatens anyone's life and if you can get a clear shot.' It would then be left to the operator (the sharpshooter) to use discretion in deciding whether or not the suspect's actions were threatening, and when the sharpshooter's line of fire was sufficiently 'clear' to justify pulling the trigger.

4.3 Challenges to Effective Delegation

An actual case of the above hypothetical situation underlines the ambivalence of authority, delegation, and discretion for superiors and subordinates. The Federal Bureau of Investigation in the USA faced a similar situation in a standoff with suspected criminal Randy Weaver in Ruby Ridge, Idaho. Unfortunately, the sharpshooter was mistaken in thinking that his line of fire was clear, and he shot and killed Weaver's pregnant wife while aiming for Weaver. Blame for the tragedy was placed primarily on the executive at headquarters who had issued the order to take the shot if it was clear. In that case, responsibility for the results of the operational decision remained with the superior, even though the authority to use force and the discretion to decide when the circumstances were appropriate had been delegated to the subordinate. Such complications often lead superiors to resist delegating decision-making authority or granting wide discretion to subordinates, since they want to avoid being held responsible for decisions that they no longer control. Similarly, subordinates often resist delegations of responsibility that accompany delegations of authority, since they fear being made a scapegoat for undesirable outcomes that may not be entirely their fault.

A final challenge for the effective use of delegated authority is the fact that, as with authority in general, delegated authority is only legitimate in practice if the target of authority recognizes it as such. Going back at least as far as the medieval period, nobles used their personal seal or stamp on official letters of introduction and delegations of authority to ensure that the recipient of the document would be considered legitimate in speaking on behalf of the official or exercising the authority that was granted. Although many delegations of authority are still documented in similarly formal ways, others are not so clearly codified. Moreover, just as the citizens of modern societies tend to question openly the legitimacy of authority more readily than did their forebears, the legitimacy of delegated authority can be exceedingly tenuous today. Although authority may easily be delegated, the respect that is required in order for that delegated authority to be exercised effectively often must be hard-earned.

5. Conclusion

Authority is best thought of as a relationship between a superior and a subordinate wherein the commands or preferences of the superior become authoritative for

the subordinate as long as the authority is perceived to be legitimate and the action preferred or commanded falls within the bounds of what the subordinate considers to be acceptable. The legitimacy of authority may be grounded in the natural status of the superior, the charisma or cause of the superior, or the formal office and titles that are held temporarily by the superior. People in authority and systems of authority often draw upon multiple sources for legitimacy, and the extent to which the commands of authorities become authoritative depend upon the embrace by subordinates of certain shared values and social norms.

The delegation of authority and the granting of discretion to subordinates in deciding when such authority is best used is generally thought to be desirable so long as responsibility and authority are linked properly, subordinates are likely to possess better-informed judgment regarding the decision as to when and how to use the authority, and subordinates have reason to believe that they will not be made scapegoats for unfortunate outcomes. Authority relationships are ubiquitous. Our desire to live in a state of social cooperation to achieve shared goals demands that we continue to think long and hard about how authority and its delegation ought to organize our families, work, communities, societies, and our world.

Authority, Social Theories of

Authority is best defined as a relation that exists between individuals. A relation of authority exists when one individual, prompted by his or her circumstances, does as indicated by another individual what he or she would not do in the absence of such indication. This I will refer to as *the authority relation*. The *legitimacy* of an authority relation is what keeps the relationship from breaking down, and is the answer to the question: Why does the one who follows do as indicated by the one who rules?

The authority relation is perhaps as old as civilization itself. The very moment in which individuals began living in communities and tried to organize the tasks required for their survival gave birth to the need to coordinate the actions of many, to delegate among the members of the group, and to trust that this coordination and delegation process would occur. Any resolution of such demands, whether successful

or not, involved the constant creation and destruction of authority relations. In this context, a social theory of authority is a collection of principles aimed at understanding: (a) how the circumstances of living in a community affect the authority relations that exist among its members, and (b) how the evolution of the community itself is affected by this web of authority relations.

1. *Origins*

The intrinsic importance of the matter of understanding authority relations as they arise in society has led to a large list of authors who have written on the subject (an excellent survey of the early meaning of authority can be found in Arendt 1958). Plato, for example, wrote that only 'those who can apprehend the eternal and unchanging [aspects of reality]' (Plato 1945, p. 190) ought to occupy positions of authority. There are two reasons why Plato wanted this tall order to be met. First, he thought that only those who are enlightened in this way could understand that which is ultimately *Good*, and for Plato the exercise of authority is only legitimate to the extent that one brings society closer to that Good. The second reason has to do with the survival of the seekers for wisdom themselves. Plato argued that whenever those uninterested about matters of truth and wisdom are the rulers in a community, the conditions for the attainment of wisdom disappear, as community life is organized in a way that leads the seekers of wisdom to become corrupted and interested in other matters.

Aristotle makes no reference to a Good order, the understanding of which qualifies one to rule in a community. He notices simply that we all have *natural* talents and dispositions toward the different tasks. One of them is that of ruling wisely and effectively. Those in possession of such disposition ought to be the ones who rule. The act of ranking those in capacity to rule according to their abilities and scope leads to a hierarchical organization, with the orders flowing from the top.

These accounts of the authority relation are more postulates of how the relation ought to be rather than descriptions of what Plato and Aristotle witnessed happening in their times. And in both accounts the authority that an individual has over another is legitimized in a manner that is *external* to the individuals: there is either the sphere of the Good, or the Natural (or the sphere of God as in the case of the early Christian writers) to mediate between the ruler and the ruled. Indeed, in these accounts both ruler and ruled have minimal importance: it is the *solidity* of the external link between them that matters. As an explanation of how the authority relation operates this seems unsatisfactory because it does not provide a causal link through which the process of legitimization takes place. It is Machiavelli who first attempts to describe in a pragmatic manner how the external links stressed by the Greeks play a role in shaping social organization.

Machiavelli begins with a simple observation: that it is not platonic or Christian virtue but the seizure of opportunity that chiefly leads to a position of authority. An accurate reading of the times, Machiavelli would say, a carefully plotted plan, and the unapologetic use of force against the correctly identified enemy, are all that is necessary to position oneself as a ruler. And once in that position it is of capital importance, according to Machiavelli, to establish appropriate *foundations* for one's ruling. Machiavelli presents his ideas through the analysis of an example that continues to be of importance today: the establishment of the Roman republic. As Arendt artfully indicates, Machiavelli 'saw that the whole of Roman history and mentality depended upon the experience of foundation, and he believed it should be possible to repeat the Roman experience' (Arendt 1958, p. 108). What Machiavelli understood was that there is not one single (natural or metaphysical) foundational cosmogony against which all authority relations should be measured, but that these cosmogonies can be crafted to support the authority of a particular individual or group. Once in place, a foundational cosmogony that supports the ruler's actions can be tremendously useful for the ruler, for no individual in a community whose way of thinking is deeply rooted in it could be in a position to challenge the ruler's authority, not even conceptually. For anyone who sees this clearly it becomes no longer possible to understand the legitimacy of an authority relation as externally given. This is indeed what happened during the twentieth century as a deep crisis of authority bred in the midst of serious skepticism regarding the validity of the traditionally accepted cosmogonies.

Max Weber scrutinized the authority relation more as a scholar than as a political strategist. Weber distinguished between forms of authority according to the type of legitimacy underlying each form. According to Weber,

> the validity of the claims to legitimacy may be based on: (1) Rational grounds—resting on a belief in the legality of enacted rules and the right of those elevated to authority under such rules … (2) Traditional grounds—resting on an established belief in the sanctity of immemorial traditions and the legitimacy of those exercising authority under them … or (3) Charismatic grounds—resting on devotion to the exceptional sanctity, heroism or exemplary character of an individual person, and of the normative patterns or order revealed or ordained by [the person] (Weber 1978, pp. 213–14).

The importance of Weber's analysis does not rely on his particular classification of forms of authority but on his emphasis on the study of the legitimacy underlying an authority relation 'within the framework of the concrete actor and his actions' (Easton 1958, p. 74). This perspective is crucial because it is one from which one can begin to understand the

motivations underlying a particular *design* of an authority relation: one is invited by Weber to study the authority relation by focusing on the motivations, desires, and circumstances of those who rule. In a sense, Weber's work picks up the analysis of authority right at the point where Machiavelli left it.

2. *Contemporary Uses*

There is wide disagreement among contemporary scholars as to how the authority relation should be understood. Many even abstain from venturing operational definitions of authority such as the one presented at the beginning of this article. (An example of this is Robert Peabody's 1968 article on authority in the *International Encyclopedia of the Social Sciences*.) Disagreement stems from many sources. Consider the following examples: Arendt believes that the authority relation is an implausible one in a modern society, due to the absence of a unique and uncontradicted cosmogony upon which the legitimacy of a ruler may be founded. William Connolly agrees with Arendt in that a modern understanding of authority is problematic, but argues that the web of conventions regarding how social customs are interpreted and implemented is the modern equivalent of the premodern cosmogony. Writers like Nancy Rosenblum, in turn, argue that women and men understand relations of authority in very different ways. Rosenblum, following Carol Gilligan, argues that 'for women, the typical moral ideal is cooperation and interdependence rather than fulfillment of a formal obligation.' The implication is that 'authority, rules, and procedures will be less imperative for [women] than empathy or the impulse to be responsible for maintaining concrete personal relations' (Rosenblum 1987, pp. 116–17). Lucian Pye has said something of that sort regarding the differences between notions of authority that occur due to cultural differences between countries (Pye 1985). Stanley Milgram and others have studied extensively how deeply rooted the practice of obedience to authority figures is in the context of small groups (a survey of this literature can be found in Hare 1976). As the examples show, one is left not with one but with multiple perspectives for the analysis of the authority relation.

2.1 *The Multiple Perspectives View*

Rather than viewing the multiplicity of perspectives as a nuisance Stephen Lukes organized them in such a way that they, collectively, form an insightful view for the study of authority.

The multiple perspectives view cuts through an old problem in the analysis of authority: that of whether one can ask analytical questions about authority in a relativized manner, that is, independently of normative issues regarding the legitimacy of authority. For some, 'the nonrelativized notion is primary and is presupposed by the relativized notion. On this view, to analyze authority is to analyze legitimate or justified authority' (Lukes 1987, p. 60). For others, the relativized analysis is possible; one thing is to discover and scrutinize instances of obedience and a different one to assess their validity and desirability. From the standpoint of the multiple perspectives view, however, in identifying relations of authority one always operates at the *interpreted* level of the social interaction. Therefore, according to Lukes, 'every way of identifying authority is relative to one or more perspectives, … there is no objective, in the sense of perspective neutral, way of doing so' (Lukes 1987, p. 60). The multiple perspectives view provides a unified foundation for both analytical and normative inquiries.

The multiple perspectives that arise in the present times with regard to the analysis of authority can be associated with the different degrees of solidity attributed to social composites such as culture, language, social groups, and the individual. The previous section presented the view that it was with respect to a solid cosmogony that the premodern authority relation could be understood. With this perspective gone, Weber's analysis relies on the solidity of the internal world of those who occupy the position of the ruler in the relation. But the perspective of the ruler is one of many that can be held. Lukes identified many other relevant perspectives: that of the one who obeys, that of an external observer, that which describes the community as either formally or informally constituted, that describing the collective wisdom of the community, and the *objective* perspective (if it can exist at all) 'from which all other perspectives may be assessed' (Lukes 1987, p. 62). In a world devoid of a unique cosmogony, they may not all be the same.

According to Lukes, the multiple perspectives view shows the need of going beyond the classical Weberian analysis of the authority relation. A command, according to Weber is obeyed 'either through empathy or through inspiration or through persuasion by rational argument' (Weber, quoted by Lukes 1987, p. 63). But Weber never asks the question: What legitimizes the command in the eyes of the one who obeys? This failure to ask the question is unproblematic when the ruler's perspective happens to be shared by rulers and followers alike. While this is a tenable point of view on many occasions, this identification of the perspectives between rulers and followers is anything but solid, as the modern study of rebellion shows. Weber's analysis is therefore deemed incomplete due to his failure to see anything but the perspective of the 'ruling class' as important in understanding authority relations.

Richard Friedman offers an approach that includes the perspectives of both the ruler and the follower. According to Friedman, for there to be a relation of

authority one needs to understand the common ground that exists between a ruler and a follower because it is this common ground that enables the obedience. In Lukes' words: 'Legitimation claimed and the according of legitimacy coincide in a shared recognition of entitlement' (Lukes 1987, p. 65). Lukes sees two problems with this point of view. First, one can think of cases where authority seems to go unrecognized by either the ruler or the follower. Richard Flathman provides a solution to this problem. He suggests that the authority relation belongs to a wider web of practices and beliefs that provide meaning to all relations in a community, even unwittingly (see Lukes 1987, pp. 66–7). The second problem, according to Lukes, is that Friedman gives no indication as to how to distinguish between the common grounds that enable obedience from the ones that do not. In other words, it still leaves unanswered the critical question regarding obedience: What legitimizes the command in the eyes of the one who obeys?

When is, then, authority legitimate? Joseph Raz advances the *dependence thesis*, namely that 'all authoritative directives should be based, in the main, on reasons which already independently apply to the subjects of the directives and are relevant to their action in the circumstances covered by the directive' (Raz 1990, p. 125). In other words, authority is legitimate when there are reasons, from the follower's perspective, that already compel the follower to obey. Obedience is then investigated from the point of view of the motivations, desires, and circumstances of both the ruler and the follower.

2.2 The Game Theoretic View

The point of view put forward by Raz is an advance both on Weber, as it includes the perspective of the follower as well as that of the leader, and on Friedman, as it displays all the elements necessary to investigate the question of legitimacy. To see this it is convenient to adopt the terminology and analysis of *game theory* (for an introduction to this mode of social analysis see Dixit and Skeath 1999). In a basic game theoretic formulation of an interaction between individuals one first begins by identifying the choices available to each, and then by delineating how the situations (that is, the motivations, desires, and circumstances) of all those involved affect each individual's choice. The goal is to be able to understand the choices of all individuals in the interaction by focusing on what beliefs are reasonable for each individual to hold about what will unfold in the interaction given each individual's situation. The beliefs held by the individuals in an interaction are in equilibrium when they are not contradicted by the choices that they justify given each individual's situation. While controversial, the game theoretic mode of analysis is gaining recognition as a valid and powerful mode of social analysis. See Bates et al. (1998) and Binmore (1994, 1998) for examples of game theoretic applications to the fields of political science and political philosophy, respectively. For these authors, social composites such as language, culture, and social groups are as solid as the equilibrium beliefs underlying the individual choices that, collectively, support the social composite in question.

The perspective given by beliefs that are in equilibrium is one with respect to which one can evaluate the plausibility and legitimacy of an authority relation: an individual can be in a position of authority with respect to another individual to the extent that there are equilibrium beliefs that support choices that an analyst of the relation denotes as 'ruling' for the ruler and 'following' for the follower (Zambrano 1999). Hobbes understood this well when he wrote: 'The power of the mighty hath no foundation but in the opinion and belief of the people' (Hobbes, quoted by Binmore 1998, p. 457). Equilibrium beliefs: (a) are at the interpreted level of the social interaction (Lukes); (b) serve as the common ground that sustains an authority relation (Friedman); (c) are determined with respect to both the ruler and the follower's situation (Raz); and (d) are part of the web of practices and beliefs that provide meaning to all relations in a community (Flathman).

Now, the problem is: 'how are we to ascertain what the reasons that apply to authority's subjects are and in what 'success' in acting on them or guiding us to them consists?' (Lukes 1987, p. 69) In other words, can we recover equilibrium beliefs that legitimize the authority relation by looking at the situation of the individuals involved? The answer seems to be: in general one could recover *many* such equilibria, not simply one. How is one to decide on which leads to the right justification? According to Lukes, the answer seems to be: there is no right justification. Different justifications suggest themselves depending on the perspective that one uses to interpret the authority relation. *There is no single social theory of authority*; there are only multiple perspectives that are plausible and valid to the extent to which they are equilibrium beliefs that legitimize the authority relations in a community. In Michel Foucault's words: 'Each society has its regime of truth, its 'general politics' of truth: that is, the types of discourse which it accepts and makes function as true' (Foucault 1980, p. 131).

The game theoretic analysis of authority helps us understand the kinds of belief systems that could support the authority of one individual over another. But there where its strength lies, lies its weakness as well. As mentioned before, in this mode of analysis one evaluates the plausibility of a belief system by checking its consistency with the choices that it justifies given each individual's situation. There are two problems with this. First, the analysis is silent as to how beliefs configure themselves in equilibrium proportions. One is at the mercy of history, as it perhaps should be, to teach us about how different institutions of authority

have emerged in different cultures. Part of the narrative of the evolution of authority can be thought of as occurring spontaneously (Aristotle), but part of its narrative can only be understood with respect to a design functional to some (Machiavelli). Game theory provides only a language in which the story can be parsimoniously told and formally analyzed.

2.3 The Cognitive Science View

The second problem is more severe. Just as recent social science challenges the solidity of social composites such as truth, language, culture, social groups, and authority (as seen in this article), recent research on cognitive science challenges the solidity of individuals themselves. As Francisco Varela puts it:

> What we call 'I' can be analyzed as arising out of our recursive linguistic abilities and their unique capacity for self-description and narration … the selfless 'I' is a bridge between the corporeal body which is common to all beings with nervous systems and the social dynamics in which humans live. My 'I' is neither private nor public alone, but partakes of both. And so do the kinds of narratives that go with it, such as values, habits and preferences (Varela 1999, p. 62).

This poses problems for a game theoretic understanding of authority, since this mode of analysis is grounded on the solidity of the individual and his or her cognitive situation.

Notice, however, the similarities between both approaches: the self, just as the other social composites, arises at the interpreted level of a collection of behaviors centered on a single body and its social history. Varela himself points out this similarity: 'whenever we find regularities such as laws or social roles and conceive of them as externally given, we have succumbed to the fallacy of attributing substantial identity to what [like the self] is really an emergent property of a complex, distributed process mediated by social interactions' (Varela 1999, p. 62). For Varela, the self, and the authority of a self over another self, are notions that give meaning to each other through their arising in the context of a collection of bodies and social histories in a way that preserves the identity of the selves and of the relations between them. In other words, they are equilibrium beliefs of a larger game, with respect to which the actions of all can be legitimized; and those actions, in turn, reinforce the apparent solidity of the authority link, and of the individuals themselves.

Autism, Neural Basis of

Autism is recognized as a genetic disorder with a profound impact on the development of the central nervous system. Affected individuals display a variety of behavioral and neuropsychological deficits. Autism strikes before the age of three years, and it affects boys at least four times as often as girls. Its early onset, symptom profile, familial pattern, and chronicity strongly argue for a biological basis, and in fact, there is now substantial data implicating core biological mechanisms. However, there is still no biological marker that is pathognomonic of autism, that is, invariantly present in all cases, but absent in the normal population. Scientific progress has been slowed by changing diagnostic standards during the last two decades of the twentieth century, making it difficult to accumulate a coherent corpus of knowledge, and by clinical heterogeneity that appears to be inherent to the disorder. Current conceptualizations emphasize a broader autism phenotype that includes Asperger syndrome and subsyndromal variants. It is not known whether these autism spectrum conditions share common neural foundations, but given their highly overlapping symptomatology, it is generally assumed that they do.

Research with modern neuroimaging techniques such as magnetic resonance imaging (MRI), and positron emission tomography (PET) is beginning to map out the neural systems affected by autism. However, this work is still in its infancy. Functional MRI (fMRI), in particular, promises to speed the discovery process, because it is noninvasive and applicable to children of all ages. Recent progress has been made in identifying select brain systems that appear as part of the pathophysiology. These include brain areas responsible for emotional and social functions, perceptual systems specific to face and affect recognition, and cognitive systems involved in understanding the intentions of others. Working models of the pathophysiology of autism commonly include the amygdala as a key component of a distributed cortical-subcortical system, but other competing models exist. Moreover, attention is now focused on the earliest stages of child development, and many now believe that a set of initial neural deficits may be compounded by transactions with the social environment during the first years of life, thereby creating a more widespread neural pathology.

1. *Core and Associated Features*

Autism was first described by Leo Kanner, a psychiatrist at The Johns Hopkins University, in 1943. Although his patients suffered from a multitude of problems, Kanner's description emphasized the social and emotional features of the disorder. He described persons with autism as suffering from an inborn deficit in their ability to make 'affective contact' with other people. The prevailing zeitgeist in the years after Kanner's report provided fertile ground for unwarranted speculation about cold and distant parenting styles causing autism (i.e., the 'refrigerator mother' theory). Today autism is recognized as a biologically based disorder.

Modern conceptualizations continue to highlight the social–emotional impairments in autism as the core deficit. European and American diagnostic criteria for autism require a triad of deficits that include developmental problems with communication, reciprocal social interaction and the presence of repetitive, rigid and odd behaviors. Of these three, the profound deficit in social functioning is the unique feature that distinguishes autism from other neuropsychiatric disorders.

1.1 *Developmental Course and Neural Hypotheses*

The social, language, and behavioral problems that occur with autism suggest that the syndrome has affected a functionally diverse and widely distributed set of neural systems. At the same time, however, the affected systems must be discrete, because autism spares many perceptual and cognitive systems; autism is not incompatible with superior skills in many areas, including the visual arts, music and even general intelligence. Even though the full syndrome likely involves 'hits' to multiple systems, it remains possible that the initial insult is localized. Attempts to explain the neural basis of autism should take close account of the developmental course. Autism is never identified at birth. In fact, the large majority of cases go unnoticed during the first year of life. One possibility is that the emergence of the syndrome toward the end of the first year and into the second is an unmasking of a complex set of congenital liabilities. However, the rule of parsimony demands that simpler alternatives first be considered. There is important evidence on this score from animal models of autism. These show that an initial insult to one system can propagate to affect other systems during the earliest months and years of development. These two developmental possibilities are currently under active investigation.

2. *Etiology*

2.1 *Genetic Factors*

Autism is a familial disorder. Statistical modeling of twin and family data suggests that autism is one of the most strongly genetic of all the neuropsychiatric disorders. Specific susceptibility genes, however, have yet to be discovered. When autism is more broadly

defined, identical twins show a concordance rate of about 90 percent, compared to a concordance rate in fraternal twins of 10 percent or less. Autism is thought to be caused by a small number of genes acting in concert, rather than any single gene. Preliminary data from family linkage studies suggest that susceptibility genes for autism may lie on chromosome 7, with some other evidence also pointing to chromosome 15.

2.2 Medical Conditions Associated with Autism

In addition to polygenic pathways to autism, perhaps 10 percent of all cases are caused by a known medical condition, such as Tuberous Sclerosis, Fragile X syndrome, and prenatal illnesses (e.g., rubella). While children with autism are at a somewhat greater risk to endure pre- and peri-natal hardships, this mechanism explains only a tiny fraction of the cases. Moreover, autism is associated with other conditions that are not implicated as causes of the disorder, and that are not mandatory features of the disorder. For example, about three-quarters of individuals with autism are mentally retarded, and many never develop functional language. About half of all lower functioning persons with autism also develop a seizure disorder, often around adolescence, a time when neural connections are typically instantiated through a final wave of neural pruning. Some individuals, however, have normal or even superior intellectual development, and thus general intellectual impairment is not a necessary component. General intellectual impairment, therefore, can be a barrier to specifying the neural basis of the disorder. Moreover, those with high IQs are not necessarily less impaired with regard to the defining triad of symptoms. The high rates of mental retardation and seizure disorder, nevertheless, demand a neural explanation and it suggests that the pathobiological mechanism of autism is such that 'collateral' damage is common.

3. Neural Theories

Nearly every neural system in the brain has been proposed at some point as the cause of autism. Theories typically derive from beliefs about the most salient behavioral and psychological features of the disorder. For example, those who emphasize difficulty with complex information processing as the principle characteristic of autism, postulate widespread cortical abnormalities sparing early sensory processes as the neural basis of autism. Alternatively, those who focus on the emotional deficits and their role in social difficulties often highlight the limbic system in the pathogenesis of autism. Currently, the research data suggest that select aspects of the temporal and frontal lobes, and portions of the amygdala are key nodes in systems affected by autism. These data are not yet specific enough to point to any one theory in clear favor over others.

Before reviewing the research evidence, it is important to note that clinical examination and laboratory tests have mixed success in identifying anomalies. Routine clinical brain scans, including MRIs to picture brain anatomy and Single Positron Emission Computed Tomography (SPECT) to assess brain metabolism typically fail to document neurological problems in the vast majority of patients. It is likely that the detection rate can be improved once research better defines the specific systems affected, allowing implementation specific image acquisition and analysis protocols in clinical practice. On the other hand, up to one third of all persons with autism develop seizures at some time in their life, often in adolescence, and these can be documented with electroencephalography (EEG). Absent of epilepsy, the majority of persons with autism have abnormal EEGs. The abnormalities are often bilateral without a consistent regional focus. Moreover, EEG evoked potential studies consistently show deficits in cognitive information processing components, such as the P3, but intact early components. These results have been interpreted to mean that autism is a disorder of complex information processing that spares early perceptual processes.

3.1 Brain Size, Functional Connectivity, and Cortical Morphology

One of the more intriguing findings to emerge in the past few years is that overall brain size appears to be increased in autism (by about 5 to 10 percent on average). It is not yet understood whether all brain regions and systems are equally affected by the expansion. It also is not clear how whole brain enlargement would serve as a risk factor for autism; it could be merely a marker for a disturbance in the fine structure of the brain that actually causes autistic symptoms. Increased brain size might come at the expense of interconnectivity between specialized neural systems, giving rise to a more fragmented processing structure. In fact, some evidence suggests that the corpus callosum, the major fiber pathway between the hemispheres, is reduced in size, in autism. Moreover, one PET study found a reduction in coordinated brain activity. Less neural integration would be consistent with Uta Frith's (1989) influential theory that attributes autistic symptoms to a lack of 'central coherence,' a processing style that makes integration of parts into wholes problematic (see *Autistic Disorder: Psychological*).

Debate continues as to whether the growth abnormality is postnatal or prenatal. Specifying the developmental epoch with the most abnormal growth rate would provide better clues as to the underlying mechanism. An origin at particular times of fetal brain

development, could suggest, for instance, disturbances in the regulation of neuronal or glial cell proliferation, neuronal migration, or apoptosis (programmed cell death). Prenatal origins of disturbed brain development have been suggested by studies finding an increased frequency of morphological abnormalities of the cerebral cortex in autistic individuals (e.g., regional alterations in the size and number of gyri). Such abnormalities stem from disturbances in neuronal migration during fetal brain development. These gross neuroanatomical abnormalities are much more common among autistic individuals with mental retardation, but still occur in a minority of cases. Thus, these findings do not appear to be specific to the core social deficit in autism.

3.2 Posterior Fossa Abnormalities

Postmortem studies of a small number of persons with autism have revealed a range of abnormalities, including a significant decrease in the number of Purkinje cells and granule cells in the cerebellum (see Bauman and Kemper 1994). The precise nature of these abnormalities, including a lack of gliosis indicative of scarring, suggests a prenatal origin. A focus on the cerebellum would be consistent with some neuroimaging evidence. A variety of posterior fossa abnormalities have been reported in autism from MRI. These include abnormalities of the pons, fourth ventricle, and cerebellar vermis, the midline portion of the cerebellum. One influential set of findings ties autism to hypoplasia of the neocerebellar vermis, but this abnormality has not consistently been observed across studies. Moreover, it seems likely that posterior fossa abnormalities are not specific to autism, but rather evident in many persons with developmental disabilities and mental retardation. Thus, specificity of the findings for the core autistic features seems doubtful.

3.3 The Amygdala and the Temporal Lobe

Of the specific brain regions implicated in the pathobiology of autism spectrum conditions, none has attracted as much interest as the limbic system, especially the amygdala and its functional partners in the temporal and frontal cortices. The limbic system lies largely within the medial and ventral aspect of the temporal lobe, providing a girdle around the phylogenetically older, deep brain structures. The amygdala, in particular, plays a critical role in emotional arousal, assigning significance to environmental stimuli, and mediating the formation of visual-reward associations or 'emotional' learning.

Postmortem examination of the brains of persons with autism finds consistent evidence for abnormalities in size, density, and dendritic arborization of neurons in the limbic system, including the amygdala, hippocampus, septum, anterior cingulate, and mammillary bodies. There is a stunting of neuronal processes and an increased neuronal packing density, suggesting a curtailment of normal development. These affected regions are strongly interconnected, and together they comprise the majority of the limbic system. The limbic system, especially the amygdala, is part of a neural structure that supports social and emotional functioning. These postmortem findings, therefore, are often heralded as the first good entrance points for understanding the pathobiology of the autism spectrum disorders.

There is supportive evidence for an amygdala theory of autism from the experimental monkey work of Jocylene Bachevalier and co-workers (Bachevalier 2000). She has produced an animal model of autism by lesioning the amygdalae of monkeys shortly after birth. Across the first year of life, these animals developed patterns of behavior reminiscent of autism, that is, social isolation, lack of eye contact, expressionless faces and motor stereotypies. Similar lesions in adulthood fail to produce autistic-like sequelae. These findings are consistent with the idea that autistic symptoms are in part a function of faulty, early emotional learning mediated by limbic system pathology. Moreover, as monkeys with early lesions to the amygdala and surrounding entorhinal cortex mature into adulthood, additional abnormalities are found in the neurochemistry of the frontal cortex and in the frontal—subcortical regulation of dopaminergic activity. Thus, early discrete damage can produce widespread abnormalities across development.

Persons with autism have deficits in their ability to recognize and discriminate faces, and to understand facial expressions (Klin et al. 1999). Functional neuroimaging and lesion data show that the fusiform gyrus, a region on the underside of the temporal lobe, is normally a nexus area for face perception, while neighboring regions in the posterior aspects of the middle and superior temporal gyri are important for reading facial expressions and social intent through eye gaze direction. Several fMRI studies have now shown hypoactivation of the fusiform gyrus during face perception tasks (e.g., Schultz et al. 2000). Preliminary evidence also links hypoactivation of the amygdala and lateral temporal cortices to autism. One hypothesis is that the principal pathology in autism resides in limbic regions, and that disturbance in affective orientation early in life causes a cascade of neurodevelopmental events, including failure to develop perceptual competence for faces and for visual and auditory displays of emotion.

Other evidence implicating the temporal-amygdala system in autism includes case studies of patients with temporal lobe lesions and autistic-like sequelae and reduced functional activity on SPECT scans in the temporal lobes in autism. An association between tuberous sclerosis and autism has long been recog-

nized. More recently, autism has been specifically related to tubers of the temporal lobe vs. tubers elsewhere in the brain.

3.4 Frontal Lobe Involvement

Aspects of frontal lobe integrity and function have been implicated in the pathogenesis of autism. Older studies using lower resolution neuroimaging techniques reported general hypoactivation of the frontal lobes. Functional neuroimaging data collected in the last decade are converging to show that subregions of the prefrontal cortices with especially strong connectivity to limbic areas are critical for 'social cognition,' that is, thinking about other's thoughts, feelings and intentions. Deficits in such 'theory of mind' abilities are common in autism (see *Autistic Disorder: Psychological*). Theory of mind ability has been linked to functional activity in the medial aspect of the superior frontal gyrus (primarily Brodmann area 9) and to prefrontal cortex immediately above the orbits of the eyes (i.e., orbital frontal cortex). The orbital and medial prefrontal cortices have dense reciprocal connections with the amygdala providing the architecture for a system that could regulate social-emotional processes. Bilateral lesions to orbital and medial prefrontal cortex lesions cause deficits on theory of mind tasks. Moreover, nonhuman primate studies have documented abnormal social responsivity and loss of social position within the group following lesions to orbital and medial prefrontal cortex.

Preliminary functional imaging evidence in autism spectrum conditions suggests altered functional representation in prefrontal cortex regions during theory of mind tasks. Moreover, medial prefrontal dopaminergic activity as measured by flourine-18-labeled fluorodopa PET has been found to be significantly reduced in autism. Reduced glucose metabolism during memory activities has also been reported in a subdivision of the anterior cingulate gyrus, a region that lies along the medial surface of the frontal lobe.

3.5 Hyperserotonemia

The best-documented biological marker of autism is elevated blood level of the neurotransmitter serotonin, found in 25 to 30 percent of the patients. However, the association between autism and platelet hyperserotonemia is complicated by the fact that peripheral and central serotonin levels are independent, with different synthesis and metabolism. Other evidence suggestive of a possible role for serotonin includes the fact that powerful psychiatric drugs that affect the serotonergic system are frequently used in autism with some benefits. However, these medications, known as selective serotonin uptake inhibitors (SSRIs) are not effective for the primary symptoms of autism, but rather are of modest help for some of the secondary symptoms (such as aggression and stereotypies). Moreover, preliminary neuroimaging data from PET suggests that persons with autism may have altered serotonin synthesis capacity; this could disrupt synaptic connectivity in the sensory cortices. Other types of neurochemical analysis in the blood, urine and spinal fluid shows inconsistent abnormalities, and psychopharmacological efforts related to the compounds have generally failed to show much benefit in autism.

4. Future Directions

The major findings to date on the neural basis of autism concern aspects of the limbic system, and functionally related and connected regions of the orbitomedial prefrontal cortex, and visual areas of the temporal lobe. While good progress toward understanding the neural basis of autism has been made in recent years, much work still needs to be done. fMRI is revolutionizing psychiatry and systems level neuroscience, and there is little doubt that this exciting new tool will be a powerful device at the disposal of autism researchers in the years to come. It ultimately should enable researchers to define dynamic brain processes that give rise to each specific symptom and feature of autism.

A challenge for research in this area will be to adapt *in vivo* neuroimaging techniques so that they are applicable to the developing infant and toddler. Studying younger children may be a prerequisite for a comprehensive understanding of the neural basis of autism, because the disorder evolves into its full form in rather a short period of time around the second year of life. Capturing this process would clearly be valuable. Moreover, newer MRI techniques, such as diffusion tensor imaging, which spotlights previously unresolved fiber pathways intermingled in the brain's white matter, could also prove quite valuable for this area of research. It could be especially important for studies of young children, since diffusion imaging is more forgiving of patient movement than fMRI, and does not require compliance with a task.

Finally, with the completion of the first complete mapping of the human genome, the promise of identifying susceptibility genes for autism in the near future seems likely. Genetic advances naturally will lead to novel treatments, some of which will be instituted early in brain development. This will open a host of new research problems and opportunities, including characterizing the effect of genes and gene combinations on the developing brain.

Autistic Disorder: Psychological

Autism is a disorder of social and communicative development. Although biologically based, with a strong genetic component, autism is diagnosed by behavioral criteria. Qualitative impairments in social interaction and communication, with rigid and repetitive interests and activities, are necessary features for diagnosis of 'autistic disorder' according to current manuals. This set of core features, however, covers a spectrum of behaviors, and the manifestation of autism varies greatly with age and ability, from the silent, aloof, and developmentally delayed child, to the verbose, overfriendly, and intelligent adult. With recognition of this spectrum, the incidence of autism is estimated at one per 1,000, and the male to female ratio at least 3:1. Most of these individuals will also have general learning difficulties and low IQ, but a striking feature of the disorder is the existence of otherwise highly intelligent people with autism who nevertheless show severe social and communicative impairments and a lack of flexible behavior.

Autism typically is diagnosed around three years or later, although recent research has suggested that screening at 18 months may be possible. Young children with autism typically fail to communicate by showing and pointing, fail to follow others' eye gaze, and do not develop pretend play. Autism lasts throughout life, and although there is no cure, the disorder is not degenerative and developmental progress and compensation can continue into adulthood, especially where specialist educational intervention is given.

1. History

There is little doubt that autism has always existed. Frith, among others, has pointed to evidence from folktales and 'wise fools' to show the presence of people with autistic features throughout history (Frith 1989). Autism was first named, however, by Leo Kanner in 1943, who reported a group of puzzling children who showed as core impairments an 'extreme isolation and the obsessive insistence on the preservation of sameness.'

Following Kanner's first description, autism (then also referred to as childhood schizophrenia or childhood psychosis) quickly became established as an important clinical entity in child psychiatry (see *Child and Adolescent Psychiatry, Principles of*). In the absence of knowledge of biological causes, and prompted perhaps by the normal physical appearance of the children, the first interest in autism focused largely on psychogenic explanations. However, psychological and epidemiological work in the 1960s and 1970s, pioneered by Beate Hermelin and Neil O'Connor, established autism firmly in the discipline of mental handicap, separating it from mental illness in general and from schizophrenia in particular. The idea that you might make your child autistic by being an unloving 'refrigerator mother' has received no support from research.

Epidemiological work in the late 1970s, by Lorna Wing and Judith Gould in the UK, established autism as a true syndrome, marked by a triad of reliably co-occurring impairments in socialization, communication, and imaginative or flexible behavior. They also introduced the notion of an autism spectrum, which included not only children who were withdrawn and silent (like many of Kanner's cases) but also children who showed their social impairment in unusually passive, or in active-but-odd social behavior, and their communication impairment in pedantic, overformal

speech (see Wing 1996). Wing's triad formed the basis for the criteria set out in subsequent diagnostic manuals, and raised awareness that the manifestation of autism varies with age and ability.

2. *Differential Diagnosis and Asperger's Syndrome*

Current diagnostic schemes place autistic disorder within the category of pervasive developmental disorders (disorders characterized by severe impairments in more than one area of development), which also includes Rett's disorder, childhood disintegrative disorder, and Asperger's disorder. Other categories from which autism is distinguished include disorders of receptive language (with secondary emotional/social consequences) and early onset schizophrenia. Current descriptive categories, whose validity remains controversial and whose relation to autism is as yet unknown, include nonverbal learning disability, schizotypal personality disorder, and semantic–pragmatic disorder.

Research recently has focused on the distinction between autism and Asperger's syndrome—a disorder taking its name from Hans Asperger, a Viennese clinician who described children similar to Kanner's cases contemporaneously. The status of Asperger's syndrome as a separate entity is somewhat contentious. However, present consensus is that this syndrome falls at the high ability end of the autism spectrum, but deserves its own label because the course of the disorder, and consequently prognosis and management, may diverge somewhat from typical autism. People with Asperger's syndrome tend to be less aloof, more socially interested, more verbal in a pedantic style, and tend to have special interests to the point of obsession (see Frith 1991). Diagnostic manuals, which introduced 'Asperger's disorder' as a category in the early 1990s, stipulate that cases must show social impairments and restricted interests as for autism, but should not show significant delay in language or cognitive skills (distinguishing them from classic autism). This latter criterion is problematic, in view of developmental change and late diagnosis. The only epidemiological study to date, by Ehlers and Gillberg in Sweden, reflects this difficulty in using strict criteria, but estimated the prevalence of Asperger's syndrome at 3–7 in 1000 school-age children, with a male to female ratio of, perhaps, 8:1.

3. *Etiology*

In contrast to early psychogenic explanations of autism, the disorder is now considered among other organically caused developmental disorders. Around three quarters of individuals with autism also have general developmental delay (i.e., IQ below 70), epilepsy is present in approximately a third of all cases, and a number of different medical disorders are associated with autism (e.g., Fragile-X syndrome, tuberous sclerosis).

Because autism (at least in its nuclear form) is a rare disorder, and because people with autism are unlikely to have children, the familial clustering of autism was at first overlooked. However, siblings, and especially identical twins, of people with autism do have a significantly raised incidence of the disorder. There are suggestions, too, that some relatives may show mild features reminiscent of autism, and these may have prompted the erroneous notion of 'refrigerator' parents causing autism.

Many mothers report that the pregnancy of their child with autism was affected by pre- and perinatal problems. The causal status of these adverse factors is uncertain, however; they may be effects, rather than causes, of some pre-existent abnormality in the child. Various infectious agents (including vaccines) have been suggested to play a role in the etiology of autism, although it appears at present that such agents could account for only a small number of cases.

There has been a great deal of research aiming to discover the brain basis of autism, with biochemical, anatomical, and neurological investigations. Almost every brain region has been proposed, at one time or another, as the site of the core anomaly in autism. Current contenders include the frontal lobes, limbic system, and cerebellum. To date, however, findings are equivocal and the specificity to autism of many of the features must still be in doubt, since appropriate control groups equated for degree of developmental delay, are often missing.

4. *Psychological Theories*

While limited progress has been made in discovering what is different in the brains of those with autism, much more has been discovered about the mind in this condition. The rise of psychological accounts can be traced back to Hermelin and O'Connor, who first contrasted autism with other forms of mental and sensory handicap. Subsequent theoretical approaches to autism have followed O'Connor and Hermelin in looking for what is specific to autism, in contrast to general intellectual impairment. At present, the major psychological accounts can be divided into those that propose a specific social deficit, and those that posit a core non-social anomaly at the root of autism (see Happé 1995).

4.1 *The 'Theory of Mind' Account*

In the 1980s interest swung from investigations of language, perception and memory, to explorations of the social impairments in autism. The task for psycho-

logical theories became to explain the concurrence of imagination, communication, and socialization impairments. Perhaps the most influential of these attempts has been the 'theory of mind' deficit account; the hypothesis that people with autism are unable to represent the mental states (e.g., beliefs, desires) of themselves and others, and to understand and predict behavior in terms of these states. Baron-Cohen, Leslie, and Frith in 1985 proposed such a deficit on the basis of failure on a simple test of theory of mind, or 'mentalizing'; children with autism, unlike normal 4-year-olds or children with Down's syndrome, were unable to predict where a character would look for an object moved in their absence. Instead of taking into account the character's mistaken belief about the object's location, the children with autism answered on the basis of the real state of affairs (see Frith 1989). This failure to attribute mental states independent of reality and of the child's own belief, has now been replicated in a number of studies. Importantly, children and adults with autism succeed on closely matched tasks not requiring theory of mind (see Happé 1995).

The notion of a deficit in mentalizing seems to account well for the triad of impairments. Children with autism lack insightful social reciprocity, but often like company and physical contact. A person with autism may transmit a message accurately, verbatim, but fail to recognize who does and does not already possess the information. Pretend play, in which real and imagined states are contrasted, is strikingly absent in autism, but physical play is seen. A theory of mind deficit thus accounts for the core features of autism, while allowing intact skills in other areas. Whether the mentalizing deficit is itself the result of impairments in earlier social processes (e.g., emotional interaction, imitation, sharing attention), is as yet unclear (see Baron-Cohen et al. 1993).

To date, a delay in theory of mind development appears to be a universal feature of autism. A minority, especially those with Asperger's syndrome, do develop some understanding of other minds in adolescence, perhaps using their general intelligence to puzzle out what others' think and feel. There is considerable interest in trying to teach theory of mind to children with autism, although to date generalization of these taught skills has been limited. However, the use of concrete props and supports, such as cartoon strips and thought bubbles, appears to be effective in helping some children develop greater social understanding (see Howlin 1998).

4.2 Explaining Nonsocial Features

The interest in social impairments in autism during the 1980s left unexplained the nonsocial aspects of the condition; clinical features such narrow interests, insistence on sameness, and special skills. More recently, psychological accounts have attempted to encompass these aspects of autism. One nonsocial feature that forms a diagnostic criterion for autism is restricted and repetitive behavior. Researchers have been struck by the parallel between the perseverative and repetitive behavior in autism and that seen in patients who have suffered injury to the frontal lobes of the brain—and this has given rise to a theory of autism as a disorder of frontal functions. Neuropsychological studies suggest that the frontal lobes are responsible for higher cognitive processes of control, planning and flexible adaptive behavior, so called 'executive functions.' There is evidence that individuals with autism, even those of normal IQ, have problems in at least some of these functions (Russell 1997). Executive function impairments are not, however, specific to people with autism. A variety of other groups with developmental disorders also show these difficulties (e.g., Attention Deficit disorder, Tourette's syndrome). How these disorders—so different in clinical presentation—differ in their executive impairment is as yet unclear.

Problems in executive functions cannot explain all aspects of the nonsocial impairments in autism and, more importantly, cannot explain why people with autism are so good at certain things. From the beginning, autism has been linked with special skills in rote memory, jigsaw-type puzzles, and the 'savant' abilities in calculation, drawing, and music. Savant skills, superior to the individual's other functioning or even to normal performance, occur in approximately 1 in 10 people with autism—much higher than in other groups. No current deficit account of autism can explain why people with autism tend to be so unusually good at certain things.

Different from other theories of autism, in that it does not present a deficit account, is the notion of weak 'central coherence.' It is striking that normal and mentally handicapped groups process meaningful and patterned information far better than random and meaningless stimuli. This benefit from meaning, which Frith (1989) termed 'central coherence,' appears to be reduced in autism. For example, while ordinary children recall meaningful sentences better than random word strings, children with autism are almost as good at recalling the latter as the former. In the same way, while normal subjects typically extract the gist of a passage or story while forgetting the details, people with autism may retain the actual words used but fail to extract the meaning.

The idea that people with autism make relatively little use of context and pay preferential attention to parts rather than the whole, can go some way towards explaining the assets seen in autism, as well as some of the deficits. So, for example, people with autism may be good at certain sorts of jigsaw-type tests because they can ignore the whole picture and focus on the specific details. Savant skill in music may begin with a tendency towards perfect pitch, as a result of attention

to details (actual pitch) rather than wholes (melody, irrespective of specific pitch). Frith and Happé have suggested that this 'weak central coherence' has both benefits and disadvantages, and as such is better characterised as a cognitive style rather than deficit. Indeed, it may be this aspect of autism that is transmitted genetically—some fathers of children with autism also excel on visual or verbal tasks where detail-focus is advantageous (Happé 1995).

It remains to be seen how these three psychological accounts fit together, or which anomaly is primary. Possible causal relations between executive functions, social insight, and cognitive style are being investigated. It remains a possibility, however, that autism is a disorder of multiple primary psychological deficits, or that different subgroups within the spectrum show different core deficits.

5. *Treatments and 'Cures'*

Given the devastating impact which autism can have on the individual and family, it is not surprising that every year sees a new claim for a miracle cure, be it biochemical or behavioral. Such claims have so far failed to find objective support, although significant improvement and compensation can occur. Programs of behavioral management can be successful in controlling problem behavior, and educational approaches that give structure and concrete prompts in a stepwise program are demonstrably effective. Use of visual material has proved helpful for the many children with little or no language, and self-injurious behavior and distress can be reduced by making environmental events and social demands easier to understand and predict (Howlin 1998).

A feature of the 1990s has been the recognition of autism in very able people, and the introduction of the Asperger's syndrome diagnosis. This has led to the emergence of groups of highly articulate individuals who can speak about their autism. This is a new voice, which in many cases challenges the 'neurotypical' perspective; some individuals with autism/Asperger's syndrome would strongly resist the notion of 'cure.' Clearly there is a considerable gray area between clinical-level difficulties and personality type—it is likely that a great many people with Asperger's syndrome never come to clinical attention.

6. *Impact and Importance*

In the last quarter of the twentieth century autism has attracted more media interest and research attention than would be warranted simply on the basis of its incidence in the population. This, no doubt, has a number of causes; at a personal level, autism challenges us to look at what we consider fundamentally human—social interaction, communication, and imagination. Autism also tests a number of mainstream psychological notions. The existence of savant skills, for example, in otherwise severely intellectually impaired individuals challenges our notions of general intelligence. The fact that people with autism may, on the other hand, have very high IQ while lacking social insight and a sort of cultural common sense, suggests that 'theory of mind,' and perhaps something like social intelligence, is quite distinct from general reasoning ability and knowledge acquisition. Thus, autism has become a test case for a number of theories of normal development.

7. *Future Directions*

Autism is the focus for research using cutting-edge scientific methods. The search is on for genes acting in the disorder. Advising families on the meaning of genetic susceptibility will, however, be problematic. At present we do not know why one child develops severe autism requiring life-long care, while another becomes an intelligent but socially impaired adult, whom colleagues might merely call eccentric.

Sophisticated brain imaging technology will give us pictures of brain functioning, to compare the developmental trajectory in autism and normal development. This may highlight brain regions for further biochemical investigation and, ultimately, connection to genetic anomalies. In the meantime, educational approaches are the most likely source of hope, with earlier identification and intervention reducing the vicious cycle in which children with autism retreat from an incomprehensible social world, thus losing opportunity to learn about minds and feelings. Finally, recognition of the unique skills and perspective of people with Asperger's syndrome should bring an appreciation of the positive aspects of autism, and the value and rights of people across the autism spectrum.

Automaticity of Action, Psychology of

Automatic thoughts and behaviors are ones that occur efficiently, without the need for conscious guidance or monitoring. Most of our thoughts and behaviors tend to be automatic or have automatic components, and for good reason. These processes are fast, allowing us to do things like drive to work without having to think about how to turn the steering wheel each time we get into a car. There are two main categories of automaticity defined by how the thought or behavior is initiated: Some automatic processes are triggered quite unconsciously, often by stimuli in the environment, whereas others require a conscious act of will to get started.

1. Unconscious Automaticity

Some automatic processes do not require any willful initiation and operate quite independently of conscious control. These processes can be instigated by stimuli of which we are not yet conscious, or by stimuli of which we were recently conscious but are no longer (Bargh 1994). Research has often used *priming* as a technique to trigger these automatic processes. A prime is a stimulus that biases further processing of the same or related material. An everyday example might be buying Tide laundry detergent after having recently seen a nature program about the ocean. Thoughts of the ocean may have primed you to choose Tide, perhaps without any conscious knowledge of the connection.

In a study by Bargh et al. (1996), some participants solved scrambled sentences containing words related to the concept of elderly (e.g., Florida, gray, wrinkles), while other participants solved sentences with neutral words. Each participant was then surreptitiously timed walking down a hallway on the way out of the experiment. The researchers wanted to test whether priming participants with the concept of elderly would automatically and unconsciously change their behavior to become more like that of the elderly. They found that participants who were primed with the elderly concept walked out of the experiment more slowly than the other participants. Careful questioning immediately afterwards revealed that the participants were not conscious of the concept of the elderly or of their reaction to it. In a related study, Dijksterhuis and Van Knippenberg (1998) found that priming the concept 'professor' made participants more successful at answering trivia questions compared to participants who were primed with 'soccer hooligan.' And as in the previous study, participants were unaware that the prime had affected their behavior.

Much of our behavior in social life is unconsciously automatic. There is evidence that people can respond automatically and unthinkingly to facial expressions, body gestures, hints about a person's sex, ethnicity, or sexual orientation, information about someone's hostility or cooperativeness, and a variety of other social stimuli (Wegner and Bargh 1998). People also have unconscious automatic responses to things they like and dislike, from foods or books to ideas and social groups. Although people may have conscious responses to all these items as well, this rich and detailed array of unconscious automatic responses provides a background of reaction to the social world. When we do not have time, inclination, or the ability to study or consciously correct these reactions, we may still find that we are behaving quite satisfactorily on 'autopilot' nonetheless.

2. Conscious Automaticity

Many of the automatic behaviors we do every day are things of which we are perfectly aware—at the outset. We know we are getting in the car and heading off to work, for instance, or we know we are beginning to take a shower. Yet because we have done the act so often—driving to work every day, showering every darn year, whether we need it or not—we no longer need to think about the act after we have consciously launched it. These behaviors are often acquired skills, actions that become automatic only after significant repetition.

When we begin to learn an action, such as driving, we think of the action at a very detailed level (Vallacher and Wegner 1987). We think 'engage clutch, move gear shift down into second, lift left foot off the clutch and right foot onto gas.' Skill acquisition starts off as labored, conscious learning and after consistent, frequent practice becomes more automatic and unconscious. Once the action is well learned, the behavior becomes automatic in the sense that it does not require constant conscious monitoring. This automaticity allows us no longer to think about the details, and instead to think about the act at a higher level ('I am driving to work. Gosh.'). It is as though practice leads to a mental repackaging of our behavior, a chunking together of formerly stray details into a fluid sequence

that can then be set off with only a brief conscious thought rather than a continuing commentary of them. Once the conscious decision is made to drive to work, the drive itself can be quite unconscious and automatic—as we chat on the cell phone along the way—and we may remember very little of the experience once we arrive at our destination.

When we have conscious thoughts prior to our behaviors, we typically experience these behaviors as willed. So, even though 'driving to work' is largely automatic throughout its course, the fact that we thought of doing it just before it started makes us interpret the entire sequence as consciously caused. However, the more frequently we notice our intentions occurring as we act, the more we experience behavior as consciously willed and nonautomatic. If we do something that requires a lot of thinking (such as a difficult math problem, or driving when we don't know how), for example, we are more likely to feel that we have consciously willed what we have done. Behaviors that happen without any conscious thoughts at all, in turn, are not likely to be experienced as willed. Although it is common to assume that automatic behavior is the opposite of consciously controlled behavior, this analysis suggests that automaticity can characterize both behaviors we experience as consciously caused and those we experience as involuntary (Wegner and Wheatley 1999).

3. *Benefits and Costs of Automaticity*

Automatic processes do not need constant conscious guidance or monitoring, and therefore use minimal attention capacity. For this reason, they are very fast and efficient. Sometimes we might wish our automatic actions or reactions were different, such as when we mindlessly say 'fine' after a waiter asks about our inedible meal. Metaphorically speaking, it is as if the waiter had come out with a little rubber hammer and struck just below our knee. Such automatic behaviors are so often mindless that they can pop out in inappropriate contexts. For the most part, however, the fact that many of our behaviors become automatic is extremely beneficial. If all our actions required conscious thought, we would spend time planning every step instead of just 'walking.' Everything would take as much time and be as difficult to do as the first time we did it.

Automaticity allows a familiar and comfortable interaction with our environments. With experience, we learn what is likely to happen in different situations. When we walk into a grocery store, we know automatically how things are supposed to go. We go in, grab a cart, pick food off the shelf, line up for a cashier who will take our money for the food, and we can go home. It is not as if we walk into the store and think 'OK, what happened the last time I was here' or 'Why are people looting food off the shelves?' We automatically know the proper assumptions of the situation based on our experience. This automatic activation of norms makes the world a much more predictable place. We are thus free to think about Bob's annoying table manners and Jane's infectious laugh as we wander down the aisles, selecting all the necessary ingredients for the dinner party the next night.

It is the very ease and fluency of automatic thought and behavior, however, that brings with it important costs. One such pitfall comes from thinking about things the same way over and over again such that a particular way of thinking becomes the default. For example, if you learn that black men are not only male and black, but may be hostile and lazy, your responses to a particular black man could be determined by automatic processes quite beyond your conscious control. You could hate him or avoid him or treat him poorly without any knowledge of his actual characteristics. Automatic responses to people and groups may be based on stereotypes—characterizations of persons based on their membership of a particular group (e.g., Asian, Jewish, basketball player, etc.). Stereotypic ideas may be so well learned that they pop into mind automatically.

If there is plenty of time to think, as well as no distraction, a stereotype that pops into mind does not always have to be acted upon and can be corrected. Gilbert's two-factor theory of attribution suggests that automatic attributions of why someone behaved a certain way tend to be dispositional in nature (e.g., thinking someone is lazy because they are watching TV). However, with enough mental resources, we can correct those attributions for situational causes (e.g., realizing that the person had a hard day and is trying to unwind; see Gilbert and Malone 1995, for a review). In the same way, stereotypes may be automatically activated but can be countered by consciously thinking about why that stereotype is false, about other characteristics of the person that do not fit the stereotype, or about explanations that take into account the person's situation.

The attempt not to think about a stereotype can, however, ironically make that stereotype come more readily to mind. This is because weak yet measurable automatic processes regularly arise to monitor the failure of conscious intentions. When a person tries not to think about a white bear, for example, thoughts of the white bear are likely to come back repeatedly despite the attempted control. The theory of ironic processes of mental control (Wegner 1994) suggests that such ironic processes are produced whenever people try to control their thoughts—and particularly when they do so under conditions of stress or mental load. These processes are required to search for the failure of mental control and reinstate the control process when this is necessary—but they also introduce an unfortunate sensitivity to the very thoughts the person desires to suppress.

This ironic effect on stereotyping has been observed in experiments by Macrae et al. (1994). These researchers asked participants to suppress stereotype thoughts in imagining the life of a person belonging to a stereotyped group (a 'skinhead'), and then later gave these participants the opportunity to write their impressions of another person of this group. As compared to the impressions of participants who did not first suppress stereotyping, these participants formed more stereotypical impressions of the second target. Another study examined the effects of this manipulation on participants' choices of how close to sit to a target just after having controlled their stereotypes of the target in an earlier impression-formation session. Participants instructed to suppress stereotyping succeeded in creating less stereotypical imaginings about the target, but they subsequently chose to sit at a greater distance from the target than did other participants who had not been instructed to suppress the stereotype.

4. *Summary*

The automaticity of social thought and behavior is both a blessing and a curse. On the blessing side, our ability to respond unconsciously and effortlessly to a range of social settings, people, and events allows us the luxury of speedy responses that are largely appropriate. And because the conscious initiation and practice of responses can shape them yet further, we can, over the course of interaction, become skilled social agents who can interpret and react to social settings with remarkable aplomb. The curse of automaticity inheres in the lack of flexibility and control that results when we learn things too well and are not conscious of doing them. We may make maladaptive or immoral unconscious responses that we then regret or simply fail to notice. And we may find under conditions of mental load or stress that the automatic processes that occur to monitor the failure of our conscious intentions ironically create that failure. When this happens, we find ourselves thinking or acting in social situations in precisely the ways we wish we would not.

5. *Future Directions*

Automaticity researchers have just begun to examine the underlying brain mechanisms associated with automatic and controlled processes. By studying these mechanisms, we may better understand *how* thoughts and behaviors become automatic, and what brain systems underlie automatic versus consciously controlled thoughts and behaviors.

Wegner's ironic-process model is one model of how unwanted automatic thoughts may be generated and influenced by controlled processes. Brain-imaging techniques offer direct testing of such models with the goal of understanding how automatic and controlled processes influence each other. For example, conscious deliberation may be most effective at determining what becomes an automatic process but less effective at influencing deeply ingrained automatic processes. Brain imaging may be a useful tool to shed light on which processes are likely to be automatic from their inception, when processes cross the threshold between control and automaticity, and how that crossover can occur.

Automation: Organizational Studies

1. *The Concept of Automation*

The word automation, as a contraction of automatic production, was first used in both by John Diebold—author of the book *Automation: The Advent of Automatic Factory* (1952)—and by D. S. Harder, vice-president of manufacturing at Ford Motor Company.

According to Gallino ( ), automation as a popular term

> indicates different situations where the human physical and intellectual work is replaced by machines and by mechanical, hydraulic, pneumatic, electrical, electronic servomechanisms which may automatically perform sequences of operations

The main components of automation indicated by most authors are:

(a) control systems based upon closed-loop control mechanism of feedback (on standards) and feed forward (on goals or week signals), performed by any kind of technological device;

(b) integration of different devices, processes into a unitarian architecture at the level of a factory, firm, network, achieving continuity of processes and management control; and

(c) system adaptation and innovation, through rapid detection both of the internal state of the system and of the environment (technical, economic, commercial, etc).

In any case, those components include tight collaboration among Information and Communication Technologies, advanced managerial systems, and operative work.

Applications and literature indicate that automation is in all cases a dynamic process. In fact:

(a) different levels of automation depend upon the quantity of human tasks embedded in the technical system,

(b) different patterns of automation result from forms and degrees of collaboration between the technical and the human system, and

(c) systems are developed along discrete stages and through change management processes.

Essentials of automation are:

(a) the need for human work because without it there would be only automatic machines;

(b) the need for collaboration among men and machines because, without interrelated activities, there is not a man-machine system; and

(c) integration of technological, fiscal, organizational, social system adopted in any single case.

As a result of 50 years of discussions about a changing phenomenon, we define automation as a stage in the process towards integrated systems of processes, technology, organization, roles, and values where technology performs a large variety of existing and new tasks, while cooperation is designed among men and technical systems with the goal of achieving optimal products and services.

2. *Applications*

The essence of automation is automatic control. This concept has been developed as an academic discipline and as a set of technologies applied in a large variety of intelligent human artifacts, that is, machines that can read complex data, signals, and symbols, have feedback loop and feed-forward mechanisms, interpret external and internal variables, adjust their conduct accordingly; and that, sometimes, can find new solutions, act without human intervention, do something which resembles thinking. We live in an environment where most of the artifacts display these features to different degrees: an elevator, a remote-controlled automatic train, an auto-piloted aircraft, a personal computer, a robot, and many others. In the following discussion, we concentrate only upon automation related to organizations that initial literature designated as industrial automation. We will adopt the term 'socio-technical automation' which includes applications that go beyond factories.

Concept, research, and debate on automation evolved since 1952 according to the available technologies and areas of applications. Factory automation came first when mechanical engineering, together with production engineering, mechanized both machine tools and conveyors in the automobile industry, giving rise to that primitive but seminal type of automation called Detroit Automation, i.e., transfer lines where products, such as engines, are manufactured and moved without human effort. Electromechanical engineering developed ingenious devices for automatic control of continuous process industries—oil, chemical products, cement—and of discontinuous flow processes—steel mills, casting. They were applied also to traffic control of material flows—in railway control rooms—and of energy flows—in power plants.

Automation introduced major disruptions in assembly, packaging, bottling in various manufacturing industries, actually turning them from discontinuous processes into continuous ones. The development of electronic and computer sciences in the 1960s increased the depth and breadth of this evolution. Computer control in the 1970s also extended automatic control into individual operating machines of numerically controlled machines (CNC), advanced robots, integrated CNC, and robots in flexible manufacturing systems (FMS). CNC and FMS were a breakthrough: manufacturing operations were automated and at the same time it was possible to manufacture small batches at costs of economy of scale, since the optimization of planning processes was embedded in the system. In recent cases of automation, processes of research and development (R&D), manufacturing, logistics, and distribution were integrated into internal and external functions or external units. To achieve this, a new architecture of telecommunication and information systems and new network organization structures were designed.

Task displacement and production integration pursued two distinct models. The first was the unmanned factory aimed at cutting costs and controversies with blue-collar workers through advanced mechanization and use of robots, as in the case of Toyota and Fiat

Cassino of the 1970s. The second model was the integrated factory which deliberately kept a meaningful portion of human tasks away from machines, as in the late Toyota developments and in Fiat Melfi. Cost savings and productivity gains were reported in Japanese firms making considerable steps back from automation, as in Toyota plant by 66 percent.

In the integrated factory, an optimal distribution of skilled work and automatic control takes place where advantages are not related to the reduction of direct manpower, but to the integration of various functions and units to achieve continuity and flexibility in business processes.

Another side of automation was office automation. Because of the development of large mainframe computers, electronic data processing (EDP) automated large areas of the operations of data collection, retrieval, and processing in public and private administrations: the work and organization in accounting, planning and control, and commercial departments were deeply affected. Electronic data exchange (EDI) supported communication among different departments and firms. First video terminals, then stand-alone personal computers (PCs), and finally networked PCs in the 1990s deeply affected the typical clerical and professional operations such as calculating, typing, editing, copying, printing, retrieving, mailing, etc. Automation of planning and control procedures gave rise to decision support systems (DSS) for managers, ranging from pioneering applications of management information systems (MIS) to the recent applications of electronic resource planning (ERP) such as the well-known SAP.

Computers in the 1980s could perform parts of very skilled tasks, such as f.i., scientific calculus, drafting, planning for designers, and manufacturing planners through computer-aided design (CAD/CAM), or project management for project leaders (Project Management SW). Automation for professionals was intended to substitute and accelerate routine tasks of scientists and other professionals. Computer graphics and multimedia first, followed by the Internet, did not automate tasks but offered opportunities to inform and communicate which did not exist before (Zuboff 1988).

Automation in services is a recent appearance. The activity of a cashier at a bank, or a booth in a public office is now widely performed by automatic teller machines (ATM) with which customers interact. Behind an ATM, there are complex changes in the banking processes, such as the advent of electronic money and electronic banking. Customer relations management (CRM) is frequently run by call centers that are going to employ 2 percent of the working population. CRM systems allow the delivery of a quick and reliable answer to customers through an integrated system of distributed intelligence including human beings, automatic telephone answering systems, web resources, and agent software.

It is uncertain whether the advent of the Internet may efface the concept of automation or will revamp it. A huge amount of functions are run automatically by Internet technology, one of the most powerful ever to have appeared. In addition to the instant and worldwide communication of texts, images, videos, and sound, the Internet will include functions and structures which in the past were work and organizational systems. The search engines automate f.i., the process of research of data displacing bibliographic searches and allowing access to data mines that were inconceivable without that technology. 'Click' is the action which instantly allows an individual to activate complex processes and actions such as retrieving, downloading, mailing, chatting, signing, buying, and many others. Disruptive applications, such as e-business, may encompass some previous stages of automation in organizations. Business-to-consumer f.i. creates a direct connection between the firm and the final customer, making the purchasing process a matter of a click. Business-to-business applications connect managers, workers, suppliers, co-maker companies, and clients using extranets to link the internal EDP with external EDPs, encompassing in the system ICT applications of the 1980s and the 1990s as EDI, ERP, CSCW, and making various organizations a unique network organization, a real organization through 'virtual organizing,' as described by Venkatraman and Handerson.

3. *Social Effects of Automation*

The literature on the social effects of automation has had discontinuous progress. In the late 1950s, development of automation in various industries gave rise to a wide program of research on the social effects of automation, financed by the governments of USA and other industrialized countries. Under union pressure, this research gave rise to concerns about an imminent wide diffusion of automation. This resulted in fears of potential consequences in terms of unemployment, deskilling, working conditions, work organization, and union/management relations. Outstanding research was carried out in this field but, by the mid 1960s, this research suddenly stopped when the US National Commission for Technology, Automation, and Economic Progress came to the conclusion that employment would not be affected, due to difficult implementation and limited diffusion of automation in most industries. In the 1970s, automation continued to increase incrementally but did not receive much attention from social scientists, except where it appeared relevant for ongoing studies and criticisms of Taylor–Fordism. In the 1980s, automation grew at a faster pace, bringing new concerns about employment and working conditions. In the 1990s, discussion and research focused more on information and communication technologies and their impact on the

service sector. By the beginning of 2000, use of the Internet was attracting great interest with a large number of case studies and prophecies, but little solid research.

Discussion about the nature and scope of automation may be grouped around two basic divides. The first focuses on the issue of continuity/discontinuity of technical development. Bright (1958) offers a classification of types of mechanization based upon degree of task allocation among men and machines, including automation. For economists, automation is no more than a particular case of technical development and no different social effects should be expected:

> the term automation is used in a loose way and there is not any advantage in distinguishing it from advanced forms of technical change.

Wild sees automation encompassing the task displacement of traditional mechanization, while he sees it as a new phenomenon as far as automatic control is concerned. For the British Social Science Council (1980) the novelty of automation lays in control systems. Drucker sees automation as 'the use of machines to run machines' ( ).

Crossman (1960), one of the first major scholars on the subject, stated that automation is the second stage in the displacement of human work substitution by information processing to machines, since in automation

> to steer, control, operate a machine, calculate, solve problems, take decisions, discussion may be performed by machines as by the human brain.

Artificial intelligence made computers more able to cope with complex problems. Development of advanced robotics gave machines sensor-motor skills (Sheridan 1988).

However, a breakdown was envisaged by Diebold (1952) who first saw automation as a new concept of integrated systems allowing continuous flow in the production process. When computers where not yet in operation, Pollock defined automation as 'the integration of continuous and discontinuous processes under the coordination of electronic systems'. For Buckingam, automation is a new pattern of manufacturing.

For sociologists such as Touraine (1955), Woodward (1965), Blauner (1964), Meissner (1969), Braverman (1974), automation is a breakdown, because massive displacement of skilled and unskilled work to machines overcomes both the craft-based organization model and the mass-production model. New tasks, roles and organizations are created, while the amount of work force required per product unit sharply diminishes: men undertake mainly control tasks. This occurred particularly in the 1980s and 1990s, with supervisory control of systems fully controlled by a computer and men controlling the computer, with tasks ranging from, at a minimum, switching the computers on and off, to at a maximum, controlling how the computer controls the computer.

Automation, in this discussion, becomes a breakdown: it not only substitutes any kind of human work, but also generates new functions not affordable by the human being. Automation is the integration of complex systems by means of automatic devices. Human work on the other hand does not disappear. Knowledge workers increase and concentrate on the design, development and supervision of 'intelligent machines.' Automation in this view is the creation of distributed knowledge among men and machines, and human-machine cooperation (HMC) according to Bagnara (Hoc 2000).

The second great divide concentrates on the pessimistic and optimistic views of automation. The pessimistic view holds that a new type of Taylorism is under way, the technological Taylorism. The 'intelligence of the system' as a whole would shift upwards towards functions which will become more specialized. This will result in a new wave of de-skilling amongst operatives and employees who will become 'transitional ancillary workers' and 'data entry workers.' As a consequence, there will be a polarization of the labor force, with a growing divergence between the unskilled masses and a super-skilled elite (Braverman 1974, Rifkin 1995).

The opposite view—the optimistic view—sees technology as a way of freeing workers from monotonous or dangerous tasks and from physical fatigue. Machines will do the work and men will supervise them (Blauner 1964). Although new technologies require less manpower, they should boost the cycle of expansion, giving rise to new firms and new professions (Freeman 1997).

Research has supported both the above-mentioned positions. It was clear since the beginning that different levels of allocation of tasks to machines affect differently the amount and quality of operative and managerial work (Bright 1958), with potential unemployment. Authors such as Jaffe and Froomkin assumed that the continuity of technical innovation would not generate dramatic changes in the content and amount of work. Rifkin (1995), Forester, and De Masi argued that technological development results in large unemployment. Economists note that job losses are due not only to technological development but in larger proportion to international trade, business process reengineering, and reorganization. Studies have reported that technical innovation creates new jobs and new enterprises with a potential gain in jobs. Sylos Labini (1997) maintains that a steady growth in national GNP of more than 3.5 percent will reduce unemployment even during a period of intense technological innovation.

Early research on skills focused first on the change in the nature of tasks in automation. Braverman

(1974) suggested that a fatal de-skilling should take place, the first Kern and Shuman (1970) found data supporting the dequalification thesis. Empirical research found that manipulation, traditional craft skills, dexterity, and operational ability (Bright 1958) were fading. On the contrary, tasks of supervision (Friedman 1971), 'control skills' (Crossman 1960), responsibility, and relationship with the entire production system (Touraine 1955), mental or visual jobs (Blauner 1964), sophisticated skills to respond to stochastic events (Davis and Taylor 1976) were all increasing.

Undesirable effects and risks of automation in dangerous processes have been studied as normal accidents (Perrow 1984), human and organization errors (Reason 1990), and misinterpretation and sense-making of technological events (Weick 1990).

Most early research into automated plants found that job design criteria moved away from the Taylor–Fordist tradition and that new criteria were emerging: interdependence of role and fewer levels of supervision, group behavior, multiskilling and shared responsibility, decline of strict job specifications and close supervision, communication, cooperation and influence, and group autonomy to cope with uncertainties. Recent developments of advanced computers enhance face-to-face and remote group behavior, human–computer cooperation (Hoc 2000), and, towards the beginning of the twenty-first century, the human–agent interaction (Lewis 2000).

The impact of automation on the composition of the workforce has been studied. Mallet ( ) found the potential development of technicians as a new working class. Kern and Shuman (1984) corrected the dequalification thesis but reported about potential polarization of the workforce. This thesis returns with Rifkin (1995) who charged modern technology with the responsibility of bringing work to an end, with the emergence of a small fraction of privileged individuals. Burris ( ) indicates that computerized work generates overall up-skilling, some de-skilling and skill bifurcation; Barley and Butera, Donati, Cesaria found that knowledge workers, managers, professionals, and technicians were rapidly increasing in industrial countries from the present 30 percent to a likely 50 percent.

Early studies on the Quality of Working Life had shown that with automation physical fatigue was decreasing, but there were increasing risks for workers: relaxation, nervous strain (WHO), problems of mental health, stress due to isolation and responsibility for catastrophic events, alienation, and powerlessness. The huge work edited by Martin Helander (1988) gives an exhaustive review of the different instances and differentiated impacts.

Workforce education influences wages and grades more than jobs and technology, coming back to the early findings of the Aix-en-Provence school of Maurice, Sellier, Silvester (*effect societal*). Plants adopting automation have more skilled workers, but this was found pre- and post-adoption. Wage premiums associated with technological change are actually a result of educational level. The wages of computer users are 15–20 percent more than for nonusers, but these were better compensated before the introduction of NTs.

4. *Conclusions: Effects or Design?*

Technology in itself has a direct influence on the physical universe of work (light, noise, heat, vibrations, radiation) and the operational universe of work (psychosocial conditions). Design of equipment has a major effect on:

(a) the amount of work per product unit (work displaced by technology);

(b) the operational 'tasks' (man/machine task allocation); and

(c) the coordination and control functions left to the managerial system.

Technology has only a moderate impact, if any, on components of work systems such as roles, organizational structures, communications, work allocation systems and policies, work management systems (such as skills, pay, working hours, regulations), and in particular the cultural and value systems which govern cooperation and conflict (Butera 1990).

Automation implies more than sheer displacement of human tasks because it includes the creation of new tasks of design, maintenance, and coordination and generates new forms of organization of production and restructuring of the labor market. Automation is at the same time a process of social and technical change, a measurable degree of distribution of knowledge and operational properties among men and technical equipment, and a set of advanced forms of socio-technical systems in manufacturing and services. Automation is a socio-technical system as a combination of business processes, technology, organization, and work, according to Trist and Murray (1993). Different patterns of supervisory control (Sheridan and Hennessey 1984), human–computer interaction (Norman 1986), and human–computer collaboration (Hoc 2000) may make a difference at the same level of automation. Participation of stakeholders in the design of the system and of new business, along with the process of introduction of the new technology, may change the final pattern of socio-technical systems (Davis and Taylor 1976).

If technology upsets work, only design resets work. Social and technical methodologies take the opportunity of 'room for maneuver' for planning, design, and experimentation of systems (such as territories, firms, factories, offices, and professional units), which may jointly meet economic, social and technical goals (Butera 1990). In synthesis, social dimensions in technological development are not effects but instead a matter of design. Designing integrated architectures of socio-technical systems, patterns of organization and

work, and interaction among men and computers is a social event and should be a participative one.

Autonomic Classical and Operant Conditioning

Autonomic classical conditioning is a type of conditioning in which the conditioned response (CR) is expressed through one or more organs that are targets of the autonomic nervous system. Among these are the cardiovascular system, digestive organs, and endocrine glands. The CR that develops during conditioning involving the autonomic nervous system has been characterized as either a discrete autonomic CR (Pavlov 1910, Dworkin 1993) or a nonspecific autonomic CR (Weinberger et al. 1984). A discrete autonomic CR is one that has been elaborated from an unconditioned reflexive response to a highly specific unconditioned stimulus (US). The autonomic CR is considered to be nonspecific when it is one of a cluster of concurrent responses elicited by a CS associated with a noxious US (Weinberger et al. 1984). This nonspecific autonomic CR is thought to acquire functional utility within the context of a cluster of CRs that develops during conditioning. The term conditioned fear is used to refer to the change in the CNS that accounts for the cluster of autonomic-mediated responses that, as a result of conditioning, is elicited by the CS.

1. Functional Utility of Discrete CRs

A fundamental observation made by Pavlov (1910) was that an autonomic CR, as it grows in strength, becomes increasingly similar to the UR. The development of a conditioned autonomic reflex was seen as a way to augment the homeostasis-promoting effect of the UR. For example, placing an irritating acidic substance in the mouth will trigger an (unconditioned) reflexive salivary response. The saliva lubricates the mouth and diminishes the impact of the acidic substance upon the mucosa, thereby promoting homeo-

stasis. The CR to a CS that precedes the US is also salivation and the latency of this CR decreases, and its magnitude increases, as conditioning progresses. Because this secretion (the CR) precedes the US it improves the effectiveness of the unconditioned reflex.

Pavlov saw autonomic conditioning as a way to study central nervous system (CNS) processes, and most of his research efforts were dedicated to studying these processes rather than the adaptive functions of discrete autonomic CRs. One of his students, Bykov, was among the first investigators to study the functional utility of discrete autonomic CRs. The focus of his research was understanding the role of classical conditioning in the control of visceral functioning, specifically regulatory mechanisms involved in conditioned diuresis (Bykov 1957). The UR in these studies was an increase in urine secretion in response to an intrarectal infusion of water. His observations regarding the temporal relationship between the CR and US that developed during conditioning were similar to those made by Pavlov in that he found that the latency of the urine flow decreased after repeated exposure to the US. Eventually, urine flow was initiated prior to the presentation of the US: a discrete autonomic CR was developing and the response was anticipatory in that it preceded the onset of the US. The CS in this experiment was the laboratory setting. Bykov (1957) also conducted studies which demonstrated that conditioned autonomic responses could be developed in the cardiovascular system. In these studies the dependent measure was the increased cardiac output that occurs when an animal is required to run on a treadmill. A discrete tone was used as the CS for this experiment. Similar to the results of the conditioned diuresis studies, Bykov found that the latency of the cardiac response (increased cardiac output) became shorter with repeated testing on the treadmill. Eventually, increases in cardiac output occurred well in advance of running. This discrete autonomic CR was smaller than the UR but it was adaptive in that it anticipated the increases in metabolic demands that are associated with running.

The observations made by Pavlov and by Bykov regarding the temporal relation between the CR and the US suggest that the conditioning of a discrete autonomic CR is a form of predictive homeostasis. Predictive homeostasis is distinguished from reactive homeostasis by the time at which the autonomic regulatory response mechanism is engaged. Regulatory response mechanisms that mediate reactive homeostasis are engaged after the occurrence of a regulatory challenge. For example, the pancreas secretes insulin in response to a rise in blood glucose level. Similarly, cardiac output and blood flow to the skeletal muscles increase in response to the elevated metabolic requirements of exercise. The regulatory response usually remains engaged until the controlled variable is returned to a preset reference level. In contrast to a reactive homeostatic mechanism, a predictive homeostatic mechanism is engaged prior to the onset of the regulatory challenge, and thus results from conditioning. It is a preemptive response that mitigates (or totally nullifies) the impact of the forthcoming stimulus that poses a challenge to homeostasis. Thus, based on the observations of Pavlov and Bykov, one possible adaptive function of a discrete autonomic CR is that it promotes homeostasis by mitigating, in advance, the impact of the regulatory challenge (the US).

It is axiomatic that if conditioned autonomic responses are involved in predictive homeostasis, the CR must be very similar to the UR. The results of studies assessing CRs to drug injections appear to be paradoxical with respect to this view. In general, the CR to a drug is opposite to the pharmacological effect of the drug (Siegel 1983). For example, epinephrine causes a decrease in gastric secretion, whereas the autonomic CR is an increase in gastric secretion (Guha et al. 1974). The CRs to almost two dozen drugs have been studied and in each case the direction of the CR is opposite to the pharmacological effect of the drug (Siegel 1983). These findings provided the foundation for a model of drug tolerance that is based on the idea that learned responses to environmental cues (the CS) associated with drug ingestion are conditioned compensatory responses (Siegel 1983).

If the discrete autonomic CR is to be viewed as a component of a predictive homeostatic process, it is essential to delineate the regulatory characteristics of the unconditioned reflex; otherwise it is not possible to determine if the CR is a replica of the UR. A question that naturally arises from studies involving conditioned autonomic responses to drugs is: Among the various physiological changes that occur as a result of drug ingestion, what is the effective US and the effective UR? For example, eating candy eventually will lead to a conditioned hypoglycemic response that precedes the arrival of the candy in the stomach. There are a number of physiological reactions to the ingestion of a piece of candy including salivary secretions, secretions in the stomach, an initial rise in blood glucose level, the secretion of insulin by the pancreas, and a subsequent lowering of blood glucose level. Which of these reactions is the US and which one is the UR? The tradition has been to refer to the drug as the US and the effect of the chemical (drug) as the UR. Thus, in the candy example the increase in glucose would be identified as the UR. Viewed from this perspective, the hypoglycemic CR is opposite in polarity to the UR, and hence appears to be a compensatory response. Viewed in terms of regulatory mechanisms and homeostasis, the effective UR is the insulin response (which is reflected by the hypoglycemic response) and the effective US is the increase in glucose. The rise in glucose is considered to be a 'challenge' to the control system involved in the regulation of blood glucose level and this system responds to this challenge by secreting insulin. In

general, most autonomic URs are homeostatic in that they diminish the impact of the US. Thus, the UR serves to limit the disruptive effect of the US upon the physiological state of the organism. Viewed in this way, the effective US is always the physiological change that engages a homeostatic response—the effective UR—that serves to return the controlled variable (blood glucose in this example) to its reference level. The CR is also an increase in insulin, and like the UR, is reflected by the hypoglycemic response. The CR is a response to the sweet taste of candy, the CS; it precedes the absorption of glucose (Deutsch 1974) and thus promotes homeostasis by anticipating a rise in blood glucose.

In our view, the reason why the autonomic CR appears to be a compensatory response to a drug is rooted in the manner in which the results of these experiments have been conceptualized (see Dworkin 1993 for a thorough analysis). More specifically, the pharmacological effect of the ingested drug has been considered to be the UR. However, if autonomic conditioning is viewed in terms of homeostatic mechanisms, the UR is always a corrective homeostasis-promoting response that serves to return a controlled variable to its reference level. The (effective) US is always a change in the physiological state of the organism that poses a regulatory challenge. If unconditioned reflexes are viewed as participants in reactive homeostasis and conditioned reflexes participants in predictive homeostasis, the CR and (effective) UR will be similar.

2. *The Adaptive Utility of Conditioned Fear and Nonspecific Autonomic Conditioned Responses*

In general, autonomic CRs develop more rapidly than most CRs mediated by skeletal muscles (referred to as somatic CRs) and in many cases this rapid development has adaptive utility. This observation, along with others, has led to the theoretical position that conditioning involving an aversive US may occur in two stages. The initial phase consists of the development of a changed state of the CNS, referred to as conditioned fear. Autonomic CRs and behavioral changes, such as CS-elicited behavioral freezing, are a reflection of this changed state of the CNS. Conditioned fear is followed by the acquisition of discrete, skeletal motor responses that mitigate or totally nullify the impact of the US (Miller 1948, Mowrer 1947). Weinberger (1982) used the term nonspecific CR to refer to a response learned in the initial phase and the term specific CR to refer to the responses mediated by skeletal muscles during the later phase. By nonspecific he meant that it was not linked to any particular US and that its functional utility is only gained within the context of the cluster of CRs elicited. Thus, an aversive US, regardless of it specific characteristics (e.g., airpuff to the cornea vs. loud noise), elicits a similar pattern of URs. The constellation of nonspecific autonomic CRs that develop during conditioning are usually similar to their corresponding URs. Conditioned fear is the term used to refer to the CNS state that generates the cluster of nonspecific CRs.

3. *Conditioned Fear and the Development of Somatic CRs*

According to one view (Weinberger et al. 1984), conditioned fear responses are thought to facilitate the development of somatic CRs that attenuate or totally nullify the impact of the US. The nonspecific autonomic CRs associated with conditioned fear are thought to reflect a general change in behavioral state. It not only leads to changes in activity in the autonomic nervous system, it alters the organism's orientation towards the environment in a way that enhances the reliability and efficiency of feature extraction from sensory input (Sokolov 1963), thereby facilitating the detection of stimuli that are most relevant to the development of adaptive somatic CRs. For example, conditioned decreases in heart rate (bradycardia) to a tonal CS are observed well in advance of the development of eye blink CRs to the same CS. The bradycardia CR is thought to be one of many nonspecific autonomic CRs that emerge as a result of the CS-US pairings. The altered CNS state (i.e., conditioned fear) that underlies the constellation of nonspecific autonomic CRs is thought to facilitate the development of the eye blink response. Once this adaptive somatic CR develops, the previously conditioned bradycardia disappears (Powell et al. 1990). Within this context, conditioned fear may be considered a CR that can be involved in predictive homeostasis because it motivates behavioral changes that lead to avoidance, in advance, of the presentation of an aversive stimulus that would disrupt homeostasis. The CNS changes associated with conditioned fear serve to improve the organism's ability to detect sensory stimuli that may be linked to danger and threat or may guide coping responses such as instrumentally conditioned responses that allow the organism to avoid an aversive stimulus.

Alternatively, the autonomic CRs in aversive conditioning studies may be interpreted solely in terms of autonomic responses involved in predictive homeostasis (Schneiderman 1972). The UR to an electric shock US in the restrained rabbit, for instance, involves an increase in arterial blood pressure, whereas the CR consists of bradycardia. Thus, the CR appears to mitigate the blood pressure increase elicited by the US, which becomes attenuated after several conditioning trials. In contrast, the UR to an aversive US in the unrestrained rat consists of an increase in arterial pressure as does the CR. Thus, the blood pressure CR

appears to be facilitating the metabolic needs of the organism (i.e., predictive homeostasis) by what Obrist and Webb (1967) referred to as the cardiac–somatic linkage. In conclusion, it appears that much of autonomic classical conditioning can be interpreted within the context of predictive homeostasis although its relationship to such concepts as conditioned fear remain to be explored.

4. *Operant Conditioning of Autonomic Responses*

In addition to classical conditioning, operant (instrumental) control has been demonstrated over a wide variety of autonomic responses in humans, including heart rate (e.g., Engel and Hansen 1966), blood pressure (e.g., Brener and Kleinman 1970), and vasomotor activity (Snyder and Noble 1968). Similar observations have been made in nonhuman animals (e.g., Miller and Banuazizi 1965).

Although there is ample evidence for instrumental conditioning of autonomic responses, the level of specificity of operant control over these responses remains an issue. When human subjects are asked to increase their respiratory activity, for example, there are changes in heart rate, but equivalent changes in heart rate occur when subjects are asked to alter their blood pressure. Equivalent heart rate changes are produced by instructions to alter heart rate, blood pressure or respiration. Moreover, the heart rate changes observed in this type of experiment have been found to be inversely proportional to the degree of somatomotor restraint imposed upon the subjects. In view of the cardiac–somatic linkage (Obrist and Webb 1967), it seems reasonable to hypothesize that the CNS programs for somatomotor and cardiorespiratory responses are coupled in the CNS, and these functionally related efferent systems are influenced in parallel by the same processes. This type of organization would lead to integrated cardiorespiratory/somatomotor responses whose characteristics are dictated by the metabolic requirements of the task at hand (see Brener (1974a) for a more thorough discussion of the issue). The results of studies by DiCara and Miller (1969) support this view. Using a shock-avoidance procedure, these investigators conditioned increases in heart rate in one group of curarized rats and decreases in heart rate in a second group. Subsequently, when tested in the noncurarized state, the rats previously reinforced for heart rate increases showed substantially higher levels of behavioral activity and respiration rate than animals reinforced for decreasing their heart rates.

Afferent feedback signals from skeletal muscles are extremely important to the regulation of motor activity. One view is that the activation of the mnestic trace of the central representation of these feedback signals is necessary for the development of instrumentally conditioned somatomotor responses (James 1890). Instrumental conditioning of cardiovascular responses is thought to involve a similar mechanism (Brener 1974b). In view of the somatic-cardiac linkage (Obrist and Webb 1967), a question that naturally arises is whether operant control of cardiovascular responses can develop in the absence of afferent feedback from skeletal muscles. Initial studies by Miller and co-workers (DiCara and Miller 1968; Miller and Banuazizi 1965) revealed that operant conditioning of autonomic responses occurs in curarized animals, thereby providing evidence that afferent feedback from skeletal muscles is not necessary for the development of instrumentally conditioned autonomic responses. Subsequent studies from the same laboratory (Miller and Dworkin 1974), however, failed to replicate these findings.

Summary

When viewed in terms of homeostasis, both discrete and nonspecific autonomic CRs are seen as homeostasis-promoting responses that prepare an organism for an impending unconditioned aversive stimulus. From this perspective, the unconditioned autonomic reflex is considered to be a reactive homeostatic mechanism, and discrete URs as compensatory regulatory responses. The conditioned autonomic reflex is considered to be a predictive homeostatic mechanism because the discrete CR that develops mitigates (or totally nullifies), in advance, the impact of the regulatory challenge (the US), thereby improving the regulatory properties of the unconditioned reflex. Autonomic conditioning involving a nonspecific CR is also considered to be a predictive homeostatic process. The constellation of nonspecific CRs that develop during autonomic conditioning is thought to be produced by an altered CNS state, referred to as conditioned fear, which results from the conditioning process. The change in behavioral state associated with conditioned fear serves two purposes: it facilitates the development of somatic CRs that mitigate the impact of the US, or the development of a instrumentally learned response that allows the organism to actively avoid the US.

Operant control over a variety of autonomic responses has been demonstrated, though these responses are usually linked to somatic responses. Thus, it appears that CNS programs for somatomotor and cardiorespiratory responses are coupled in the CNS, and that these functionally related efferent systems are influenced in parallel by the same processes.

Autonomous Agents

Autonomous agents are software programs which respond to states and events in their environment independent from direct instruction by the user or owner of the agent, but acting on behalf and in the interest of the owner. The term agent is not defined precisely, and agent software can range from simple programs composed of a small number of rules to large and complex systems. Agent technology was developed in artificial intelligence (AI) research, and can include complex AI techniques. Important application areas are those where the human user can benefit from continuous data analysis, monitoring of data streams and large databases, and where routine reactions to events are required. Many applications are related to user interface technology and the Internet. A weak position sees agents as tools which relieve humans from routine tasks suited to computational solutions, but there is also a strong position which asserts that agents can be constructed to mimic or even surpass cognitive functions of the human.

1. *What are Autonomous Agents?*

Agents are defined as software programs which:

(a) sense events and analyze data streams in a defined environment;

(b) react to certain events and states with defined responses;

(c) exhibit goal-oriented behavior representing the intentions of the owner or user of the agent;

(d) act proactively on their own initiative;

(e) function in a temporally continuous manner.

The following functions may also be implemented in agents.

(a) Learning, most often adaptation, which is the simplest form of learning, based on statistical data analysis and observation of process parameters (potentially more complex forms of learning can be included).

(b) Communication with other agents or humans, including the exchange of data, parameters, and goal functions.

The autonomy of agents is limited by the interests of the owner. The degree of autonomy ranges from task-specific agents with a restricted domain of application to viruses which proliferate widely and do not ever report back to their owners.

1.1 Distinction Between Robots and Agents

Autonomous robots and agents are closely related, but agents are software programs only, whereas robots comprise hardware designed for the specific functions of the robot. Robot behavior can be optimized by tuning sensors, effectors, or the control program; agents are composed of software functions for data analysis and communication only. Robot behavior must also be optimized with regard to energy and physical performance parameters, which are usually not important for agents.

1.2 Specific Properties of Agents with Respect to Software in General

Agents differ from software programs in general by their continuous operation, their reactive behavior, and their (partial) autonomy. It should be noted that feedback control systems also have some of these properties, but are generally restricted to the monitoring of continuous variables and the control of set points or simple forcing functions (e.g., the thermostat).

2. Constructing Agents

Agents are task-specific, and the design of a specific agent is optimized for its application to maximize performance and reliability, to minimize error probability, cost, and other relevant properties. For a well-understood task in a predictable context agent software can be specified as a discrete control system or a state machine. Autonomous agents are expected to be 'intelligent.' Intelligence refers to the extent to which the agent responds in an optimal manner to the events which he or she monitors. The quality criteria are correctness, speed, and reliability of responses. The goal of an agent is to optimize the benefit for the owner of the agent. It is thus important to note that it is the behavior only which is judged to be intelligent, not whether the underlying computational processes are implemented as a fixed control algorithm, or include planning, learning, and reasoning (McFarland and Bösser 1993).

2.1 Design Principles for Agents

The main principles for designing agents are as follows.

(a) Development of a reactive system based on profound analysis and understanding of the tasks and context in which the agent is operating. An agent of this type may be implemented as a limited number of rules, or a state machine. The intelligent behavior is not a function of the real-time computations of the agent, but of the optimal selection of a limited number of rules or behaviors which overall generate successful behavior.

(b) AI principles, including planning and learning, can be used to make an agent react successfully in many different states which need not be anticipated in the design phase.

(c) Use of inspirations and parallels to biological system.

2.2 Implementation of Agents

Agents may be implemented in widely varying forms, ranging from simple event–response formalisms or state machines (where the specification translates directly into implementation) to complex AI architectures with the aspiration to represent human behavior such as SOAR (Tambe et al. 1995). Brooks (1991) has argued that robots do not necessarily have to use cognitive functions, reasoning, or planning to behave efficiently and to appear intelligent, but that the selection of optimal features for sensors and effectors and simple rules governing the response and an appropriate architecture permits the implementation of robust and effective robots. The bottom-up composition of robots in a hierarchical fashion from separate components with their own independent behavior is called subsumption architecture, using for example legs comprising mechanical structures, sensors, and motors plus basic wiring which allows them to move independently, or a vision system which includes preprocessing and active control of the sensors as building blocks. The advantage of the subsumption architecture is that there is no need for a centralized representation of all sensor data, and complete planning of all behavior in detail. The central control system may be much smaller, and the behavior of the entire robot is more robust. As components are combined, the resulting behavior becomes more complex than that of the components, which is often called emergent behavior.

Agents, by analogy, would use existing data capture and analysis functions and initiate actions by calling

other programs, and thus can be restricted to the decision-making algorithms which are the essence of the agent's behavior.

2.3 Adaptation and Learning

The combination of a form of learning with autonomy is highly attractive because the ability of the agent to adapt to changing environmental conditions further decreases the need for supervision and instruction by the owner. In most instances simple forms of learning (adaptation of parameters) are used. More complex forms of learning (concept formation, elaboration of new response patterns based on planning) are hard to implement, require massive amounts of information, and are much less reliable and secure than pre-programmed responses. The ability to learn can have advantages, but also carries high cost during design and run-time.

2.4 Multiagent Systems and Cooperating Agents

Autonomous agents have particular strengths due to their task-specific and encapsulated nature, but this also limits them to the particular tasks and contexts for which they are designed. As the functionality of an individual agent increases, the optimization effort and maintenance effort is likely to increase unproportionally. There are more good reasons for developing distributed systems: robustness and reliability increase, access to local data and users demands fewer common resources, and the need for communication decreases. The composition of large systems as a collection of agents is attractive because of the potentially open architecture, where new agents can be added as required without the need to modify the existing system. The amount of communication and coordination in the system remains restricted due to the autonomous operation of agents. The technical field of multiagent systems is growing rapidly and receives particular interest for safety-critical systems engineering.

When there is not one owner for all agents, but many agents from different owners become active in the same context, these agents may communicate, negotiate, and share their resources (i.e., cooperate). Preconditions for multiagent systems and cooperative agent systems are defined communication languages and rules which govern a fair and beneficial exchange of information between agents.

2.5 Anthropomorphic and Mentalistic Concepts

The output from agents to human users is not restricted to text and figures, but can include natural language, speech, and animations using virtual reality techniques. The agent mimics the communication behavior of humans, making it easier for some users to understand messages (Babski and Thalmann 2000). This can help users, but may also be irritating, especially when the load on human communication resources conflicts with other needs (display space, sound). A different approach is to use mentalistic concepts in the design of agent features, such as motivation, emotions, consciousness, or moods, which are not only presented to the user but also are meaningful concepts to describe the internal state of the agent (Sloman 1997). At this stage it may be best to consider these concepts as metaphors for some aspects of communication, but it would be hard to equate these to human communication or even human mental processes.

3. Applications for Autonomous Agents

Interesting application domains for agents are those where the relative strengths of agent technology can be used to augment or partly replace direct interaction of the human user with an application. Where continuous monitoring of data streams, repeated quick responses to events, statistical analysis and pattern detection in large amounts of data, and fast access to databases are required, agents can be more efficient and reliable. The WWW and other networks are interesting domains for the use of agents because they provide access to large amounts of information, create the need to search and select data, and make it attractive to enable automatic responses. The advantages are to relieve the user from routine tasks, and also to improve the quality of his or her performance.

3.1 Intelligent User Interfaces

User interface agents (Lieberman 1997, Maes 1994) observe user behavior and have access to all information in the system. Agents can interpret user requests, suggest actions, and automate routine functions based on observations of previous user behavior and knowledge of defaults and standard options. A drawback is that users may no longer be aware of available functions, and have no opportunity to learn to use them.

3.2 Information Filtering and Access

Access to large amounts of information, for example catalogues, the CD and book market or scientific publications, but also TV programs, can be supported by agents which use instructions from the user in the form of keywords, reference to relevant similar items, and user profiles elaborated from previous user requests to actively search and display information selectively. Other agents (such as the web spiders employed by search machines) analyze and index proactively large amounts of information and make this index available for queries, resulting in much faster responses than is possible if a full search had to be carried out in response to individual queries.

3.3 E-commerce Agents

In an open e-commerce environment agents may implement some functions of a market, carrying out negotiations about prices and conditions, and for the optimization of logistics. Beyond technical and legal issues remaining to be solved, these applications also require appropriate formalization of the functions of a market. The design of agent-based systems also stimulates the development of a better understanding of market mechanisms (Sandholm 2000).

3.4 Help, Performance Support, Training, and Tutoring

Help functions in user interfaces can include agents which analyze previous user input and provide specific help for the user in his or her application context. More specific performance support uses a database of procedures specific to, for example, a particular company, a complex technical device, or an application domain. Performance support consists of guiding users to select and carry out prescribed procedures, relieving the user from the need to memorize and practice these procedures previously, and also to standardize procedures and to reuse knowledge in an organization (Chin 1991).

An important trend is to make tutoring and training accessible to users specific to their need (sometimes called 'just-in-time-learning'). Archiving relevant knowledge (knowledge management) is often not sufficient; the learner also needs guidance to direct him or her to learn the most appropriate information, and to evaluate his or her progress appropriately. Agents provide guidance in on-line learning situations.

Operators for safety-critical tasks such as power station control or piloting are trained extensively in simulators. Where the nature of the task includes cooperation with other individuals, these are implemented as agents, representing a wide array of human behavior (Tambe et al. 1995).

4. Evaluation of Agent Performance

Agent performance is judged by the owner and user according to the advantages obtained from the agent. Most agents incur only minimal costs for storage and computing power, but may have considerable costs for communication with other agents, their environment, and the user. The main advantage should be reduced communication effort for the user in instructing his or her systems to perform his or her tasks.

The bandwidth of user–agent communication should be much lower than the bandwidth required for direct user–application interaction. The quality of performance must also be considered. Quality criteria for the information obtained and for the decisions made by the user include the number of hits and errors compared to other means of accessing the same information, the erroneous decisions made, and opportunities missed. Precise and detailed analyses of the benefit of agent applications are still scarce, but should become an essential part of the design process for agent-based systems.

Studies where users were asked to assess their subjective impression of agents indicate that users are pleased to receive active support in situations where they feel helpless, but that they are easily irritated by verbose and redundant information when they have relatively mature knowledge of a domain. Agents should include strategies and thresholds for presenting information in adequate form. Games and entertainment, where agents are opponent players, gain in popularity with improved display and reality of presentation.

4.1 User Models and Manipulation

Agents which are instructed by users and observe user behavior subsequently attempt to predict user behavior. The ability to predict user reactions is a precondition for influencing, and potentially a means to manipulate, user behavior. Robots, since their conception in the twentieth century, are postulated to have a built-in rule not to harm humans. Agents, however, are mediators of human-to-human communication: an agent represents the interests of an owner, and in this role may pursue goals which are in conflict with the interest of other users. Because ethical behavior is hard to enforce universally by rules, users are likely to be cautious against giving too much information to agent-based systems which are outside their control.

This is a particularly relevant aspect for e-commerce where the integration of data-processing systems opens the possibility to test and model the behavior and state of a partner or even a competitor's system. The ability to predict the behavior of other players in the market offers considerable advantages: the own strategy can be adapted: for example, when it is possible to observe that the production facilities of a supplier are not fully used, it is likely that lower prices can be negotiated. The stability and safety of agent-based systems must also take the time dynamics of the processes into account.

5. Grand Visions and the Ontological Incongruence Between Agent Implementations and Biological Entities

Some authors (among these Moravec 1988) advocate a strong point of view of agent technology: they are seduced by the expected further growth of computa-

tional power to believe that agent technology will help to automate most of human work within the lifetime of some of us, and even surpass human cognitive abilities. These visions should be viewed with caution: the ontological incongruence of the theories of natural and biological processes on the one hand, and the engineering principles for constructing autonomous and intelligent systems may not permit this. When the core concepts in the two domains are examined, an essential difference between theories of cognition and the design specifications for artificial intelligent systems becomes apparent: formal and mathematical theories of natural processes are understood to be abstractions of a qualitatively different reality; they are generally not assumed to be able to represent the entire essence of the processes modeled, not even when extended dramatically in size. Specifications of computational artifacts must be assumed to be self-contained and complete—they could not work otherwise and would be useless for applications. Unfortunately the terms used to describe mental processes, such as emotions or consciousness, are often only names to describe entities which we recognize when we see them, but do not yet understand sufficiently in a reductionist sense. These theories may mislead some to believe that implementing these theories as computing machines will produce the full behavior of the entities in question. If not hubris, the ambition to build human-like intelligence still represents a goal which transcends today's realistic possibilities. The challenge is either to develop much more precise knowledge of the cognitive mechanisms which we fail to understand with precision today, or to develop methods to construct complex systems from imprecise and incomplete specifications.

6. *Further Developments*

The concept of agents is still evolving, but offers promise that truly intelligent tools to help humans to carry out tasks beyond their natural cognitive abilities can be implemented. This is likely to be the support for increasingly complex routine tasks. As Marvin Minsky (1986) stated, 'We have built cranes to lift 10-ton weights, and computers will enable humans to carry out tasks which are beyond their ability so far.' Given the specific advantages of agent technology, agents will automate routine cognitive skills where reliable monitoring of large amounts of data and statistical analyses of information are carried out as a basis for decisions and actions. The main advantage for human users is that with human–machine communication at reduced bandwidth, complex tasks can be carried out successfully. It will probably be difficult to deploy systems for general use which are so complex that humans are unable to understand and if necessary correct their behavior.

The visions of the future abilities of agents are associated with worries that human work will be taken over by machines. Rather than a threat, this should be seen as an opportunity to free the cognitive capacity of the human, which can be directed towards more creative work and more sophisticated decision making. This development should increase the efficiency of the human user, and create value by making the use of working time, energy, and scarce resources more efficient.

Autonomy at Work

Autonomy may be defined as the condition or quality of being self-governing or free from excessive external control. According to Immanuel Kant, the eighteenth-century German philosopher often credited with laying the groundwork for modern philosophy, autonomy is important to human beings because it is the foundation of human dignity and the source of all

morality (Hill 1991). In most Western cultures, an adult person's dignity (poise and self-respect) is usually based on possessing some degree of control in making the decisions that deeply affect their life. Likewise, the source of their morality lies in the volitional self that rises above socially conditioned desires and partisan attachments in order to adopt impartial ethical principles and standards of conduct.

The theme of self-governance and autonomy has been central in theories of human growth and development in society for several decades. More recently, it has moved to the center of theory and research on work and organizational behavior. In this article, two general models concerned with self-governance and human well-being will be reviewed briefly and attention will focus on four streams of research on autonomy at work.

In one prominent approach to theorizing autonomy, the internal–external locus of control model of human personality, it is proposed that individuals perceive that their actions can affect the events in their lives, but vary in the degree to which they believe forces outside their control typically influence the events (Langer 1977). Some people (externals) have a relatively consistent tendency to perceive that the outcomes in their lives are governed by external forces, such as powerful others and social conditions, fate, luck, or chance. Others (internals) have a relatively consistent tendency to believe they control their own destiny; they perceive themselves as masters of their own fate and as in control of the actions and events that affect their lives. This model has been researched extensively, leading to the conclusion that people who do not see themselves as self-governing (externals) are handicapped in numerous ways.

Among the models of human growth and development that are centered on autonomy, the most theoretically sophisticated approach has been developed around the concepts of self-regulation and intrinsic motivation (Ryan and Deci 2000). Self-determination theory proposes that 'higher behavioral effectiveness, greater volitional persistence, enhanced subjective well-being, and better assimilation of the individual within his or her social group' result when individuals act from motivations that emanate from the inner self (intrinsic motivation) rather than from sources of external regulation (Ryan and Deci 2000 pp. 72–3). Although not without controversy (due to the entrenched, commonsensical belief that tangible rewards govern behavior), research in a wide array of social conditions has demonstrated that individuals develop a perceived external locus of causation (i.e., a sense of diminished autonomy) when tangible rewards are administered contingently, based on evaluated performance at a task. For self-determination theorists, it is the experience of an external locus of causation (or the belief that one's actions are controlled by external forces) that undermines the most powerful source of natural motivation and that (when chronic) also can lead to stultification, weak self-esteem, anxiety and depression, and alienation. Thus, health and well-being as well as effective performance in social settings are closely related to the experience of autonomy. Interestingly, Ryan and Deci (2000, p. 74) point out that 'autonomy refers not to being independent, detached, or selfish, but rather to the feeling of volition that can accompany any act, whether dependent or independent, collectivist or individualist.'

During the 1960s, amidst massive social upheaval in many of the advanced industrial nations of the world, organizational and management theorists began to turn their attention to the sources of discontent in the workplace, manifesting in 'accelerating absenteeism, job turnover, shoddy workmanship, sabotage, and the greatest outbreak of wildcat strikes since the 1930s' (Greenberg 1975, p. 192). Several now classic texts called attention to the neo-Marxist thesis of alienation and the notion that lack of control over the product and process of work would lead to intense and widespread feelings of powerlessness, meaninglessness, social isolation, and self-estrangement (e.g., Blauner 1964).

In one of the first systematic attempts to address the phenomenon of work alienation and freedom, Hackman and Oldham (1976) developed the Job Characteristics Model, a framework that focused attention on autonomy and four other key factors involved in designing enriched work. Work designed to be complex and challenging (characterized by high levels of autonomy, skill variety, identity, significance, and feedback) was theorized to promote high intrinsic motivation, job satisfaction, and overall work performance. Two decades of research in this tradition have shown that job scope or complexity, an additive combination of autonomy and the four other job characteristics: (a) is correlated significantly with more objective ratings of job characteristics; (b) may be reduced to a primary factor consisting of autonomy and skill variety; and (c) has substantial effects on affective and behavioral reactions to work, mostly indirectly through critical psychological states such as experienced responsibility for the outcomes of the work. There is some evidence suggesting that the positive effects of complex and challenging work have thresholds, but the main lesson we can draw up from this line of research is that the experience of autonomy at work has positive consequences ranging from higher job performance to enhanced general well-being.

A second stream of research in which autonomy at work is central was launched by Karasek's (1979) study of national survey data from Sweden and the USA. In this research, he proposed the Job Demands–Job Control Model that included a thesis about the causes of physical and mental strain and health problems. Job demands include requirements for working fast and hard, having too much to do and too little time to do it, conflicts among demands, and

personal conflicts with one's role. Job control is specified in terms of decision latitude and relates to the theme mentioned earlier about possessing some degree of control over decisions that deeply affect one's life. Karasek (1979) proposed two dimensions to job control (authority to make decisions on how to work and having say over what happens; and latitude to use a variety of skills on the job), which parallel Hackman and Oldham's (1976) two central concepts of autonomy and skill variety. The main proposition in Karasek's model is that when jobs are simultaneously high in demands and low in decision latitude, physical and mental health problems are more likely to occur—the 'high strain job' (Karasek 1979, p. 288). Demanding jobs that permit high decision latitude are challenging and create opportunities for arousal, learning, and healthful response, thus mitigating the stressful effects of demands and generating the potential for job satisfaction and life fulfillment.

Subsequent research on Karasek's model has been mixed. Most studies have reported that demands have negative effects regardless of the degree of job control, but in other studies, the predicted interaction effect has been found. Researchers have not yet determined what accounts for mixed support of the Job Demands–Job Control Model, but current studies have begun to develop the model further by examining the role of individual differences in moderating the importance of decision latitude. For example, the role of self-efficacy and the role of proactive personality have been explored. It was found that high strain was mitigated when decision latitude was exercised by more self-confident and proactive individuals. As with the Job Characteristics Model, research on Karasek's (1979) framework has underscored the importance of autonomy at work while also revealing some of the intricacies involved in explaining the specific processes through which autonomy exerts its positive effects.

The theme of autonomy at work also runs through five decades of research on groups and teams in organizations. Of primary concern here are the streams referred to by Moldaschl and Weber (1998) as the sociotechnical systems theory approach (STS) and the lean management approach. Both approaches focus on teams that are, to varying degrees, autonomous or self-organizing. Self-organizing teams have been theorized as having processes of self-management and collaborative teamwork. In self-organizing teams, members experience relatively high autonomy by collectively controlling, for example, the pace of work, task allocation, performance evaluation, recruitment and selection of new members, training, and even reward distributions. As noted by several researchers, because groups can undertake much larger pieces of work than individuals can, the potential to experience positive outcomes through heightened control is greatly enhanced.

Beginning with Trist and Bamforth's (1951) classic study of autonomy among underground coal miners, through recent reviews and meta-analyses of research in the STS tradition, some positive results have been reported. Despite 'substantial variance' in research findings regarding the consequences of autonomous work groups (Guzzo and Dickson 1996, p. 326), positive impacts on motivation and productivity (especially performance quality and cost savings), attitudes and perceived quality of work life, and (to a lesser extent) attendance and retention are routinely reported. Failures of some STS projects and the fact that STS interventions in organizations have not been used as widely as initially anticipated have been attributed to poorly designed (imbalanced) programs and internal political conflicts.

The lean management approach, used initially by Japanese manufacturers such as Toyota, differs from the STS approach primarily in the degree of autonomy experienced by team members. The lean management approach tends to be more supervisor-centered as team leaders are appointed rather than elected, decision making is consultative rather than consensual, and the domain of decision making authority for the team is more limited. As pointed out by Ilgen et al. (1993), when team-based structures are created in organizations, there is a tendency to retain an overarching hierarchical structure and to require teams to report to leader-managers in a very formal and traditional way. In situations where teams are teams mostly in name, autonomy is very limited, leading to negative results. When interventions empower teams to become more self-directed and autonomous, results tend to be positive across a number of indicators, including financial performance.

Although autonomous and self-organizing teams can produce positive results, the approach assumes that freeing members from hierarchical control automatically creates organizational democracy and emancipated practice. Some writers contend that while workers in the typical self-managed team situation might feel a measure of influence, upon closer inspection, it is only an illusion of self-control. This theme is developed further by Ezzamel and Willmott (1998) and others who show that teams, through peer pressure and behavioral regulation, can coerce their members in ways that are perhaps even more tyrannical than are the forms of control exercised by managers.

The fourth and final stream of research on autonomy at work that we will touch on is best labeled organizational democracy, and is more familiar to researchers in Europe than in North America (see the academic journal *Economic and Industrial Democracy* 1980–2001 volumes, for a review of this approach). This tradition is vitally important because it helps sharpen distinctions among the varieties of macrofactors operating in the world that shape self-regulating organizational systems and their effectiveness. In line with this approach is the conclusion that self-directed teams tend to be more effective in

nations other than the USA. Why should this be so? Studies of autonomy at work from the standpoint of organizational democracy provide some answers to this question and open the field up in at least two important ways. First, they suggest how individualistic and collectivist nation-state cultures shape attitudes and other reactions toward team-based organizing, in effect constraining and prefiguring the effectiveness of any intervention aimed at enhancing autonomy at work. This point corresponds with Guzzo and Dickson's (1996) statement that the effects of team-based organizing are highly situationally dependent and extends it into the realm of nation-state contingencies. Second, they suggest a need to develop programs of inquiry that go beyond the psychology of autonomy, programs that describe and explain the emergence of objectively different structures of control that are anchored in political–economic, legislative, and cultural factors (see Forbes and Jermier 1995). This is important because so long as studies of autonomy at work rely exclusively on micro thinking, the politics of 'empowerment' in any given culture at any given time will probably be limited to regimes of illusory control.

The four streams of research on autonomy at work reviewed in this essay all support the idea that being truly self-governing and free from excessive external control produce positive outcomes for individuals, groups, and work organizations. The more general thesis, that autonomy promotes human growth and development as well as positive health and well-being, is also supported. Autonomy sometimes is considered to be synonymous with individualism and egoistic willfulness but there is increasing evidence supporting the idea that collectivist autonomy is equally beneficial. The concept of autonomy at work has received considerable attention from researchers in several traditions of study. While more research in each of the traditions is needed, a more pressing need is to begin integrating insights from all the traditions to develop a general theory of autonomy at work

Autonomy, Philosophy of

The notion of personal autonomy (or free agency) is ubiquitous within the philosophical literature. It is construed variously as a fundamental right which justifies further rights, such as those of abortion or free speech; as a basic political good of liberal political theory; as a character ideal on a par with courage or integrity; and as a necessary condition of full moral agency. Although there are many different conceptions of autonomy, there is a common theme. Being autonomous is usually taken to mean being self-governing in one way or another; an autonomous state is one in which a person's will is genuinely *their own*.

Individual autonomy (including moral autonomy) is to be distinguished from political autonomy. Political autonomy is a property of nations or states, and is usually characterized as requiring the *absence* of certain autonomy-undermining conditions. For instance, a nation is self-governing or self-determining

when it is not subject to interference or coercion by others. Individual autonomy requires that agents satisfy some positive conditions in addition to the absence of interference. Consider, for example, two typical failures of personal autonomy: first, agents who habitually and uncritically adopts others' social preferences and values as their own; and, second, agents who have so internalized the outlooks and morés of the family in which they grew up that these are treated as authoritative without critical reflection (Feinberg 1986, p. 32). Although in neither case is there any overt interference or coercion, agents in both cases lack autonomy because they fail to exhibit a characteristic necessary for autonomy—for example, a capacity for 'subjecting these governing ideals to rational criticism and then modifying them when necessary' (Feinberg 1986, p. 32). The development of such positive capacities can be undermined by oppression, and therefore the articulation of a conception of autonomy is an important tool for feminists and other social critics.

Conceptions of autonomy in the contemporary literature divide roughly into two classes: Kantian conceptions and nonKantian—or procedural—conceptions. Broadly speaking, each reflects a different approach to the following question: How can agents be genuinely self-governing in the face of the physical and social forces in which they are embedded, and which appear to determine their states and capacities? Traditional Kantian conceptions endorse a version of *incompatibilism*, namely the thesis that genuine free agency cannot be reconciled with socialization or physical determinism. They characterize autonomy by introducing either idealized conditions of free agency or metaphysical conceptions of the autonomous self. Non-Kantian conceptions are *compatibilist*, and attempt to explicate autonomy within the network of physical and social forces in which agents operate. The key task of these conceptions is to distinguish the conditions in which socialization undermines autonomy from the conditions in which it does not.

This article traces the main theories of autonomy in the current philosophical literature. The first section outlines the traditional Kantian account, which conceives of moral autonomy as an ability of rational agents to formulate universal moral principles. These moral principles are said to originate in the will of the agent and to be, in this sense, the agent's 'own.' The second section turns to three procedural accounts of autonomy: endorsement, historical, and self-knowledge accounts. Each proposes a condition on critical reflection which distinguishes autonomous from nonautonomous preference formation. The third section describes neo-Kantian responses to procedural analyses. These propose that autonomy requires a kind of normative competence, namely an ability to identify norms, for example moral norms, or norms that are 'correct' for an agent to endorse. The final section outlines two further approaches—psychological and self-realization—both of which focus on the relationship between conceptions of autonomy and the nature of the autonomous agent.

1. *The Kantian Conception of Autonomy*

A major strand in theories of autonomy is derived from the philosophy of Immanuel Kant. For Kant, autonomy has a special meaning: 'Autonomy of the will is the property the will has of being a law unto itself (independently of every property belonging to the objects of volition)' (1785/1948, p. 108). Rational beings make the moral law for themselves, and can regard themselves as authors of the law. Thus autonomy is manifested when rational agents 'will' the moral law. An important feature of the moral law is that it is a categorical, not a hypothetical, imperative. When agents formulate a categorical imperative, they formulate a maxim of the form 'I ought to do this,' not of the form 'I ought to do this if I desire that.' For example, agents formulate the moral law when they will 'I ought not to lie,' but formulate a hypothetical imperative when they will 'I ought not to lie if I desire not to be punished for lying.' The act of formulating the moral law is an act of a pure autonomous will: it is untainted by the influence of the desires and interests that an agent may have relative to a particular situation. The pure autonomous will amounts to a metaphysical conception of the self, to be distinguished from empirical conceptions of the self. The metaphysical self is unconstrained by desires, interests and social forces. Thus Kant's conception of freedom is incompatibilist.

A contemporary parallel of Kant's conception of autonomy is John Rawls' influential notion of free and rational agents formulating principles of justice in the 'original position' (Rawls 1971). Rawls argues that rational agents formulate principles of justice from behind a 'veil of ignorance,' namely from a position in which they are making decisions about how a society will function before they know who in that society they will turn out to be. In the original position, they have abstracted themselves from a particular location in the society to which the principles of justice apply. This means that such agents, like Kantian agents, are uninfluenced by the particular desires and preferences that arise from being embedded in an actual situation. Because of this, their formulation of the principles of justice is genuinely *self*-originating.

The Kantian conception of autonomy has two aspects. First, autonomy is a function of a conception of morality that is encapsulated in the categorical imperative, or, in Rawls' account, in the principles of justice. The categorical imperative provides a standard according to which we can judge whether a particular example of moral reasoning is autonomous. If the moral reasoning issues in the categorical imperative, then it is autonomous. Otherwise, it is not. Second,

autonomy is a function of a metaphysical conception of the self, because autonomy manifests itself when the Kantian 'true' self is expressed through the formulation of the moral law. Both aspects of the Kantian view are contentious. Critics challenge the notion of a universally valid moral law as well as the concept of a pure autonomous will, which is said to be implausibly metaphysical. In addition, Rawls' account of the agent operating in the original position has been criticized as being unfaithful to empirical reality. Feminists and communitarians have argued that this agent is 'atomistic'; that is, existing in a vacuum divorced from the social relations in which actual agents are embedded (e.g., Sandel 1982). No such agent exists, because agents are always the product of family influences, socialization, and so on. Moreover, an agent stripped of desires, interests, and preferences cannot engage in the imaginative moral reasoning required to formulate principles of justice. A further difficulty is that the Kantian conception is said to lead to an impoverished account of the *value* of autonomy. It is associated with the claim that autonomous agents are, and ought to be, substantively independent or self-sufficient, which in turn is associated with the character ideal of the 'self-made man.' Critics—especially feminists—have challenged this character ideal, and questioned whether substantive independence is really a value that a theory of autonomy, or normative theories in general, should promote. They have argued that a conception of autonomy should not exclude the possibility of agents having significant relationships of interdependency, such as those obtaining with family members (see Friedman 1997).

2. *Procedural Theories of Autonomy*

Procedural theories eschew substantive independence in favor of procedural independence. It is enough that agents' reasoning processes satisfy certain formal and procedural conditions for the outcomes of those processes (decisions, preferences, and desires) to count as autonomous. Procedural accounts are 'content neutral.' There are no specific beliefs, goals, or values that the autonomous agent must adopt. Nor are there any standards or conditions external to the agent that operate as touchstones of autonomous reasoning or place constraints on the contents of agents' preferences and desires. Procedural theories, therefore, are congenial to the concerns of critics of the Kantian conception.

2.1 *Autonomy as Endorsement*

Perhaps the most prominent procedural approaches are those of Gerald Dworkin and Harry Frankfurt (Dworkin 1970, 1988, Frankfurt 1971). Both argue that what distinguishes autonomous from nonautonomous critical reflection is endorsement—the agents' sense of engagement or identification with their preferences or desires. In Frankfurt's terms, an autonomous will is *the will the agent wants*. Consider the difference between a willing and an unwilling drug addict. Frankfurt argues that although both are addicted, only the unwilling addict is nonautonomous. This person is a 'passive bystander' with respect to the desire to use drugs, whereas the willing addict engages and identifies with that desire, and hence endorses it. In Frankfurt's account, the idea of endorsement is spelled out using a hierarchical distinction between different levels of desire. First-order desires—such as a desire to inject heroin—are autonomous just in case they are endorsed by second-order desires—such as a desire to desire to inject heroin (Frankfurt 1971).

Important objections have been raised to endorsement accounts. The first focuses on their hierarchical nature. Even if first-order desires can be characterized as endorsed with respect to second-order desires, this is not sufficient to ensure autonomy unless the second-order desires themselves are endorsed. The problem results in a regress unless we introduce a qualitative distinction among levels, for example, between higher-order *values* and first-order *desires* (Watson 1975). However, the regress objection can be generalized to many hierarchical accounts, because whatever the nature of the higher-order level, it can always be questioned whether it truly represents free agency. The second-order level itself will always be the outcome of the social forces influencing an agent. A second objection is that the endorsement condition is too stringent, because it seems that certain unendorsed desires should count as autonomous. Suppose that, out of habit, an agent chooses to go on vacation to the same destination every year. The fact that the agent fails to attend critically to the desire and does not endorse it each time should not rule out its being autonomous. Third, it has been suggested that the endorsement condition is too weak. The endorsement account relies on the idea that although the unwilling addicts inject themselves intentionally with heroin, they prefer not to. Since they prefer not to inject themselves, they do not endorse the desire to inject themselves. It has been argued that (all things considered) intending to do something and preferring to do something are indistinguishable, and thus if agents intend to so something, they also prefer to do it, and endorse it. Therefore, insofar as the unwilling addicts intend to inject themselves with the drug, they also endorse it. The objection claims that endorsement merely distinguishes intentional from nonintentional agency, and not autonomous from nonautonomous agency. The apparent lack of autonomy of the unwilling addicts is therefore not due to a lack of endorsement (Buss 1994).

2.2 *Autonomy as Historical Critical Reflection*

Most hierarchical approaches to autonomy are structural. They propose conditions that an agent's existing

motivational state must satisfy. Alternative approaches introduce conditions that allow reflection on the processes of development of the motivational state. For example, Gerald Dworkin analyzes autonomy as 'a second-order capacity of persons to reflect critically on their first-order preferences, desires, wishes and so forth and the capacity to accept or attempt to change these in the light of higher-order preferences and values' (1988, p. 20). A capacity allows reflection on the processes by means of which an agent acquires desires and preferences. It also distinguishes between an agent's autonomy on the one hand, and a particular exercise of autonomy on the other. A related approach is the *historical criterion of autonomy*. This proposes that agents are autonomous with respect to a certain preference or desire only if they do not resist its development when attending to the process of its development, or would not have resisted had they attended to the process (Christman 1990, 1991). Notice that this criterion can account for preferences formed out of habit because, although in most cases of habit agents do not attend each time to the process of development of their preferences, it is true that they would not have resisted the process had they attended to it.

The historical criterion is difficult to maintain in the face of apparent counterexamples. Consider agents who have internalized an oppressive ideology—for example, a young student who is so influenced by the norms of the fashion industry that an excessive amount of time and energy is devoted to the student's appearance. Such agents are usually characterized as nonautonomous with respect to the norms of the ideology, yet the historical condition cannot adequately explain why. Even if the student had reflected on the fashion norms that have been internalized, as well as the processes of development of the student's preferences and their relationship to the norms, the norms or the development of the preferences would probably not have been resisted. The very fact that the ideology is effectively internalized makes it unlikely that an agent would resist the development of preferences based on the ideology (Benson 1991). The historical condition therefore does not account for cases that are thought to be paradigms of nonautonomous preference-formation.

2.3 Autonomy as Self-knowledge

Another set of procedural conceptions proposes that authenticity is the key factor in explicating autonomy. Having one's own will is having the will one *really* wants. One important approach characterizes authenticity in terms of self-knowledge. For example, Diana Tietjens Meyers argues that self-discovery is a necessary capacity for achieving autonomy. Suppose an agent—Martin—has 'always been groomed to follow in his father's footsteps [and] his parents have taught him to feel deeply guilty whenever he disappoints their expectations' (Meyers 1989, p. 46). He completes medical school dutifully and becomes a successful surgeon. Although there are opportunities along the way for Martin to 'probe' his feelings and reconsider his career path, it does not occur to him to do so. Meyers suggests that Martin's 'insensitivity to his own responses' and 'blindered approach to life' indicate that whereas 'He may be doing what he wants ... there is no reason to suppose that he is doing what he really wants' (Meyers 1989, p. 47). The distinction between doing what one wants and doing what one really wants is important for a range of cases in which authenticity is questionable. For instance, conventional gender roles can shape values and desires through being omnipresent in culture, or instilled since birth by family socialization. Meyers points out that the enforcement of gender roles can interfere with a person's ability to distinguish between apparent and authentic desires.

This conception of autonomy must give a plausible account of the difference between 'real' and 'apparent' desires, as well as identify how self-knowledge fails in cases of failures of autonomy. One possibility is to argue that agents lack self-knowledge by having inaccurate beliefs about themselves, specifically about the desires and motivations in question. Perhaps Martin's 'real' wishes are being covered up by his failure to scrutinize. The desires to be a doctor operate on the surface, but his deep, 'true' desires are to follow some other career path. Since his beliefs that he wants to be a doctor are based on apparent desires, they are false beliefs about himself, and he lacks self-knowledge. A difficulty for this characterization however is that it may seem to employ a metaphysical notion of the self as the bearer of real desires. Even if it does not, it must rely on the agent experiencing internal conflict among desires, and failing to probe or scrutinize in response to such experiences. The apparent desires are the unscrutinized ones, and the real desires are the ones that would have emerged had the agent scrutinized the apparent desires. Often, however, there is no experienced dissonance among desires, and no failed opportunity for real desires to emerge. How should we characterize the lack of self-knowledge in these cases?

A second way in which agents could lack self-knowledge is through failing to acquire their beliefs in the right way. Suppose there is no opportunity for Martin's desires to change because he does not experience appropriate internal conflict. Nevertheless, *if* Martin's desires or motivations *were* to change, his beliefs about himself ought to change as well. We can say that: if Martin's beliefs about himself would not have changed if his desires had changed, then his beliefs have not been acquired in the right way. Although they happen to be accurate, they do not

constitute self-knowledge. This approach revises the concept of authenticity, because it does not employ a clear distinction between real and apparent desires. Rather, it relies on articulating the ways in which beliefs must be acquired to constitute self-knowledge.

3. *Neo-Kantian Theories*

Procedural accounts usually assume that the conditions they identify, which are internal to agents' own thought processes, are both necessary and sufficient for autonomy. Neo-Kantian conceptions argue that agents' preferences are subject to certain *external* constraints. Hence, although procedural criteria may be necessary for autonomy, they are not sufficient.

The central idea of recent neo-Kantian approaches is that of normative competence: the failure of autonomy corresponds to a failure of a capacity to identify the difference between right and wrong. Consider JoJo, the son of an evil and sadistic tyrant. JoJo is raised to respect his father's values and emulate his desires, so that he thoroughly internalizes his father's evil and sadistic world view. Let us suppose that, on procedural theories, JoJo counts as autonomous because he identifies in the appropriate ways with his first-order desires, has the desires he really wants, etc. It has been proposed that he is neither free nor morally responsible because his upbringing has blocked his capacity to distinguish right from wrong (Wolf 1987). Similarly, the young student who has internalized the ideology of the fashion industry can be characterized as having internalized certain *false* norms, such as that most people's natural physical appearance is deficient. The internalization of the norm blocks the agent's capacity to criticize effectively this 'false construal of personal value,' and hence the ability to distinguish correct from incorrect norms—the student's normative competence—is flawed (Benson 1991). It is the failure of normative competence that explains the failure of autonomy.

One controversial issue raised by normative competence accounts is that of the status of the moral and other norms that autonomous agents identify. For example, it has been argued that moral norms are objective because they derive from the requirements of objective reason (Wolf 1990). If this is right, the capacity required for autonomy is a capacity to 'track' objective features of the world. Normative competence theories therefore place strong constraints on the contents of agents' preferences. Preferences for incorrect norms or morally wrong courses of action—that is, preferences that do not match the relevant objective features of the world—are not autonomous. The idea that morality is objective—moral realism—is controversial, despite being a well-known and widely supported position. Moreover, realism about non-moral norms is often thought to be less plausible than moral realism. An additional difficulty for normative competence accounts is the charge that they conflate autonomy with moral responsibility. In the case of JoJo, for example, it may be that the comprehensiveness of his socialization absolves him from full moral responsibility for his acts, but does it follow that the acts are not the product of his own agency? The wish to maintain a conceptual distinction between responsibility and autonomy has led to a revision of the normative competence approach (Benson 1994).

4. *Psychological and Self-realization Approaches*

Neither procedural nor neo-Kantian conceptions of autonomy give much emphasis to the nature of the autonomous agent, and how psychological and other features of the agent may be necessary to produce and maintain autonomy. Several recent theories developed by feminists and others address this aspect of the problem, focusing particularly on the putative incompatibility between autonomy and oppression. On psychological approaches, certain kinds of psychological impairment, such as impairments of self-confidence and self-esteem, are construed as undermining autonomy. Consider a person who is believed (erroneously) by family and the medical establishment to be mentally unstable because of being passionate, excitable, and 'prone to emotional outbursts in public' (Benson 1994). Since these external judgments of character and behavior are trusted by the person, this causes disorientation, and loss of self-confidence and self-esteem. The person's will is still intact, because preferences and desires can still be put into effect, but due to the lack of a sense of self-worth, the person also lacks certain important attitudes to decision-making that seem to be necessary for decisions to be autonomous. The person is not 'behind' those decisions and does not treat them as authoritative. Such failures of a sense of assurance about the capacity to form preferences and make decisions (for example, failures of self-confidence, self-trust, or a sense of self-worth) can be caused by a variety of psychological states, including many arising from oppression.

Self-realization conceptions also focus on the inauthenticity of desires in the context of oppression. Meyers's account, for example, argues that an autonomous self is one that has been expressed or 'realized' through the exercise of the capacities of self-definition and self-direction as well as that of self-discovery. The account emphasizes the way in which these capacities can be undermined or enhanced by different kinds of socialization, especially oppressive socialization. Meyers's account is meant to be procedural, because it does not place constraints on the outcomes of the

exercise of the capacities necessary for autonomy. As long as agents' capacities for self-discovery, self-direction, and self-definition are fully developed, they are fully autonomous. This suggests that preferences endorsing one's own oppression may in principle be fully autonomous on Meyers's account. It has been questioned whether such preferences are compatible with self-realization, and hence whether self-realization accounts can be purely procedural (Mackenzie and Stoljar 2000b, pp. 18–19). Self-realization has also been linked to a substantive notion of human flourishing. It has been proposed that an influence on an agent undermines autonomy when it interferes with the agents' normal functioning (Buss 1994, p. 106). 'Normal functioning' is spelled out using a normative notion—that of well-being, or human flourishing—and thus the agents' reasoning processes are subject to a normative constraint.

Psychological and self-realization accounts have several advantages. First, they do not rely on metaphysical conceptions of the self, but rather situate agents within the network of social relations that affect them. As a result, they take an important step towards understanding the effects of oppression, and how oppression is incompatible with autonomy. Second, these accounts do not require that autonomous agents have preferences and desires with specific contents, and nor do they appeal to objective conceptions of value. They do, however, place weaker external constraints on the contents of desires and preferences. For example, if a lack of self-trust undermines autonomy, desires with contents that are incompatible with self-trust are nonautonomous. Thus these accounts are not purely procedural or content neutral.

There are nevertheless questions that can be raised for both psychological and self-realization approaches. For example, how exactly is the psychological impairment (that is, the lack of self-esteem, self-trust, or self-confidence) tied to the failure of autonomy? One suggestion is that the absence of self-worth erodes agents' sense of themselves as competent 'to answer for one's conduct in light of normative demands that, from one's point of view, others might appropriately apply to one's actions' (Benson 1994, p. 660). Agents therefore are not autonomous, because they do not see themselves as authoritative with respect to the normative demands the community places on them. However, in certain typical cases of nonautonomous decision-making, this link between the lack of a sense of self-worth and the lack of normative competence does not seem to be present. In the case of the young student who has internalized fashion ideology, one may suppose that a low sense of self-worth accompanies commitment to these norms. Yet it is not clear that the student's lack of self-esteem interferes with the sense of self as being normatively competent to answer the fashion world's expectations. Indeed, the student seems to wish to increase the sense of self-worth by living up to these norms. In this sense, the student is very much 'behind' the commitment to these norms. A second issue is whether the psychological impairment itself is constitutive of the lack of autonomy, or rather if it causes the breakdown of some other constitutive process. Psychological conceptions claim that the reasoning capacities of agents are fully intact despite the psychological impairment, and hence the failure of autonomy is due to the absence of a necessary psychological or emotional state, such as that of sense of self-worth. A proponent of a procedural conception may respond that an agent's lack of a sense of self-worth makes it impossible for critical reflection to operate appropriately. Hence it leads to a procedural failing that is responsible for the agent's lack of autonomy. A third issue concerns the notion of human flourishing that is central to self-realization accounts. The value of flourishing operates as a constraint on autonomous reasoning in the same way as do the moral and other norms of Kantian conceptions, and the same questions can be raised. For example, is the self-realization conception committed to some objective and universal notion of flourishing that autonomous reasoning must reflect? If so, it may be appealing to an implausible—or at least contentious—theory of flourishing.

Avant-garde Art and Artists

Since the concept of the avant-garde appeared at the beginning of the nineteenth century, it has been applied to a wide variety of aesthetic and social practices. Analysis of different uses of the term shows that it has been applied to three types of changes: in the aesthetic content of art, in the social content of art, and in the norms surrounding the production and distribution of artworks (Crane 1987, pp. 14–15). For example, the term avant-garde is applied to the aesthetic content of art objects: (a) when those works represent a redefinition of conventions for creating art, often in such a way that they are perceived as violating taboos and as shocking or offensive; (b) when they involve the use of new tools and techniques, or concern the nature or use of techniques *per se*; and (c) when they redefine what can be considered an artwork. The term is applied to the social content of artworks when they express social or political values that are critical of or different from the dominant culture, when they attack art institutions, and when they attempt to redefine the boundaries between high and popular culture. Finally, the term is applied to creators of artworks when they attempt to alter the social context for the production of art (for example, appropriate role models, critics, and publics for artists), the organizational context in which art is displayed and distributed, and the social role of the artist in terms of his or her participation in other social institutions such as education, religion, and politics. This article examines the evolution of artistic avant-gardes since the nineteenth century, theories of the avant-garde, and sociological research on the social organization and reception of avant-gardes.

1. *Origins and Evolution of the Term*

Originally referring to a section of an army that marched ahead of the troops, the term avant-garde was first used in France in the 1830s to refer to artists as leaders and creators of a new social order (Nochlin 1968, p. 5). Until the middle of the nineteenth century, the term generally meant that an artist was both politically and aesthetically progressive. The artist was expected to lead society in new directions and to be in conflict with tradition and the Establishment. Subsequently, the term began to refer to artists whose works expressed alienation from bourgeois society in the form of ironic or destructive commentaries on social and artistic values rather than commitment to specific programs for social or aesthetic change. These different elements associated with avant-gardes—political rebellion, aesthetic rebellion, and alienation—continued to be important in the twentieth century.

At the beginning of the twentieth century, the idea of the avant-garde as alienation was given a new dimension by Marcel Duchamp who created artworks or 'ready-mades' by making minor changes in existing artworks or by arbitrarily declaring that commonplace objects, such as a mass-produced urinal, were artworks. This conception of the avant-garde became the basis for the Dadaist movement consisting of groups of artists, located in several European cities and in New York, whose members attempted to destroy artistic conventions and to shock the public. In this period, the Dadaists shared with the Italian Futurists (whose aesthetic innovations were very different) 'a belief that they were ahead of the society in which they lived and that they were breaking social bonds of restraint' (Taylor 1968, p. 97). This attitude led the Futurists to engage in flag-burnings and to stage assaults on theaters and opera houses, although they were not actually interested in changing the social order but in aesthetic change and in 'continuous revolution as a way of art' (p. 100).

During the twentieth century, the term was applied to groups of artists who developed new aesthetic programs, many of them concerned with problems of visual perception and the interpretation of visual experience. This type of art dealt with aesthetic and

technical issues and was detached from the concerns of everyday life. Although the term avant-garde appeared before the development of modernism in the arts, there was a pronounced affinity between avant-gardes and modernism which was reflected in the modernist's commitment to the development of a particular style. At the end of the 1930s, Clement Greenberg, an American art critic, provided a theoretical justification for the type of avant-garde that has proven to be most characteristic of the second half of the twentieth century, one which engages in art for art's sake and which is concerned with aesthetic values rather than with social conflict or political struggle (Orton and Pollock 1981, p. 322). Another American art critic, Harold Rosenberg (1968), argues that the suppression of avant-garde art by the Communists and later by the Nazis marked the beginning of the separation of political and artistic avant-gardes. As an example of this rupture during the postwar period, he cites the 1968 Venice Biennale where militant students denounced the artworks as 'art for dealers and the rich.'

In the late twentieth century, the success of Pop art, Conceptual art, and Neo-Expressionism signaled both the triumph of the ironic, alienated conception of the avant-garde and a decline in the priority attached to aesthetic innovation, reflecting the increasing influence of postmodernism in all forms of culture. Unlike the modernist, the postmodernist is not interested in style conceived as a consistent, integrated set of aesthetic elements or in using a style to express opposition to the dominant culture. Instead, the postmodernist engages in *pastiche*, bringing together disparate elements from many previous texts, regardless of whether they produce a coherent unity. According to Goldman (1992, p. 214), the meaning of postmodernist texts cannot generally be discerned from analyzing the texts themselves but only by asking where the elements in the text come from. Postmodernist works tend to expose or reinterpret rather than criticize or attack the dominant culture.

That the concept of the avant-garde is still relevant today appears to be confirmed by the intensity of controversies surrounding government funding for art works that challenge conventional attitudes and values. The allocation of funds by the United States government agency, the National Endowment for the Arts, to support exhibitions of artists such as Robert Mapplethorpe and André Serrano, whose works were perceived as having transgressed moral and religious boundaries, created enormous opposition and even pressure to dissolve the agency itself. However, it is significant that these artists were not members of art movements and that their activities did not engender such movements. Dunn (1991, p. 124) argues that, in the highly fragmented and ambiguous context of postmodern culture, artistic avant-gardes have been replaced by cultural avant-gardes to which the term avant-garde is seldom applied. These movements engage in collective protest and challenge tradition and hegemonic structures on a wide range of social and cultural issues such as class, gender, sexuality, race, peace, and ecology.

2. *Theories of the Avant-garde*

Theorists who have written about the avant-garde have generally based their analyses on certain types of avant-gardes, particularly those that have rebelled against the dominant culture and excluded others from consideration. A major strand of theory concerning the avant-garde derives from the critical theorists, known as the Frankfurt School. Adorno despised popular culture produced by culture industries on the grounds that it provided shallow entertainment that distracted and manipulated the unsophisticated public. He interpreted the role of high culture and its avant-gardes as that of challenging dominant institutions and conventional ways of thought. For Benjamin (1968), the significance of Dadaism as an avant-garde was that the Dadaists deliberately attempted to produce art works that lacked an aura of uniqueness and authenticity, thus undermining the status of the arts as sacred.

Two leading theorists of the avant-garde are Bürger (1984) and Poggioli (1968). A contemporary critical theorist, Bürger examines the activities of avant-gardes and the social content of their work, arguing that what is most characteristic of avant-gardes is their challenge to art institutions. Instead of creating works of art that were autonomous, complete, and separate from social life, the avant-garde attempted to create works that challenged the public to make sense of them and to relate them to their daily lives. On this basis, he restricts the title of avant-garde to a small number of movements, including Dadaism, early Surrealism, and some aspects of Futurism.

Poggioli (1968) argues that the dominant characteristic of avant-garde art is alienation in all its forms—psychological, social, economic, historical, aesthetic, and stylistic. Bourgeois, capitalist, and technological society provides avant-garde artists with freedom to create while the tensions underlying this type of society provide them with 'a reason for existing.' In Poggioli's view, the avant-garde artist is motivated by nostalgia for an earlier period when the artist was treated as a creator rather than as a parasite and a producer.

Huston (1992) is critical of these theories on the grounds that they are unable to explain and often do not even consider factors affecting the production and social reception of avant-garde arts. He argues that most styles of avant-garde art ultimately succeed in winning the support of the art establishment which initially rejected them but that theories of the avant-garde are not helpful in explaining these developments. In his view, these theories tend to legitimate avant-

garde art as *true* art and 'a certain vision of the artist as a great artist' (p. 78). In other words, he sees the concept of the avant-garde as an ideological category that accepts uncritically artists' conceptions of their situation and tends to be used in such a way as to legitimate certain types of art rather than others (p. 79).

These theories of the avant-garde can also be faulted on the grounds that they treat the distinction between high culture and popular culture as unproblematic and view high culture and its avant-gardes as being the most influential and prestigious forms of culture. In fact, the enormous proliferation of different forms of popular culture (film, television, and popular music) has made it difficult to ignore the aesthetic influence of these cultures on traditional arts and in everyday life, and has, at the same time, decreased the influence of the traditional arts such as painting, theater, dance, poetry, and experimental music. The latter tend to be appreciated by distinct and relatively small subgroups within the middle and upper classes, generally located in a few major cities.

Bauman (1997, p. 95) argues that avant-gardes have disappeared in this postmodern context because there is no longer any clear-cut distinction between styles that can be considered more or less advanced or more or less progressive than others. Instead, while there is a great deal of change in contemporary arts, these changes are 'random, dispersed, and devoid of clear-cut direction.' The importance of an artwork is determined less by aesthetic elements than by publicity and the notoriety that results from it.

3. *Sociological Studies of Avant-gardes*

While theorists of the avant-garde such as Bürger and Poggioli emphasize the aesthetic, political, and ideological programs of avant-gardes, sociological research has focused on (a) the relationships among artists and (b) the reception of artworks by arts institutions and by the public. The dominant view underlying recent studies in the sociology of art is that the significance of all types of art is socially constructed. The question becomes one of identifying the social processes through which this takes place. A major concept is that of the art world, in which art is produced through the efforts of artists in collaboration with members of many other occupations (Becker 1982).

White and White (1965) document changes in social and institutional structures that supported the activities of artists in nineteenth-century Paris. These changes facilitated the emergence of avant-garde styles. Specifically, the transition from academic art to Impressionism, a style that transformed the aesthetic conventions of the period, necessitated the development of a new occupation for buying and selling paintings, that of the art dealer, and the appearance of a new type of collector, drawn from the expanding middle class.

Becker (1982, pp. 304–5) does not use the term avant-garde, preferring to use the concept of 'artistic revolution.' The latter is set in motion by ideological and organizational activities among art world participants. Ideological changes are revealed by the appearance of 'manifestos, critical essays, aesthetic and philosophical reformulations, and revisionist histories,' while organizational changes lead to shifts in control over 'sources of support, audiences, and distribution facilities.' Like White and White, Becker argues that the most important factor affecting the success of revolutions is the extent to which their proponents are able to take over the art world's organizational structure and facilities. He says (p. 310): 'Ideas and visions are important, but their success and permanence rest on organization, not on their intrinsic worth.'

Crane (1987, pp. 137–43) traces changes in the roles of artistic avant-gardes during the twentieth century and particularly in the decades after World War II. She identifies three artistic roles that existed in the prewar period, that of the aesthetic innovator who analyzed visual reality in terms of its constituents such as color and form, the iconoclast, who attacked bourgeois conventions and art institutions, and the social rebel whose target was political and economic institutions. In the postwar period, these three roles were gradually transformed. The role of the aesthetic innovator emerged as the dominant role but in response to the expansion of public, private, and corporate expenditures and the creation of new cultural institutions, these artists increasingly identified with the middle class in terms of lifestyle and the content of their works. Iconoclasts thrived during the 1960s but after that decade concentrated upon exploring the limits of art itself or eliminating the boundaries between the arts and the media. Artists who moved in the latter direction came to see themselves as entertainers rather than members of an alienated avant-garde. There was little support for the role of social rebel. Political art and a humanistically oriented representational art remained on the periphery of the art world. The role of social rebel was replaced by the democratic artist who communicated social and aesthetic ideas to audiences in poor urban neighborhoods and who had virtually no contact with the art world. (For an examination of art avant-gardes in Israel see Greenfeld 1988.)

At the end of the twentieth century, in the absence of strong avant-garde movements within the art world, alternatives to the aesthetic and social values of the art establishment often came from outside the system, specifically from the works of untrained and often uneducated artists, including folk and ethnic artists, the homeless, prison inmates, elderly people in nursing homes, and hospice patients (Zolberg and Cherbo (1997, p. 1). The so-called 'outsider' artists who

worked alone and who had formerly been completely ignored by the art establishment were now supported by a network of dealers, curators, and collectors.

Drawing on poststructuralist theories, sociologists view the meaning of an artwork as being constructed in the process of reception as much as in the process of creation. The response of the audience constitutes part of the meaning of the artwork. Consequently, the meaning of an avant-garde movement changes in different social contexts as different social groups with particular institutional interests engage in 'a struggle over the text.' Using this perspective, Halley (1985) examined the reception of the Dada movement and showed that, in its own time, its importance was not recognized. Audiences were very small and the movement was overshadowed by Surrealism. Subsequently, different social groups such as art historians, curators, critics, and artists themselves developed competing and conflicting interpretations of Dada and often misunderstood or ignored the original intentions of Dadaist works. From the beginning, there was more interest in Dada in the United States than in Europe, which helps to explain its influence on American avant-garde groups in music, dance, and art in the postwar period. These groups incorporated Dadaist ideas into their own artworks, contributing to wider recognition of the movement.

Bourdieu's (1984) theory argues that support for art movements is associated with social class but that a specific aesthetic statement will appeal to different social strata, depending on its significance in the definition of taste in different time periods. The social positions of supporters of an emerging avant-garde movement differ from the social positions of those that admire the movement after it has received recognition. For Bourdieu, the important aspect of the avant-garde is not its aesthetic characteristics but its structural position in the art world which is subject to change over time.

Attempts to show the relationship between social class and support for artworks that have been considered avant-garde in the past, such as abstract art, have yielded ambiguous results (Halle 1992). However, appreciation of artworks that are still considered avant-garde is confined to relatively small groups even within the middle and upper classes, as is suggested by the intensity of the conflicts that arise when such works are displayed in public places (Heinich 1997).

4. *Avant-gardes and Popular Culture*

In the past two decades, the electronic media have appropriated most of the visual strategies and tactics of artistic avant-gardes from the prewar period. Caldwell (1995, p. 8) claims that 'every framework of the avant-garde…had become highly visible in some form in the corporate world of the new television.' Kaplan (1987, p. 55), in an attempt to classify music videos in the mid-1980s, found that all the categories she identified used avant-garde strategies. The originators of punk music used many of the tactics identified with early-twentieth-century avant-gardes, such as the blurring of boundaries between art and everyday life, intentional provocation of the audience, and disorganization of accepted styles and procedures of performance (Henry 1984).

However, assimilation by the mass media of oppositional stylistic devices associated with avant-gardes raises the question of the extent to which oppositional themes are being disseminated. High-culture institutions frame oppositional messages in such a way as to highlight their effect: an entire evening at the theater devoted to a particular playwright, an entire gallery or museum wing devoted to the work of a particular artist for several weeks. By contrast, the sheer volume of messages of all kinds being transmitted by the mass media tends to obliterate the effect of oppositional messages when they do appear. Kaplan (1987, p. 65) points out that oppositional messages are likely to be 'overridden by the plethora of surrounding texts.'

The commitment of popular culture creators to the tenets of the avant-garde may be questionable. Fashion designers who create luxury clothing for wealthy clienteles often incorporate avant-garde devices in their styles as part of a marketing strategy to attract attention, either to the clothes or to products licensed under their names (Crane 2000). Benetton, an Italian clothing manufacturer, has commissioned advertisements in which photographs, often reprinted from the press, graphically portray social and political crises and calamities in order to increase public awareness of social, political, and environmental issues (Guerrin 1998). However, critics have not accepted this advertising strategy at face value but have claimed that the company is exploiting tragic situations as a means of publicizing its products.

Curiously, as some of the properties of high culture are being assimilated or co-opted by certain forms of popular culture, the old hierarchy of high and low is reappearing in the latter. For example, in popular music, certain genres are deemed superior to others and some artists' works are considered 'classics' in comparison with all the rest (Regev 1994).

5. *The Contemporary Relevance of Avant-gardes*

An analysis of the evolution of avant-gardes in art history, as well as a review of theories of the avant-garde and of relevant sociological research, suggests that the concept of the avant-garde applies to the behavior and activities of artists during a period of about 150 years. At the present time the term is being less frequently used because it is more difficult to identify avant-gardes in an era when diverse and fragmented postmodernist styles predominate. Ironi-

cally, the term now tends to be applied to works created for popular consumption that incorporate techniques but not ideological content from avant-garde movements that existed earlier in the century. Meanwhile, the avant-garde artist's mission as iconoclast and social rebel has been assumed by a broad range of 'micropolitical' movements outside the arts.

D. Crane

Aviation Safety, Psychology of

Aviation psychology arose as a unique discipline within the field of psychology as the result of technological developments during World War II. Prior to this point in history, most aviation accidents occurred as a result of some structural failure of the aircraft or the failure of the engine to continue to produce power (Koonce 1999). Because of the military demands of World War II, however, the sophistication and reliability of aircraft were improved considerably. Nonetheless, these technological improvements, like many more recent advancements in aircraft capabilities, increasingly challenged the abilities of pilots. Consequently, aircrew error began to play a progressively larger role in aviation accidents, as aircraft became more sophisticated and reliable (Shappell and Wiegmann 1996). Consequently, the need to address the psychological or 'human' side of aviation safety sparked the emergence of aviation psychology.

At the beginning of the twenty-first century, aviation psychology continues to be a primary discipline responsible for addressing and preventing human error in aviation. Specifically, aviation psychologists attempt to understand the fundamental nature and underlying causes of aircrew error and unsafe acts that significantly impact flight safety. However, just as many professionals in other areas of psychology have different opinions or theories about human behavior, aviation psychologists also have varied perspectives

on pilots' performance in the cockpit (Hollnagel 1998). There are primarily four perspectives: (a) cognitive, (b) ergonomics, (c) psychosocial, and (d) organizational. In turn, these different perspectives have historically led to different approaches for addressing pilot error in the cockpit. The purpose of this article therefore, is to provide an overview of these error perspectives and their associated approaches to improving aviation safety. A brief discussion of more recent applications of aviation psychology to safety issues outside the cockpit will then be provided.

1. Cognitive Perspective

The principal feature of the cognitive perspective is the assumption that the pilot's mind can be conceptualized as an information-processing system, much like a modern computer. As such, the cognitive perspective assumes that once information from the environment makes contact with one of the senses (e.g., eyes, ears, nose, etc.), it progresses through a series of stages or mental operations to produce a response or action (Wickens and Flach 1988). These intervening mental operators include such things as information recognition, problem diagnosis, goal setting, and strategy selection (O'Hare et al. 1994). Other factors such as attention, memory capacity, and prior knowledge or experience with similar environmental conditions also affect pilots' interpretation of information and their reactions to it. Consequently, pilot errors are believed to occur when one or more of these mental operations fail to process information appropriately (Wiegmann and Shappell 1997).

According to the cognitive perspective, reducing aircrew errors and improving aviation safety necessarily requires an enhancement of pilots' information-processing abilities. However, unlike computers that can be improved by upgrading the hardware, the information-processing hardware of the human (i.e., the brain) is generally fixed inside the head! Therefore, in order to improve performance, cognitive psychologists have attempted to improve the manner in which pilots process information. One way this is accomplished is through improved training methods. Better training methods are often developed by examining the techniques used by expert pilots to solve problems and allocate their attention to the different sources of information in the cockpit. This information is then used to train novice pilots to improve their techniques and flight performance. Another way of improving information processing is through the standardization of procedures and the use of checklists. These methods facilitate information processing and performance by reducing mental workload and task demands on pilots' memories during normal operations and emergencies, thereby reducing the potential for errors and accidents.

2. Ergonomics and Systems Perspective

According to the ergonomics and systems perspective, pilot performance (both good and bad) is the result of a complex interaction among several factors (Edwards 1988). After all, flying an airplane is a very complicated and dynamic task. Indeed, military and commercial pilots interact with high-tech airplanes and cockpit equipment and must safely operate their aircraft in all types of weather conditions. According to the systems perspective, therefore, a pilot should not be viewed as a sole source of an error or cause of an accident. Rather, pilot error is believed to occur when there is a mismatch or breakdown in the interface between the aircrew and the technology. Consequently, aircrew errors are often referred to as 'design-induced' because they are viewed as resulting from a failure to design the interface in a way that optimizes the pilot–airplane interaction.

The approach to reducing errors and improving safety taken by most ergonomists and systems theorists is to improve the design of the interface between the pilot and the airplane. Such interface issues include the design of equipment used to manually control the airplane, such as the yoke and rudders. However, they more often include the design of better flight instruments that display the status of the aircraft, such as the altimeter and airspeed indicator. As technology has increased and airplanes have become more computerized, the tasks performed by the pilot and airplane have also been redesigned through the use of automation. A ready example is the development of the autopilot and other flight management systems (FMS) that can navigate and fly the airplane without pilot input. By sharing the responsibility with automation, the opportunity for pilots to commit errors is presumably reduced. However, even when errors do occur, they can often be 'caught' by the airplane's computer. Therefore, the system as a whole has become more 'error tolerant' and the negative consequences of pilot errors (i.e., accidents) are reduced.

3. Psychosocial Perspective

According to the psychosocial perspective, flight operations are best viewed as a social endeavor that requires aircrew to interact with one another, as well as with a variety of other flight support personnel, such as air traffic controllers, dispatchers, ground crew, maintenance personnel, and flight attendants. Aircrew performance, therefore, is directly influenced by the nature or quality of these interactions (Helmreich and Foushee 1993). These social interactions, however, are often influenced by both the personalities and attitudes of the individuals within each group. The major theme of the psychosocial perspective, therefore, is that errors and accidents occur when personality difference and conflicting

attitudes disrupt group dynamics and interpersonal communications.

The psychosocial approach to reducing errors in the cockpit has focused on improving the social interactions among aircrew. One method used to achieve this goal is through systematic crew-pairing procedures. These procedures attempt to match aircrew based on their level of experience, flight skills, and personalities. Another method that has been developed is crew resource management (CRM) training. This training attempts to challenge and change pilots' traditional attitudes about differences in authority between the captain and the other aircrew (e.g. the co-pilot or first officer) that have been shown to hinder communication and cause accidents (Wiegmann and Shappell 1999). Other aspects of CRM training involve educating and training aircrew to use techniques for more effectively communicating problems, dividing task responsibilities during high workload situations, and resolving conflicts in the cockpit. Such improvements in aircrew coordination and communication ultimately result in fewer errors and improved aviation safety.

4. *Organizational Perspective*

According to the organizational perspective, pilot performance must be viewed in terms of the organizational context in which it takes place (Heinrich et al. 1980). Indeed, all professional pilots in both the military and commercial aviation industries operate within an agency or company that regulates their time and performance in the cockpit. Aviation organizations are therefore responsible for ensuring that only those pilots with the 'right stuff' are hired to fly their aircraft. In addition, these organizations are also responsible for instituting appropriate procedures that ensure safe operations of the aircraft (Shappell and Wiegmann 2000). From the organizational perspective, therefore, aircrew errors and subsequent accidents are believed to occur when managers and supervisors fail to set up basic conditions within the organization that promote flight safety (Reason 1990).

Given it is the organization's responsibility to ensure that only skilled and safe pilots get into the cockpit, a primary method used by organizational psychologists to prevent aircrew errors is the use of pilot selection tests. For those organizations that train their own pilots, as do many militaries around the world, these selection tests attempt to 'weed out' those applicants who exhibit less than adequate mental aptitudes or psychomotor skills necessary for learning how to fly. Other commercial organizations that hire trained pilots often use background and flight experience as employment criteria, while others also use medical screenings and interviews to select their pilots. In addition to selection techniques, however, another organizational approach to reducing errors in the cockpit is through the establishment of policies or rules that regulate what pilots can and cannot do in the cockpit. Such rules may restrict the type of weather in which pilots may operate their aircraft, or may limit the number of hours pilots can spend in the cockpit, in order to avoid the possible detrimental effects of fatigue on performance. By placing only safe and proficient pilots in the cockpit and limiting aircraft operations to only safe flying conditions, organizations are able to reduce the likelihood that pilots will make mistakes and cause accidents.

5. *Future Directions: Aviation Safety Outside the Cockpit*

Historically, the majority of safety efforts by aviation psychologists have focused on the performance of aircrew. However, there is a growing concern within the aviation community over safety issues that arise outside the cockpit, and an increasing number of aviation psychologists are being called upon to address some of these issues. Two such areas of growing concern are air traffic control and aircraft maintenance.

During the early years of aviation, aircrew avoided becoming lost by using simple cockpit instruments and visual landmarks on the ground. However, both military and commercial demands gradually required pilots to fly in poor visibility conditions and at night. The job of air traffic control was subsequently established to help maintain safe separation between aircraft and to ensure that pilots would not fly their planes into the ground or other obstacles (Hopkin 1995). Still, as the number of aircraft and demands on air traffic control services has increased over the decades, so has the number of accidents, incidents, and runway incursions (loss of safe separation among aircraft and other ground vehicles). As with most aviation accidents today, most of these occurrences have not been due to faulty control equipment, but rather to human error, including mistakes made by air traffic controllers.

Another important factor affecting aviation safety is aircraft maintenance. Indeed, despite all the technological advances and improvements in the reliability of aircraft equipment and systems, modern aircraft still need maintenance. This maintenance often requires that the aviation maintenance technician repeatedly disassemble, inspect, and replace millions of removable parts over the long working life of the aircraft (Reason 1997). During the early years of aviation, aircraft equipment and engines were 'simple,' compared to their modern-day counterparts. As such, these maintenance inspections were relatively easy and resulted in frequent detections and replacement of failed components that often caused accidents. Today,

however, aircraft components and systems are very complex and hardly ever fail. Still, the intricate nature of inspecting and maintaining modern aircraft often lead to errors by the mechanics doing the work. As a result, the contribution of maintenance and inspection errors to aviation accidents and fatalities is on the rise.

Given these growing concerns for safety issues outside the cockpit, aviation psychologists have begun to examine the 'human' side of both air traffic control and aircraft maintenance. However, compared to the long history of efforts by aviation psychologists to address aircrew error in the cockpit, efforts to address human error in the air traffic control and maintenance arenas have only recently begun. Nevertheless, just like aircrew performance in the cockpit, the methods used by aviation psychologists to address errors made by controllers and maintenance personnel depend heavily upon the perspective they take concerning the underlying nature and causes of these errors. These perspectives are generally very similar to those taken by aviation psychologists when addressing aircrew error in the cockpit. Consequently, these perspectives will undoubtedly produce a variety of approaches for addressing human error in air traffic control and aircraft maintenance and will each make an important contribution to future improvements in aviation safety.

6. *Conclusion*

Aircrew error has played a progressively more important causal role in aviation accidents as aircraft have become more reliable. The field of aviation psychology, therefore, studies aircrew error and other pilot actions that can significantly jeopardize the safety of flight. More recently, aviation psychologists have also begun to address errors in air traffic control and aircraft maintenance, which are quickly becoming additional safety concerns within the aviation industry. Aviation psychologists, however, often have different viewpoints or perspectives when it comes to explaining the causes of human errors, both inside and outside the cockpit. These viewpoints are not necessarily incompatible. Rather, they focus on the different cognitive, engineering, social, and organizational factors that frequently contribute to a breakdown in human performance. As such, each perspective has uniquely contributed to the development of intervention techniques and methods for reducing errors and increasing aviation safety. More information regarding these approaches outside the aviation domain can be found in this volume, including discussions of the ergonomics and systems approach (e.g., *Engineering Psychology*), group dynamics and team work (e.g., *Group Processes in Organizations*; *Teamwork and Team Training*), and personnel selection (e.g., *Personnel Selection, Psychology of*).

Finally, there are other fields outside of aviation psychology that have also contributed specifically to improvements in aircrew performance but are not discussed here. One of the most significant contributors is the field of aviation medicine that has revealed several aeromedical factors that impact aircrew performance during flight (Reinhart 1996). For example, the field of aviation medicine has led to a better understanding of the physiological and behavioral factors that lead to stress and fatigue in the cockpit. This knowledge has led to more 'biocompatible' flight schedules for aircrew, particularly when traveling overseas or across several time zones. More information about the general effects of stress on human performance can be found in *Stress in Organizations, Psychology of*.

In conclusion, the field of psychology has a long history of involvement in the process of improving aviation safety. These efforts, combined with the efforts for those in other behavioral, social, and biological sciences, have contributed significantly to the reduction of human error and aviation accidents, making aviation one of the safest modes of transportation.

Avoidance Learning and Escape Learning

Avoidance learning in animals is studied using an instrumental (operant) training paradigm that was created and first reported by L. H. Warner (1932a) in a study of the 'association span of the white rat.' In this procedure, a warning signal (WS) predicts the subsequent occurrence of an aversive event, typically a mild electric shock delivered to the feet of the animal. A response defined by the experimenter, e.g., pressing a lever in a 'Skinner box' or running and/or jumping over a hurdle to the opposite side of a two-compartment chamber (a 'shuttle box'), terminates the WS and prevents the occurrence of the shock. This is an avoidance response. Failure to avoid in the presence of the WS results in the predicted shock, which, in most procedures, can be terminated by the 'same' response, which is then classified as an escape response. Warner's procedure had its roots in one used by Yarbrough (1921), in which a mild shock was used as a cue for turning right or left for food reward in a maze; he found that the rats would respond similarly to a light signal that preceded the shock cue. Warner used what is now known as a 'trace-conditioning' procedure in which the warning signal was presented for 1 s, and the shock occurred 1, 10, 20, or 30 s after the onset of the WS in separate groups of animals (the trace intervals were 0, 9, 19, and 29 s, respectively). Difficulty of learning increased as a function of the WS-shock interval, which is, of course, confounded with the duration of the trace interval. Essentially no learning occurred in the 30-s group.

1. *Procedural Variations*

There are two forms of avoidance training: active and passive. In the active form, pioneered by Warner's early work noted above, the avoidance contingency requires the occurrence of a specific response, whereas in the passive form the avoidance contingency requires the nonoccurrence, i.e., the suppression, of some specific response. This is often called punishment. The punished response may occur because it is 'spontaneous,' i.e., innate, or because of prior reward or avoidance training. One form of the passive procedure that depends on innate behavior is the so-called one-trial passive avoidance procedure. A rat or mouse, both of which are nocturnal species, will readily leave a brightly lit, elevated platform to enter a dark compartment. If this photophobic response is then punished with a brief shock in the dark compartment, latency to re-enter the dark compartment is increased on subsequent tests, which is taken as a measure of the strength of the memory of the previous experience. This procedure has been used extensively to study the neuropsychological and neuropharmacological bases of memory, because the learning is exceptionally fast (one trial often suffices) and the learning event that establishes the memory is relatively fixed in time. The procedure has been especially useful in the study of retrograde amnesic events, such as electro-convulsive shock, stress, and hypothermia (see Duncan 1949, for an early example of this approach). If the punished response is learned and based on reward, the passive avoidance contingency usually results in suppression of the response, whereas if it is based on prior avoidance or escape training, the response is often facilitated or enhanced, at least temporarily, which can be viewed as a somewhat paradoxical effect of punishment. Note that in the active form, what the animal does to avoid the aversive event is well-defined and measured, whereas in the passive form, the avoidance response is not defined and rarely measured; only the punished response is defined and measured.

There are two kinds of avoidance training procedures: discrete-trial and free-operant. The experiment by Warner is an active form of the discrete-trial kind, but the passive form may also be of this kind. In such a case, a response in the presence of a discriminative stimulus or cue is punished. For example, an animal such as a rat may be trained to press a lever for food reward, and each response may be rewarded. However, in the presence of a specific cue, the responses may also be punished, either at every response or only some responses (partial punishment). In the active form of the free-operant kind of procedure, which originated with Sidman's (1953) initial publication of this method, there is typically no WS to predict the impending shock, only the passage of time since the last response or shock. Operationally, two timers control events: a response-shock (R-S) timer set, for example, at 30 s and a shock-shock (S-S) timer set, for example, at 5 s. Training begins with the S-S timer in control, and brief, e.g., 0.5 s, shocks occur every 5 s. A response interrupts the S-S timer and starts the R-S timer. If the R-S interval elapses, a shock is presented and the S-S timer takes over until another

response is made. Typically, rats pressing a lever under these conditions make a burst of responses immediately after a shock, and only with extensive training do they distribute some of their avoidance responses into the R-S interval. When a running response, as in the shuttle box, is used, long inter-response times well into the R-S interval are frequent, and the avoidance response is quite efficient. A variant of this procedure does not use the S-S timer, but terminates all shocks contingent on the response, so that the animal determines their duration. Another variant introduces a cue part way through the R-S interval, in which case responses tend to occur shortly before or after the onset of the WS.

2. *Theories of Avoidance Learning*

Early theorists had trouble accounting for avoidance learning because it appeared not to be a simple product of Pavlovian conditioning. One interpretation of Pavlovian conditioning, especially as it was applied to escape/avoidance learning, is that of stimulus substitution. The idea here is that the warning signal is a Pavlovian conditioned stimulus (CS) that is paired with shock on escape trials and, by association with the shock, becomes a substitute for that eliciting stimulus. An avoidance response is simply an escape response that has been transferred to the WS. This implies that the avoidance and escape responses should be the same, but in a companion piece to his original paper, Warner (1932b) showed that although the two responses accomplish 'the same end-result' they are 'clearly unlike' each other. He went on to demonstrate this fact in three different test situations which utilized three different forms of motor behavior. In each case the avoidance response appeared to be somewhat different from the escape response. Subsequently, Bolles and Tuttle (1967) showed that the avoidance and escape responses need not even be topographically similar, although there are some apparently innate constraints that make some combinations of escape and avoidance responses easier to learn than others.

Because avoidance learning appeared not to be a simple Pavlovian phenomenon, alternative interpretations were sought. These were based on the early work of behaviorists such as Watson (1913) and Thorndike (1913), who postulated that responses are learned as a result of their consequences. Thorndike's law of effect (Thorndike 1932) posits that responses are learned (reinforced) because of their effects or consequences, now termed 'response-contingent outcomes.' Simply put, responses increase if they are rewarded by desirable outcomes and decrease if punished by aversive consequences. But what is the reward for escape/avoidance learning? Perhaps it is the 'negative reinforcement' accruing from termination of the painful electric shock that clearly supports the escape response. What about the avoidance response, which seems to be acquired because of the nonoccurrence of a future aversive event. Hilgard and Marquis (1940), two early learning theorists, stated:

> Learning in this [avoidance] situation appears to be based in a real sense on the avoidance of the shock. It differs clearly from other types of instrumental training in which the conditioned response is followed by a definite stimulus change—food or the cessation of shock. In instrumental avoidance training the new response is strengthened in the absence of such a stimulus. Absence of stimulation can obviously have an influence on behavior only if there exists some sort of preparation for or expectation of the stimulation.

Several theorists answered the question, in various ways, of what mediates the avoidance response. With theoretically important variations as to detailed mechanisms, all approached the problem by postulating conditioned or learned fear (Mowrer 1950, Miller 1951, Solomon and Wynne 1954, Rescorla and Solomon 1967) or, more operationally, conditioned aversion (Anger 1963), as the mediating process. For Miller, fear was learned, along with the escape response, as a result of negative reinforcement accruing from the instrumental termination of pain from the electric shock. For the others, fear was a Pavlovian conditioned response that came to be elicited by the WS as a result of the temporal contiguity of the WS and shock on escape trials. Thus, two learning processes were assumed to account for the phenomena of escape/avoidance learning: (a) acquisition of fear during escape trials, either by Pavlovian conditioning (S-S contiguity) or operant learning reinforced by shock termination, and (b) acquisition of the instrumental escape response reinforced by shock termination and acquisition of the instrumental avoidance response reinforced by termination of the now aversive warning signal, and reduction of conditioned fear. Kamin (1956) showed that both termination of the WS and avoidance of the shock are sufficient for avoidance learning, although termination of the WS is not necessary. Additional experiments that support this two-process model have employed a transfer procedure in which animals undergo Pavlovian conditioning in one situation, and the CSs of that procedure are superimposed on an operant baseline of responding in another situation. A CS^+ from excitatory aversive conditioning facilitates a Sidman avoidance response during transfer, and, conversely, a conditioned inhibitory CS^- from various forms of discriminative conditioning inhibits the operant baseline of responding (Rescorla and LoLordo 1965).

Countering the two-process model are more recent 'cognitive' approaches, e.g., Bolles (1972) and Seligman and Johnston (1973). For example, Bolles hypothesized that two expectations are learned during avoidance training: (a) some stimuli in the situation are followed by shock and become signals of danger, and (b) a certain response will lead to safety and

becomes a signal of that safety. In this model, reinforcement is irrelevant, as all avoidance responses are innate species-specific defense responses (SSDR) (Bolles 1971), and avoidance responding consists simply of these innate (prewired) responses: withdrawal from cues of danger and approach to cues of safety. Despite the prevalent cognitive 'zeitgeist,' not all learning theorists find such mentalistic models adequate.

3. *Individual Differences*

Bolles' SSDR hypothesis, however, raises the question of what are the biological bases of avoidance learning. The general finding is that at least some animals of most species can learn the avoidance contingency, but the proportion that can learn varies among species and among the various forms and kinds of training procedures. Dogs are particularly good at learning in an active, discrete-trial or free-operant procedure in a shuttle box, and they also typically show strong resistance to extinction (Solomon and Wynne 1954). In contrast, rats are especially difficult to train using an active, lever-pressing discrete-trial procedure, although with the aid of relatively long WS-shock intervals and strong exteroceptive safety signals following each avoidance response, most rats learn rapidly (Berger and Brush 1975). An additional general finding is that with most procedures, individual differences are rather large, with some individuals learning in just a few trials, whereas others never learn to avoid but behave unremarkably in other respects. There are also large differences in the proportion of animals that learn among different strains of rats, among animals of the same strain from different commercial suppliers, and even between successive shipments of the same strain from the same supplier.

4. *Genetic Contributions*

Given this rather great variability, several researchers have bred rats selectively for extreme differences in avoidance learning. Bignami (1965) developed the Roman High- and Low-Avoidance strains in Italy, Brush et al. (1979) developed the Syracuse High- and Low-Avoidance strains in the USA, and Bammer (1978) first reported on the Australian High- and Low-Avoidance strains. In all three experiments, selection criteria were based on extreme differences in avoidance learning using discrete-trial, active, two-way shuttle-box procedures that were remarkably similar but differed in important details. Bidirectional selection was successful in all three experiments, and the strains, particularly the Roman and Syracuse animals have been used extensively in behavioral, anatomical, physiological, and neurochemical studies to identify characters that might be genetically correlated with and possibly mediate genetic expression in the selected phenotypes. Overall, these studies indicate clearly that avoidance learning has a major genetic component and that although the strains do not differ in general learning ability, they do differ in complex ways in the affective domain, i.e., in emotional reactivity or lability, in innate fearfulness or timidity, and in ease of conditioning fear. Not surprisingly, differences in brain anatomy and function, especially in those structures known to be involved in aversive conditioning and learning, and differences in the stress-related endocrine systems of the brain and body have also been found. Current research with these strains is now using population-level and state-of-the-art molecular genetic analyses to identify patterns of inheritance of phenotypic correlations and genetic polymorphisms between animals of these strains.

F. R. Brush

Axiomatic Theories

Axiomatic development of theories is common practice in pure mathematics and is also now widely used in many sciences. The main ingredients of the methods for axiomatizing theories are the following: statement of the primitive concepts of the theory, statement of the prior mathematics basis assumed, statement of the axioms, characterization of models of the theory and a definition of two such models having the same structure. Theories formulated in this way can easily satisfy the standard set-theoretical approach to axiomatization. The further step of formalizing the language of the theory, especially in the case of elementary theories, can lead to specific positive and negative results about the axiomatizability of theories in restricted languages.

1. *Historical Background*

Of all the remarkable intellectual achievements of ancient Greek civilization, none has had greater subsequent impact than the development of the axiomatic method of analysis. No serious traces are to be found in the earlier civilizations of Babylon, China, Egypt, or India. The exact history of the beginnings is not known, but elements that can now be identified emerged in the fifth century BC. A good reference is Knorr (1975). What can be said, and is important for the subsequent discussion here, is that, already in the next century, the fourth century BC, the detailed and elaborate theory of proportion of Eudoxus emerged in quite a clear and definite axiomatic form, most of which is preserved in Book V of Euclid's *Elements* (Euclid 1925). What is important about Eudoxus's work, and even the commentaries of the work of this time, for example, by Aristotle, in the *Posterior Analytics* (1994 74a–17), is that the theorems were proved, not for single geometric objects, but for magnitudes in general, when applicable. The recognition of the correct abstraction in the general concept of magnitude, its technical and thorough implementation by Eudoxus and the philosophical commentary by Aristotle, represent a genuinely new intellectual development. The language of Eudoxus's famous Definition V in Book V of Euclid's *Elements* matches in its abstractness and difficulty the standards of modern axiomatic theories in mathematics and the sciences.

Definition 5 *Magnitudes are said to be in the same ratio, the first to the second and the third to the fourth, when, if any equimultiples whatever be taken of the first and third, and any equimultiples whatever of the second and fourth, the former equimultiples alike exceed, are alike equal to, or alike fall short of, the latter equimultiples respectively taken in corresponding order.*

The codification of the Greek axiomatic approach in Euclid's *Elements* was a great success and remained almost unchallenged until difficulties in the details were found in the eighteenth and nineteenth centuries, as discussed later.

Various scientific examples of axiomatic theories existed already in ancient Greek times and, of course, from the Greek standpoint, they were regarded as essentially homogeneous with the axiomatic theory of geometry, no sharp distinction being made between geometry and mechanics, for instance. A good example is Archimedes' set of partial qualitative axioms for measuring weights on balances. This is undoubtedly the first partial qualitative axiomatization of conjoint measurement, a form of measurement that has received both much axiomatic attention and manifold applications in modern theories of measurement in the social sciences. (For detailed treatment of conjoint measurement, see Krantz et al. 1971. Also see *Measurement Theory: Conjoint*.)

Other early examples of axiomatic theories aimed at empirical matters can be found in the large medieval literature on qualitative axioms for the measurement of weight (Moody and Clagett 1952). Even more impressive examples are to be found in the medieval literature on physics. Some of the most subtle and interesting work is that of Nicole Oresme (1968) in the fourteenth century. (See especially his treatise, *Tractatus de Configurationibus Qualitatum et Motuum*.) What is surprising is Oresme's unexpectedly subtle approach in a geometrical framework to the phenomena of intensive qualities and motions. An

example for Oresme would be that of a surface being more or less white.

Finally, in the geometric axiomatic tradition of analyzing phenomena in natural science, the two great late examples of deeply original work were the seventeenth-century treatises of Huygens' *The Pendulum Clock* (Huygens 1673/1986). And, of course, as the second example, Newton's *Principia* (Newton 1687/1946). Both Huygens and Newton formulated their axioms in the qualitative geometric style of Euclid and other Greek geometers two thousand years earlier.

1.1 Axiomatic Geometry in the Nineteenth Century

Without question, development in axiomatic methods in the nineteenth century was the perfection and formalization of the informal Greek methods that had dominated for so many centuries. The initial driving force behind this effort was certainly the discovery and development of non-Euclidean geometries at the beginning of the century by Bolyai, Lobachevski, and Gauss. An important development later in the century was the discovery of Pasch's (1882) axiom as a necessary addition to the Euclidean formulation. Pasch found a gap in Euclid which required a new axiom, namely, the assertion that if a line intersects one side of a triangle, it must also intersect a second side. This was just the beginning for Pasch. He created the modern conception of formal axiomatic methods, which has been the central aspect of the model for axiomatic work up until present times. The axiomatic example in geometry that had the most widespread influence was Hilbert's *Grundlagen der Geometrie*, first published in 1897 and still being circulated in later editions (Hilbert 1956).

2. Ingredients of Standard Axiomatic Practice

Building, especially, on the work in the later part of the nineteenth century in axiomatizing geometry, early in the twentieth century there was widespread axiomatization in mathematics and, to a lesser extent, in the empirical sciences. The main ingredients of the methods for axiomatizing theories were the following: statement of the primitive concepts of the theory, statement of the prior mathematics basis assumed, statement of the axioms, characterization of models of the theory and a definition for isomorphism of two such models, proof of a representation theorem when possible, and, finally, some analysis of invariance of the models of the theory. Before turning to an explicit discussion of these ingredients, it is worth noting that the emphasis should really be on models of the theory, which is what axiomatizing a theory makes clear. For it is models of the theory, i.e., structures which satisfy the theory, as explained in Sect. 2.3, that exhibit the nature of the theory, whether it be in geometry, economics, psychology or some other science. (For an elementary, but detailed, account of the concepts discussed in this section, see Suppes (1957/1999, Chaps. 8 and 12).)

2.1 Primitive Concepts of a Theory

The first point to recognize in axiomatizing a theory is that some concepts are assumed as primitive. Their properties are to be stated in the axioms, and, therefore, it is important to know how many such concepts there are and what is their general formal character, as relations, functions, etc. In Hilbert's axioms for elementary plane geometry, the five primitive concepts are those of point, line, plane, betweenness, and congruence. In contrast, in psychological theories of measurement, an ordering of the stimuli or other phenomena is almost always assumed—in this case, a weak ordering; that is, a binary relation that is transitive and connected, rather than the geometric ordering of betweenness. In addition to a primitive concept of ordering, there are other relations, for example, a primitive concept of the comparison of stimulus differences or an operation of combination for extensive measurement, as in the case of subjective probability. These measurement examples also apply to a large literature on utility and subjective probability in economics. In psychological theories of learning, even of the simplest nature, we would need such concepts as that of stimulus, response and a conditioning relation between stimulus and response. Theories without much more elaboration would require the important concept of similarity or resemblance, in order to develop a theory of the fundamental psychological phenomena of generalization, discrimination and transfer.

There are also important theories that use much simpler primitive concepts. A good example would be the theory of zero-sum, two-person games in normal form. The primitive concepts are just that of two nonempty sets X and Y that are arbitrary spaces of strategies for the two persons and a numerical function M, defined on the product space $X \times Y$. The intuitive interpretation of M is that it is the payoff or the utility function for the player whose space is X. The negative of that is the payoff for the player whose space is Y. Later a representation theorem is given for finite games of this sort.

2.2 Axioms as Defining Theories

As is widely recognized, axioms are what intuitively characterize a theory, whether it be of geometry, game

theory or a psychological theory of measurement. From a formal standpoint, something more can be said. The essence of the matter is that to axiomatize a theory is to define a certain set-theoretical predicate. This is just as valid in the empirical sciences as in pure mathematics. The axioms, of course, are the most important part of such a definition.

Because the theory of weak orderings is used widely in both economics and psychology, as part of the theory of choice, it will be useful to give a formal definition and, therefore, the axioms for a weak ordering.

Definition 1 *Let A be a nonempty set and R a binary relation on A, i.e., let R be a subset of the product space $A \times A$. A structure (A, R) is a weak ordering if and only if the following two axioms are satisfied, for every a, b and c in A:*

Axiom 1 *R is transitive on A, i.e., if aRy and bRc then aRc.*

Axiom 2 *R is connected on A, i.e., aRb or bRa.*

There are various general methodological and folklore recommendations about the way in which axioms should be written—clarity, lack of ambiguity and simplicity are familiar. More substantive results about the form of axioms are discussed in Sect. 4 on first-order formalization. There are many definite mathematical results about the form of axioms, some of which are also discussed later.

2.3 Independence of Axioms

An early and important substantive recommendation is that the axioms be independent; i.e., none can be derived from the others. The question then arises from a methodological standpoint: How is independence to be established? The answer is in terms of *models* of the axioms. To make the matter still more explicit, we consider *possible realizations* of the theory. These are set-theoretical structures that have the right form. For example, in the case of weak orders, a possible realization is an ordered pair consisting of a nonempty set and a binary relation on that set. Such an arbitrary pair is called a possible realization because as a possible realization it is not a *model* of the theory unless the axioms of the theory are also satisfied. An obvious example of a model of the theory of weak ordering is the pair consisting of the set of positive integers and the relation of weak inequality $\geqslant$.

The independence of a given axiom of a theory is established by finding a possible realization of the theory in which all the axioms, except the particular one in question, are satisfied. The deductive argument to show that this yields a proof of independence is intuitively obvious and will not be made in a more formal manner here. But the essence is that if the concept were not independent, but definable, then it would necessarily hold in the model, just like the remaining axioms, and so a contradiction of its both holding and not holding in the given model would be obtained. So, by *reductio ad absurdum* it must be independent. It will be useful to consider an example or two.

To show that the axiom of connectedness for weak orders is independent of the axiom of transitivity, it is necessary to take a possible realization that is also a transitive relation. So, let $A = \{1, 2, 3\}$ and $R = \{1, 2\}$. In other words, R is just the strict numerical $<$ relation on the subset $\{1, 2\}$ of A. Then it is obvious that this relation is transitive but not connected for the number 3, which is in the set A, and does not stand in the relation R to any other element in A. To show that transitivity is independent of connectedness, that is, Axiom 1 for weak orders is independent of Axiom 2, it is sufficient to take the same set A as before, but now, the relation R is the set of the ordered pairs $\{(1, 2), (2, 3), (3, 1), (1, 1), (2, 2), (3, 3)\}$. Then it is clear that any two elements in the set A are connected by the relation R, but the relation R is not transitive, for, in order to be transitive, it must also have the pairs (1, 3), (2, 1) and (3, 2).

The examples of independence given are trivial, but it is to be emphasized that it can often be a difficult task to establish whether or not an axiom is independent of the remaining axioms; that is, whether or not it can be derived from the remaining axioms. A very familiar mathematical example, with a long history in the twentieth century, is the proof that the axiom of choice is independent of the other standard axioms of set theory.

2.4 Padoa's Principle for Proving Independence of Primitive Concepts

Less familiar than proving the independence of axioms is the method of using models of a theory to prove independence of the primitive concepts of the theory. To prove that a particular primitive concept of a theory, for example, the notion of congruence in Euclidean geometry, is independent of the other primitive concepts, it is sufficient to find two models of the theory, such that the domain of both models is the same, the two models are the same for all the other primitive concepts of the theory, but the two models differ only in their realization of the concept in question. Thus, to prove congruence independence, what is required are two different models of the axiom in question, which are the same for all the other concepts, such as point, line, etc., but which have two distinct notions of congruence.

In the case of weak orders, Padoa's principle can be used in an obvious way to show that the concept of the binary relation is independent of the given set A. It suffices, for example, to use the two different orderings $\leqslant$, $\geqslant$ on the set of positive integers. On the other hand, since R is connected, the set A is definable in terms of the relation R for the special case of weak

orderings by taking the union of the domain and range of the relation. But for different orderings, for example, partial orderings, which are reflexive, antisymmetric and transitive on the set A, it is easy to show that the set A is an independent concept. Just let A in one model be a proper subset in the other, and elements in the relation come only from the first set.

3. Isomorphism of Models of a Theory

The separation of the purely set-theoretical characterization of the possible realizations of a theory from the axioms proper, which characterize models of a theory, is significant in defining certain important concepts. For example, the notion of two models of a theory being isomorphic is often said to be axiom-free, since the definition of isomorphism of the models of a theory really depends on just the set-theoretical characterization of the possible realizations. A satisfactory general definition of isomorphism for the structures that are possible realizations of any sort of theory is difficult, if not impossible, to formulate. The usual practice is to formulate a special definition for the possible realizations of some particular theory. This is what will be done here, as already illustrated in the case of binary relations. A possible realization is a set-theoretical structure that is a nonempty set and a binary relation whose domain and range are included in that set. In this case the definition of isomorphism is as follows.

Definition 2 *A binary relation structure (A, R) is isomorphic to a binary relation structure (A', R') if, and only if, there is a function f such that*

(a) $D(f) = A$ and $R(f) = A'$

(b) f is a one–one function

(c) For a, b in A, aRb if and only if $f(a)R'f(b)$.

The definition of isomorphism for possible realizations of a theory is used to formulate a representation theorem, which has the following meaning. A certain class of structures or models of the axiomatized theory is distinguished for some intuitive or systematic reason and is shown to exemplify within isomorphism every other model of the theory. This means that, given any model of the theory, there exists in this distinguished class an isomorphic model. A good example of this can be found in the axiomatic theory of extensive measurement. Given any empirical structure that represents the data about subjective judgments of probability and satisfies the axioms of the theory, there is a numerical structure satisfying the axioms that is isomorphic to the empirical structure. Note, of course, that there is not any one single such isomorphism. Different individuals can have different empirical structures realizing their subjective probabilities, but there will be for each of them a particular numerical model of the axioms that is isomorphic to each given empirical structure.

Here is a simple and obvious, but useful, example of a representation result for two-person, zero-sum games that are finite. A game (X, Y, M), as introduced earlier, is finite just in case the sets X and Y are finite. So, with the definition of isomorphism obvious from the result now to be stated, any finite game $G = (X, Y, M)$ with $X = (x_1, \ldots, x_m)$ and $Y = (y_1, \ldots, y_n)$ is isomorphic to the game $G' = (I_m, I_n, M')$, and $M'(i, j) = M(x_i, y_j)$, where the notation I_k denotes the set of positive integers $1, \ldots, k$. Therefore, any finite two-person zero-sum game may be represented by a game where X and Y are initial segments of the positive integers, even if vivid substantive descriptions of the individual strategies x_i and y_j have been given.

3.1 Invariance Theorems for Axiomatized Theories

In addition to having representation theorems for the models of a given axiomatized theory, it is also significant and useful to have explicit invariance theorems. The intuitive idea of invariance is most naturally explained either in terms of geometric theories or measurement theories.

Given a class of models, for example, analytical models in geometry and numerical models in measurement, with respect to which any other model of the theory can be represented, the invariance theorem is an expression of how unique is the representation in terms of such an analytic model. For example, in the case of the representation theorem for axiomatic formulations of Euclidean geometry, the invariance theorem states that any analytic model is unique only up to the group of Euclidean motions. This means that for any analytic representation of Euclidean geometry, any reflections, rotations or translations of the analytic model will produce a new analytic model, also isomorphic to the set-theoretical model satisfying the qualitative synthetic axioms of Euclidean geometry. In fact, the most general theorem widens the scope to what is often called the group of generalized Euclidean transformations, namely, those that also permit a change in scale, so that no unit of measurement is fixed.

The situation is very similar in the case of theories of measurement. Given an empirical structure and a representing numerical model isomorphic to that structure, then, in the case of intensive quantities such as cardinal utility, for example, the numerical model is unique only up to the group of affine transformations; that is, transformations that multiply the unit of measurement by a positive real number and add a constant as well. This means that in fundamental measurement of a cardinal utility there is nothing but convention in the choice of a unit of measurement or a zero value.

Classical examples of important invariant theorems in physics are that structures of classical physics

are invariant up to Galilean transformations, and in special relativity, invariant up to Lorenz transformations—in both these cases, further generalizations arise by also permitting changes in the units of measurement.

4. Theories with Standard Formalization

The set-theoretical framework for axiomatizing theories just discussed is used implicitly throughout the mathematical social sciences. Most of the axiomatic work that takes place in the social sciences can be put in a straightforward way within the framework just described. On the other hand, there is a tighter framework for discussing the axiomatization of theories that leads to clarification of problems that arise in the conceptual or qualitative thinking about theories in the social sciences. The purpose of this section is to describe in an informal way this more narrowly defined framework and to give a sense of the kind of results that can be obtained. Most of the results are of a negative sort, important because they show what cannot be done by apparently very natural qualitative formulations of theories of preference, of subjective probability or related kinds of qualitative measurement, or scaling problems, especially in economics and psychology, but also in anthropology, political science, and sociology.

A language with standard formalization is a language that is given a precise formulation within first-order logic. Such a logical framework can be characterized easily in an informal way. This is the logic that assumes:

(a) one kind of variable;

(b) logical constants, mainly the sentential connectives such as *and* ;

(c) a notation for the universal and existential quantifiers; and

(d) the identity symbol $=$.

A language formulated within such a logical framework is often called an elementary language. Ordinarily, three kinds of nonlogical constants occur in axiomatizing a theory in such a language—the relation symbols, also called predicates, the operation symbols and the individual constants.

The grammatical expressions of the language are divided into terms and formulas, and recursive definitions of each are given. The simplest terms are variables or individual constants. New terms are built up by combining simpler terms with operation symbols in a recursive manner. Atomic formulas consist of a single predicate and the appropriate number of terms. Compound formulas are built up from atomic formulas by means of sentential connectives and quantifiers.

Possible realizations of elementary theories, i.e., theories formulated in an elementary language, assume an especially simple form. First, there is a nonempty domain for the structure. Second, corresponding to any relation symbol of the theory, there is a corresponding relation, including sets representing predicates as one-place relations. Corresponding to any operation symbols in the theory are operations defined on the domain of the structure, and, finally, individual objects of the domain correspond to the individual nonlogical constants of the theory. It is worth noting in passing that the definition of isomorphism for such elementary structures is straightforward and simple, which is not always the case for theories formulated in more complicated set-theoretical languages.

4.1 Some Positive Results About Axiomatizability

The first positive result uses two concepts. First, the set of all the finite models of a theory is called a *finitary* class of elementary structures. Second, a theory is recursively axiomatizable when there is an algorithm for deciding whether or not any formula of the language is an axiom of the theory in question.

Theorem 1 *Any finitary class of models of an elementary theory is axiomatizable, but not necessarily recursively axiomatizable.*

The importance of this result is showing that the expressive power of elementary languages is adequate for finitary classes but not necessarily for the stating of a set of recursive axioms.

A more special positive result about finitary classes of models can also be given:

Theorem 2 *Let K be the finitary class of measurement structures with respect to an elementary language L and with respect to a numerical model $\mathscr{R}$ of L such that K includes all finite models of L homomorphically embeddable in $\mathscr{R}$. If the domain, relations, functions, and constants of $\mathscr{R}$ are definable in elementary form in terms of $(Re, \leqslant, +, \cdot, 0, 1)$ then the set of sentences of L that are satisfied in every model of K is recursively axiomatizable.*

A *universal sentence* is one that has only universal quantifiers at the beginning with the scope of a quantifier the remainder of the sentence. In practice, such sentences are written as quantifier-free statements to simplify the notation. The axioms of weak ordering given earlier are of this kind. To be explicit, the conjunction of the two given axioms is a universal sentence, and this single universal sentence is, in this form, the single axiom for a weak ordering.

Theorem 3 *(Vaught's Criterion 1954). Let L be an elementary language without function symbols. A finitary class K of measurement structures (with respect to L) is axiomatizable by a universal sentence iff K is closed under submodels and there is an integer n such that if any finite model M of L has the property that every submodel of M with no more than n elements is in K, then M is in K.*

The intuitive idea of Vaught's criterion for finitary classes of models of a theory is easy to explain. Consider again weak orderings. Because the axioms

involve just three distinct variables, it is sufficient to check triples of objects in the domain of an empirical structure to determine if it is a model of the theory. Generally speaking, the number of distinct variables determines the size of the submodels that must be checked to see if universal axioms are satisfied. To have a universal axiom for a theory, or what is equivalent, a finite set of universal axioms, it is necessary that the number of distinct variables be some definite number, say n. By examining submodels involving no more than n objects, it is then sufficient to determine satisfaction of the axiom or axioms, and this is the intuitive idea of Vaught's criterion.

4.2 Some Negative Results About Axiomatizability

To begin with, it is useful to state as a theorem what is a corollary of Vaught's criterion. It is simply the negation of it for determining when a finitary class of models of a theory is not axiomatizable in an elementary language by a universal sentence.

Theorem 4 *Let L be an elementary language without function symbols and let K be a finitary class of measurement structures (with respect to L) closed under submodels. Then K is not axiomatizable by a universal sentence of L iff for every integer n there is a finite model M of L that has the property that every submodel with no more than n elements is in K, but M is not in K.*

It is natural to interpret the negative result stated in the general form here as showing that the complexity of relationships in finitary classes satisfying the hypotheses of the theorem is unbounded, at least unbounded when the theory must be expressed by quantifier-free formulas of elementary logic.

The first application is something rather surprising. A semi-order is a structure $(A, \succ)$ satisfying the following three axioms.

Axiom 1 It is not the case that $(a \succ a)$.

Axiom 2 If $(a \succ b \ \& \ a' \succ b')$ then $(a \succ b' \vee a' \succ b)$.

Axiom 3 If $(a \succ b \ \& \ b \succ c)$ then $(a \succ d \vee d \succ c)$.

When the set A is finite, the following numerical representation holds:

$$\text{for every } a \text{ and } b \text{ in } A,\ a \succ b$$
$$\text{if and only if } f(a) > f(b) + 1.$$

What is now surprising is a result about the indistinguishability relation for semiorders, that is, the relation $\sim$ that is the negation of the characterization of the semiorder, namely, for a and b in A

$$|f(a) - f(b)| \leqslant 1 \text{ iff } a \sim b.$$

The following theorem is due to Roberts (1969).

Theorem 5 *Let L be the elementary language whose only nonlogical symbol is the binary relational symbol $\sim$. Then the finitary class J of measurement structures for the indistinguishability relation $\sim$ is not axiomatizable in L by a universal sentence.*

The next case of a negative result applying the negation of Vaught's criterion (Theorem 3) is the proof that the qualitative theory of utility differences or the qualitative theory, more generally, of various psychometric sensations is not axiomatizable by a universal sentence, contrary, of course, to the simple theory of order. This result is due to Scott and Suppes (1958).

Consider the elementary language whose only symbol is the quaternary relation symbol 'D' with the intended numerical interpretation

$$abDcd \text{ iff } f(a) - f(b) \geqslant f(c) - f(d).$$

We then define the finitary class of measurement structures for algebraic difference as consisting of all models (A, D) such that

(a) A is a nonempty finite set;

(b) D is a quaternary relation on A; and

(c) (A, D) is isomorphic to (A', Δ), where A' is a finite set of numbers and Δ is the quaternary numerical relation such that for real numbers x, y, u and v, $xy\Delta uv$ iff $x - y \geqslant u - v$.

Theorem 6 *Let L be the elementary language whose only nonlogical symbol is the quaternary relation symbol D. The finitary class $\mathscr{D}$ of measurement structures for (algebraic) difference is not axiomatizable in L by a universal sentence.*

The intuitive idea of the proof can be seen from construction of a ten-element structure, all of whose substructures have a numerical representation, but which does not itself have such a representation. The idea of this construction can then be generalized for arbitrary n in order to apply Theorem 4.

Using the same ideas, Titiev (1972) extended the results of Theorem 6 to additive conjoint measurement and to multidimensional scaling with the Euclidean metric. Titiev (1980) also gives a negative proof for the city block metric for $n \leqslant 3$ dimensions. Using more sophisticated logical results, it is possible to extend most of the results just stated to not being finitely axiomatizable. This means that existential quantifiers can be introduced, but the number of axioms must be finite in character. The main results here are due to Per Lindstrom, which together with the other results mentioned in this section are presented in detail in Luce et al. (1990).

Theorem 7 *The finitary class of measurement structures for algebraic difference is not finitely axiomatizable in the elementary language whose only nonlogical symbol is the quaternary relation symbol D.*

In a way, a still stronger negative result about axiomatizability can be proved for Archimedean axioms. Here is one standard formulation of such an axiom. If $a \succcurlyeq b$ then for some n, $nb \succcurlyeq a$, where nb is the combination of n copies of b. Notice that it is necessary

to introduce a quantifier for integers not just for the empirical objects of the domain. Because the exact formulation of the negative result is rather complicated, the following informal theorem is given.

Theorem 8 *For any standard elementary language used to formulate a theory of measurement there is no set of elementary formulas of the language equivalent to an Archimedean axiom for the theory.*

The best way to think about the Archimedean axiom in this context is that it is a second-order axiom and, therefore, cannot be formulated by an equivalent set of formulas, in first-order logic.

Still another way of looking at this result is that to characterize the real numbers we need some sort of second-order axiom such as Dedekind completeness, the Cauchy sequences or the least-upper bound axiom, but none of these axioms, including the Archimedean axiom, can be formulated in a first-order language whose variables take real numbers as values. Narens (1974) provides a general account of Archimedean axioms in various forms.

For deeper and more general results on axiomatizability there is much recent work that can be cited, especially concerning the definability of linear orders for classes of finite models and the problem of the complexity of the class (Stolboushkin 1992, Gurevich and Shelah 1996, Hella et al. 1997).

American Studies: History

1. *Why Study American History?*

As a nation of immigrants with ongoing processes of invention and reinvention of their national identity, America continues to capture the attention of people throughout the world. Since the founding of the new Republic the American people have questioned what meaning America and its history has for them. Professional historians in particular have repeatedly attempted to answer this important question by explaining the stories of American experiences. 'History' for Americans is a key element in the construction of their national consciousness and national identity.

Aiming to discover and define their own self-identity as individual citizens, as well as those of the members of the other diverse racial, cultural, and ethnic groups that make up America, those who study American history constitute a distinct and integral part of an American Studies that is, by definition, interdisciplinary, an Area Studies. American Studies aims to comprehend what makes the American people uniquely American in the unfolding annals of mankind and attempts to answer J. Hector St. John Crevecoeur's famous question, 'What then is the American, this new man?'

American Studies remains fascinating not only for the American people themselves but also for people living abroad as well. Perhaps as often as their American counterparts, American Studies specialists abroad have also often raised the same old but important question 'What is America?' They have sought to understand the totality of and thus appraise the quality of American civilization in the context of the history of mankind, and also, in so doing, to define themselves as individual citizens in their own country.

At the same time, in light of one of the unwritten objectives of American Studies, to contribute to world peace through mutual understanding, the field remains enormously important, particularly when one considers the position that the United States now holds in the present world. In this sense, American Studies is one of the fields that is as rewarding and challenging for specialists as laymen throughout the world.

2. *Why American Studies in Japan?*

Scholarship in American history throughout the world has considerably come to resemble its American counterpart, even if it lags behind scholarship in the United States. Even so, it seems that some approaches and conceptualizations that America specialists abroad invent and utilize in their American Studies must be original and, therefore, different from their American counterparts. If this observation is correct, it follows that Japanese scholarship may be distinct from that in the United States.

Many America specialists in Japan posit that the United States is a nation of ideas and ideals, such as freedom, equality, and democracy, and see the country as a nation that not only discusses such universalistic ideas and ideals but also aspires to achieve those high goals, as Nagayo Homma, the dean of America specialists in Japan, states (Homma 1976, 1999). In fact, the United States has been a unique country, having been engaged in a significant experiment in the history of mankind. In studying American history, Japanese scholars of American Studies endeavor to grasp the essential components that make up American civilization and make efforts to elucidate the uniqueness that is America. They pursue American Studies not simply because the subject matter they have chosen is stimulating but because they believe that United States–Japan relations are vitally important for their country and that by deepening mutual understanding they will contribute to maintaining amicable relations between these two peoples across the Pacific Ocean.

At the same time, American Studies specialists in Japan explore the American past for lessons to present to their audience. As Japan's distinguished America specialist Tadashi Aruga describes in his article in the *Journal of American History*, Japanese intellectuals invoked the example of the United States to encourage the development of a liberal constitutional ideal in Japan (Aruga 1992, Thelen 1992a). America specialists in Japan also use the American past to help them define alternatives for their society and contribute to improving their own society in these ways. As experts on the United States, they are expected to participate actively in discussions on contemporary American affairs by introducing to the public their historical perspectives on America. America specialists in Japan play a key social role in making knowledge and information gleaned from their scholarly work available to public discussions on American affairs and US–Japan relations. In addition, these scholars hope to gain a more accurate sense of the future direction in which humanity in general is moving, as well as to be able to better see where they now stand.

This short article intends to describe the present state of American history as one of the components of American Studies. With particular emphasis on American Studies in Japan, it surveys a 30-year US historiography of American history, and, then, reviews, from a Japanese perspective, some of the important Japanese works that have been written in American Studies since the 1970s. It examines what Japanese scholars have studied in American history and how they have done it, delineating changes in the milieu of their profession, as well as current trends that are seen in Japan and the United States. Perhaps

it is hardly necessary to explain that there is no good reason to justify the dividing of the 30-year period exactly by decades except for the reasons of artificiality and convenience, as history proceeds like a seamless web. In this essay, our survey starts with a review on the New Left historiography in the United States in the 1960s. In the present writer's view, an attempt to discuss New Left historiography is necessary before any appraisal of American history in the United States in the 1970s is made, because both of them are closely interrelated.

3. *American History in the 1960s and 1970s as a Background*

Revisionism is inherent in the historian's craft. American history is by no means an exception. Open to challenge and response, the stories of the American past have been written and rewritten ceaselessly, while at the same time, the field of American history has grown increasingly specialized in recent years. The intensification of specialization and the attendant fragmentation in American history have largely reflected a part of the vast expansion of higher education in post-World War II America. To survey the recent trend of historiography in American history, let us begin with the New Left revisionists among the historians of the 1960s.

Buoyed by the rising tide of social protest movements at home, New Left historians challenged all the assumptions and the entire interpretive framework that the so-called 'consensus' historians of the 1950s had constructed in understanding the American past (Hofstadter 1955, Boorstin 1953, Hartz 1955). Anxious to use the American past to make social changes, New Left scholars blamed the 'consensus' historians for celebrating the status quo of a middle class liberal society. Revisionists criticized the 'consensus' historians severely for placing too much emphasis on historical continuity in American history and overly stressing unity, the stability of institutions, and agreement on central value systems among the American people.

Those young New Left scholars, who gathered around their scholarly journal, *Studies on the Left*, regarded social and economic conflicts as major forces in American history and stressed the importance of economic factors and class analysis in interpreting the American past, as the Progressive historians of the 1930s and 1940s had similarly done previously. The revisionists of the 1960s placed new emphasis on minority and lower socioeconomic groups and saw a pressing need to reconstruct American history as 'seen from the bottom up,' urging that 'the history of the powerless, the inarticulate, the poor' be written (Lemisch 1967).

America was in great turmoil then. Intellectuals seriously questioned the legitimacy of authority, and many of them had lost faith in it. New Left historians, for instance, called upon the American people to undergo a soul-searching re-examination of the record of imperial America's expansionist foreign policy (Williams 1959). On the domestic front as well, they critically analyzed the quality of American liberalism by utilizing the key concept of 'corporate liberalism' as an analytical device. Moreover, they cast serious doubt on the American tradition of reform, while, at the same time, leveling scathing criticism at America's racism, sexism, economic exploitation, and power structure, the most typical example of which was the military–industrial complex (Williams 1961). (For a further discussion of historical writing of the New Left revisionists, see Williams 1989, Buhle 1990, van der Linden 1996; for a critical review on New Left Revisionism, see Tucker 1971.) In the midst of America's turbulence at home and abroad, New Left Revisionism presented not only a penetrating critique of the American present and the past but also an alternative theoretical framework and compelling explanatory power to make better sense of American experiences. Today, however, with the rise of trans-nationalism and globalization, the explanatory power that New Left Revisionism once enjoyed seems to have waned considerably and somehow needs to be reinvigorated. In addition to the rise of trans-nationalism and globalization, the reasons why the influence of New Left revisionism waned seem to be the following: (1) New Left revisionists lost concrete targets with which to criticize America and its imperialistic expansionism, particularly after the Vietnam War which they saw as a glaring example of American imperialism came to an end in 1975; (2) As the declensionist's idea of America losing comparative advantage in several sectors of strategic importance in the world economy came into vogue in the 1970s and 1980s, overly harsh criticism leveled at American business became unpopular, if not entirely unacceptable, among the American people; (3) Coupled with New Left revisionists' tendency to study unilateral national history, their orientation toward analyzing elite leaders' *weltanschaunng* came to be under fire as elitist, while their political dreams to create a 'community of love' in America cooled and came to be totally dismissed as romantic and visionary when America became more conservative in the 1970s; and (4) New Left revisionists lost considerable power and influence in the historical world in America as they fought among themselves and split into factions in the 1970s. For example, the *Studies on the Left* group became the nucleus of a theoretically minded cadre for a New Left, while the *Radical America* group was more or less inclined toward activism.

Historians of the 1970s in America succeeded largely to these legacies that New Left revisionists had bequeathed them and made their own careers by building on some of the works that the historians of

the 1960s had embarked on. Receiving insights from the works of European theorists (these include, for example, Claude Levi-Strauss, Roland Barthes, Michel Foucault, and Jacques Derrida, to name only a few) and scholars, particularly British historians and the French *Annales* school (British scholars are, for example, Edward P. Thompson whose influential work is *The Making of the English Working Class* (New York: Vintage Books, 1963) and Eric J. Hobsbawm whose main work, among others, is *Primitive Rebels* (Manchester, England: University Press, 1959). French historians of the *Annales* school are, for example, Fernand Braudel whose major work, among others, is *Capitalism and Material Life, 1400–1800*, Trans. Miriam Kochan (New York: George Weidenfeld and Nicolson Ltd., 1973) and Emmanuel Le Roy Ladurie whose main work is *Le Territoire de l'historien* (Paris: Edition Gallimard, 1973, 1978). For discussions on the French *Annales* school related to historical writing about the United States, see Richard Mowery Andrews, 'Some Implications of the *Annales* School and Its Methods for a Revision of Historical Writing About the United States,' *Review* 1.3/4 (1978): 165–80), many American historians of the 1970s saw politics as fleetingly transient, turning their back on traditional 'event-oriented' political history and their attention toward slow but important changes in social structure and their relationship to political, economic, and social events in America. (Scholars who placed new emphasis on the importance of studying social structure and institutional bureaucratization in modern America are identified as the historians of the 'organizational school.' They include Samuel P. Hays, Robert H. Wiebe, Louis Galambos, Alfred D. Chandler, Jr., and Robert D. Cuff, to name only a few.)

Historians of the 1970s redefined history to include entire areas of social life not before thought to be part of the subject. An increasing number of scholars, much interested in such issues as race, class, ethnicity, and gender, paid more attention to the common people, as well as to members of racial, ethnic, and cultural minority groups in America who had previously been either neglected or slighted as subjects of serious historical inquiry. Convinced that the 'new' social history approach was highly promising as a mode of systematic inquiry for future scholarship in American history, scholars and social historians placed new emphasis on the role of culture in the formation of class and class-consciousness, analyzing the dominant culture in society as something directly related to social structure. They richly described the private as well as the public spheres of people's lives by marshalling sophisticated analytical tools borrowed from the social and behavioral sciences, such as sociology, demography, econometrics, psychology, and cultural anthropology (Geertz 1973). As a result, historians of the 1970s made significant contributions toward enriching the understanding of American history (although their claim to the rediscovery of the extraordinary diversity of social groups and cultures that compose America was by no means the monopoly of the 'new' social historians (the works of social scientists such as Talcott Parsons and Edward Shils and those of the 'consensus' historians revealed the pluralistic nature of American society, taking cognizance of the vast multiplication of diverse social groups in America)).

The profound influence of the social and behavioral sciences, coupled with the use of new quantitative methods and systematic analysis by employing computer technology (Swierenga 1974, Erickson 1975, Fogel 1975) resulted in the multiplication of subdivisions in the field of American history. American history came alive again and social history in particular became vibrant. This 'new' social history spawned many other subspecialties in the field of American history. It reinvigorated the historical profession by multiplying the variety of new subfields that represented social groups within American society (the histories of Afro-Americans, Native Americans, labor, immigrants, and women, to name only the most outstanding). Few could deny the fact that this spectacular rise of the 'new' social history represented a general trend in the profession of American history in the 1970s and even beyond (for discussions on promises and problems in a 'new' social history approach, see Henretta et al. 1979, Tilly 1984).

No doubt the historians of the 1970s made remarkable achievements in enhancing our understanding of the American past. Yet, however remarkable their positive achievements were, the scholars of the 'new' social history brought with them certain attendant liabilities and serious consequences. Most scholars, with a few exceptions, continued to embrace the nation-state as a unit of analysis. They still had the luxury of thinking exclusively in national terms and indulged in an excessive focus on unilateral national history. But was it not true that a national history required the context of other national histories? In other words, as has been pointed out well, American scholarship was marred by its myopic parochialism with a unilateral national perspective divorced from the rest of the world.

Scholarship in American history suffered from something of an irony as well. It paid the heavy cost of the breakup of history into many disconnected histories. The more subjects were probed and the more monographic studies of women, immigrants, lesbians and gays, workers, children, Native Americans, Asian and Hispanic Americans, and so forth were produced, the more fragmented the images of America became and the more obscure the whole picture of American civilization became. The rise of the 'new' social history proliferated knowledge and

diverse categories, but it only fragmented the field of American history into a multitude of subdivisions that were not necessarily related to each other (Megill 1991).

Take studies in ethnic and labor history, for instance. A sharp dichotomy was observed between the studies that emphasized the importance of cultural analysis, on the one hand, and those that stressed the importance of a structural understanding, on the other (Higham 1982). The same can be said of Afro-American women, too. Given fine and fixed categories, such as race and gender, writing a history of African-American women in a coherent and organized way became increasingly difficult, with, for example, Afro-American women classified by race in African-American history, while in women's history being analyzed by gender (Higginbotham 1992). Despite the fact that such richly described lives of the American people came to be more fully appreciated, little was gained in deepening an understanding of the more complex relations of race, ethnicity, gender, and class within the totality of American society, as long as those studies remained disconnected from each other. Therefore, it was still difficult to find a satisfactory answer to the fundamental question, 'What is America?' While continuing their work, historians came to realize that there existed an urgent need for a new paradigm that would make it possible to bring these variegated pieces together with the goal of encompassing and synthesizing them. (For further discussions on historical writing in the United States in the 1970s, see Kammen 1980, Amerikashi-Kenkyukai 1985.)

4. *Japanese Scholarship in American Studies: The 1970s*

Strange as it may sound, a quick look at the table of contents of professional Japanese journals of American Studies gives one the impression that Japanese scholarship in American history, with a few exceptions, such as Afro-American history and Native American studies, follows its counterpart in the United States after about ten years. Take the 'new' social history, for instance. It was symbolically the year 1979 when *Shiso* (*Thought*), one of Japan's most prestigious journals, published a special issue featuring the promises and problems of social history. Equally curiously, it was the same year when *Tokyo Daigaku Amerika Kenkyu Shiryo Sentah Nenpoh* (The *Bulletin of the Center for American Studies of the University of Tokyo*) featured the studies of American social history for the first time. The former was published in response to the growing interest in social history among Japanese historians in general, while the latter, which introduced to its Japanese readers the current state of the field in the United States, was issued primarily with a view to capturing American Studies specialists' attention to the rise of social history.

Yet, it was not until the 1980s, especially after 1982, the year the late Professor Herbert Gutman, the then leading American scholar of social history, lectured in the Kyoto American Studies Summer Seminar, when Japanese scholarship in social history began to bear full fruit, as Natsuki Aruga, one of Japan's pioneering social history scholars, later recalled (Aruga 1979, 1998). The 1989 publication of *Amerika Shakaishi no Sekai* (*The World of American Social History*) edited by Sozo Honda was a case in point. The book was a brilliant anthology in which a group of 15 scholars including the editor worked together to cover a variety of important problems in American social history ranging from the liberation of Afro-Americans to feminism in America (Honda 1989).

The same can be said of the influence of American New Left historiography and of the so-called Organizational School of American history. From 1970 to the early 1980s, less than ten years after their American counterparts had started, Japanese scholars discussed and hotly debated the extent to which American New Left Revisionism and Organizational Historiography contributed to deepening an understanding of modern America, focusing around the key phrase 'corporate liberalism.' The concept of 'corporate liberalism,' which brings America's political economy at home and its foreign policy together, was believed to be quite helpful in not only exploring the meaning of reform anew in the context of the emergence of corporate America but also in synthesizing modern American history as well (Amerikashi Kenkykai 1980). (Historian Akira Takahashi is one of the first and leading scholars who introduced American New Left historiography to his Japanese peers. See Takahashi 1982; see also Takahashi's brilliant book, especially part III (Takahashi 1999).)

Another feature characterizing Japanese scholarship in the 1970s was that America specialists carried out a considerable number of historical analyses, having been stimulated by dramatic events that had happened in the United States in the previous years. In other words, every time a sensational affair or a festivity to celebrate a historic event was reported in the United States, Japanese scholars made it an occasion to trace its origin in the American past and sought to give new meanings by placing the subject in historical perspectives.

For instance, they re-examined US–China and US–Japan relations immediately after America's dramatic shift in China policy and Sino-American reconciliation in 1971. After going through the tumult of President Nixon's Watergate scandal and his subsequent resignation in 1974, Japanese historians and social scientists probed the quality of American democracy and its institutions by placing the problem in a historical context. Likewise, the bicentennial

celebration of the American Revolution in 1976 was made an opportunity to study that great historical event that lasted from 1763 to 1787. Some of the impressive pieces on the American Revolution produced by historians such as Makoto Saito, Tadashi Aruga, Takeshi Igarashi, and Akira Imazu deserve special mention (Saito 1976, 1992, Aruga 1976, 1988, Igarashi 1976, 1984, Imazu 1976; see also Imazu's earlier work on the American Revolution (Imazu 1960)).

In the diplomatic history field, Japanese scholars began to take advantage of the new access to previously classified State and Defense Department documents that were made available in the latter part of the 1970s. In addition, the transition to the floating exchange rate system made it easier for Japanese scholars and students alike to visit the United States and conduct research there. As a result, the latter half of the decade began to reap the rich harvest of studies of Occupied Japan and postwar US–Japan relations, complementing those joint bi-national studies in the prewar relations between Japan and the United States (Iokibe 1975, Igarashi 1979a, 1979b, 1979c; for collaborative joint works of Japanese and American scholars on the prewar bilateral relations, see Hosoya and Saito 1978, Hosoya et al. 1971–1972; for a critical review of these US–Japanese collaborative joint works, see Matsuda 1986). New findings obtained by these studies helped deepen an understanding of the US occupation of Japan, revealing an incessant and intricate interaction between the occupiers and the occupied.

5. *American History in the United States in the 1980s*

Historians in America remained intensely interested in the 'new' social history approach during the 1980s. More scholars joined the ranks of social historians. The sharp increase in the number of female historians and of monographs on women's history especially attests to that fact. In 1960, women had only 10 percent of the Ph.Ds conferred, but 30 years later they earned 37 percent of the Ph.Ds (Levine 1993). More diversification in themes, perspectives, and methodologies, the phenomenon of which had started during the previous decade, characterized scholarship in the American history of the 1980s. This resulted in even further fragmentation of the larger picture of American civilization.

Needless to say, the changing academic landscape represented historians' response to changes in demographic composition and the continuing fragmentation of American society itself. As a result, the sense of wholeness with regard to the American past seemed almost completely lost, as if the images of America had exploded into a multitude of isolated pieces. Nothing was more deeply felt than the need for synthesis in American history so as to meet the needs of the American people and the society, as well as to maintain the legitimacy of the profession.

Major scholarly journals, such as the *Journal of American History* and the *American Historical Review*, called upon historians to reflect on the 'unhealthy' conditions that afflicted the field of American history, publishing special issues addressing the central problem of synthesis in American history (e.g. Bender 1986, 1987, Megill 1991). These journals sought to remove the barriers that divided American history into diverse specialized subdivisions, while suggesting ways to help cross the walls of disciplinary specializations and to explore and reinvent a larger synthetic history (for a superb and informative book that systematically treated the 1980s state of American scholarship in American history, see Foner 1990).

Coupled with the general trend mentioned above, a set of new developments that took place in the 1980s considerably changed the texture of scholarship in American history and an approach with culture as the central focus became dominant from this decade. For one thing, the so-called conservative Reagan revolution of the 1980s forced many scholars to confront themselves with the need to explain how conservatives had succeeded in mobilizing the American people so that they could reverse the egalitarian victories won by the oppositional movements of the 1960s. Scholars then came to recognize the importance of the role of culture as a powerful political force. As a result, culture became the defining and dominant theme in the field of American history.

At the same time, as the term 'culture wars' implied, a bitter controversy over multiculturalism swept through the United States during the 1980s and 1990s, transforming the landscape of American academia. (Because it is impossible to list all the literature on the controversy over multiculturism here, it may be sufficient to name only a few. They are the following: Asante 1987, Schlesinger 1992, Takaki 1993, Bell 1992.) The controversy, in part, represented historians' awareness of and their response to change in demographic compositions that had been taking place in American society since the passage of the Immigration and Naturalization Act of 1965. It should be noted, however, that behind all this was a larger change in the cultural climate, in which cultural populism and even cultural relativism took hold.

Scholars were influenced profoundly by the work of cultural anthropologists, especially Clifford Geertz, while gaining significant insights from the works of European philosophers and theorists, such as Antonio Gramsci (i.e., his concept of 'hegemony') and Michel Foucault (i.e., his concept of 'discourse'), in particular (for discussions on the influence of Antonio Gramsci, see, for example, Lears 1985, Fink et al. 1988; with regard to Michel Foucault, see

Foucault 1969; see also Said 1978). They placed new emphasis on the role of culture in their studies, while continuing to pay sufficient attention to other factors, such as politics and economics. The end result was an approach that dominated the study of American history during the 1980s and 1990s with culture as the key theme and that, with further influence from the United Kingdom and France, would eventually come to be the new and influential field of Cultural Studies. But it does not necessarily mean that an approach with culture as the central focus had no problem. While intensively engaged in 'discourse' analyses, historians regrettably showed little interest in either reconstructing a larger synthetic history or presenting the future direction in which humanity in general is moving.

6. *Japanese American Studies Scholarship in the 1980s*

The 1980s witnessed American Studies, especially studies in American social history, in full bloom in Japan. Subtle sophistication in empirical work based on primary source materials characterized the Japanese state of the field now that primary documents became more easily accessible than previously thanks to the appreciated value of the Japanese yen.

There existed two forces at work in opposite directions. While one force was diversifying American history in terms of its topic, approach, methodology, and perspective, the other was an effort to search for an organizing theme and a synthetic American history.

The former was, of course, the 'new' social history in which American labor, immigrants, women, Afro-Americans, Native Americans, other minority groups, children, education, and so forth were each scrutinized from a new perspective. In a special issue of *Amerikashi-Kenkyu* (1981) that featured 'American Democracy Revisited,' for instance, a scholar of Afro-American history picked up the problem of the origins of racial discrimination in America and raised an important question whether discrimination against minorities including blacks and other ethnic or other racial groups should be understood as something that was primarily based in the American capitalist structure in the context of world capitalism, or whether it was something that represented an American form of Europe's colonial domination of the peoples of the non-European world (Ohtsuka 1981, Ikemoto 1987).

Another historian stressed the importance of a 'new' social history approach and placed new emphasis on elucidating relations between ethnicity and class in order to describe the world in which immigrants lived in America (Nomura 1982, 1995). As the influence of America's 'new' social history was strongly felt and became quite noticeable in the 1980s, Japanese scholarship in American history became sub-divided and the image of American civilization consequently became increasingly fragmented.

Evidence of a synthesis appeared particularly in the 1986 issue of *Amerikashi-Kenkyu*, which featured problems focusing on a structuralist understanding of American history and also in the publication of Tadashi Aruga's *Amerikashi Gairon* (*An Introduction to American History* 1987). Aruga picked up themes in American history that he believed to be important in grasping the totality of American civilization, and elaborated on the current state of American scholarship around each theme with the aim of describing a holistic image of America (*Amerikashi-Kenkyukai* 1986, Aruga 1987). These publications, although dwarfed in number by specializing studies, represented the powerful voice and persistent effort of American Studies specialists of Japan to reconstruct and synthesize American history.

In addition, Japanese scholars made the bicentennial year 1987 an occasion to re-examine and discover new meanings in the writing of the American Constitution. For instance, the November 1987 issue of *Shiso* featuring the two-hundredth anniversary of the Constitution of the United States carried impressive articles that dealt with the problem of American Constitutionalism from new and Japanese perspectives ('The Bicentennial of the Constitution of the United States.' *Shiso* 761 (1987)).

Last, but by no means the least, thanks to the new accessibility of documents and collaborative joint work between Japanese and American specialists, the 1980s saw studies in Japanese Occupation and American foreign policy covering the 1940s and 1950s making great progress both quantitatively and qualitatively, shedding new light on US–Japan relations and US global strategy in the Cold War (good examples of such works include Yui, 1985, 1989, Iokibe 1985, Igarashi 1986, Ishii 1989; see also Tokyo Daigaku Amerika Kenkyu Shiryo Sentah 1988).

7. *American History in the United States in the 1990s*

Added to studies based on cultural, post-colonial, and feminist critique, two phenomena helped define the general trends in scholarship in American history in the late 1980s and 1990s. One of those phenomena was the increasing internationalization of American history. As indicated previously, the effort to internationalize US history in part corresponded to demographic changes in American society. But the idea was primarily conceived with the hope that an internationalized American history focusing on interactions between different cultures would not only help broaden the visions of US scholars but also help

American historians rediscover new meanings in the American past by learning from America specialists abroad (Telen 1992b).

The other phenomenon was the innovation of new approaches to the American past. Scholars placed new emphasis on comparative history for one thing, and looked anew at American history from macro-history perspectives, for another. Historians sought to enrich understanding by broadening their vision and comparing ideas, institutions, and social developments in the historical settings of more than two different countries and cultures. A good example of such work might be a group of studies around the topic of slavery, although comparative studies in slavery were not entirely new by any means (for example, see Patterson 1982, Kolchin 1986, 1987, Davis et al. 2000; for discussions on comparative history, see Frederickson 1995, 1998).

At the same time, scholars began to look at the American past by placing the subject in the context of the evolving modern world-capitalist system and historic change over time. Looking at America from transnational perspectives, some immigration scholars, for example, analyzed their field from the perspective of the international movement of labor, as well as in the context of the evolving modern capitalist world system (for references on world-systematic analysis, see Wallerstein 1974, 1980, 1988, Shannon 1989, McCormick 1990, 1995; for discussions on the methodology of macro-historical sociology, see Skocpol 1984). Historians of the slave trade did likewise. By comparing that infamous trade in different countries and regions, they examined the trans-Atlantic slave trade by placing it in the context of the development of the modern world-capitalist system (e.g., see Rawley 1981, Lovejoy 1986, Miers and Roberts 1988). While doing so, these scholars put new emphasis on the forces, constraining as well as promoting, that the external world imposed on the United States and studied the complex and unforeseen consequences that American expansionism had brought to the United States. These scholars hoped that novel approaches and new perspectives would help them rethink American history and raise new questions that had not been asked previously.

With the end of the Cold War and the dismantling of the Soviet Union, American historians responded to the new issue of the rise of ethnic nationalism and other challenges that globalization and transnationalism had aroused for American society and the profession. In fact, American historians spent a considerable amount of time in the 1990s hotly debating critical issues such as 'American exceptionalism' and the writing of a national history vs. the writing of an international history (Iriye 1988, 1989, McMahon 1990, Tyrrell 1991, McGeer 1991, Appleby 1992, Kammen 1993, Nelles 1997, Koschmann 1997, Nolan 1997, 1999). During the same decade, American scholars also tackled the vexing problem of 'objectivity' in historical writing, a problem that primarily resulted from professionalization and specialization in American history. They also sought to ameliorate some of the past parochialism and national bias of their writings (Novick 1988; see chap. 4 'Objectivity in Crisis'; Kloppenberg 1989, Hexter et al. 1991, Megill 1991). As was mentioned earlier, the Organization of American Historians launched the project to internationalize American history as part of the efforts to rectify its members' tendency toward excessive focus on unilateral national history.

8. *Japanese Scholarship in American History in the 1990s*

Japanese scholarship in American history in the 1990s paralleled its American counterpart in several important ways. First, Japanese studies in American history became increasingly subdivided, and so gravely diversified in terms of topics, themes, analytical viewpoints, and methodologies that it became next to impossible to visualize the whole image of the United States. To illustrate the situation, one might note the new procedure that Amerika Gakkai (the Japanese Association for American Studies, hereafter abbreviated as JAAS) adopted at its Annual Meeting from 1998, whereby a number of small sectional meetings were simultaneously divided according to topics and themes in order to cope with problems arising from the diversification of scholarly interests among Japan's America specialists. The acute sense of crisis manifested itself in a symposium held at the JAAS's 1999 Annual Meeting in which these scholars discussed whether or not an integrative image of America was even possible. The provisional conclusion that was reached at that meeting was not very optimistic. Against this backdrop, Nagayo Homma's trilogy, written with the specific aim of presenting a comprehensive picture of America, deserves special mention (Homma 1991a, 1991b, 1991c).

Second, both women's history and critical cultural approaches that constituted a part of the 'new' social history became fashionable and dominant in the profession. These helped make scholarship in American history truly interdisciplinary. To illustrate these trends, it may be sufficient to point out that the number of female scholars specializing in women's history has increased by leaps and bounds during the decade. To meet the needs and interest of these scholars, for instance, Amerikashi-Kenkyukai (The Society of American Historical Studies) published its 1997 issue of *Amerikashi-Kenkyu* with articles on 'American History and Gender,' while in 1995 JAAS prepared a special number of its professional journal featuring articles on 'Family, Children, and Education.' In the following year, the 1996 issue of *Amerikashi-Kenkyu* featured articles on 'multi-culturalism and minority groups,' while the prestigious

journal *Shiso* devoted its entire space to discussing 'Cultural Studies' in the same year. In this connection, among several works using critical cultural studies approaches, books of high quality that are worthy of note included *Esunikku Jokyo no Genzai* (*The Current State of Ethnicity*) edited by Tadashi Aruga and the anthology, *Tabunkashugi no Amerika* (*Multiculturalism in America*), coedited by Daizaburo Yui and Yasuo Endo (Aruga 1994, Yui and Endo 1999).

Third, that historians broadened their horizons and treated their subject from transnational and comparative perspectives characterized Japanese scholarship in American history in the decade. It meant that scholars broadened not only the scope and breadth of the subject of historical inquiry but also the visions in terms of time and space in order to rectify their proclivity toward excessive focus on unilateral national history.

In 1992, for instance, a group of historians made the year an occasion to look anew at the American past, placing each one of their subjects in the context of the entire Western Hemisphere, including Canada, the Caribbean Basin, and Latin America. Their collaborative joint work produced a five-volume history of North and South America to commemorate the quincentenary of the 'discovery' of the New World and elucidated several different paths of development in each country and region treated (Rekishigaku Kenkyukai 1993; for a work that analyzed the nineteenth-century American expansionism from world-systems perspectives, see Matsuda 1993).

Historians also sought to revise previous interpretations tainted with Euro-centric views of history by posing critical questions about linear developmentalist perspectives and the range of assumptions which had been uncritically accepted previously. The 1997 publication of Iwanami Koza's world history volume entitled *Kan Taiseiyo Kakumei* (*The Atlantic Rim Revolution*) was a case in point (Iwanami Koza Sekai Rekishi 17 1997, Matsui 1991). (Needless to say, this was, by no means, the first book of this kind written by Japanese scholars. In fact, some time before a group of economic historians had already produced a couple of brilliant works by looking at the subject from a transnational and global perspective; see Kawano and Iinuma 1967, 1970; for American scholarship that has a trans-Atlantic perspective, see Kraus 1949, Palmer 1959, McCuster and Menard, 1985, Greene 1986, Greene et al. 2000.) Influenced by the work of European historians, such as Fernand Braudel and Immanuel Wallerstein, scholars who participated in the project sought to elucidate the structure of the eighteenth to nineteenth century trans-Atlantic world and the unfolding of the major revolutionary movements that had happened in a hierarchically but interdependently structured trans-Atlantic world from the latter part of the eighteenth century to the early nineteenth century. In their analysis of the American Revolution, for example, they treated the subject from a perspective of international relations, placing new emphasis on the interconnectedness in the development of the countries that comprised the Atlantic Rim Community. It was an ambitious project by any standard of historical writing, seeking to reinterpret modern history from a fresh and transnational perspective.

Several important studies in comparative history were carried out as well (Yui et al. 1994, Toyoshita 1992, Rekishigaku Kenkyukai 1989). Space precludes the present writer from dwelling on the content of each work here. Suffice it to mention the names of a couple of excellent works that treated the problem of occupation reform from a transnational perspective. *Senryo Kaikaku no Kokusai Hikaku* (*International Comparative Studies in Reform in Occupied Areas*), a joint work of 14 scholars, compared different shades and aspects of postwar reform in occupied areas of Europe and Japan as well as other Asian countries, such as the Philippines and Korea. Naruhiko Toyoshita's *Nihon Senryo Kanritaisei no Seiritsu* (*The Establishment of the Control System of Occupied Japan*) is another work worthy of note. The author explored similarities and differences in occupation policy by comparing the case of the US occupation of Japan with that of the postwar occupation of Italy, Germany, Hungary, and Bulgaria. This work set a good example of a comparative study conducted by an individual scholar for those scholars who would come after him.

The commitment of Japanese scholars to internationalize their work was the fourth and last feature that, characterized Japanese scholarship in American history in the 1990s. The English language publication by the Japanese Association for American Studies of its professional journal of American Studies illustrated the point. It is true that JAAS had started doing this from 1980 as part of the effort to promote international exchange with its foreign scholars, yet what distinguished the record of the 1990s from that of the previous decade was the diversification of featured topics, not limiting them to US–Japan relations and their related themes alone. A wide range of topics were presented, for example, from 'Nature and Environmental Issues' to 'Another "American Century"?' Japanese scholars displayed their intention to live up to the global standard of scholarship as well as to contribute to deepening an understanding of American civilization by sharing scholarly findings with their foreign peers (for a historigraphical essay that succinctly reviews Japanese scholarship in the history of US–East Asian relations, see Aruga 1996).

This feature, together with others mentioned above, seems to suggest simultaneity and interaction in the scholarship in American history that has taken

place in and between Japan and the United States, but at the same time it shows the independence of one from the other. In the age of globalization, American Studies specialists in Japan seem at last to be catching up with their American counterparts in terms of the times as well as in the quality of the scholarship they produce. From now on, non-American scholars like the Japanese are increasingly expected to exchange ideas and thoughts freely with US scholars on an equal footing, contributing to a deeper understanding of the United States. In order to do this, it goes without saying that what is required is an ongoing effort to produce original, creative work by questioning, constantly and rigorously, both uncritical assumptions and conventional views, opening up new horizons in the field of American Studies.

Amnesia

1. Introduction

The term *amnesia*, as a description of a clinical disorder, refers to a loss of memory for personal experiences, public events, or information, despite otherwise normal cognitive function. The cause of amnesia can be either primarily *organic*, resulting from neurological conditions such as stroke, tumor, infection, anoxia, and degenerative diseases that affect brain structures implicated in memory; or it can be primarily *functional or psychogenic*, resulting from some traumatic psychological experience (see *Amnesia: Transient and Psychogenic*). This article will focus on organic amnesia. The following questions are addressed: What are the characteristics of amnesia? What structures are involved in forming memories (and whose damage causes amnesia) and what function does each serve in the process? Does amnesia affect recent and remote memories equally and, by implication, are memory structures involved only in memory formation and shortly thereafter, or are they also implicated in retention and retrieval over long intervals? Are all types of memory impaired in amnesia or is amnesia selective, affecting only some types of memory and not others? What implication does research on amnesia have on research and theory on normal memory?

2. Characteristics of Organic Amnesia

The typical symptoms of organic amnesia are the opposite of those of functional amnesia: old memories and the sense of self or identity are preserved but the ability to acquire new memories is severely impaired. Though capturing an essential truth about organic amnesia, this statement needs to be qualified in important ways in light of new research.

The scientific investigation of organic amnesia effectively began with Korsakoff's (1889) description of its symptoms at the turn of the century, during what Rozin (1976) called the 'Golden Age of Memory Research.' Likewise, it can be said that the modern era of neuropsychological research on memory and amnesia was ushered in by Scoville and Milner's (1957) publication of the effects of bilateral medial temporal lobectomy to control intractable epilepsy in a single patient, H.M. (see Fig. 1.

Some aspects of the disorder Korsakoff described are peculiar to a kind of amnesia that now bears his name (amnesia related to vitamin (thiamine) deficiency typically associated with alcoholism), while others are common to all forms of amnesia, including the one described by Scoville and Milner. The symptoms are best described by contrasting impaired abilities with preserved ones. They are as follows:

(a) Memory is impaired for various types of material, which is why the amnesia is often referred to as global, though as we shall see not all memories are affected equally. Perception, intelligence, and other cognitive functions are relatively preserved. Thus, amnesic people perform normally on standard tests of intelligence, but are impaired by comparison on standard tests of memory. They can play chess, solve crossword and jigsaw puzzles, comprehend complex instructions, and reason logically.

(b) The memory that is impaired is only *long-term* or *secondary memory*; that memory which lasts long after the information has been received and registered, and not *short-term or primary memory* which is used to hold information briefly in mind. Unaffected also is *working memory* (Baddeley 1986) which is used to operate on the information held in mind. As an example, amnesic people have a normal digit span which refers to the number of digits one can repeat immediately in sequence (typically seven, plus or minus two) and even a normal backward digit span in which the digits must be recalled in reverse order. They are impaired, however, at retaining and recalling even a sub-span list of words after a short interval that is filled with distracting activity, even if given ample opportunity to rehearse the material before. In a more ordinary life example, amnesic people can remember sentences well enough to respond to them, but cannot follow a conversation to the end if reference is made to utterances that occurred at the beginning. The same dissociation between long- and short-term memory holds for words, stories, complex visual patterns, faces, melodies, and some esthetic stimuli (Kolb and Whishaw 1996).

(c) Long-term memory loss in amnesia is most noticeable for events and information acquired after the onset of the disorder and into the future as well as in the period immediately preceding it, but not for information acquired long before that. That is, they have an *anterograde amnesia* that extends into the future but a *retrograde amnesia* limited to the time preceding the onset of the disorder. Thus, amnesic people have difficulty remembering what they learned or experienced since the onset of the disorder, even their current address and neighborhood if they had moved to a new place, but they can remember their old home and neighborhood, and some old experiences and events (Milner 1966, Squire and Alvarez 1995). Retention of such old memories, however, may be more selective and not as well-preserved as had once been believed (see below).

(d) Anterograde long-term memory loss in amnesia applies only to information that can be recollected consciously or *explicitly*. Acquisition, retention, and recovery of memory without awareness or *implicitly*

is normal. For example, having studied a set of words or pictures, amnesic patients perform poorly when their memory is tested explicitly with recognition (Which of the following items do you recognize as having been presented to you?) or recall (Tell me the items you had studied). Their memory for studied items is normal if they are tested implicitly by seeing how performance is altered by the study experience

Figure 1
A recreation of H.M.'s lesion from the surgeon's report (left drawings A, B, C, D) and from a recent MRI scan (see bottom panels) of the lesion (right drawings, A, B, C, D). The surgeon overestimated the posterior extent of the lesion. The right side of each drawing is intact for comparison purposes. The two MRI scans labeled B are of H.M.'s brain, and the remaining one is of a control's brain. MMN = Mammilary bodies; A = Amygdala; H = Hippocampus; CS = collateral sulcus; PR = Perirhinal cortex; EC = Entorhinal cortex

without making any explicit reference to the study episode. Thus, though they cannot recall or recognize the items they studied, amnesic people will perceive them more quickly and accurately than items they did not study, or complete them better when they are degraded, such as by filling in the missing letters in a word or completing the lines in a picture. Performance on these implicit tests of memory indicates that information about the studied items is held in memory though they are not aware of that (Tulving and Schacter 1990, Schacter and Buckner 1998).

These characteristics will serve as the foundation for later discussion of empirical and theoretical investigations of amnesia, normal memory, and brain function. Indeed, research on amnesia, fascinating in its own right, has had a powerful impact on memory research and theory, especially since the landmark discovery of Scoville and Milner. This research can be divided into two interacting streams: a *functional neuroanatomical* one, concerned with identifying the neuroanatomical substrates of memory and determining their precise function; and a *(neuro)psychological* one, concerned with the implication that amnesia has for understanding normal memory at a functional level. Each is dealt with in turn.

3. Neuroanatomy of Amnesia

Amnesia is caused by bilateral damage to structures in the limbic system and to adjacent cortex in the medial temporal lobes (see Figs. 2 and 3). The hippocampal formation, in the medial temporal lobes, is the most prominent of the memory structures. It consists of the hippocampus proper with its various subfields and regions, plus the dentate gyrus and the subilculum. Communication between the hippocampus and neocortex occurs thorough a series of relays. The hippocampus is connected directly to the entorhinal cortex which in turn is connected to the parahippocampal gyrus and

Figure 2
The limbic system and memory circuit (from Hamilton, 1976)

Figure 3
The hippocampal-diencephalic systems (modified from Aggleton and Brown 1999). There are two inter-related systems: The *hippocampal-fornix-anterior thalamic system* indicated by solid lines and the *perirhinal-medial dorsal thalamic system* indicated by dashed lines

perirhinal cortex which project bidirectionally primarily to the temporal and parietal lobes of neocortex, respectively. There are also projections from the hippocampus and perirhinal cortex via the fornix and anterior cingulate to the mammillary bodies and the dorsomedial nucleus of the thalamus, which are in the diencephalon. The loop of medial temporal and diencephalic structures constitute the limbic system. The hippocampus is thus ideally situated to collate information both about the cognitive (neocortex) and emotional (limbic) state of the organism and bind that information into a memory trace that codes for all aspects of a consciously experienced event (Moscovitch 1995).

3.1 Functions of the Neuroanatomical Substrates of Memory

There is considerable debate about the role that each of the components of the memory system have and how they interact with one another. Korsakoff's amnesia is associated with damage to the diencephalon whereas amnesia caused by anoxia, encephalitis, and some degenerative disorders such as Alzheimer's Disease is associated most often with medial temporal lobe damage. Although close inspection reveals differences in memory loss among the various conditions, some have not been substantiated reliably

and others could not be attributed with certainty to differences associated with diencephalic and medial temporal lobe damage, as compared to damage to other structures that often accompanies the various disorders. For example, it had been proposed that the medial temporal lobes were necessary for consolidation and retention of new information whereas the diencephalon was needed for encoding. Investigators claimed that people with diencephalic amnesia had difficulty acquiring information, but once they did so they retained it normally. People with medial temporal damage, however, showed abnormally rapid forgetting. Other investigators, however, found no difference in forgetting rates between amnesic groups, or even between them and controls (see review in Aggleton and Brown 1999).

Others noted that people with Korsakoff's, but not medial temporal, amnesia showed a number of memory deficits in addition to loss of memory for the content of an experienced event. These included confabulation, poor memory for the source and temporal order of events, susceptibility to interference, and poor meta-memory (knowledge about memory) (Moscovitch and Wincour 1992). These deficits, all of which involve strategic aspects of memory, were shown to be related more to frontal dysfunction that often accompanies Korsakoff's amnesia, rather than to diencepahlic damage *per se*.

Influenced by research on animal models of memory, investigators focused on differences among the structures in the medial temporal lobe itself, and its projections to the diencephalon. O'Keefe and Nadel (1978) proposed that the hippocampus is needed for representing allocentric spatial information, or cognitive maps but not for representing egocentric representations, routes and landmarks. While acknowledging the role of the hippocampus in allocentric spatial memory, other investigators disputed that its only function is spatial. Instead, they claimed that the hippocampus is needed for memory for all types of relational information, whether it be among spatial elements, among objects, or among words (Cohen and Eichenbaum 1993). In support of the latter idea, investigators working with animal models showed that memory for single objects is affected little, if at all, by hippocampal lesions, but is disrupted severely by lesions to the perirhinal cortex, whereas memory for the association between objects and locations is affected by parahippocampal lesions (Murray 1996, Aggleton and Brown 1999). This division of labor is consistent with the connection these regions have to neocortex. The perirhinal cortex is connected primarily to the temporal lobes which are concerned with processing objects, whereas the parahippocampus is connected to the parietal lobes which specialize in processing spatial information.

Aggleton and Brown (1999) proposed that the functional differentiation among medial temporal lobe structures extends to the diencephalon, thus forming two integrated medial–temporal–diencephalic memory systems. One system, consisting of the hippocampus and its connections to the mamillary bodies and anterior thalamic nuclei, mediates memory for recall which relies on relational information; the other, consisting of the perirhinal cortex and its connections to the dorsomedial nucleus of the thalamus, is necessary for item recognition which depends on familiarity judgments.

The lesion evidence in humans is roughly consistent with these proposals based on animal models where dissociations of function are observed along the lines predicted by the models (but see commentary in Aggleton and Brown 1999). Because amnesic people with circumscribed lesions are rare, investigators have turned to neuroimaging studies in normal people to test the hypothesis that different aspects of memory are mediated by different regions of the medial temporal lobe. In general, the evidence has been supportive of the hypotheses that have been advanced here, with greater activation in the right hippocampus on tests of spatial (Maguire et al. 1998) and relational memory (Henke et al. 1999) and in the parahippocampal gyrus (possibly entorhinal cortex) on tests of object-location memory (Milner et al. 1997) and navigation (Agguire and D'Esposito 1999).

Whatever the final verdict is regarding the role of the various regions of the medial temporal lobe and diencephalon, the evidence indicates that the type, extent, and severity of anterograde amnesia is a function of the size, side, and location of the lesion. This rule applies as well to the deficits indicative of retrograde amnesia.

4. *Retrograde Amnesia and Memory Consolidation: Where and When Are Memories Stored?*

Whereas studies of anterograde amnesia tell us about memory acquisition, studies of retrograde amnesia provide clues about the time course involved in consolidating long-term memories and the physiological processes and neural substrates which contribute to consolidation and storage. Until recently, it was widely believed that retrograde amnesia associated with medial temporal and diencephalic damage was short-lasting and temporally graded, such that memory loss was more severe for information acquired near the time of amnesia onset than for that which was acquired long before (see Sect. 2.2 above). Accordingly, the medial temporal lobes, particularly the hippocampus, and possibly the diencephalon, were considered to be temporary memory structures, needed only for memory retention and retrieval until memories were consolidated in neocortex and other structures. They were then permanently stored there and could be retrieved directly from those regions.

Nadel and Moscovitch (1997) and Nadel et al. (2000) noted a number of problems with the accepted view. Though the duration of retrograde amnesia sometimes is short, more often retrograde amnesia for details of autobiographical events after large medial temporal (or diencepahlic) lesions can extend for decades, or even a lifetime (Warrington and Sanders 1971), far longer than it would be biologically plausible for the consolidation process to last. Retrograde amnesia for public events and personalities, however, is less extensive and often is temporally graded; this is truer still of semantic memory which includes knowledge of new vocabulary and facts about the world and ourselves (our address, the names of our friends, our job), what some have called *personal semantics* to distinguish them from autobiographical episodes (see Fig. 4). The distinction between temporally extensive and temporally limited retrograde amnesia also applies to spatial memory. Schematic cognitive maps of old neighborhoods that are adequate for navigation are retained but they lack topographical details and local environmental features, such as the appearance and location of particular homes, that would allow the person to have detailed cognitive maps of their locale (see Nadel et al. 2000).

Based on this evidence, Nadel and Moscovitch concluded, contrary to the traditional consolidation model, that the function of the medial temporal system is not temporally limited but that it is needed to represent even old memories in rich, multifaceted detail, be it autobiographical or spatial, for as long as the memory exists. Neocortical structures, on the other hand, are sufficient to form domain-specific and semantic representations based on regularities extracted from repeated experiences with words, objects, people, environments, and even of autobiographical episodes that one recollects repeatedly, creating a gist of each episode. The medial temporal lobe system may aid in the initial formation of these neocortical representations, but once formed they can exist on their own. Recent evidence from studies of children whose hippocampus was damaged at birth or shortly thereafter supports this view. Vargha-Khadem et al. (1997) found that they acquired sufficient general knowledge (semantic memories) to complete high school even though their memory for autobiographical episodes was impaired. Corroborating evidence is also provided by neuroimaging studies of recent and remote autobiographical and semantic memory. These studies found that the hippocampus is activated equally during retrieval of recent and remote autobiographical memories, but not of memory for public events or personal semantics (Ryan et al. in press, Maguire 2001) (see Fig. 5).

To account for this evidence, Nadel and Moscovitch (1997) and Nadel et al. (2000) proposed a Multiple Trace Theory (MTT) according to which a

Figure 4
Example of (a) temporally-graded retrograde amnesia and (b) temporally-extended retrograde amnesia for autobiographical incidents and personal semantics in patients with bilateral medical temporal-lobe, hippocampal, and other lesions (modified from Kopelman et al. 1999 and Cipilotti et al. 2001)

Figure 5
Hemodynamic response of the hippocampus during recall of recent and remote memories, and two baseline conditions (rest and sentence completion) (Ryan et al. in press)

memory trace of an episode consists of a bound ensemble of neocortical and hippocampal/medial temporal lobe (and possibly diencephalic) neurons which represent a memory of the consciously experienced event. Formation and consolidation of these traces, or cohesion (Moscovitch 1995), is relatively rapid, lasting on the order of seconds or at most days. Each time an old memory is retrieved, a new hippocampally mediated trace is created so that old memories are represented by more or stronger traces than are new ones, and therefore are less susceptible to disruption from brain damage than more recent ones. With respect to autobiographical episodes, the extent and severity of retrograde amnesia and perhaps the slope of the gradient are related to the amount and location of damage to the extended hippocampal complex. Remote memories for the gist of events, and for personal and public semantics, are not similarly dependent on the continuing function of the hippocampal complex (see McClelland et al. 1995 for a computational account for the usefulness of having complementary hippocampal and neocortical learning and memory systems).

Proponents of the standard consolidation model, however, argue that severe and temporally extensive retrograde amnesia is observed only when the lesion extends beyond the hippocampus to include neocortical structures where remote memories, both autobiographical and semantic, are represented (Squire and Zola 1998, but see Cipilotti et al. 2001). It remains to be determined what specific contributions the different regions of the medial temporal lobes and diencephalon make, and how they act in concert with the neocortex and other brain areas, to form and retain both detailed, contextually rich representations and context-independent knowledge (McDonald et al. 1999, Rosenbaum et al. in press).

5. *Amnesia and Neuropsychological Theories of Normal Memory: Which Types of Memory Are Affected?*

Research on amnesia and other memory disorders has influenced theories of normal memory at least since the end of the nineteenth century (Rozin 1976), but at no time has this been more apparent than in the last quarter of the twentieth century. Because amnesia is selective, affecting some memories and not others, research on amnesia has been used to promote the view that memory is not unitary, but rather consists of dissociable components, each governed by its own principles and mediated by different structures. For example, evidence showing that retrograde amnesia affects detailed autobiographical memory more than semantic memory supports the idea that episodic and semantic memory are distinct both

functionally and neurologically (Tulving 1983, Kinsbourne and Wood 1975, but see Squire and Zola 1998).

One of the characteristics of amnesia is that it affects long-term or secondary memory more than short-term or primary memory. This observation was one of the crucial pieces of evidence used in the 1960s and early 1970s to argue for a functional separation of memory into at least these two major components. The idea has since become almost universally accepted and opened the field to investigation of the functional differences between the two major components, to development of the concept of working memory (Baddeley 1986), and to identification of the mechanisms supporting working and primary memory in frontal and posterior neocortex (Smith and Jonides 1999, Petrides 2000).

Beginning in the late 1960s, research on animal models and humans indicated that the formation and retention of some types of long-term memory are spared in amnesia though there is continuing debate on how best to characterize them. Generally it is accepted that only conscious recollection is affected by amnesia. Memory retrieval without awareness seems to be intact. For example, it was noted that people with bilateral medial temporal lobe lesions, such as the patient H.M., could learn and retain motor skills for months or years, though he had no memory of the learning episode minutes after it was over. The same was true of perceptual skills involved in reading mirror-reversed words or in identifying degraded or fragmented pictures and words. That more than just a skill was involved became apparent when patients could complete or identify items to which they had been exposed more accurately and more quickly than new items, suggesting that they stored information peculiar to that item even though at a conscious level they could not recall or recognize that they had studied it (Warrington and Weiskrantz 1970) (Fig. 6). At the same time, similar phenomena were reported in normal people for material they could not consciously recollect, suggesting that the dissociation between memory with and without awareness was not peculiar to amnesia but was indicative of something fundamental about the organization of memory (see reviews in Cermak 1982, Cohen and Eichenbaum 1993, Kolb and Whishaw 1996, Tulving and Schacter 1990, Schacter and Buckner 1998, Squire and Knowlton 1999). These observations not only had a major impact on our understanding of normal memory, but also were instrumental in revitalizing research on unconscious processes in cognition and emotion, an area of investigation that had been abjured by mainstream experimental psychology for almost a century.

A number of terms have been used to refer to memory with and without awareness, including declarative and nondeclarative (or procedural memory), direct and indirect memory, memory and habit,

Figure 6
Example of amnesic and control performance on two implicit (stem completion and perceptual identification) and two explicit (forced choice and yes–no recognition) tests of memory (from Squire and Knowlton 1999)

controlled and automatic. We prefer the terms explicit and implicit memory because they are descriptively accurate, refer to the types of tests used to assess memory, and are close to theoretically neutral as to the processes and mechanisms involved.

Since the 1980s, research on normal people and on people with amnesia has identified a number of characteristics of implicit memory. The structures implicated in amnesia, the medial temporal lobes and diencephalon, are not needed for normal implicit memory. Instead, performance is mediated by a variety of structures, depending on the type of implicit memory that is being tested. Like explicit memory, implicit memory is not unitary and consists of a variety of different subtypes. Although a detailed description of all them is not possible, we mention three types that have been identified and about which we know a great deal: *perceptual implicit memory or priming, conceptual implicit memory, and procedural memory* (Knowlton and Squire 1999, Moscovitch 1992, Moscovitch et al. 1993, Schacter and Buckner 1998, Tulving and Schacter 1990).

On tests of perceptual implicit memory, the test stimulus resembles the studied target perceptually (e.g., a perceptually degraded version of it, or even an identical repetition of it) whereas on tests of conceptual implicit memory, the test stimulus resembles the target semantically (e.g., having studied the word 'horse,' the participant may be asked to make a semantic decision to the word at test, or asked to produce it in response to the word 'animal'). Performance is measured by speed or accuracy of

the response to the test stimulus, without explicit reference to the studied items. The implicit nature of the test is corroborated if the person is not aware that the response or test item refers to a studied stimulus. Increases in accuracy or decreases in response latency to old studied items as compared to new ones are indicative of implicit memory for the studied items.

Research on perceptual implicit memory suggests that performance is mediated by the same perceptual modules or representation systems in posterior neocortex that are involved in perceiving the stimuli. These modules are modified by the act of processing some given material, leaving behind a record of that process. As a result, processing is faster and more accurate when the system is re-exposed to that material as compared to new material (Wiggs and Martin 1998). The modules are domain specific, in that separate ones exist for objects, faces, words, and possibly places. They are also presemantic in that they do not represent the meaning of the item but only its structure. Thus, performance on perceptual implicit tests is sensitive to changes in perceptual or structural aspects of the stimulus but not to changes in semantic aspects.

The opposite holds for performance on conceptual implicit tests which is mediated by conceptual systems in the lateral temporal lobe and inferior frontal cortex (for reviews on implicit memory see Moscovitch et al. 1993, Gabrieli 1998, Schacter and Buckner 1998). As with perceptual modules, improvement in performance results from modifications in the conceptual systems themselves.

Tests of procedural implicit memory involve learning rules, motor sequences, conditioned responses, and subjective probabilities of stimulus–response associations without explicit memory for any of them. The structures that have been identified as crucial for procedural learning are the cerebellum for classical conditioning, and the basal ganglia for the others, with some indication of prefrontal involvement if learning rules or motor sequences involve strategic, sequential, or inhibitory components (Moscovitch et al. 1993, Squire and Knowlton 1999). Changes in these structures during execution of procedures underlies the changes in performance observed on implicit tests of procedural memory.

In studying implicit memory, great care must be taken to insure that performance on tests of memory that are ostensibly implicit are not contaminated by explicit components, such as might occur when asking participants to identify degraded stimuli they had studied earlier. It is for this reason that studies of amnesic patients is so useful. Because their explicit memory is so poor, equivalent performance between amnesic and normal people on an implicit test is taken as evidence that the test in question was not contaminated by explicit memory.

6. *Amnesia and Beyond: A Neuropsychological Component Process Model of Memory*

Studies of memory in amnesia have indicated that memory is not unitary but rather consists of a variety of different forms, each mediated by different component processes which in turn are subserved by different neural mechanisms. Because neither short-term or working memory, nor implicit memory is impaired in amnesia, it can be concluded that these types of memory are not dependent on the medial temporal lobes and diencephalic structures which are damaged in amnesia. The latter structures, however, are necessary for conscious recollection of long-term, episodic memories. It has been proposed that any information that is consciously experienced is picked up obligatorily and automatically by the hippocampus and related structures in the medial temporal lobes and diencephalon. These structures bind into a memory trace those neural elements in neocortex (and elsewhere) that mediate the conscious experience of an event. The episodic memory trace thus consists of an ensemble of hippocampal and neocortical neurons. The hippocampal component of the trace acts as an index or file entry pointing to the neural elements in neocortex that represent both the content of the event and the conscious experience of it. 'Consciousness' is, therefore, part of the memory trace. Retrieval occurs when an external or internally generated cue triggers the hippocampal index which in turn activates the entire neocortical ensemble associated with it. In this way we recover not only the content of an event but the consciousness that accompanied our experience of it. In short, when we recover episodic memories, we recover conscious experiences (Moscovitch 1995).

According to this model both encoding and retrieval of consciously apprehended information via the hippocampus and related structures is obligatory and automatic, yet we know from experience and from experimental investigation that we have a measure of control over what we encode and what we retrieve from memory. Moreover, if encoding is automatic and obligatory, the information cannot be organized, yet memory appears to have some temporal and thematic organization. How can we reconcile this model of memory with other facts we know about how memory works? One solution is that other structures, particularly those in the frontal lobes, control the information delivered to the medial temporal and diencephalic system at encoding, initiate and guide retrieval, and monitor, and help interpret and organize the information that is retrieved. By operating on the medial temporal and diencephalic system, the frontal lobes act as *working-with-memory* structures that control the more reflexive medial temporal and diencephalic system and confer a measure of intelligence and direction to it (Fig. 7). Such a complementary system is needed if

Figure 7
A schematic model of hippocampal complex-neocortical-frontal interaction during encoding and retrieval (from Moscovitch 1989, See text)

memory is to serve functions other than mere retention and retrieval of past experiences (Moscovitch 1992). As invaluable as studies of amnesia have been to our understanding of memory, those studies need to be supplemented by investigations of memory in people with other types of disorders, particularly those implicating the frontal lobes, to have a full appreciation of how memory works.

Baby Booms and Baby Busts in the Twentieth Century

Baby booms and busts are not a phenomenon peculiar to the twentieth century (Easterlin 1961). There appear to have been marked cycles in fertility rates and population growth in earlier eras (see *Population Cycles and Demographic Behavior*), and in virtually every immediate postwar period there has been a compensatory 'postwar baby boom' that resulted when military personnel were reunited with their families. But the baby boom experienced by the industrialized nations after World War II is unique for at least two reasons. It occurred after a prolonged secular decline in fertility (see *Fertility Transition: Economic Explanations*), when rates were already at or below replacement level and were expected to remain low indefinitely—and yet it was too prolonged and extreme to be merely a postwar 'catching up' phenomenon; and it was much more widespread than any previous boom.

It is generally assumed that there have been two significant baby busts in the twentieth century (again, apart from wartime blips), one in the 1930s and the other in the last quarter of the century. As with the baby boom these constitute a departure from past experience in that fertility rates on both occasions fell below replacement level in a majority of countries. However, it remains to be seen whether the most recent experience constitutes a true baby bust (implying eventual 'recovery' to higher levels) or simply normal post-transition behavior (see *Demographic Transition, Second*).

Figure 1 illustrates the general pattern of fertility in the industrialized nations (except Japan: see *Fertility Transition*: *East Asia*) since around 1850 using as examples the experience in England and Wales and the USA. Depicted in Fig. 1 is the Total Fertility Rate (TFR): a synthetic measure representing the number of children a woman would have in a lifetime spent at current age-specific fertility rates. Although this synthetic measure gives an accurate picture of aggregate fertility behavior at any given point in time, it is not necessarily a good measure of changes in completed family size for cohorts of women (see *Fertility Change: Quantum and Tempo*).

Figure 1
Using the USA and England and Wales to illustrate the general pattern of fertility in the industrialized nations in the twentieth century. Source: Coleman (1996) and Glass (1967) for England and Wales; various official sources for the USA

1. Historical Patterns

The post-World War II baby boom tends to be defined as having occurred between 1946 and 1964, since the immediate postwar booms generally occurred in the 1946–48 period and the subsequent prolonged baby booms in virtually all nations had reached their peaks by 1964. But there is a wide diversity in the patterns exhibited by the baby booms in different countries, as illustrated in Fig. 2. (For coverage of the Eastern European nations, see *Fertility Trends in the Formerly Socialist Countries of Europe*.)

Although rates have been fairly stable since the boom and bust cycle, interest has been aroused by signs of a possible resurgence in several countries since about 1985. This is most apparent in Sweden, Denmark, Luxembourg, and Iceland, with increases of 25 to 35 percent since around 1990—but also appears in Finland, Norway, North America, New Zealand, and West Germany, with increases of around 15 percent in the same period. There has been some tendency to dismiss these changes as simply the result of 'catch-up' fertility among women who postponed childbirth at younger ages, but changes in younger women's fertility rates have contributed to these mini-booms, as well (based on age-specific fertility rates in Coleman 1999).

Figure 2
The Baby Boom was most pronounced in North America, Australia, New Zealand, Iceland, and Ireland, where the TFR increased by 80 percent or more and exceeded 3.5 for an extended period. It was nearly as strong, in percentage terms, in England and Wales, Scotland and Austria, where the TFR rose by about 70 percent from its prewar low. The boom was least apparent in Denmark, where the TFR increased by only 20 percent—but in the rest of northern and western Europe the increase was 40 percent or more. Although strong increases were felt in most of the English-speaking countries in the early 1950s immediately following the postwar spike, the TFR in Europe did not begin to increase again until the later 1950s–1960 in the southern European nations. Similarly, the baby boom first peaked in North America in 1957, and then in Australia and New Zealand in 1961, followed by virtually all of Europe in 1964. Even the pattern of fertility decline after the peak differed markedly among countries. It occurred rapidly in North America and northern and western Europe (apart from Ireland), with only a minor hesitation in the late 1960s, so that rates had bottomed out in those regions by about 1975. But the hesitation in the late 1960s was much more pronounced in Australia and New Zealand, where the TFR did not bottom out until about 1980. And in Ireland and Southern Europe, despite an initial peak in 1964, a pronounced fertility decline did not occur until the late 1970s, continuing through the late 1980s. Source: Coleman (1996) supplemented by Coleman (1999), Keyfitz and Flieger (1968), Glass (1967), Lee (1979) and official sources for the USA

2. *Theories: 'Price of Time'*

Two competing, but to some extent complementary theories, developed largely with respect to US experience, are generally referred to in explaining the baby boom and bust in the second half of the twentieth century. One—the 'price of time' model—juxtaposes the desire for children, which is assumed to be positively related to family income, with the price of time spent in caring for children, and emphasizes the importance of women's labor force participation and their wages relative to men's in determining that price (Becker 1981, Butz and Ward 1979; see *Fertility Transition: Economic Explanations*). It is hypothesized that during the postwar 1940s and 1950s men's wages rose more rapidly than women's, as women were displaced by men returning from the military, so that the price of children fell relative to the families' ability to support them, encouraging a baby boom. This situation was assumed to reverse itself in the late 1960s and into the 1970s as labor market opportunities for women increased and pushed up their wage, leading to

an increase in the relative price of children and hence the baby bust.

There have been critiques of the econometrics and data employed in the analysis most closely associated with this theory (Macunovich 1995), demonstrating that the true pattern of women's wages in the USA does not support the theory during the baby bust. However, several studies—especially those by Ermisch using European and Japanese data (see his summary in Ermisch 1996)—suggest that the theory is supported by the pattern of women's wages when viewed relative to that of men's.

3. Theories: 'Relative Cohort Size'

The competing theory, usually referred to as the Easterlin or 'relative cohort size' hypothesis, also assumes a positive relationship between the desire for children and family income but juxtaposes this with a couple's material aspirations, which are assumed to be influenced strongly by the standard of living experienced by young adults when they were growing up. A couple feels able to afford children only if family income surpasses some threshold determined by material aspirations. It is hypothesized that young adults in the 1950s, who were born and raised in the Depression and war years, set a lower threshold on average than young adults in the 1960s and 1970s, who were raised in the affluent postwar years. Compounding this effect of changing tastes, young adults in the 1950s were members of a very small birth cohort (product of the 1930s baby bust) relative to the size of the rest of the labor force, so that their wages were driven up relative to those of older workers in their parents' generation (Macunovich 1999, Welch 1979). The result was higher wages relative to their own (already low) material aspirations, making children appear very affordable. The large baby boom cohorts had the opposite experience when they entered the labor force, leaving them with reduced wages relative to inflated aspirations, and the baby bust resulted.

4. Combined Theories

Although the Easterlin model appeared to fit North American postwar data extremely well, cross-country tests of the hypothesis turned up fairly mixed results. It tended to fall out of favor when fertility failed to increase in the early 1980s among members of the baby bust cohorts (see Macunovich 1999 for a comprehensive review). Pampel (1993) argues that the Easterlin effect is real but is contingent on institutional differences not controlled for in cross-country analyses to date.

A recent set of analyses suggest that a model combining these two theories can be used to explain the path of fertility in the USA both before and after 1980 (Macunovich 1996, 1998b, forthcoming). In addition, this work demonstrates that while fertility has not followed the path set by relative cohort size since 1980, it has conformed with movements in a measure designed to capture Easterlin's relative income concept. It remains to be seen whether this close conformity between fertility and relative income can explain in other countries, as it does in the USA both the upturn in fertility that began after 1985 and its attenuation in the 1990s.

Balance of Power, History of

The concept 'balance of power' can be confusing. It has two different, though interrelated, meanings. It can refer first to a situation in which the Great Powers of a particular figuration of states—whether regional or global—possess roughly equal power resources. A power equilibrium is unlikely; the differences must just be small enough to make the risk of going to war too high. To achieve hegemony or empire a highly uneven power balance is required.

A balance of power can be bilateral as well as multilateral. It was considered crucial in the hegemonial rivalry between the Soviet Union and the United States. The rivals saw arms competition as the primary indicator of the balance between them. However, by balance they in fact meant superiority. The unintended result was stalemate. The nuclear danger, at the time called a 'balance of terror,' chained them together and made 'superiority' meaningless.

Balance of power in the first sense thus refers to the state of the power balance between interdependent, rivaling states or their predecessors. The first theory about the power balances in competing kingdoms was probably formulated by Kautilya, around 450 BC in India. When states were first formed in Europe, their rivalry was guided by the maxims of 'reason of state.' But gradually their perception of common interests became stronger, as reflected in the development of diplomacy and international law and the creation of international organizations.

Balance of power in its second meaning was part of the process in which cooperation between Great Powers increased without removing their rivalry. It came to mean a policy to prevent a bid for hegemony of one of the Great Powers, by the threat of the other Great Powers allying against it. If deterrence of a hegemonist failed the alliance could become a war coalition to restore the balance. But the purpose of balance of power policy itself was to maintain the status quo. To succeed, the power differentials between the Great Powers should remain small enough to foreclose hegemonic aspirations. The first meaning of balance of power was therefore a condition for the second.

1. Background

How and why did balance of power policy emerge? The European peace conference in 1648 to end the many conflicts comprising the Thirty- and Eighty-Years wars was not yet a joint attempt to develop a more stable balance of power in Europe. But the conference brought the representatives of the hitherto separate northern and western power balances together. Though the participating states in Europe recognized one another as such by treaty, repudiating the prior claims to supreme authority of empire and church, dynastic rivalry remained. As Dame Wedgwood remarks about the long delay of actual negotiations in Munster: 'The ruling powers … asked for peace always in a general sense: when it came to practical action they were always prepared to fight for a little longer in order to gain their own particular end' (Wedgwood 1963, p. 474). The peace conference became possible after expansionist ends could no longer be reached. Popular sentiment against war, very strong in the devastated German lands, did not make much difference however. War in the dynastic period was characterized by Kant as a 'pleasure party' for princes, who themselves did not suffer from them as the people did. For durable peace, dynastic states should be replaced by republics, by their nature responsive to the people, and willing to form a commonwealth together. Indeed, when the power distribution between dynastic states was still fluid and difficult to assess as in the sixteenth and seventeenth centuries, wars were frequent.

The peace of Westphalia simultaneously ended a plurality of conflicts. It made France more powerful and reduced Habsburg power. It also contributed to the rise of new Great Powers like Russia and Prussia and to the fall of Spain, Sweden, and later the Netherlands. One European power balance came into being. The monopolization processes that had led to the forming of dynastic states out of feudal fragmentation continued in the rise of Great Powers.

In the larger dynastic states, the increase of the king's power and authority had to be at the expense of other centers of power, such as the warrior nobility and autonomous towns. The domestic consolidation of dynastic regimes made stability in interstate relations more desirable. Balance of power policy came in useful. But it was precarious. Power resources changed all the time, so attempts at acquiring hegemony and war between Great Powers could not be excluded.

2. *The Classical Balance of Power in Europe*

Balance of power policy was practiced before it became an explicit principle. The power of Louis XIV's France grew to such an extent after the Peace of Westphalia that the other European powers feared it might acquire hegemony. A French attempt to use the Spanish succession to increase its power aroused Britain into forming in 1701 in The Hague an alliance of the other Great Powers against France. This coalition won the war and the Treaty of Utrecht of 1713 considerably reduced the power of France. That treaty also readjusted power relations all over Europe, and France lost some colonies to Britain. But it followed the prescription of balance of power policy that one's adversaries should not be destroyed, as that would upset the power balance between the allies.

In the eighteenth century five Great Powers emerged that would remain until 1914. They included one global and colonial sea power (Britain), two continental powers (Prussia and Austria), one power with both continental and maritime colonial ambitions (France), and an imperial power, with its territory stretching beyond Europe (Russia). Though the Ottoman Empire was in practice part of the European power balance, it was not a member of the quintet. Though the power resources of the five Great Powers were quite different, they were not too widely divergent most of the time to make balance of power policy impossible.

What exactly was classical balance of power policy? As the pamphlet, *Europe's Catechism* (1741) defines it:

> The Balance of Power is such an equal Distribution of Power among the Princes of Europe, as makes it impracticable for the one to disturb the Repose of the other … It may be destroyed by Force or Fraud, by the Pusillanimity of some, and the Corruption of all … When any Potentate hath arrived to an exorbitant share of power, the Rest (ought) to league together and reduce him to his due Share of it. Otherwise there is but one Potentate, and the others are only a kind of Vassals.

The *Catechism* shows that balance of power policy was well understood at the time. It clearly describes its functions: to prevent hegemony includes maintaining the 'Repose' of the participating powers, implying that they were no longer interested in expansionist adventures and had become status quo powers.

Balance of power policy requires that the Great Powers are able and willing to shift their alliances to deter hegemonic aspirations. That goal can be supported by a balancer. Britain, as a global sea power, could fulfill this role by always aligning itself against the leading power on the continent.

In the long run, however, balance of power policy can only be successful if the power balance between the Great Powers does not change too drastically. It still allows for cooperative expansion, as the three divisions of Poland between Russia, Austria, and Prussia in the late eighteenth century make clear. Conquest of Poland by one of them would have disturbed the balance of power.

3. *The Congress of Vienna and the Concert of Europe*

Balance of power policy did not always deter all Great Powers. Revolutionary France no longer respected the dynastic order in Europe. First, the Jacobin regime and then Napoleon set out on conquest, supported by the new power of popular conscript and volunteer armies, motivated by nationalism. Then balance of power policy had to change into a war coalition to undo the conquests of the hegemonist and restore the balance. As France occupied most of the continent, this took time. The decisive turn in the war came when Napoleon overextended his power and failed to subdue Russia.

The main members of the war coalition (Russia, Britain, Prussia, and Austria) expressed their war aims as 'the restoration of a just balance of power and a redivision of their respective forces suitable to assure this equilibrium' (Gulick 1955, p. 128). The Congress of Vienna followed the rules of balance of power policy: France was readmitted as one of the Great Powers and as member of the Conference. As part of the postwar power balance the newly created Kingdom of the Netherlands—being in between Britain, France, and Prussia—was strengthened by the inclusion of the Southern Netherlands in the Kingdom.

With 'A World Restored' (Kissinger 1957) in Vienna, a relatively stable period began again. No great war occurred until 1914. Still, in the nineteenth century maintaining the balance went together with more intense competition, whether for military and industrial power resources or for colonial possessions. There were a few wars between a limited number of Great Powers, such as the Crimean war. Yet, rulers recognized a common interest in preserving a European balance of power.

4. *The Concert of Europe and its Global Successors*

Balance of power policy was extended at the Conference of Vienna by the balancer Britain. In 1815 its Foreign Secretary Castlereagh drafted Article VI of the Quadruple Alliance Treaty (to which France later acceded), which provided for periodic meetings between the Great Powers: 'for the consideration of the measures which shall be considered the most salutory for the repose and prosperity of nations and the peace of Europe' (Kissinger 1957, p. 186).

This 'conference system' broke down in 1822 when Castlereagh's successor Canning refused to support France's proposal for joint armed intervention in

Spain. But the idea of a Concert of Europe to prevent and solve conflicts did not disappear. In 1855, Austria called a conference to prevent a war between Russia and Turkey. But it failed and the Crimean war broke out. That was ended by the Conference of Paris (1856), at which the British Foreign Secretary Lord Clarendon tried to strengthen the role of conference diplomacy by proposing the rule that states would seek 'good offices' before going to war. Two other important conferences were held in Berlin (1878 and 1884–5), both at the initiative of Bismarck. In the first, he acted with success as 'honest broker' between Russia, Britain, Austria-Hungary, and the Ottoman empire to settle conflicts over the Balkan and in the Near East, resulting from the decline of the Ottoman empire. The most important result of the second was that the Great Powers agreed to give control over the Congo to King Leopold of Belgium. As with the Netherlands in 1815, balance of power policy required that the Congo would not be controlled by one of the Great Powers, no matter what that would mean for the Congo itself.

The idea of a Concert of Europe went further than balance of power policy. It could imply collective Great Power domination. But it could not prevent a second complete breakdown of the balance of power. The rivalry for colonial possessions, symbolized by the scramble for Africa, became closed toward the end of the century. The world had been divided. Latecomers such as Germany and Italy could not be satisfied. At the same time, the power balance in Europe became more uneven. After three wars, (with successively Denmark, Austria, and France) Prussia made itself the nucleus of a powerful new German empire. Its first Chancellor Bismarck still thought in terms the balance of power. But after he left in 1890, Emperor William II began to harbor hegemonic ambitions. The other Great Powers did not form an anti-hegemonic alliance against Germany's aspirations and growing capability. On the contrary, Austria-Hungary sided with Germany, whereas Britain, France, and Russia formed a Triple Alliance. Two inflexible alliances stood against each other. Czar Nicholas' attempt to revive the conference idea in the form of general peace conferences, held in The Hague in 1899 and 1907, was not successful. The outbreak of World War I in July 1914 demonstrated again that balance of power policy was precarious.

Still, the winning alliance of World War I depended on the balancing effect of the entry of the United States. But restoring a balance of power was not a stated purpose of the postwar conference of Versailles. President Wilson believed that balance of power policy was responsible for the continual scourge of war in Europe. He looked for a lasting basis for peaceful conduct of states in collective security and national self-determination. Collective security was based on all members of the League of Nations uniting against an aggressor. But it proved impotent even against Italy, itself not a Great Power. Wilson's critical attitude towards balance of power policy was representative of the idealist thinking about international politics that was influential after the horrors of World War I. After the even worse horrors of World War II its counterpart realism, stressing the importance of power and military preparedness, became dominant again.

In the Security Council of the UN, the idea of a Concert of Great Powers became institutionalized. American President Roosevelt, who had again balanced the hegemony of Germany and its allies, saw the role of Great Powers in the Security Council as 'international sheriffs.' But a permanent Conference embodied in an international organization could not solve the problem of Great Power competition either. Hegemonic rivalry started again after a few years between the United States and the Soviet Union, thereby paralyzing the Security Council. Their rivalry did not lead to another great war primarily because of the consequences of the shared danger of a nuclear war. After the peaceful end of the hegemonic rivalry and of the Soviet Union, consensus for a time reigned in the Security Council, making a mandate for the use of force against Iraq possible. But China abstained. Rivalry again sets the tone in the Security Council.

Development beyond balance of power policy has thus not come very far. It has not been replaced by international organization. The dynamic of rivalry between states and especially Great Powers has not fundamentally changed, even though their domestic development now requires more cooperation.

5. *Balance of Power in other Parts of the World*

Power balances have been part of the development of state systems everywhere, so have wars as part of hegemonic struggles. Thinkers about interstate relations such as Kautilya in India or the Legalists in the China of the Warring States were, like Machiavelli, advisors to princes, primarily interested in increasing the power of their own state rather than in a balance of power. That was also the case with dynastic states in Europe. But in Europe balance of power policy replaced reason of state as the dominant policy orientation. Why? The explanation may be found:

(a) in the relatively even Great Power balance that developed at the end of the seventeenth century;

(b) in the importance of 'Repose' for dynastic regimes;

(c) in colonial expansion (and Russia's frontier in Asia) as a substitute for territorial expansion within Europe; and

(d) in the increasing repugnance for war in established states, though in the nineteenth century it could be replaced by nationalism.

The European balance of power became global in the twentieth century. The bipolar balance between the two remaining Great Powers after 1945 was

perceived by both as covering the world as a whole. The smallest power advantage obtained by the one had to be compensated by the other.

In the post Cold War world regional balances became more important. In South East Asia, for example, the members of ASEAN had transformed their economic cooperation in a security alliance directed to what they saw as the hegemonic ambitions of Vietnam, demonstrated by Vietnam's intervention and occupation of Cambodia. Recently Vietnam joined ASEAN because of an unspoken common interest in balancing China's possible bid for hegemony in the region. American foreign policy has been constantly concerned with regional balances of power, in Europe, but also in East Asia and the Middle East.

6. *Conclusion: A Permanent Feature of International Politics?*

Since the Congress of Vienna all attempts to create an international order were based on an extension of balance of power policy. The exception was the League of Nations. But its impotence can be explained by the neglect of balance of power considerations and overestimation of the effectiveness of the all against one requirement of punishing an aggressor, especially if that were a Great Power.

After 1991, the United States was the only global Great Power left. It is not likely that it will remain so indefinitely. Potential challengers, such as China or the European Union, are already there, even though still much too weak. Will balance of power policy become relevant again in the future? As long as a monopoly of violence at the international level does not come into being, balance of power policy may well remain relevant.

Balance of Power: Political

As Kenneth Waltz has noted, 'If there is any distinctively political theory of international politics, balance-of-power theory is it. And yet one cannot find a statement of the theory that is generally accepted' (Waltz 1979, p. 117; for surveys of the meaning of balance of power see Claude 1962, Haas 1953, Wight 1968, 1973). But cutting through the welter of possible meanings and making a few simple and undemanding assumptions leads to a conception that explains a number of outcomes which, while familiar, cannot otherwise be readily explained: no state has come to dominate the international system; few wars are total; losers rarely are divided up at the end of the war and indeed are reintegrated into the international system; small states, who do not have the resources to protect themselves, usually survive. There is then a form of stability in international politics. Although the fates of individual units rise and fall, states and much of the pattern of their interaction remain. The system is never transformed from an anarchical into a hierarchical one. (Note that this says nothing about whether wars are more likely when power is evenly distributed among the units or whether one state, although not dominant, is clearly stonger than the others (Kugler and Lemke 1996). Although those engaged in this debate often frame it in terms of balance of power, in fact the question is quite a separate one.)

The outcomes will follow if four assumptions hold. First, there must be several independent units. Second, the units must want to survive. They can seek to expand and indeed many usually will, but at minimum they must want to maintain their independence. Third, any unit must be willing to ally with any other on the basis of calculations of interest, which means that ideology and hatreds must not be strong enough to prevent actors from working together when it is necessary for them to do so. Fourth, war must be a viable tool of statecraft. Under these conditions, the

system will be preserved even as states press every advantage, pay no attention to the common good, adopt ruthless tactics, and expect others to behave the same way. Put differently, states do not strive for balance; the restraints are not internal in the sense of each state believing that it should be restrained. Rather, restraint and stability arise as ambition checks ambition and self-interest counteracts self-interest.

The basic argument about how this happens is well known, if contested. For any state to survive, none of the others can be permitted to amass so much power that it can dominate. Although states do not invariably join the weaker side, if they are to safeguard their own independence and security they must balance against any actor that becomes excessively menacing. In a way analogous to the operation of Adam Smith's invisible hand, the maintenance of the system is an unintended consequence of states seeking to advance themselves, not the product of their desire to protect the international community or a preference for balance. Balance is then maintained by negative feedback: movement toward dominance calls up forces that put dominance out of reach.

The theory obviously passes one important test in that no state has been able to dominate the international system. But this is not definitive. Few have tried: Napoleon, Hitler, perhaps the Kaiser and Louis XIV. Although others may not have made the effort because they anticipated that they would be blocked, the small number of challenges must undermine our confidence that the system could have been maintained had there been more of them. Furthermore, although the overall balance of power system has never failed, local ones have. Not only have some countries come to dominate their regions (this can perhaps be accommodated within the theory), but isolated systems have fallen under the sway of one actor. While we consider it natural for China to be unified, in fact for centuries it consisted of independent states. Rome's neighbors did not unite to check its power, and the British conquest of India was also made possible by the failure of a local balance. But these cases were still geographically limited and did not produce a world empire and bring international politics to an end.

The other restraints and puzzles mentioned earlier—the fact that few wars become total and that losers and small states are not divided up—also follow from the dictates of self-interest within the constraints imposed by the anarchical system. Since any state can ally with any other, states do not have permanent friends and enemies. Because today's adversary may be tomorrow's ally, crippling it would be foolish. Furthermore, while the state would gain territory and wealth from dividing up the loser, others might gain even more, thus putting the state at a disadvantage in subsequent conflicts.

The knowledge that allies and enemies are not permanent and the expectation that losers will be treated relatively generously reinforce one another. Because the members of the winning coalition know that it is not likely to remain together after the war, each has to fear accretions to the power of its allies. Because winners know that they are not likely to be able to dismember the loser, why should they prolong the war? Each state's knowledge that its allies have reason to contemplate a separate peace provides it with further incentives to move quickly. The result, then, is a relatively moderate outcome not despite but because of the fear and greed of the individual states. This is one reason why international wars are much more likely to end in negotiated settlements than civil wars (Licklider 1993).

There is something wrong with this picture, however. Wars against hegemons can become total, losers sometimes are divided up, and the postwar relations among states are often very different from those prevailing previously (Jervis 1985). The reason is that a long and bitter war against the hegemon undermines the assumptions necessary for the operation of the balance. States are likely to come to believe that wars are so destructive that they cannot be a normal instrument of statecraft and to see the hegemon as inherently evil and aggressive, which means that it is not a fit alliance partner and the winning coalition must stay together. As a result, wartime allies are not regarded as being as much of a potential threat as balance of power reasoning would lead us to expect. Postwar politics may then be unusually moderate and a concert system may evolve in which the states positively value the system, develop longer-run conceptions of their self-interests, and forego competitive gains in the expectation that others will reciprocate. Ironically, then, a war against a would-be hegemon that epitomizes the operation of the balance of power is likely to produce a system in which the actors consciously moderate their behavior and restrain themselves.

1. *An Alternative View*

The model of the balance of power presented here is clearly a version of systems theory in that it sees a radical separation between intentions and outcomes. An alternative view of the balance of power that sees more congruence is summarized by Edward Gulick when he says that 'balance-of-power theory demanded restraint, abnegation, and the denial of immediate self-interest' (Gulick 1955, p. 33). Morton Kaplan's conception of the balance of power similarly posits internalized moderation as two of his six rules call for self-restraint: 'stop fighting rather than eliminate an essential national actor,' and 'permit defeated or constrained essential national actors to re-enter the system as acceptable role partners' (Kaplan 1957, p. 23). For Kaplan, these rules not only describe how states behave, they consciously guide statesmen's actions. In contrast to the version of balancing

discussed earlier, Kaplan points out that in his computer model, 'if actors do not take system stability requirements into account, a "balance of power" system will be stable only if some extra systemic factor …prevents a roll-up of the system' (Kaplan 1979, p. 136). In other words, stability and restraint are not likely unless the actors seek stability.

Here the system is preserved because states want to preserve it and there is little conflict between a state's short-run and long-run interest. The two are harmonized because the norms have been internalized through socialization as the actors watch and interact with their peers. Indeed, Paul Schroeder's important study of the transformation of European international politics caused by the Napoleonic wars stresses that stable peace and the concert were produced not only by the defeat of the aggressor, but also by the painful learning that led the victors to understand that others' interests had to be respected, that smaller states could play a valuable role, and that the eighteenth century practice of compensation and indemnities led to endless cycles of warfare (Schroeder 1994; also see Schroeder 1992 and Jervis 1992). But this view cannot readily explain how the system can be maintained in the face of actors who have interests in exploiting others' moderation.

Nevertheless, it is certainly possible that states feel internal restraints and that, if they do not, the system will be torn apart by high levels of warfare. If the proponents of the version of balance of power set forth here draw on the analogy of Smith's invisible hand, critics can respond that unalloyed capitalism, like an engine out of control, will produce so much unconstrained energy that it will soon destroy itself. Just as economic liberalism must be embedded in broader societal norms if capitalism is to be compatible with a well-functioning society (Polanyi 1944), perhaps the pursuit of narrow self-interest can yield stability and a modicum of productive peace only if it is bounded by normative conceptions that limit predatory behavior.

2. *Anticipation of the Operation of Balance of Power*

States may be restrained by the expectation that if they are not, they will be faced with intense opposition. These cases fall in between the two models discussed above. Indeed, if the view of the balance as automatic is correct it would be surprising if decision-makers heedlessly sought to expand; awareness of the likely feedback would lead them to be restrained even though this impulse does not flow from internalized norms and the desire to preserve the international order. Much has been written about self-defeating expansion, but we should not neglect the fact that leaders may be inhibited by the anticipation of these processes. These cases are literally countless—that is, they cannot be counted because they do not leave traces in the historical record. But perceptive leaders realize that the balance of power makes it dangerous for their countries to be too powerful. Edmund Burke made the point eloquently at the end of the eighteenth century:

> Among precautions against ambition, it may not be amiss to take one precaution against our own. I must fairly say, I dread our own power and our own ambition; I dread our being too much dreaded. It is ridiculous to say we are not men, and that, as men, we shall never wish to aggrandize ourselves in some way or other. Can we say that even at this hour we are not invidiously aggrandized? We are already in possession of almost all the commerce of the world. Our empire in India is an awful thing. If we should come to be in a condition not only to have all this ascendant in commerce, but to be absolutely able, without the least control, to hold the commerce of all other nations totally dependent upon our good pleasure, we may say that we shall not abuse this astonishing and hitherto unheard-of power. But every other nation will think we shall abuse it. It is impossible but that, sooner or later, this stage of things must produce a combination against us which may end in our ruin (quoted in Morgenthau 1978, pp. 169–70).

Finally, if we think of balance of power in the broadest sense of power checking power, these dynamics are built into the basic forms of domestic politics. The American Constitution was built on the concept of checks and balances because the founders believed that potentially dangerous power could best be tamed by countervailing power, to use the term that Galbraith later applied to many aspects of American political and economic life (Galbraith 1952). Other aspects of domestic politics illustrate negative feedback as the unintended consequences of the pursuit of narrower self-interest in a way even more analogous to the automatic balance. Most obviously, it is hard for any political party to gain a monopoly of power because the competition can mount matching or competing claims. If the political pendulum swings in one direction, those losing influence usually will increase their unity and activity.

Bankruptcy

Bankruptcy procedures are intended to provide an efficient and fair mechanism for the reorganization or liquidation of the assets of insolvent debtors. Debtors include both individuals and business entities. A second important objective of some bankruptcy procedures is the financial rehabilitation of overindebted individuals. Rehabilitation sometimes includes discharge of indebtedness.

1. Fair and Efficient Administration of Insolvent Estates

1.1 The Need for Bankruptcy

Reliance on the usual legal procedures to collect debts from non-paying debtors can lead to inefficient and unfair results when applied to an insolvent debtor. When there are not enough assets to pay all creditors, non-bankruptcy law commonly favors the creditor who seizes and sells assets before other creditors do. The resulting race to seize the debtor's assets can lead to inefficient dispositions of debtor's assets. For example, if a business is making a profit even while insolvent, it may be more efficient to allow it to continue to operate and pay debts from future profits, yet competition between creditors can lead to sale of assets that makes continued operation of the business impossible (Jackson 1985). Competition between creditors also leads to unnecessarily duplicative collection activities. Many people also believe it is unfair to give priority in the distribution of the limited assets of an insolvent estate to the creditors who are the first to initiate formal collection actions.

Bankruptcy procedures address each of these difficulties. Once a bankruptcy proceeding is initiated, unsecured creditors are automatically enjoined from using non-bankruptcy collection procedures. In some countries, secured creditors are similarly enjoined. These injunctions eliminate duplicative collection efforts and permit an orderly disposition of the debtor's assets. In bankruptcy, the debtor's assets constitute a bankruptcy estate, to be managed in the interests of the estate's beneficiaries, the creditors. When the bankruptcy estate makes distributions, creditors with similar contractual priorities are usually paid pro rata according to the amount they are owed. Contractual promises to subordinate or to privilege particular creditors in the distribution of debtor's assets (including security agreements) are normally respected, and a few creditors (e.g., tax creditors) receive priority payments by statutory mandate. However, priorities are not usually given to creditors who have initiated collection activities before the bankruptcy filing.

1.2 Liquidation vs. Reorganization in Business Bankruptcy

The assets of an insolvent business estate may be sold, either as a unit or in separate parts, to the highest bidder(s), which is called a liquidation. Alternatively, the assets may be retained by an entity and operated as a continuing business, which is called a reorganization. In a liquidation, creditors are paid the proceeds of the sale(s). In a reorganization, creditors are given securities (debt instruments and/or shares) in the new reorganized entity, which represent rights in the future income of the continuing business. Bankruptcy creditors often have conflicting interests in the decision whether to liquidate or reorganize an insolvent business estate.

Creditors with contractual priority over other creditors (including, most importantly, secured creditors) usually prefer rapid liquidation if the anticipated proceeds will pay them in full. Reorganization both delays repayment and introduces an element of risk, because the continuing business might lose money, thus depriving these senior creditors of full payment. This preference for liquidation exists even when reorganization seems the better option from the

perspective of creditors generally, because a reorganized business is more likely than not to make profits, yet in an immediate sale a buyer is not likely to pay for those prospective gains.

Contractually subordinated creditors, on the other hand, may favor reorganization, even when it seems more likely than not that a reorganized business will suffer losses. Immediate liquidation of the assets may not yield any payments to subordinated creditors, and there is always a possibility of payments from the future profits of a continuing business. Three other groups may also favor reorganization, even when immediate liquidation seems a better prospect for maximizing payments to creditors. Trade creditors may prefer to continue the business under the former management because of the prospect of making future sales. Management of the business is often identified as a separate interest group favoring reorganization, both to preserve their jobs and to provide an opportunity to rehabilitate professional reputations harmed by business insolvency. Finally, the owners of the insolvent business will normally favor reorganization. They will receive nothing if the business is liquidated while insolvent, but in a reorganization future profits of the continuing business may be sufficient to return the entity to solvency.

1.3 Governance Issues in Business Bankruptcy

Conflicts in interest between creditors can generate controversy about control over decision-making within a bankruptcy. In most countries, senior creditor interests control the appointment of the effective decision makers. Often, secured creditors are not even enjoined from foreclosing on their collateral by the initiation of bankruptcy, and they may be able to force liquidation simply by doing so. In these circumstances, reorganization within bankruptcy may seem unlikely. In response, management and owners of insolvent businesses may take desperate steps in order to avoid a bankruptcy filing. For example, a business might sell non-essential assets quickly at lower prices than could be obtained if more time were taken, in order to pay off a senior creditor who is threatening to seize assets (Baird 1991). Junior creditor interests may also purchase the claims of senior creditor interests, even after a bankruptcy filing, in order to forestall an immediate liquidation.

In the United States, bankruptcy procedures often allow management of the insolvent business to exert substantial control over decision-making within bankruptcy. It is widely believed that this system leads to decisions to reorganize an insolvent business when immediate liquidation would be in the overall interests of creditors as a whole. Furthermore, it causes senior-creditor interests to agree to compromise their contractual priority rights, in favor of junior interests, in order to facilitate a quicker liquidation or a reorganization in which senior interests receive debt instruments with a high likelihood of ultimate payment. There has been considerable academic criticism of the governance of business bankruptcy in the United States, describing it as inefficient for allowing insolvent businesses to continue without sufficient prospects of returning to profitability, and as unfair in failing to protect fully contractual priority rights (Bradley and Rosenzweig 1992). Its defenders point out that there are many non-creditors with an interest in reorganization—most importantly, the employees of the insolvent business (Warren 1993).

1.4 Law and Practice in Business Bankruptcy

Although frequently subject to the same formal rules, there are often important practical differences between the administration of bankruptcy estates of large and small businesses. In the case of large businesses, there are likely to be substantial assets and many creditors. Creditors with different priorities are organized into groups and represented by lawyers. Cases tend to be litigious and lengthy, but most interests are represented vigorously. Because of the influence of management, there may be a slight favoritism towards reorganization, but it is not great (LoPucki and Whitford 1993). In small-business bankruptcies, however, apart from possibly one large creditor which is likely to be secured, creditors are more likely to believe that the combination of the amount of debt at stake and the prospect of a substantial ultimate payment is insufficient to justify investment in legal fees. As a result, governance in small-business cases often is left to management and perhaps the one large creditor, and they may agree to a reorganization or to delay liquidation, to the substantial detriment of creditor interests (LoPucki 1983). There have been calls for greater judicial or administrative oversight of the governance of small cases to insure more appropriate representation of smaller creditor interests.

2. Rehabilitation of Individual Debtors

The automatic injunction upon bankruptcy filing against non-bankruptcy collection actions can help the financial rehabilitation of individual debtors. By protecting the debtor's paychecks and bank accounts from judicial attachment during the course of the bankruptcy proceedings, the automatic injunction gives the debtor time to work out financial problems. Most countries allow the debtor to extend the duration of the automatic injunction for several years by proposing and then carrying out a plan for the repayment of some or all of the debt through periodic payments.

A few countries, most notably the United States, allow an individual debtor to obtain a discharge of

many unsecured debts in a bankruptcy proceeding. Before getting the discharge, the debtor must turn over for the benefit of unsecured creditors all property that is not encumbered by a security interest, or considered exempt from this requirement because it is essential to the debtor's everyday life. In practice, individual debtors usually enter bankruptcy with little or no property that is neither exempt nor unencumbered, so unsecured creditors usually receive nothing in these bankruptcy proceedings.

The availability of discharge has been justified historically as a means of providing individuals with a 'fresh start,' so that they might again become productive economic participants in society. An overindebted debtor without realistic hope of repaying all debts in the foreseeable future has little incentive to seek new economic opportunities, because the primary beneficiary of increased income will be the creditors (Whitford 1997). Relief of individual hardship is another rationale sometimes offered for the discharge.

The majority of countries that allow for the discharge of individual debt make the availability of this relief conditional upon completion of a plan for payment of debts over a three- to ten-year period (Huls 1994). Conditional discharge availability in this manner is justified as discouraging the incurring of debt in anticipation of discharge. It is also believed that payment plans can provide debtors with the opportunity to learn the disciplined living and household budget skills that will contribute to the overall financial rehabilitation objective, but there is little information available about how well payment plans achieve that objective. It is known that in the United States, where debtors have certain incentives to enter a payment plan voluntarily rather than seek an immediate discharge, more than two-thirds of payment plans are not completed successfully. Countries vary in whether they will grant a discharge to a debtor who has attempted, but not completed, a payment plan. Where discharge is denied, the result is a significant restriction of the availability of a fresh start to individual debtors.

The use of credit cards and unsecured indebtedness by individuals has increased dramatically throughout the world since the 1980s. Probably as a result of this, many countries are now reconsidering their laws concerning individual bankruptcy. Many countries that have not previously permitted discharge of consumer indebtedness now allow an individual to gain a fresh start, provided the debtor makes an attempt in good faith to complete a payment plan (Niemi-Kiesilainen 1997). In the United States, where traditionally debtors have been able to obtain a discharge without first attempting a payment plan, there has been a rapid increase in the bankruptcy filing rate. As a response, there is a significant political effort to limit the availability of the discharge for debtors whose income exceeds certain standards. These debtors would be required to complete a five-year payment plan before receiving a discharge of any amount not paid under the plan. If adopted, the result is likely to be a significant decrease in the bankruptcy filing rate, and, because most payment plans will not be completed satisfactorily, an even greater decrease in the number of discharges in bankruptcy.

Basal Ganglia

1. Basal Ganglia Anatomy and Neurochemistry

As an anatomical entity, the basal ganglia have undergone significant revision. In 1664 anatomist Thomas Willis originally termed this subcortical region of the telencephalon 'corpus striatum.' The development of neuronal tracing techniques by Nauta and colleagues in the mid-1950s (e.g., silver degeneration) allowed for elucidation of efferent connections within the broadly defined corpus striatal region, and the term 'basal ganglia' was eventually adopted to refer to a relatively restricted group of subcortical structures that originally included the caudate nucleus and putamen, the globus pallidus, the claustrum, and the amygdala. As the amygdala became more closely identified as a component of the limbic system, its inclusion as a basal ganglia structure was dropped.

Heimer and colleagues adopted the term 'ventral striatum' to delineate the most ventral aspects of the striatum from more dorsal regions (i.e., caudate-putamen), and this striatal region includes the nucleus accumbens and portions of the olfactory tubercle. Today many neuroanatomists would agree that the core structures of the mammalian basal ganglia include the caudate nucleus, putamen, ventral striatum, and globus pallidus. In addition, the substantia nigra, ventral tegmental area, and the subthalamic nucleus are considered associated basal ganglia structures via their reciprocal connections with the core structures.

The basal ganglia receive input from virtually all regions of the cerebral cortex, and these corticostriatal pathways are topographically organized. The presence of cortico-basal ganglia loops is an important feature of the anatomical and functional organization of the basal ganglia. Specific cortical regions project to the basal ganglia, and output from the basal ganglia 'loops' back into these same cortical regions via various thalamic nuclei. An example of one such pathway is the projection from the primary motor cortex $\gg$ putamen $\gg$ globus pallidus $\gg$ ventrolateral thalamus $\gg$ primary motor cortex. Evidence suggests that at least four other parallel cortico-basal ganglia loops exist.

Neurochemically, the basal ganglia are characterized by a substantial input from midbrain dopaminergic pathways originating in the substantia nigra and ventral tegmental area, and primarily innervating the dorsal and ventral striatum, respectively. Medium spiny output neurons of the neostriatum utilize gamma-amino butyric acid as a neurotransmitter, and corticostriatal afferent projections are predominantly glutamatergic. Several neuropeptides are localized in the basal ganglia including various opioids, cholecystokinin, substance P, somatostatin, and neurotensin. A final prominent component of basal ganglia neurochemistry is a large population of cholinergic interneurons.

In the 1980s, a series of important findings demonstrated the existence of two neural 'compartments' in the mammalian neostriatum that are neurochemically and anatomically differentiated, and are commonly termed the striatal 'patch' and 'matrix.' Neurochemically, the patch compartments of the striatum (also termed striosomes) are characterized by low levels of acetylcholine and high levels of various opiates and substance P. In contrast, the matrix compartment is characterized by cholinergic and somatostatin-containing neurons. Both compartments receive dopaminergic input, although dopamine pathways originating in the ventral tegmental area and substantia nigra primarily innervate the patch and matrix, respectively. Anatomically, corticostriatal and thalamostriatal projections are closely associated with the striatal matrix, whereas projections from limbic structures to the striatum (e.g., hippocampus, amygdala) appear primarily to innervate striatal patches. Elucidation of the functional significance of the neurochemical and anatomical differentiation observed between these two striatal compartments represents an important and evolving area of basal ganglia research.

2. *Basal Ganglia and Neurodegenerative Disease*

In 1817 the English physician James Parkinson first described a neurological disorder characterized by limb rigidity, tremors, and difficulty initiating movement. Parkinson's disease is a progressive neurodegenerative disorder that may affect up to 1 percent of the population and increases in incidence with advancing age. Fundamentally, Parkinson's disease is a disorder of basal ganglia function that involves the loss of neurons in the substantia nigra, leading to a concomitant decrease of the neurotransmitter dopamine within the nigrostriatal dopamine pathway. Although there is no known cure for Parkinson's disease, a major breakthrough in the treatment of this disorder came with the discovery that administration of the dopamine precursor 3,4-dihydroxyphenylalanin (L-DOPA) improved the symptoms of Parkinson's patients, presumably by increasing the availability of dopamine within the neostriatum. In recent years, dopamine-containing neural tissue from human fetus or adrenal cortex has been stereotaxically implanted directly into the neostriatum of Parkinson's patients in an attempt to provide a long-term reversal of dopaminergic dysfunction. The results of some of these studies have been encouraging, and investigation of the efficacy of neural grafting techniques in Parkinson's disease appears a promising avenue for further research.

A second neurological disorder that involves the basal ganglia is Huntington's chorea, first described in a group of patients by George Huntington in 1872. Huntington's disease has a clear genetic basis and is characterized by the production of involuntary 'choreic' movements. In contrast to Parkinson's disease, the nigrostriatal dopamine system is largely intact in Huntington's disease. Instead, degeneration of intrinsic GABAergic and cholinergic cells in the basal ganglia may disinhibit the nigrostriatal dopamine system, resulting in excessive inhibition of pallidal neurons projecting to the thalamus, and leading to involuntary movements.

3. *Basal Ganglia, Reward, and Drug Addiction*

In the mid-1950s, James Olds and colleagues initiated the neuroscientific study of brain reward processes with their fortuitous discovery of self-administration of electrical stimulation in the mammalian brain. In addition to implicating hypothalamic pathways,

subsequent research revealed that animals readily self-stimulate the medial forebrain bundle, a neural pathway includes fibers containing the dopamine projection from the ventral tegmental area to the ventral striatum. Research conducted over the ensuing four decades has implicated the basal ganglia in reward processes mediated not only by 'artificial' electrical brain simulation, but also by natural reinforcers such as food, water, and sex. In particular, the nucleus accumbens may be a critical component of the neural circuitry by which various drugs with abuse potential in humans (i.e., addictive drugs) produce rewarding affect. Several lines of evidence are consistent with this hypothesis. First, damage to the nucleus accumbens and/or the ventral tegmental area influences self-administration of several drugs of abuse in experimental animals. Second, accumbens damage attenuates conditioned place preference behavior, in which animals learn to approach environmental cues that have been previously associated with drug administration. Finally, conditioned place preference behavior and self-administration of various drugs are affected by intracerebral administration of neurotoxic agents that selectively damage dopamine neurons, and by injection of dopamine antagonist or agonist drugs directly into the nucleus accumbens. These findings have in large part led to the prominent view that dopamine acts as a reward signal in the mammalian nucleus accumbens. Although not without controversy, this hypothesis continues to have a tremendous impact on basic research investigating the neurobiological bases of drug addiction, and the basal ganglia remain a prominent focus in this field.

4. *Basal Ganglia and Learning and Memory*

Early studies on the possible role of the basal ganglia in learning and memory were guided in part by anatomical evidence demonstrating the existence of the corticostriatal pathways. One hypothesis that has gained increased support is that the participation of the basal ganglia in learning and memory is organized by the nature of the topographical cortical input that these subcortical structures receive. For example, in experimental animals lesions of either the frontal cortex or the medial region of the dorsal striatum to which it projects produce similar impairments in performance of delayed alternation tasks. In addition, lesions of regions of the caudate-putamen that receive visual or olfactory input selectively impair conditioned emotional responding based on visual or olfactory stimuli, respectively.

Within a multiple memory systems framework, Mishkin and Petri (1984) have hypothesized that the dorsal striatum mediates a noncognitive form of stimulus-response (S-R) or 'habit' memory, in which associations between stimuli and responses are acquired in an incremental fashion. This hypothesis was based in part on early findings in monkeys of impaired simultaneous visual discrimination learning following lesions of the ventral putamen, and is now supported by studies in rats, monkeys, and humans. For example, double dissociation experiments indicate that lesions of the caudate-putamen of rats selectively impair S-R visual discriminations in rats, while leaving cognitive forms of memory mediated by other brain regions (e.g., spatial memory/hippocampal memory) intact. Selective deficits in habit learning have also been demonstrated in early to mid stages of Parkinson's disease and Huntington's chorea. For example, Parkinson's patients show impaired probabilistic classification learning that is based on arbitrary S-R associations. Functional neuroimaging studies have also revealed a role for the human neostriatum in performance of motor habits and motor sequence learning, and various computational approaches to information processing in the basal ganglia have been recently developed.

Mogenson and colleagues (1980) proposed that projections from limbic brain regions including the basolateral amygdala and hippocampus to the ventral striatum (e.g., nucleus accumbens) provide an interface between motivational states and behavioral action. This general hypothesis has received increasing support, and is reflected by recent evidence suggesting that the nucleus accumbens plays a selective role in stimulus-reward learning and memory via connectivity with the amygdaloid complex. Similarly, the nucleus accumbens may participate in hippocampus-dependent memory processes (e.g., spatial memory) via projections from the hippocampal subiculum.

Behavioral pharmacology experiments indicate a role for cholinergic, dopaminergic, and glutamatergic neurotransmission in learning and memory processes mediated by the neostriatum, in particular during memory consolidation. Long-term potentiation and long-term depression, two forms of synaptic plasticity that putatively mediate learning and memory processes occurring in other brain regions (e.g., hippocampus and cerebellum), are also experimentally inducible in the neostriatum via stimulation of corticostriatal fibers. The extent to which these forms of striatal plasticity mediate the selective learning and memory functions of the neostriatum is not currently known.

5. *Basal Ganglia and Psychopathology*

In addition to the long recognized role of the basal ganglia in neurodegenerative diseases compromising human motor behavior, recent evidence indicates a role for the neostriatum in obsessive-compulsive disorder (OCD), an anxiety disorder characterized by obsessive thought processes and compulsive behavioral acts. Structural neuroimaging studies have implicated the caudate nucleus in OCD pathology, although such studies have variously reported in-

creases or decreases in caudate volume. The overall pattern of findings from functional neuroimaging studies suggests increases in activity of the caudate nucleus and associated afferent cortical structures, including primarily the orbitofrontal and anterior cingulate cortices. One important study found that either medication or behavioral treatments resulted in similar reductions of activity in the caudate nucleus and frontal corticostriatal regions of OCD patients.

An interesting 'evolutionary' link between basal ganglia function and motoric aspects of OCD has been suggested by Rapoport and colleagues, who have pointed to similarities between the role of the caudate-putamen of lower animals in stereotypical species-specific behaviors (e.g., grooming), and the high incidence of washing and cleaning behaviors exhibited in OCD. In addition to OCD, basal ganglia dysfunction has also been associated with the compulsive and involuntary motor tics and vocalizations characterizing Tourette's syndrome. Finally, involuntary movements and OCD-like symptoms also accompany Sydenham's chorea, an autoimmune disease that attacks various brain regions including the basal ganglia.

The basal ganglia have also been hypothesized to play a role in schizophrenia, a disorder characterized by disturbances in thought, affect, and sensory processes. The discovery that the phenothiazene class of antipsychotic drugs act as dopamine receptor blockers led to an examination of the role of brain dopamine pathways innervating the basal ganglia in schizophrenia. In particular, the mesolimbic/mesocortical dopamine pathways originating in the ventral tegmental area (VTA) and innervating the nucleus accumbens and cortical regions including the prefrontal cortex may be an important component of the neural circuitry by which dopamine antagonist drugs exert their antipsychotic effects.

6. *Summary*

The basal ganglia are one of the most well studied groups of brain structures in the mammalian brain. Anatomical considerations and the long documented role of the basal ganglia in neurodegenerative diseases such as Parkinson's and Huntington's chorea have in part led to the traditional association of the basal ganglia with motor behavior. However, as this brief survey of basal ganglia research indicates, neuroscientists today recognize that the role of these structures in behavior is not restricted to motor functions. Rather, progress in understanding the neurobiological bases of numerous psychological processes is being made in basal ganglia research, including drug addiction and reward, learning and memory, and psychopathology. The anatomical and neurochemical heterogeneity reflected by the presence of cortico-basal ganglia loops and striatal patch/matrix compartmentalization may ultimately provide clues to understanding these various functional roles, and the study of basal ganglia–behavior relationships will continue to be an exciting and promising field of psychological research.

Bayesian Graphical Models and Networks

1. Introduction

A graphical model represents the probabilistic relationships among a set of variables. Nodes in the graph correspond to variables, and the absence of edges corresponds to conditional independence. Graphical models are becoming more popular in statistics and in its applications in many different fields for several reasons. For example, they provide a language to facilitate communication between a domain expert and a statistician, provide flexible and modular definitions of families of probability distributions, and are amenable to scaleable computational techniques. (e.g., Pearl 1988, Lauritzen 1996, Whittaker 1990).

The subject of this article is directed acyclic graphical (DAG) models. These models have numerous uses including data analysis (e.g., Whittaker 1990, Spiegelhalter and Thomas 1998), modeling of causal relationships (e.g., Pearl 2000, Spirtes et al. 2001), and representing and reasoning about uncertainty in expert systems (e.g., Cowell et al. 1999). Specific applications of graphical models include diagnosis and troubleshooting, medical monitoring, genetic counseling, information retrieval, natural language processing, weather forecasting, manufacturing, digital communication, and machine vision.

In Sect. 2, we define the DAG model and describe its basic properties. In Sect. 3, we describe the use of DAG models in expert systems and decision analysis. In Sect. 4, we describe methods for constructing the structure and distributions of DAG models from data. In Sect. 5 we conclude with additional pointers to the literature.

2. Definition and Basic Properties

Let us begin with some notation. We denote a variable by a capitalized token (e.g., X, X_i, Θ, *Age*), and the state or value of a corresponding variable by that same token in lower case (e.g., x, x_i, θ, *age*). We denote a set of variables by a bold-face capitalized token (e.g., $\mathbf{X}$, $\mathbf{X}_i$, $\mathbf{Pa}_i$). We use a corresponding bold-face lower-case token (e.g., $\mathbf{x}$, $\mathbf{x}_i$, $\mathbf{pa}_i$) to denote an assignment of state or value to each variable in a given set. We use $p(x|y)$ to denote the probability or probability density that $X = x$ given $Y = y$. We also use $p(x|y)$ to denote the probability distribution for X given Y. Whether $p(x|y)$ refers to a probability, probability density, or a probability distribution will be clear from context. Finally, we use $\mathbf{X} \perp \mathbf{Y} | \mathbf{Z}$ to mean that $\mathbf{X}$ and $\mathbf{Y}$ are conditionally independent given $\mathbf{Z}$.

Figure 1
A DAG model for troubleshooting a printing problem

A DAG model for a set of variables or *domain* $\mathbf{X} = \{X_1, \ldots, X_n\}$ consists of (a) a network structure $\mathbf{s}$ that encodes a set of conditional independence assertions about variables in $\mathbf{X}$, and (b) a set $\mathbf{p}$ of local probability distributions associated with each variable. Together, these components define the joint probability distribution for $\mathbf{X}$. The network structure $\mathbf{s}$ is a directed acyclic graph, that is, each edge is directed and there are no paths along these directed edges that lead from a variable to itself. The nodes in $\mathbf{s}$ are in one-to-one correspondence with the variables $\mathbf{X}$. We use X_i to denote both the variable and its corresponding node, and $\mathbf{Pa}_i$ to denote the parents of node X_i in $\mathbf{s}$ as well as the variables corresponding to those parents. The *lack* of possible directed edges in $\mathbf{s}$ encode conditional independencies. In particular, given structure $\mathbf{s}$, the joint probability distribution for X is given by

$$p(\mathbf{x}) = \prod_{i=1}^{n} p(x_i | \mathbf{pa}_i) \tag{1}$$

The *local probability distributions* P are the distributions corresponding to the terms in the product of Eqn. (1). Consequently, the pair $(\mathbf{s}, \mathbf{p})$ encodes the joint distribution $p(\mathbf{x})$.

As an example, consider Fig. 1, which illustrates the structure of a DAG model for troubleshooting a

Figure 2
Undirected (a) and directed (b) graphical-model structures

printing problem on the Microsoft Windows 95 operating system. This model structure was constructed from expert knowledge using judgments of cause and effect. Note that, in general, the probability distributions in a DAG model may be subjective or objective.

In the remainder of this section, we discuss several basic issues concerning DAG models. Equation (1) implies that, for all X, the nondescendants of X are independent of X given the parents of X. Many additional independencies are entailed by this basis of independencies. In Fig. 1, for example, we have that *Print Output OK* and *Application Output OK* are conditionally independent given *Print Data OK*. Pearl (1988) describes a condition, called *d-separation*, that allows one to read off any independency from a DAG model in a computationally efficient manner.

Another commonly used graphical model is the undirected graphical (UG) model, also known as a Markov Random Field or Markov Network (e.g., Whittaker 1990, Lauritzen 1996). The independencies that can be encoded by DAG and UG models overlap, but there are independencies that can be encoded by UGs and not DAGs, and vice versa. For example, consider the UG model in Fig. 2a for the domain (X, Y, Z, W). This graph encodes the independencies $X \perp Z | (Y, W)$ and $Y \perp W | (X, Z)$. There is no DAG model for these four variables that can encode both of these independencies. In contrast, consider the DAG model in Fig. 2b for the domain (X, Y, Z). This graph encodes the marginal independence of X and Z and the possible dependence of X and Z given Y. No UG model for these variables can encode this set of relationships.

The relationships encoded by the 'v structure' or 'collider' in Fig. 2b has an intuitive explanation. For example, consider the subgraph in Fig. 1 for the variables *Correct Local Port*, *Local Cable Connected*, and *Local Path OK*, which has this structure. Before one observes the value of *Local Port OK*, the remaining two variables are marginally independent. When we observe that *Local Port OK* is false, however, the remaining two variables become dependent. If—say—*Correct Local Port* subsequently is observed to be false, then *Local Cable Connected* is more likely to be true, because the faulty local path has been explained by the first observation. In general, this pattern of relationships is sometimes referred to as the 'explaining away' phenomenon (Pearl 1988).

Another interesting point about DAG models is that two or more DAG models can be equivalent in the sense that they represent the same independencies. Given the domain (X, Y, Z),for example, the DAG models $X \rightarrow Y \rightarrow Z$, $X \leftarrow Y \rightarrow Z$, and $X \leftarrow Y \leftarrow Z$ encode the same independency: $X \perp Z | Y$. Chickering (1995) describes a simple and computationally efficient algorithm for determining whether two DAG models are equivalent. First, he defines a directed edge from X to Y to be *covered* if the parents of X and Y are the same with the exception that X is also a parent of Y. He then proves that two DAG models are equivalent if and only if there exists a sequence of reversals of covered directed edges that transforms one model to the other.

Finally, we note that the definition of DAG model does not restrict the form of the local distributions $p(x_i|\mathbf{pa}_i)$. Later, we describe several commonly used models for local distributions. Here, we mention that, when a variable and its parents are continuous, a commonly used local distribution is the linear regression with Gaussian error. When all variables in a domain are continuous and the error terms are mutually independent, the resulting DAG model is equivalent to a structural equation model with independent errors (e.g., Pearl 2000).

3. *DAG Models for Expert Systems and Decision Analysis*

The modern use of DAG models began with researchers in Management Science and AI communities (e.g., Howard and Matheson 1981, see *Artificial Intelligence: Uncertainty*) who used them to encode prior or 'expert' knowledge for decision making and expert-system inference. These communities refer to this class of model as Knowledge Maps and Bayesian Networks, respectively. In this section, we examine this use of DAG Models.

First, let us consider how a person—who we will call the decision maker—constructs a DAG model for a given domain $\mathbf{X}$ from their knowledge. One method for construction starts with a total ordering on the variables provided by the decision maker. For simplicity, let us relabel the variables $\mathbf{X} = (X_1, \ldots, X_n)$ so that X_i is the ith variable in this ordering. From the chain rule of probability, we have

$$p(\mathbf{x}) = \prod_{i=1}^{n} p(x_i | x_1, \ldots, x_{i-1}) \tag{2}$$

For every X_i there will be some subset $\Pi_i \subseteq$

$\{X_1, \ldots, X_{i-1}\}$ such that X_i and $\{X_1, \ldots, X_{i-1}\}\backslash\Pi_i$ are conditionally independent given Π_i, that is, for any $\mathbf{x}$

$$p(x_i|x_1, \ldots, x_{i-1}) = p(x_i|\pi_i) \tag{3}$$

Combining Eqns. (2) and (3), we obtain

$$p(\mathbf{x}) = \prod_{i=1}^{n} p(x_i|\pi_i) \tag{4}$$

Comparing Eqns. (1) and (4), we see that the variables sets $(\Pi_1, \ldots, \Pi_n)$ correspond to the DAG-model parents $(\mathbf{Pa}_1, \ldots, \mathbf{Pa}_n)$, which in turn fully specify the directed edges in the network structure $\mathbf{s}$. Consequently, to determine the structure of a DAG model, a decision maker (a) orders the variables somehow and (b) determines the variables sets that satisfy Eqn. (3) for $i = 2, \ldots, n$. Finally, the decision maker assesses the local distributions $p(x_i|\mathbf{pa}_i)$.

The approach for constructing model structure just described has an important drawback. If one chooses the variable order carelessly, then the resulting network structure may fail to reveal many conditional independencies among the variables. Fortunately, there is another often-used technique for constructing DAG models that does not require an ordering. The approach is based on two observations: (a) people can often readily assert causal relationships among variables, and (b) absent causal relationships typically correspond to conditional independencies. Thus, to construct a DAG model for a given set of variables, one simply draws arcs from cause variables to their immediate effects. In almost all cases, doing so results in a network structure that satisfies the definition Eqn. 1. The DAG model in Fig. 1 was constructed in this manner.

Once a DAG model is constructed (whether from prior knowledge, data, or both), we can use it to answer probabilistic queries. In the context of decision analysis, the answers to these queries can be used for decision making. In the context of expert systems, these answers convey 'expert advice.' For example, given the DAG model in Fig. 1, we may be interested in the probability that *Printer On* and *Online* is true, given *Print Output OK* is false. We can obtain this probability by applying the rules of probability to the joint distribution defined by the DAG model. Many researchers refer to this process as *probabilistic inference*.

Direct computation via the joint distribution is expensive. Investigators, however, have developed probabilistic-inference algorithms that use the conditional independencies in the DAG model to speed up inference, sometimes dramatically. Many of these algorithms are limited to DAG models in which all variables are discrete. For example, Howard and Matheson (1981) and Shachter (1988) developed an algorithm that reverses arcs in the network structure until the answer to the given probabilistic query can be read directly from the graph. In this algorithm, each arc reversal corresponds to an application of Bayes's theorem.

Pearl (1988) developed a message-passing scheme that updates the probability distributions for each node in a DAG model in response to observations of one or more variables. Lauritzen and Spiegelhalter (1988) created an algorithm that first transforms the DAG model into a tree where each node in the tree corresponds to a subset of variables in $\mathbf{X}$. The algorithm then exploits several mathematical properties of this tree to perform probabilistic inference. Lauritzen (1992) extended this algorithm to include DAG models that encode multivariate-Gaussian or Gaussian-mixture distributions.

When the edges of a DAG model structure form a tree, these methods for exact probabilistic inference scale linearly in the number of domain variables. In general, however, these algorithms are NP-hard (Cooper 1990). The source of the complexity lies in undirected cycles in the DAG model—cycles in the structure where we ignore the directionality of the edges. When a DAG model contains many undirected cycles, inference is intractable. For many applications, however, structures are simple enough (or can be simplified sufficiently without sacrificing much accuracy) so that inference is efficient. For those applications where generic inference methods are impractical, researchers are developing techniques that are custom tailored to particular network topologies or to particular inference queries. In addition, approximate algorithms involving Monte Carlo techniques (e.g., Spiegelhalter and Thomas 1998) and variational methods (e.g., Jordan 1998) are proving useful in many applications.

4. *Learning DAG Models from Data*

There are a variety of methods for constructing DAG models from data or a combination of data and prior knowledge. We concentrate here on the Bayesian approach, but briefly consider other approaches.

First, suppose the structure $\mathbf{s}$ of the DAG model is known and we are interested in inferring the local distributions from our prior knowledge and a set of data $\mathbf{d} = (\mathrm{x}^1, \ldots, \mathrm{x}^N)$ considered to be a sample from an infinitely exchangeable sequence. For simplicity, we assume that each local distribution is parametric so that the data form a random sample from

$$p(\mathbf{x}|\boldsymbol{\theta}_s, \mathbf{s}) = \prod_{i=1}^{n} p(x_i|\mathbf{pa}_i, \boldsymbol{\theta}_i, \mathbf{s}) \tag{5}$$

where $\boldsymbol{\theta}_s = (\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_n)$ are the parameters of the local distributions.

If the parameters in $\boldsymbol{\theta}_s$ are mutually independent and there are no missing data, then the parameters in $\boldsymbol{\theta}_s$ are independent *a posteriori* and we can infer

each local distribution separately. Because a local distribution can be thought of as a probabilistic classification or regression model, learning the local distributions of a DAG model under the assumptions above is a familiar task. Examples of classification/regression models that have been used in conjunction with DAG models include probabilistic decision trees, generalized linear models, neural networks, and probabilistic support-vector machines.

One class of local distributions used frequently are distributions from the exponential family. For example, when X_i and its parents are discrete, $p(x_i|\mathbf{pa}_i, \boldsymbol{\theta}_i, \mathbf{s})$ can be a set of mutually independent multinomial distributions, one for each instance of the parents of X_i. When X_i is continuous, $p(x_i|\mathbf{pa}_i, \boldsymbol{\theta}_i, \mathbf{s})$ can be a set of linear regressions with mutually independent error terms, one for each instance of the discrete parents of X_i. In these cases, the posterior uncertainty can be determined and integrated over in closed form (e.g., Heckerman and Geiger 1995).

When the parameters in $\boldsymbol{\theta}_s$ are not mutually independent, when there are missing data (and/or latent variables), when local distributions from outside the exponential family are used, or when complex expectations over posterior uncertainty are required, closed-form expressions are unavailable and Markov Chain Monte Carlo methods are often employed. The BUGS system (Spiegelhalter and Thomas 1998) is a popular software tool designed for these situations. If maximum-likelihood or maximum *a posteriori* (MAP) approximations are sufficient, then optimization-based algorithms such as Expectation–Maximization and gradient descent typically are used.

Now, let us suppose that we are also uncertain about the structure of the DAG model. Again concentrating on the Bayesian approach, we model this uncertainty with a probability distribution $p(\mathbf{s})$ over the possible structures (see e.g., *Bayesian Statistics*). Given data $\mathbf{d}$, we update these uncertainties using Bayes's rule

$$p(\mathbf{s}|\mathbf{d}) \propto p(\mathbf{s})\, p(\mathbf{d}|\mathbf{s}) = p(\mathbf{s}) \int p(\mathbf{d}|\boldsymbol{\theta}_s, \mathbf{s})\, p(\boldsymbol{\theta}_s|\mathbf{s}) d\boldsymbol{\theta}_s \quad (6)$$

where $p(\mathbf{d}|\mathbf{s})$ is the marginal likelihood of the data given the model structure. Given the posterior uncertainties, we can either 'construct' a single DAG model by—say—selecting the most likely structure, or average over some or all of the model structures.

Under the assumptions described above—(a) mutual independence of the parameters in $\boldsymbol{\theta}_s$, (b) complete data, and (c) local distributions from the exponential family—the marginal likelihood can be computed efficiently and in closed form (e.g., Heckerman and Geiger 1995). Furthermore, simple heuristic search methods, such as greedy hill climbing, can be used to find a structure whose posterior is relatively large. In applications where computational efficiency is important such as data mining, where both the number of domain variables and the number of data samples is large, these techniques are used extensively (Heckerman 1996).

There are several non-Bayesian methods for learning structure from data. One set of techniques mimics Bayesian model selection, but incorporates non-Bayesian criteria for selection such as Akaike's information criterion (AIC). Another, developed independently by Pearl (2000) and Spirtes et al. (2001) uses local non-Bayesian tests for conditional independence together with search to identify model structures compatible with the data.

5. *Pointers to the Literature*

Perhaps the first person to use DAG models was Wright (1921),who employed what are now called structural equation models for the analysis of crop failure. Good (1961) also developed the representation. In both cases, researchers attributed causal semantics to DAG models. In fact, this model class remains quite popular for encoding and reasoning about causal interactions (Glymour and Cooper 1999, Pearl 2000, Spirtes et al. 2001; see *Latent Structure and Casual Variables*).

In addition to directed models, researchers have developed and used graphical models containing undirected edges, bidirectional edges, and mixtures of directed and undirected edges (e.g., Wermuth 1976, Whittaker 1990, Lauritzen 1996, Jordan 1998). These representations are discussed in the article *Graphical Models: Overview*.

Finally, there are numerous software packages available for the knowledge-based and data-based construction of DAG models. A summary is provided at http://http.cs.berkeley.edu/murphyk/Bayes/bnsoft.html.

Bayesian Statistics

Bayesian statistics refers to an approach to statistical inference characterized by two key ideas: (a) all unknown quantities, including parameters, are treated as random variables with probability distributions used to describe the state of knowledge about the values of these unknowns, and (b) statistical inferences about the unknown quantities based on observed data are derived using Bayes' theorem (described below). The Bayesian approach shares many features with the traditional frequentist approach to inference (e.g., the use of parametric models, that is to say, models dependent on unknown parameters, for describing data) but differs in its reliance on probability distributions for unknowns (including the parameters). The traditional approach to inference relies on the repeated sampling distribution of the data for a fixed but unknown parameter value, essentially asking what would happen if many new samples were drawn; the Bayesian approach treats the parameter as a random variable and assigns it a probability distribution. Qualitatively, the Bayesian approach to inference begins with a probability distribution describing the state of knowledge about unknown quantities (usually parameters) before collecting data, and then uses observed data to update this distribution. In this article the basic elements of a Bayesian analysis are reviewed: model specification, calculation of the posterior distribution, model checking, and sensitivity analysis. Additional sections address the choice of prior distribution, and the application of Bayesian methods. Additional details about most of the topics in this article can be found in the books by O'Hagan (1994), Gelman (1995), Carlin and Louis (2000), and Gilks et al. (1998).

The earliest developments related to the application of probability to questions of inference date to the contributions of Bayes and Laplace in the second half of the eighteenth century (Stigler 1986). Prior to that point researchers focused on the traditional pre-data probability calculations, i.e., given certain assumptions about the random process, what is the probability assigned to various possible outcomes for a variable in question? Bayes and Laplace receive independent credit for 'inverting' the probability statement to make probability statements about parameter values, given observed data values. There was little activity after that time, though some individuals, notably the physicist Jeffreys (1961), continued to develop the field of inductive inference. Modern Bayesian inference developed in the period around and after World War II (e.g., see *Statistics: The Field*). The name Bayesian inference replaces 'inverse probability' only at this later time. Some key contributions: Savage (1954) is an influential book using decision theory to justify Bayesian methods; de Finetti (1974) contributed crucial work concerning the role of exchangeability (which plays a role analogous to that of independent identically distributed observations in the traditional frequentist approach to inference); Raiffa and Schlaifer (1961) developed the use of conjugate distributions in detail; Lindley (1971, 1990) and Box and Tiao (1973) contributed greatly to the popularization of the approach. Most recently, the last decade of the twentieth century saw the discovery (or rediscovery) of computational algorithms that make it possible to apply the Bayesian approach to a wide array of scientific fields.

1. Model Specification

The basic ideas needed to carry out a Bayesian analysis are most easily described with a simple and general notation. In this article y denotes all of the data

collected and θ denotes all of the associated unknown quantities. The unknown quantities are assumed to be parameters in a probability model. There are, of course, limits to what can be done using this simple notation. For example, there may be covariates x in the data set, variables that help explain y but are not modeled as random variables. Similarly the unknowns, θ, may include missing data, or latent variables in addition to model parameters. It is straightforward to extend the basic notation to accommodate such situations.

The specification of a Bayesian model for data y requires two probability distributions, a probability distribution for the data given (or conditional on) the parameters θ, and a probability distribution for the parameters. The distribution of the data conditional on the parameters is denoted $p(y \mid \theta)$, and identified as the data distribution, the data model, the sampling distribution, or the likelihood function. The latter two names serve as a reminder that this portion of the model is also used in the traditional approach to statistics. The distribution for the parameters θ, denoted $p(\theta)$, is known as the prior distribution. It can be thought of as describing the relative frequencies for different values of the model parameters before considering any of the data values. For the initial part of this article, it is assumed that a prior distribution has been specified. Details related to the choice of prior distribution are considered in Sect. 4.

In practice, the data distribution can have several components describing a number of variables of interest. Moreover, the prior distribution for θ is often specified hierarchically with the distribution of parameters θ depending on still other parameters. The simple description provided here is convenient for demonstrating the Bayesian approach. Sect. 5 briefly describes applications of Bayesian methods in more realistic models.

Example. The following very simple example will be carried through the article. Suppose that a study is carried out to determine the mean intelligence score (using a standardized scale) for a population of interest, perhaps siblings of children with a psychological disorder. A random sample of n such children is obtained. Let $y_1, \ldots, y_n$ denote the test scores for the n children. Assume that test scores in this population can be modeled as coming from a normal distribution with unknown mean μ. For convenience it is assumed that the standard deviation σ is known. (This assumption is generally avoided in practice but is helpful here.) Thus the data model is the traditional model of independent identically distributed random variables, given the unknown mean μ. Under the Bayesian paradigm the unknown mean μ is also a random variable. To complete the specification of the model, a probability distribution, the prior distribution, for the unknown parameter μ must be specified. Suppose the μ is assumed to follow a normal distribution with mean μ_0 and variance τ^2 where μ_0 and τ^2 are specified constants. This means that, *a priori*, the value of μ is expected to be near μ_0, i.e., the probability under the prior distribution is 0.95 that μ is between $\mu_0 - 2\tau$, and $\mu_0 + 2\tau$. This prior distribution is merely one possible choice; others are considered in Sect. 4.

2. *Calculation of the Posterior Distribution*

The information about θ contained in the prior distribution, and the information about θ contained in the data y, are combined in forming the posterior distribution $p(\theta \mid y)$. This distribution, the conditional distribution of the unknown quantities given the observed data, is obtained directly using the laws of probability, namely Bayes' theorem,

$$p(\theta \mid y) = \frac{p(y \mid \theta)p(\theta)}{p(y)} = \frac{p(y \mid \theta)p(\theta)}{\int p(y \mid \theta)p(\theta)\,\mathrm{d}\theta} \qquad (1)$$

The posterior distribution is fundamental to Bayesian inference for θ. The Bayesian approach makes probability statements concerning the unknown quantities, after fixing the things that have been observed at their known values. Note that Bayesian methods differ from traditional methods which are justified by repeated sampling considerations—only the sample at hand is considered relevant in the Bayesian approach.

The posterior distribution describes the state of knowledge about θ after observing the data. Graphical displays or numerical summaries of the posterior distribution provide the basis for inferential statements about the parameters. A point estimate is a one-number summary of the posterior distribution, e.g., the posterior mean or the posterior median. To derive a single optimal point estimate it is necessary first to specify a loss function that gives the cost of estimation errors. The optimal point estimate is the value that minimizes the expected loss (computed from the posterior distribution); see *Decision Theory: Bayesian*. The posterior distribution allows us to identify intervals that contain a given parameter with any specified probability; such intervals are analogous to the standard confidence intervals. One difference is that the posterior intervals have a natural probabilistic interpretation; they contain the unknown quantity with the specified probability. Formally, probability statements are not possible for a single instance of the classical confidence intervals, where the stated confidence level describes behavior over many repeated samples. Tests of hypotheses are possible using the Bayes factor, a ratio that measures the degree to which two competing models explain the observed data.

In relatively simple problems, it is possible to analytically determine the form of the posterior distribution and subsequently obtain statistical inferences. In more sophisticated models it can be quite difficult to determine the form of the posterior dis-

tribution. For those cases it is sometimes possible to approximate the posterior distribution, e.g., by a normal distribution. One important approximation approach involves studying the posterior distribution by generating a sample of simulations from the distribution (see *Monte Carlo Methods and Bayesian Computation: Overview*), thereby obtaining an empirical approximation to the posterior distribution. Then inferences are drawn empirically using the simulations.

Example. For normally distributed measurements with mean μ, and with a normal prior distribution for the parameter μ, the posterior distribution is also normal with

$$\text{mean} = \left(\frac{n/\sigma^2}{(n/\sigma^2)+(1/\tau^2)} \right) \bar{y} + \left(\frac{1/\tau^2}{(n/\sigma^2)+(1/\tau^2)} \right) \mu_0 \quad (2)$$

and

$$\text{variance} = \frac{1}{(n/\sigma^2)+(1/\tau^2)} \quad (3)$$

where $\bar{y}$ is the mean of the sample of observations. It is possible to interpret the posterior mean as a weighted average of the sample mean, $\bar{y}$, and the prior mean, μ_0, with the weight attached to each piece related to the precision (reciprocal of the variance) of that source of information. If the prior information is extremely precise (τ^2 small), then the posterior mean for the unknown μ will be heavily influenced by the prior mean (μ_0). If on the other hand the prior information is vague (τ^2 large), then the posterior mean will be primarily determined by the data. The precision of the posterior distribution is just the sum of the precisions of the prior distribution and the data distribution. It is also noteworthy that for a given choice of prior distribution, as the sample size becomes large, the posterior distribution does not depend on the prior distribution. In fact, for large samples, the Bayesian posterior distribution resembles the sampling theory distributional result that leads to classical statistical procedures.

The simple example demonstrates the use of a conjugate family of prior distributions, where the prior distribution (a normal distribution) and the likelihood function (based on a normal distribution) combine to yield a posterior distribution in the same family as the prior distribution (a normal distribution). The interpretation of the posterior distribution is especially convenient for conjugate families; the posterior distribution can be seen to combine the prior information and the information provided by the data. In fact this result holds more broadly than with conjugate families; a Bayesian analysis represents a compromise between the prior information available and the information derived from the data. The more data that is available, the less influence the prior distribution has on the form of the posterior distribution. One complication is that, in sophisticated models, the amount of data for different parameters will vary and consequently so does the importance of different components of the prior distribution.

3. *Model Checking and Sensitivity Analysis*

It is essential in all model-based statistical inference to examine the validity of the assumptions made in the model. For the Bayesian approach to inference the assumptions include the form of the prior distribution, the form of the data model, and any other assumptions embodied in the data model (independence, constant variance, etc.). Model checking can take the form of a sensitivity analysis where the prior distribution (or other aspect of the model) is varied and the effect on the posterior inferences assessed. Model checking can also be done by embedding the original model into a bigger family of models, e.g., a normal model might be replaced by the Student-t family of models that includes the normal distribution as a limiting case. Finally, model checking can resemble model checking in traditional statistics with residuals (now functions of the parameters) and diagnostic measures used to assess the fit of the model.

4. *The Prior Distribution*

For many users of statistical methods the largest question about the use of Bayesian methods concerns the choice of prior distribution. One key result, mentioned earlier, is that in large samples the prior distribution becomes irrelevant. For the normal distribution example, as the sample size become large, the properties of the posterior distribution do not depend on the parameters of the normal prior distribution. In the limit, the posterior distribution would behave as if there were no prior information; $p(\mu|y)$ is the normal distribution with mean $\bar{y}$ and variance σ^2/n. This limiting result is similar to the usual sampling distribution result, except of course that in the Bayesian approach μ is random and $\bar{y}$ is fixed. A consequence of this result is that although the conclusions obtained from a Bayesian analysis in the normal example may differ from those obtained using traditional methods, the two approaches will tend to agree asymptotically. This result holds more generally as well. Of course, data analysts can not always rely on large sample results, so a review of methods for selecting prior distributions is provided next.

The subjective approach to choosing a prior distribution is to take the prior distribution to be an

honest assessment of prior beliefs about the values of the model parameters. Although people are sometimes hesitant to supply such subjective prior distributions it is often the case that some prior information is available. In the example, psychological or biological theory may suggest plausible values for the mean test score in the subpopulation of interest. If it is possible to specify a prior distribution, then the Bayesian paradigm provides the way to update that prior distribution given observed data. In multiparameter problems one can argue that prior information is not as rare as one might initially think. For example, prior information may suggest that a set of parameters can be treated as a sample from a common population (as in a random-effects or hierarchical model). Tools for helping researchers develop prior distributions is one area of Bayesian research (e.g., see *Elicitation of Probabilities and Probability Distributions*).

Often the choice of a prior distribution is made primarily because of considerations of computational convenience. Conjugate families, families of prior distributions that combine with a given data distribution to produce posterior distributions in the same family as the prior distribution, are useful in this regard. As described earlier, conjugate prior distributions are convenient to use because they make calculations easy, and because they can be easily interpreted. Conjugate prior distributions are capable of supporting a variety of prior opinions (e.g., by making different choices of the parameters within the conjugate family) but of course not all. Choosing a specific prior distribution from the conjugate family remains a bit of a stumbling block for some. Empirical Bayes methods use the data to help choose the parameters of the prior distribution; this approach may be applied in more complex models (e.g., analyses that incorporate random effects).

The desire to avoid using subjective prior information and/or arbitrary distributional forms has motivated some to use vague or 'noninformative' prior distributions. Formally, a vague prior distribution is one that assigns roughly equal probability to a wide range of possible values. In the normal example, a prior distribution with large variance would be considered a vague prior distribution. A vague prior distribution will not have a strong influence on the ultimate form of the posterior distribution. In this way, the use of vague or noninformative prior distributions represents the pursuit of a form of objective Bayesian inference. One difficulty is that, in the limit, vague prior distributions may become so vague as to no longer be proper distributions (they may not integrate to one!). It is 'legal' to use such improper prior distributions as long as it is verified that the resulting posterior distribution is a proper distribution. Improper prior distributions are popular because sometimes they appear to be noninformative in the sense that they rely only on the likelihood. It is probably best to think of improper prior distributions as approximations to real prior distributions. If the improper prior distribution leads to a proper posterior distribution and sufficiently accurate conclusions, then one might use the results from this analysis without needing to work any harder to select a more appropriate prior distribution.

A final word is in order here. It is disturbing to some that individuals with different prior distributions will obtain different analyses. Of course this occurs every day in the real world when individuals with different information make different decisions. There, as in the normal example, as everyone obtains the same large pool of information, a consensus is reached independent of the prior distribution.

5. *Bayesian Methods in Applications*

The relatively simple example discussed here, normally-distributed test scores with a normal prior distribution for the population mean, is useful for demonstrating the Bayesian approach; however, it is not a particularly compelling application. Standard methods for such data are well known and widely applied. More to the point, the posterior distribution of μ in the example resembles the frequentist sampling distribution that underlies standard methods when the sample size is large or the prior distribution is vague. There can be large differences between the two approaches when an informative prior distribution is used, but most investigators appear to avoid reliance on informative prior distributions. How well do Bayesian methods do in more substantial applications? Fortunately, there is a large body of literature on such applications in diverse fields such as medicine, archeology, and political science.

Two social science applications are described in some detail next. Raftery (1995) introduced the use of Bayesian hypothesis testing via Bayes factors to sociologists in the 1980s; he developed the simple BIC (Bayesian information criterion) approximation which made Bayesian model selection as straightforward as other methods. This work was motivated by a number of concerns about traditional significance tests and the P-values used to summarize them. Specifically a number of researchers had found that P-values were not satisfactory in large sample sizes when all models tend to be rejected, nor could they accommodate situations in which a large number of models were under consideration. Bayes factors or BIC addressed these issues by relying on Bayesian principles and calculating the quantity that is most relevant the marginal probability of the data given the model.

A recent application in psychology by Rubin and Wu (1997) models responses in schizophrenic eye-tracking experiments using a sophisticated mixture model. Their model reflects psychological theory, in allowing some schizophrenic subjects to be susceptible

to disruptions that delay responses while others are not. The indicators to which subjects are susceptible are not observed, but are incorporated in the model. In the same manner, unobserved indicators identify which specific trials are affected by disruptions for those individuals that are susceptible. The model also incorporates between-subject factors like gender and within-subject factors such as the type of eye-tracking task. There appear to be at least three benefits of the Bayesian approach in this application: model specification is reasonably straightforward using conditional distributions and incorporating latent variables; it is possible to obtain inferences without relying on large sample approximations; and methods for model checking are easily developed for a model which does not satisfy the regularity conditions required for traditional tests.

The specific details of every application differ, but a few points occur often enough in serious Bayesian applications to be noteworthy. The models underlying such applications often incorporate both fixed and random effects (see *Hierarchical Models: Random and Fixed Effects*), with the random effects given a prior distribution that depends on additional parameters. In addition realistic applications often need to accommodate cases where some data-providing units are missing observations for some variables (see *Statistical Data, Missing*) or for all variables (see *Factor Analysis and Latent Structure: Overview*). In those cases the missing values are treated as unknown quantities just like the parameters of the underlying model. Finally, these applications are also characterized by the need for advanced computational methods for computing or approximating the posterior distribution (see *Monte Carlo Methods and Bayesian Computation: Overview*). Specific examples of substantive applications can be found in Gelman (1995), Carlin and Louis (2000), Gilks et al. (1998), and the published proceedings of the *Case Studies in Bayesian Statistics* workshops (e.g., Bernado et al. 1998) and of the Valencia International Meetings (published under the title *Bayesian Statistics*) (e.g., Bernado et al. 1999).

The arguments favoring the use of the Bayesian approach for data analysis follow from its use or probability distributions to describe uncertainty about unknown quantities. There is a natural probability-based interpretation for Bayesian results (e.g., interval estimates) and great flexibility in the types of inferences that can be obtained (e.g., one can easily obtain a posterior distribution on the ranks of a set of parameters). The reliance on formal probability distributions also means that it is possible to draw valid Bayesian inferences in finite samples without relying on large sample results.

Bayesian Theory: History of Applications

Bayesian theory concerns the generation of ideas about inductive or probabilistic reasoning that stem from studies of a certain well-defined probabilistic process that were performed over two centuries ago by the Reverend Thomas Bayes, FRS (1702–61). Bayes was a Unitarian minister who lived in Tunbridge Wells, England and whose mathematical accomplishments were sufficient to justify his election as Fellow of the Royal Society in 1742. The conclusions Bayes reached in his studies have led to what is now called Bayes' rule, a canon for the inductive reasoning process of revising our probabilistic beliefs about hypotheses in light of relevant evidence. In spite of lingering controversy about how some of the probabilistic ingredients in this rule are ever to be determined, Bayes' rule, and extensions of it, are now repeatedly applied in a variety of situations, many of which involve choices made in the face of uncertainty. Indeed, some persons believe that Bayes' rule is the canon or prescription for how we should revise our probabilistic beliefs about hypotheses in light of relevant evidence.

1. Foundations

Thanks to the works of George Boole (1815–64) and John Venn (1834–1923), we now have a very rich and flexible language for formulating and solving probabilistic problems that Bayes himself never employed. Consequently, Bayes' rule is commonly described in ways that do not appear in Bayes' original work. The probabilistic process Bayes studied involves what we now call a Bernoulli trial sequence in which n independent binary trials are performed, each of which results in either a success (S) or failure (F). Further, we suppose there is some probability of success $P(\mathrm{S}) = p$ that, under the independence assumption, remains the same from trial to trial. What we only know for sure is that p can take on any value in $0 < p < 1.0$. Under ordinary conceptions of probability, we suppose that $P(\mathrm{F}) = 1 - p$. Suppose we do not know the exact value of p and can only estimate its value by performing n Bernoulli trials. In these n trials, suppose we observe r successes. The problem Bayes addressed was how do we determine the probability that p lies between any two values, say $t > 0$ and $u < 1.0$, given that we have observed r successes in n Bernoulli trials? In modern terms we express Bayes' problem as the conditional probability

$$P(t \leqslant p \leqslant u \,|\, r \text{ successes in } n \text{ trials})$$

In this expression our hypothesis H is that

$$t \leqslant p \leqslant u$$

our evidence E consists of the observation of r successes in n trials. In modern terms, we require the conditional probability $P(H|E)$, called the posterior probability of H in light of evidence E.

Bayes' solution to the problem of finding $P(t \leqslant p \leqslant u \,|\, r \text{ successes in } n \text{ trials}) = P(H|E)$ troubled him and so he never tried to publish his findings; he died in 1762. But the executor of Bayes' will, Richard Price, discovered Bayes' unpublished paper, recognized its value, and communicated it to the Royal Society of London. Bayes' paper was subsequently published (Bayes 1763). Reprinted versions of Bayes' original paper can be found in Pearson and Kendall (1970) and in Barnard (1958). In his enthusiastic prefatory comments about Bayes' work, Richard Price observed that Bayes' studies represented the very first attempt to formalize the process of inductive reasoning (Bayes 1763, pp. 370–5).

One problem that troubled Bayes, and that has troubled so many persons since Bayes, is that, in order to determine the posterior probability that p lies between t and u, given r successes in n trials, we must also determine the probability that p lies between t and u, before we have obtained this evidence. In symbols, we must somehow determine $P(t \leqslant p \leqslant u) = P(H)$. Such probabilities are called prior probabilities. Under enumerative conceptions of probability, mentioned again later, $P(H)$ cannot be determined empirically; it can only be judged or estimated subjectively, something that many persons cannot accept. In Bayes' original problem, how are we to determine $P(H) = P(t \leqslant p \leqslant u)$ before we have made any empirical observations? In other words, in probabilistic reasoning about hypotheses, based on evidence, how do we get this inferential process started before we have obtained any specific evidence? Issues raised by this nagging question also influenced the directions taken in research on decisions made in the face of uncertainty.

In addition to probabilistic assessments, decisions also require assessments of the worth or value of consequences of decisions together with rules or algorithms for combining these two kinds of assessments. Credit for establishing the first formal rules for choice under uncertainty is usually assigned to Daniel Bernoulli (1700–82). Bernoulli and other mathematicians at the time were interested in determining rules for deciding which wagers or gambles a person ought to accept or reject (e.g., see Todhunter 1965, pp. 213–38). The rule Bernoulli advocated involves ordinary mathematical expectation for random variables:

$$E[X] = \sum_{i=1}^{t} x_i P(x_i)$$

where x_i are the possible values or random variable X and $P(x_i)$ is the probability of observing value x_i. These probabilities must sum to 1.0 across all the t possible values that X can take. So, in a simple gamble G, involving a win (W) or a loss (L), the expected dollar value of G can be stated as $E(\mathrm{G}) = \$_{\mathrm{W}} P(\mathrm{W}) + \$_{\mathrm{L}} P(\mathrm{L})$. According to this rule, it seems that we ought to accept gambles for which $E(\mathrm{G}) > 0$, reject gambles for which $E(\mathrm{G}) < 0$, and be indifferent regarding gambles for which $E(\mathrm{G}) = 0$, the latter being 'fair bets.' But Bernoulli recognized that different persons would value a certain amount of money in different ways. In particular, for you, the prospect of winning (or losing) 10 dollars depends upon how many dollars you already have. Bernoulli proposed that we consider what he termed the 'moral worth' of monetary consequences of gambles or wagers. He conjectured that the moral worth of a certain number of dollars varies as the logarithm of this number of dollars: i.e. that $U(\$) = k \operatorname{Log} \$$. Today, we would use the terms 'utility' or 'value' in preference to Bernoulli's term 'moral worth.' So, for the simple gamble just described, what we should determine is the expected utility of this gamble $E(U(\mathrm{G})) = U(\$_{\mathrm{W}})P(\mathrm{W}) + U(\$_{\mathrm{L}})P(\mathrm{L})$.

Any single stage decision (D) made in the face of uncertainty can be represented as a random variable X having, say, t possible outcomes or consequences (C_i)

that occur when hypothesis H_i is true. The expected utility of D can then be represented by the following expression, which will also illustrate how problems with Bayes' rule affected the acceptability of Bernoulli's canon for deciding upon which choices to accept or reject:

$$E[U(D)] = \sum_{i-1}^{t} U(C_i)P(H_i \mid E)$$

where H_i is the hypothesized event that produces consequence C_i, when action D is taken, and E represents the body of evidence bearing on the likeliness of the hypotheses being considered. In this expression it is vital to note that the probabilities $P(H_i|E)$ must sum to 1.0 across the t hypotheses being considered. The rule for choice implied by the above expression is simple: Choose that action or decision for which $E(U(\mathrm{D}))$ is greatest. In the situation just posed, posterior probabilities according to Bayes' rule are given as follows. Suppose we wish to determine $P(H_j|E)$, where H_j is any one of the t mutually exclusive and exhaustive hypotheses under consideration:

$$P(H_j|E) = \frac{P(H_j)P(E|H_j)}{\sum_{i-1}^{t} P(H_i)P(E|H_i)}$$

where E is some item or body of relevant evidence in the inference at hand. The denominator of the expression above is called a *normalizing constant* and it ensures that the sum of the posterior probabilities across the t hypotheses will equal 1.0. We must also have a distribution of prior probabilities $P(H_i)$ that also sums to 1.0 across the t hypotheses. The other terms in Bayes' rule, $P(E|H_i)$, are called likelihoods and, as discussed later, they grade the inferential force, weight, or strength of evidence E. These likelihoods are not required to sum to 1.0 across the t hypotheses. These facts about Bayes' rule are very important in showing why Bayes' rule for inductive reasoning along with Bernoulli's expected utility canon for choices under uncertainty were dismissed for nearly 200 years. Bernoulli's canon requires probabilities that normalize and likelihoods alone do not satisfy this requirement.

2. *Applications in Statistics*

In 1933, Kolmogorov provided the first axiomatic treatment of probability (Kolmogorov 1956). We all learn about his three basic axioms of probability:

For any event A, $P(\mathrm{A}) \geqslant 0$

For an event S that is sure to happen, $P(\mathrm{S}) = 1.0$

For any two mutually exclusive events A and B, $P(\mathrm{A \text{ or } B}) = P(\mathrm{A}) + P(\mathrm{B})$.

In this initial and in his later discussions of this formal system (Kolmogorov 1969), it is quite apparent that he considered only enumerative conceptions of probability, i.e., those in which probabilities are determined by counting.

There are two cases of enumerative probabilities, the first of which concerns aleatory probabilities or chances that arise in well-defined games of chance. In such situations we have a finite collection (S) of outcomes, each of which is assumed to be equally likely. In such instances, for any event A, defined as a subset of outcomes in S, $P(\mathrm{A}) = n(\mathrm{A})/\ n(\mathrm{S})$, where $n(\mathrm{A})$ is the number of outcomes favoring A and $n(\mathrm{S})$ is the total number of outcomes. The other case involves the relative frequencies encountered in statistical inferences. The relative frequency of event A, $f(\mathrm{A})$, is defined to be $f(\mathrm{A}) = n(\mathrm{A})/N$, where $n(\mathrm{A})$ is the number of observed cases of A and N is the number of observations taken. As recognized, $f(\mathrm{A})$ is just an estimate of actual $P(\mathrm{A})$ since N may be small relative to the total number of observations that might be taken. Observe that in either case we have restricted attention to processes that are replicable or repeatable. Under strict enumerative conceptions of probability, it is difficult to see how the prior probabilities required in Bayes' rule can ever be determined. But Bayes' rule follows as a direct consequence of the three axioms just mentioned along with Kolmogorov's own definition of a conditional probability: $P(\mathrm{A}|\mathrm{B}) = P(\mathrm{A\&B})/P(\mathrm{B})$, where $P(\mathrm{B}) > 0$.

Generations of statisticians adhering to an enumerative and relative frequency view of probability have acknowledged the formal adequacy of Bayes' rule at the same time they have argued that this rule can never be applied on grounds that subjective judgments of probabilities have no place in fields such as science. Examples of this view are to be found in the works of Fisher (1959, pp. 8–16, 1960, pp. 6–7). One result has been that frequentistic statisticians have been forced, in statistical inference, to rely on the remaining terms in Bayes' rule, those concerning the likelihoods such as $P(E|H_i)$ mentioned above. Examples are to be found in any textbook that discusses statistical hypothesis testing from a frequentistic view. The trouble here is that these likelihoods are not required to sum to 1.0 across the t hypotheses being considered. Thus, by themselves they are not sufficient in any calculation of expected utilities according to Bernoulli's canon for choice.

The works of several individuals in quite different fields resulted in a renewed interest in Bayes' rule and in Bernoulli's expected utility canon for choice. In works by Ramsey (1990), de Finetti (1972), Savage (1972), and others, subjective, personal, or epistemic interpretations of probability were defended as being both reasonable and necessary in probabilistic reasoning. On this view of probability, resistance to the use of Bayes' rule in statistical and other contexts vanishes. In addition, the work of von Neumann and Morgen-

stern (1947) was instrumental in restoring interest in Bernoulli's expected utility canon for choice. They showed how, from a collection of what they regarded as axioms for asserting preferences in assessing the worth of consequences, Bernoulli's expected utility canon follows. One result of the works just mentioned is that there has emerged a very wide array of statistical inferential methods involving Bayes' rule that can be applied in nearly every inferential problem in statistics. Examples are to be found in the works of Winkler (1972), Box and Tao (1973), O'Hagan (1988), and Howson and Urbach (1989).

3. *Other Applications*

All statistical reasoning is probabilistic, but not all probabilistic reasoning is statistical. In many contexts people routinely make probabilistic judgments about events that are unique, singular, or one of a kind, and for which no relevant statistics exist. In short, there is a necessity for nonenumerative conceptions of probability. For example, we cannot play the world over again 1000 times to tabulate the number of occasions on which defendant committed the crime or a witness reported an event that actually occurred. Along with increased interest in applying Bayesian theory in statistics, applications of this theory began to be made in many contexts in which relevant statistics are difficult if not impossible to obtain. One of the first such applications was Ward Edwards's proposals for a PIP (probabilistic information processing) system (Edwards 1962). In such a system people make judgments of prior probabilities and likelihoods and computers calculate required posterior probabilities from these judgments. In its original forms, Edwards' PIP idea did not survive. One reason was the gradual recognition that, in other than contrived problem situations, all inferences based on evidence involve complex arguments or chains of reasoning linking the evidence to hypotheses of interest. Such inferences are said to be cascaded, catenated, or hierarchical. By such chains of reasoning we defend the three major credentials of evidence: its relevance, credibility, and inferential force.

At this point, great assistance in thinking about complex probabilistic reasoning was provided by the rich legacy of evidential scholarship and experience in the field of law. A US evidence scholar named John H. Wigmore was the first to study systematically the task of constructing defensible and persuasive arguments based on masses of evidence (Wigmore 1913, 1937). His studies provide the very first examples of what today are termed inference networks. Wigmore's inference networks are extremely useful in the study and analysis of the many recurrent and substance-blind forms and combinations of evidence that exist. The likelihood terms in Bayes' rule provide very useful and informative metrics for grading the inferential force of evidence. A very wide array of evidential and inferential subtleties lie just below the surface of even the simplest of probabilistic inferences. A recent work gives an account of these subtleties and how they can be captured in Bayesian terms (Schum 1994). The major vehicle for capturing evidential and inferential subtleties or complexities by Bayes' rule involves the concept of conditional nonindependence. At its simplest level this concept involves the idea that two or more things considered jointly can mean something quite different than they might do if considered separately or independently. Another recent work illustrated how evidential subtleties are captured in a Wigmorean and Bayesian analysis of the mass of trial and post-trial evidence in a celebrated US law case (Kadane and Schum 1996).

One of the most significant recent advances in Bayesian theory concerns probabilistic analyses of complex inference networks. In the work of Pearl (1988), Lauritzen and Spiegelhalter (1988), and others, various attempts have been made to develop computationally efficient means for propagating and aggregating large numbers of probabilities that are required in the analysis of complex inference networks. A number of very useful software systems, based on the formal developments just mentioned, are now available for such analyses and they are finding ready application in a variety of contexts including science, medicine, intelligence analysis, and business.

During the past three decades alternative formal systems of probability have been proposed including the Shafer–Dempster system of non-additive belief functions (e.g., Shafer 1976) and the Baconian system of probabilities (e.g., Cohen 1977). Probabilistic reasoning is a remarkably rich intellectual task and it is perhaps too much to expect that any one formal system of probability can capture all of this richness. One matter that divides opinion across the alternative formal systems concerns what is meant by the weight of evidence. In the theory of belief functions the weight of evidence is related to the support it provides hypotheses being considered. In the Baconian system the weight of evidence concerns how completely existing evidence covers recognized relevant questions that could be asked and how many of these questions remain unanswered by existing evidence.

Since the very beginnings of interest in the mathematical calculation of probabilities in the early 1600s, there have been skeptics who have argued that mathematical systems can never capture the true complexities of probabilistic reasoning in the variety of contexts in which it occurs. Though the Bayesian theory of probabilistic reasoning is not complete in answering all questions that arise during probabilistic reasoning, it is nevertheless capable of capturing a wide array of elements of complexity as they have been recognized recently in the emerging science of complexity (e.g., Cowan et al. 1994, Coveny and Highfield 1995). All complex processes are dynamic, hierarchi-

cal, and recursive, in which complex patterns of interaction occur among the elements of these processes. Phenomena emerging from such processes are the result of distinctly nonlinear combinations of these elements and cannot be inferred or predicted just from knowledge of the elements themselves. In linear models wholes are always equal to the sum of their parts and do not produce any surprises. As noted recently (Schum 1999, pp. 183–209), Bayes' rule incorporates these elements of complexity and, as a nonlinear model, it will produce many surprises. The results of Bayesian probability calculations made in complex inference networks do not always correspond to what intuition may suggest. In such cases we must either examine the adequacy of the argument structures to which Bayes' rule has been applied, or examine the adequacy of our intuitions. No complex mathematical system is guaranteed to produce results that always correspond to intuition.

D. A. Schum

Beauvoir, Simone de (1908–86)

Novelist, philosopher, essayist, and autobiographer, the author of one of the founding texts of feminism in the twentieth century, Simone de Beauvoir can be considered to be one of the major intellectual figures of her generation. Born in Paris on January 9 1908 into a conservative middle-class milieu, she received the narrow primary and secondary education deemed appropriate for a marriageable girl of her class. However, after a sudden deterioration in her family's financial circumstances, she was permitted to study philosophy at the Sorbonne, and in 1929 she became the youngest person ever to succeed in the prestigious *agrégation de philosophie* examination, a success which enabled her to earn her own living from a series of teaching posts which she held first in Marseilles, then

in Rouen and, from 1936, in Paris. Occupying a series of cheap hotel rooms, she led a remarkably independent life, free from domestic obligations, and, despatching her teaching in the minimum time necessary, she spent her days writing in cafes and participating in a complex web of relationships, at the center of which was the couple she formed with Jean-Paul Sartre. The two never set up home together, setting their face against the idea of marriage and children, but referred to their close circle of former pupils and ex-lovers as 'the family.' The outbreak of the Second World War disrupted both this network of relationships and Beauvoir's assumption that her freedom was virtually total. As she writes in her autobiography she had to 'face the weight of reality.' Continuing her life in occupied Paris without Sartre she completed the manuscript of her first novel, *She Came to Stay* (1943), an exploration of the Hegelian dictum 'Each consciousness pursues the death of the other,' and went on to publish in quick succession *The Blood of Others* (1945), exploring some of the ethical and political dilemmas posed by the Resistance, and *All Men Are Mortal* (1946) which deals with the problem of the historical dimension of human existence. Sartre, meanwhile, had completed his philosophical essay *Being and Nothingness*, also published in 1943; in postliberation Paris the couple became famous figures as existentialism, as Sartre's philosophy came to be known, dominated the Parisian intellectual scene. In 1946 Beauvoir turned her attention to the situation of women, and in 1949 published the two volumes of radical and multidisciplinary thinking which constitute *The Second Sex*. Its frank treatment of sexuality and its critique of the maternal role expected of women made her a figure of some notoriety, and though she went on to write bestselling novels, and won the Goncourt prize for *The Mandarins* in 1954, her name was forever to be associated with her seminal work of feminist theory. From 1958 onwards she also began to publish volumes of autobiography, constructing an account of life as a twentieth-century intellectual woman followed by millions of readers worldwide. The 1950s also opened up a phase of active political engagement as she campaigned against French atrocities in Algeria during the Algerian war, supported the Maoist groups in the events of 1968, and, in the 1970s, joined with the newly formed MLF (Women's liberation movement) in campaigns on abortion, contraception, sexism, and violence against women. After Sartre's death in 1980, she published his letters to her, and her own letters both to Sartre and to her American lover Nelson Algren, were published in 1990 and 1997, respectively, after her own death in 1986. It is thus as philosopher, feminist, activist, novelist, memorialist, and correspondent that Beauvoir has made a deep mark on her era.

Nonetheless, it is principally as the author of *The Second Sex* that Beauvoir has come to be considered as one of the most significant feminist voices of the twentieth century. Beauvoir's study of women began life as an autobiographical question (what had it meant to her personally to be a woman), developed into an essay about the cultural myths which construct femininity and eventually became an ambitious multidisciplinary work, studying women's situation from a panoply of directions to demonstrate that 'one is not born, but rather becomes, a woman.' This crucial distinction between sex and gender was to open up the entire field of women's and gender studies. Beauvoir stresses in the introduction that her approach is ontological and existentialist: if there is no fixed human nature then neither can there be a fixed nature for women. This intellectual origin does indeed provide a strong impetus to the work, driven by the assumption that, like all human beings, women can and should shape their own destinies. However, the existentialist approach stresses individual responsibility rather than the way in which patriarchy functions as an institution and, taken to the extreme, it could suggest that women's oppression is a form of individual bad faith.

One of the strengths of *The Second Sex* is that although Beauvoir does not admit explicitly the extent to which social and economic analyses complement her ontology, she does in fact offer a balance between the weight of social, cultural, and economic oppression on the one hand, and the free construction of the subject on the other. Her argument that women historically have been positioned as the object or 'other' to men as subject is supported by a socially constructionist view of patriarchy.

The book begins with a series of attacks on the notion that there is a fixed destiny for women. In part 1 she investigates what biology, psychoanalysis, and Marxism appear to prescribe about female destiny to conclude that women are not defined or inevitably doomed to oppression by the laws of nature, by their psychoanalytic situation, or by economic history. The section on psychoanalysis attacks Freud for his definition of female sexuality in terms of penis envy, an attack that was responsible for a long feminist mistrust of Freud. The section on biology as destiny has proved particularly controversial since, despite insisting that female physiology offers no justification for the hierarchy of the sexes, Beauvoir paints a dispiriting picture of the daily experience of the body for women. In her account the female body is organized to such a high degree to ensure the reproduction of the species that it constitutes a burden against which women must continually struggle in their bid for freedom. Part 2 is devoted to a wide-ranging survey of women's historical role from Ancient Greece and Rome up to the 1940s. It describes women as fundamentally handicapped by maternity from the earliest times, stresses women's role as a medium of exchange, and analyses how tools of patriarchy such as Christianity and the feudal system have corralled the vast majority of women into the margins of historical narratives.

Moving on to the myths of femininity, in part 3, Beauvoir dissects a rich set of constructs ranging from the Christian images of Mary and Eve to the pervasive myth of feminine mystery. The section ends on a discussion of five male writers, showing how literature has served as a vehicle for the creation and circulation of myths about women. This analysis later became the inspiration for the work of Kate Millett and the branch of feminist literary criticism that reads male-authored texts with a deconstructive eye.

Parts 4 and 5 of the essay turn to the social and sexual roles which women are called upon to play, tracing the way in which the girl gradually becomes socialized into her role as wife and mother, under the eye of her own mother, the unwitting accomplice of patriarchy. Up to the age of puberty Beauvoir nevertheless credits the young girl with a strong sense of her own autonomy; it is at the moment when the traits of female sexuality install themselves in her body that the girl sees the social trap closing, according to Beauvoir. A section considering female sexual response and case histories of women's first experiences of sexuality follows. Drawing on the Kinsey Report, and on other studies of sexuality, Beauvoir gives serious and detailed consideration to female sexual pleasure, including a discussion of the supposed distinction between the vaginal and clitoral orgasm. She also devotes a chapter to lesbianism in which she rejects the idea that lesbianism is an anatomical or physiological destiny. On the contrary, she presents it as positive choice for women that can lead to an authentic exercise in freedom just as much as heterosexuality. Unsurprisingly, she does not produce a theory of lesbian identity, since she consistently presents identity as following from choice and acts, not as preceding action and being.

Part 5 examines the two central roles which patriarchy calls upon women to play: those of the wife and the mother. Romantic love is in itself a dangerous condition for women, Beauvoir argues, because it tends to encourage their dependency on men and discourage them from pursuing their own goals. Marriage she describes as based on an obscene principle, because it makes a duty of what should be a freely given exchange. Her attack on the role of wife is closely linked to the role of women as maintainor of the home—the thankless round of domestic tasks that have by their nature to be repeated endlessly without achieving any final aim are described graphically by Beauvoir, and the illusory joys of the gleaming interior are analyzed with penetrating insights. Motherhood, another concomitant of marriage, is presented as even more problematic. Pregnancy acts as a positive incitement to women to sink passively into a fixed destiny; after the birth, the mother–child relationship is described as a battlefield yielding few positive results for either party. She concludes that the upbringing of children care is unsafe within maternal hands and should be organized within a collective framework. Beauvoir's analyses of the dangers and social pressures of the roles of wife and mother bring sharply into focus her dual insistence on, on the one hand, the weight of social conditioning to which women are exposed, and, simultaneously, individual women's responsibility to resist such pressures. Women are both victims and complicitous.

The final two parts of the book are entitled 'Justifications' and 'Towards liberation.' In part 6, 'Justifications,' Beauvoir considers some of the false routes which women have taken in a doomed attempt to flee from their responsibility by glorying in their imprisonment. One route is that of narcissism, in which the woman cultivates her body in an impossible attempt to be simultaneously subject and object, simultaneously both source of the gaze and object of it. A second false route is that of mysticism, the attempt to achieve sovereign being through an identification with God—also, for Beauvoir, an impossibility. The third route is that of the *amoureuse*, the woman who makes a cult of her love for a man whom she has appointed as her savior. She aspires to authenticity by attempting to live vicariously through him. Beauvoir demonstrates both the philosophical impossibility of this stance and the inevitable destruction that it brings about of the relationship on which the *amoureuse* depends, as she becomes increasingly tyrannical.

Part 7, entitled 'Towards Liberation,' offers a synthesis of women's situation and a portrait of 'The Independent Woman.' Beauvoir shows how women's blocked situation even creates what we think of as the female character. The reader is urged to accept that femininity is a social product—if we can accept this, she argues, then we can change society to change the possibilities open to women. She insists on the importance of economic independence for women, and pleads for men and women to work together towards a better future, but she has no confidence that anything of substance can be achieved without a radical restructuring of society. The independent woman is not in a position to achieve much without the socialist revolution that Beauvoir assumes, in 1949, would create a society in which everyone would be free. This rather unsatisfactory ending is indicative of the exploratory, theoretical rather than campaigning spirit in which Beauvoir wrote the book; it was not until over 20 years later, in the context of French second wave feminism, that Beauvoir declared the necessity of actively pursuing the women's struggle independently of any broader political movement.

On its publication in French in 1949 the book caused moral outrage; the Catholic novelist François Mauriac, led a newspaper campaign to have it banned as pornography, and it was in fact put on the Index. Its status as a daringly sexy book written by a woman seems to have partly obscured its political thrust, and the French postwar climate was particularly inimical to the language of women's rights. In America the

book was translated in a truncated form by the zoologist Parshley, and it was this version, published in 1953 and still the only English language version available today, which a generation of American and English women including Kate Millet, Betty Friedan, Germaine Greer, and Anne Oakley read during the 1950s and 1960s. Through them the work began to exert its influence, although they did not always acknowledge their debt. Betty Friedan, for example, whose book *The Feminine Mystique* (1963), is often considered to have been the launch pad for the American women's movement, offered her readers a watered down version of Beauvoir's analysis of the housewife and has only one mention of her in the index, which refers to the charge by an American critic that Beauvoir 'didn't know what life was all about' and 'besides she was talking about French women.' Where Beauvoir offers a radical critique, insisting that the institution of the family must be destroyed, that women must become economically independent, and that a radical restructuring of society will need to take place, Friedan advises women to think about their personal growth. However, it is atleast arguable that in translating some of Beauvoir's analyses into terms acceptable to a more conservative audience, Friedan did act as a channel of communication between two cultures in which political radicalism historically have played very different roles.

The key phrase 'one is not born, but rather becomes, a woman' is, as Haraway (1991) writes, at the root of 'all the modern feminist meanings of gender' and has been developed in many different directions. Butler (1986), for example, in a reading of the phrase, stresses Beauvoir's use of the verb 'becomes,' arguing that it allows for a process of gender acquisition that is a daily act, an interplay between individual choice and acculturation of which 'styles of the flesh' are a constitutive part. This important article prepares the way for some of the influential theoretical texts which Butler has gone on to write in the 1990s: *Gender Trouble* (1990) and *Bodies That Matter* (1993) propose a performative theory of gender which build on and develop Beauvoir's original insight. Second-wave feminism in France had a complicated relationship with Beauvoir. The construction of 'French feminism' in the Anglo-Saxon world as being constituted uniquely by the theorists of difference, Cixous, Irigaray, and Kristeva, whose theories are at odds with Beauvoir's stress on individual agency and freedom, has tended to obscure the work of other French feminists such as Christine Delphy and Monique Wittig working in Beauvoir's radical tradition. Feminists reading *The Second Sex* 50 years after its first publication encounter a number of problems: the text's ethnocentricity, its tendency to regard masculinity as unproblematic, the distaste displayed for the female body, and the devaluation of the maternal are largely at odds with contemporary sensibility. Despite this, there is considerable evidence in the 1990s of a renewed interest in *The Second Sex*, as the feminism of difference finds itself in turn in difficulties. Thus, Moi (1994) writes: 'In an intellectual field dominated by identity politics, *The Second Sex* represents a real challenge to established dogmas: if we are to escape from current political and theoretical dead ends, feminism in the 1990s cannot afford to ignore Beauvoir's pioneering insights.'

The Second Sex, with its confidence in the possibility of individual agency and a freely chosen identity, combined with an awareness of how patriarchal structures are at work in the construction of female subjectivity, offers a third way through the choice between essentialism on the one hand and postmodern dissolution of the subject on the other. *The Second Sex* founded many of the feminist strands of scholarship that are being pursued—in women's history, in philosophy, in literary criticism, in social studies. It offers a model of the multidisciplinary approach that the study of women requires, and has made the discussion and theorization of gender possible. It was not intended originally as a manual of liberation or a political tool, but it became one through the impact it had on others. In her autobiography, Beauvoir describes her own astonishment at discovering, in her forties, that there was a way of looking at women with new eyes; that vision is one which has now become a part of our consciousness.

Behavior Analysis, Applied

Applied behavior analysis consists of the use of basic behavioral processes, research methods, and derivative procedures, in order to prevent and alleviate problems of social importance. Applied behavior analysis is accountable on seven dimensions: Its procedures are applied to problems of relatively immediate social importance; its behavioral measures are valid and reliable; its procedures are described in sufficient technological detail for replication; its research methods are analytic; its effectiveness is socially significant; its generality is demonstrated across time, settings, and behaviors; and it is relevant to an overall conceptual system of behavior. This article presents the foundations of applied behavior analysis, its main techniques, and the principal areas of application. Innovative procedures and techniques are pointed out.

1. *What is Applied Behavior Analysis?*

Applied behavior analysis has been defined as the application of the methods, procedures, and techniques derived from the experimental analysis of behavior to a wide range of clinical and social institutions. The main assumption of behavior analysis is that behavior is a function of its consequences. Environmental variables are utilized in order to produce behavioral changes. A wide range of intervention techniques has been developed based on the principles of laboratory research, such as stimulus control, reinforcement, extinction, and punishment.

In the context of applied behavior analysis, the term 'behavior,' is interpreted broadly to include overt responding and also covert responses (cognitions, emotions). Behavior is defined as everything that the organism does or says, in the case of human beings. Behavior is a broad term, with different ways of being interpreted. In applied behavior analysis it includes muscular contractions, visceral secretions, cognitive factors, emotional responses, language, and social behavior.

Applied behavior analysis is mainly associated with 'Skinnerian' (i.e., operant) psychology. The term is contrasted with behavior therapy, behavior modification, behavioral engineering, cognitive behavior therapy, multimodal therapy, social learning, and others. The differences are in some cases just a matter of terminology, and there is not complete consensus in relation to the use of each term.

In applied behavior analysis, the emphasis is on a body of experimental work dealing with the relationships between changes in the environment and changes in the subject's responses. Great importance is given to the experimentally established procedures and principles. The applications to socially relevant issues are considered to be derived from basic laboratory research. Clinical problems are studied by means of experimental research studies.

The model of applied behavior analysis is psychological rather than medical. The emphasis on behavior (maladaptative in the case of clinical populations) implies that the therapist is not interested in underlying or disease factors that 'cause' the symptoms. In the case of clinical or maladaptative behavior, the term 'behavior therapy' centers on behavior that is observable and definable.

Applied behavior analysis can be traced back to several conceptualizations and experimental strategies. Particularly important is the Skinnerian analysis of behavior, leading to behavioral shaping, token economies, and environmental design. The emphasis upon the application of experimental methodology to individual cases is a distinctive feature of applied behavior analysis. Social learning, modeling, and classical conditioning procedures are also taken into account.

It is possible to state that the main techniques used in applied behavior analysis are operant conditioning, extinction, systematic desensitization, modeling, self-control procedures, and techniques for the modification of cognitions—a wide range of procedures that are tailored to the particular individual, the specific situations, and the behaviors to be modified.

2. *Behavior Analysis and Applied Behavior Analysis*

Behavior analysis—the natural science from which applied behavior analysis is derived—comprises three subdisciplines: the experimental analysis of behavior for basic research elucidating fundamental behavioral processes; applied behavior analysis for the application of these processes, derivative technologies, and research methods for clinical and community

problems; and the conceptual analysis of behavior, for historical, philosophical, theoretical, and methodological investigations.

The experimental analysis of behavior (EAB) involves conceptual analysis as a matter of course, that is, ontological assumptions. The EAB seeks: (a) to describe functional relations between classes of responses and classes of stimuli, and (b) to demonstrate the reliability and generality thereof, and thus their lawfulness. The dependent variable is the probability of an organism's response as a function of independent variables, which occur in real time.

On the other hand, applied behavior analysis employs basic behavioral processes, research methods, and derivative procedures, in order to prevent and alleviate problems of social importance. Applied behavior analysis is accountable on seven dimensions: Its procedures are applied to problems of relatively immediate social importance; its behavioral measures are valid and reliable; its procedures are described in sufficient technological detail for replication; its research methods are analytic; its effectiveness is socially significant; its generality is demonstrated across time, settings, and behaviors; and it is relevant to an overall conceptual system of behavior (Baer et al. 1987). Applied behavior analysis has derived from the EAB with 'their procedual emphases of reinforcement, punishment, and discriminative-stimulus contingencies as behavior-analytic environmental variables, their reliance on single-subject designs as the formats of analysis and proof, and their consistent use of the Skinner box as their arena' (p. 313). However, in the last decades, applied behavior analysis has been characterized by seven key terms: applied, behavioral, analytic, technological, conceptual, effective, and capable of appropriately generalized outcomes.

The importance of a conceptual analysis has been pointed out since the beginning of the EAB. The conceptual analysis includes metatheory and philosophy, history and historiography, methodology, and system and theory.

3. *Development of the Area*

Applied behavior analysis began in the 1950s. The first decade was characterized by polemics and paradigmatic clashes. The second decade was the time of consolidation. The third saw the development of a refined methodology and new conceptual models. The last period has been characterized by applications to new fields, even in the so-called nontraditional areas (see Mattaini and Thyer 1996).

A very relevant problem refers to the role of conditioning in applied behavior analysis and in behavior therapy. This area was sometimes called 'conditioning therapy,' and it was considered as the application of the laws of 'modern learning theory.' Discussion has arisen concerning the differences between conditioning in the animal laboratory, in the clinic, and in daily life. Conditioning as the explanatory foundation of all applied behavior analysis has been very controversial. Some authors have insisted on the need to include knowledge drawn from psychobiology and social psychology, instead of relying only upon conditioning-learning theory.

The role of cognition in applied behavior analysis has been a central topic of discussion. Due to the desire to eliminate all reference to mentalism and to inner processes, early behavioral analysts rejected all forms of cognitive influence. But in the 1980s the 'cognitive revolution' led to some reformulations and reconceptualizations, and there was discussion about the role of cognition in behavior change. The term cognitive behavior therapy was used, rather than just behavior therapy. However, if behavior includes cognitive processes, the addition of 'cognitive' is redundant. The controversy continues at the beginning of the twenty-first century, and several positions and disputes exist concerning this issue. The precise relationship between behavior and cognition remains equivocal.

4. *Techniques*

A large number of techniques have been developed in the area of applied behavior analysis. Some of them are based on operant conditioning, others on classical conditioning, social learning, or a combination of them. Some involve principles derived from social psychology, developmental psychology, physiological, and cognitive psychology. Only the main techniques are presented here, and the list is not exhaustive.

4.1 *Systematic Desensitization*

This is a term applied to a class of methods used for gradually weakening unadaptative anxiety response habits through the use of responses that compete with anxiety. As an example, a physiological state inhibitory of anxiety is produced in the patient by means of muscle relaxation; the patient is then exposed for a few seconds at a time to a stimulus arousing weak anxiety. With repetition of the exposure, the stimulus progressively loses its ability to evoke anxiety. In a progressive way, stronger stimuli are presented.

The standard procedure in systematic desensitization consists of several sets of operations: (a) introduction to the subjective anxiety scale, (b) training in deep muscle relaxation, (c) construction of anxiety hierarchies, and (d) counterposing relaxation and anxiety-evoking stimuli from the hierarchies.

Counterconditioning is the basis of the change that follows systematic desensitization, according to Wolpe and other researchers and clinicians.

4.2 Biofeedback

This term refers to a number of clinical techniques which provide feedback to patients concerning changes in a particular physiological response, so that they can learn to modify the physiological response. Two methods of providing information feedback to the patient have been developed: binary feedback (yes/no information) and analogue feedback (proportional). A number of physiological responses have been shown to be modifiable using biofeedback. The most common physiological responses to be used clinically are electromyogram activity (EMG), skin temperature, blood pressure, EEG (electro-encephalogram), vasomotor, and heart rate.

Biofeedback is used in lowering the blood pressure of essential hypertensives, for achieving relaxation, for epilepsy, migraine headaches, and many other clinical problems (see Carrobles and Godoy 1987).

4.3 Punishment

Punishment is an operant conditioning procedure in which the future probability of occurrence of a response is reduced as a result of response-dependent delivery (positive punishment) or removal (negative punishment) of a stimulus (punisher). An example of positive punishment is spraying water mist in the face of a self-injurious child each time an instance of self-injurious behavior is observed. An example of negative punishment is taking an earned token from a person each time he or she curses. In the first case the aim is to reduce the occurrence of self-injury; in the second case it is to reduce the rate of cursing.

Punishment may weaken, strengthen, or have no effect on other response classes. Its effects are controversial and subject to discussion. In the early stages of applied behavior analysis, punishment procedures were used more frequently than now. Alternatives to punishment are usually preferred.

4.4 Escape Training

In this training procedure an individual learns to perform a response in order to terminate a punishing stimulus.

4.5 Avoidance Training

This is a training procedure in which an individual learns to keep away from a designated stimulus in order to prevent punishment. The first step consists in pairing the designated stimulus with a punisher. Then the individual is negatively reinforced by performing a response that terminates the punishing stimulus. The individual subsequently learns to prevent punishment from occurring by either responding with an alternative behavior (active avoidance) or not responding at all (passive avoidance) prior to coming in contact with the designated stimulus.

4.6 Extinction

Extinction is a response-weakening procedure which can involve consistent failure to deliver a reinforcer following an operant response which had previously produced that reinforcement (operant extinction). It eventually results in nearly complete elimination of the operant response, although a transient rate increase is frequently observed soon after operant extinction is arranged.

This technique is widely used in behavior modification and is preferred to punishment, avoidance training, escape training, and similar aversive procedures.

4.7 Shaping

This technique consists of reinforcing successive approximations to the desired response. Usually a simple response is required initially, and criteria for reinforcement are gradually made more stringent so as to produce more complex or refined response. Initially a simple response (in the direction of the desired goal) would be sufficient to receive reinforcement. After this behavior is performed reliably, reinforcement is given only for a more complex or difficult response. The next step consists of giving reinforcement for the slightly more complex response. The pattern continues until the final desired behavior is achieved regularly.

4.8 Contingency Management

Contingency management involves the analysis and change of the functional contingencies in the environment that determine a person's behavior. As a result, the behavior changes from its initial rate to a different rate of occurrence. In clinical work, this involves the development of new or alternative forms of adaptative behavior. Within a certain environmental context, a contingency describes a functional relationship among stimuli antecedent to a particular behavior (the target) and the consequences that follow the occurrence of the behavior.

The functional environment for a particular person is often different from the functional environment of another person. Many stimuli or events that occur in a person's environment do not have any effect on the person's behavior. In those cases we can say that the particular part of the environment is not functional, it is just present.

Contingency management involves the analysis and modification of contingencies involving discriminative stimuli, reinforcement, punishment, and extinction. It

focuses on public and observable behaviors and controlling environments. The environment of interest is primarily that part which functions to increase, decrease, or control the occurrence of certain behaviors. Contingency management in clinical practice typically is concerned with appropriate discrimination and generalization of adaptative behavior changes.

After a comprehensive functional analysis of environmental contingencies, the therapist plans a program of intervention to modify contingencies to change the rate of the target behavior. Contingency management involves a thorough functional analysis of controlling contingencies, the rearranging of the functional analysis of controlling contingencies, the rearranging of the functional environment, and a careful monitoring of outcome.

4.9 Environmental Design

This consists of the application of empirically derived principles of behavior for the modification and design of the environment. It involves the planning of a coherent program and set of procedures to affect the total human and nonhuman environment in ways that increase the probability that certain goals will be achieved.

The goal of environmental design relates to social behavior, for instance, planning a therapeutic or educational system. It includes linking applied behavior analysis and environmental psychology. It involves training people to conceptualize the environment so that they can apply the general principles of behavior analysis to design planning. Social design and physical design should be considered. The larger context is the planning of a whole society, such as *Walden Two* (Skinner 1948), or *Walden Three* (Ardila 1990).

4.10 Token Economy

In the token economy intervention, reinforcers are delivered for specific target behaviors. Reinforcers are tokens (tickets, coins, points, stars) that can be exchanged for a variety of other rewards. Tokens help bridge the delay between the person's performance of a desired behavior and delivery of a reward.

As an example of the use of token economies in complex settings we can mention the University of Kansas Experimental Living Project, a behaviorally managed experimental community of 30 college students (see Johnson et al. 1991). Token economies have also been used in prisons, in nursing homes, on psychiatric wards, in normal classroom settings from preschool to university classes, on wards for the treatment of drug addicts and alcoholics, in various work settings to increase safety behavior, in community settings to increase recycling of waste and improve energy conservation, and in many other contexts.

4.11 Premack Principle

This principle says: For any pair of responses the more probable one will reinforce the less probable one. The technique derived from the Premack Principle consists of a special class of reinforcing operations in which access to high probability behaviors is made contingent upon clinically targeted activities. For instance, children may be allowed to eat candy after (contingent upon) doing their homework.

4.12 Modeling

This consists of the presentation of a live demonstration, a filmed or pictorial presentation, or an imagined one. Based on the presentation, the viewer learns a method of responding or the contingencies under which the target response will fall.

Observational learning, imitation, and modeling are terms frequently used with respect to this phenomenon. These techniques are useful in the treatment of phobias, and in forming social skills and many other desired behaviors.

4.13 Cognitive Procedures

Cognitive therapy or cognitive applied behavior analysis refers to a wide range of approaches, based on two explicit hypotheses: (a) cognitive factors such as thoughts, images, and memories, are intimately related to dysfunctional behavior, and (b) modification of such factors is an important mechanism for producing behavior change.

4.14 Behavioral Self-control

This set of techniques involves training patients to control their own behavior through the systematic use of behavior principles. The therapist educates patients regarding the technical aspects of various behavior change procedures. In a self-reinforcement program, patients are taught to administer consequences to themselves contingent upon the performance of the target behavior.

In the majority of cases behavioral self-control involves self-monitoring, self-evaluation, and self-delivered rewards. There are many potential benefits from teaching patients self-control rather than using external agents to administer treatment contingencies. Self-control therapy allocates a great responsibility to patients. It is clear that teaching individuals to be their own therapists will contribute to generalization of treatment effects because patients will be able to

continue to administer the program or develop new treatment following the termination of therapy.

5. Main Areas of Application

Applied behavior analysis is a broad term and covers many fields of applied psychology, both traditional and nontraditional. A brief description of some of these areas follows.

5.1 Behavior Analysis Applied to Clinical Problems

This field is also referred to as behavior therapy, and has a long history. Behavior therapy has been defined as follows:

> 'Behavior therapy is the attempt to utilize systematically that body of empirical and theoretical knowledge which has resulted from the application of the experimental method in psychology and its closely related disciplines (physiology and neurophysiology) in order to explain the genesis and maintenance of abnormal patterns of behavior; and to apply that knowledge for the treatment or prevention of those abnormalities by means of controlled experimental studies of the single case, both descriptive and remedial.' (Yates 1970, p. 18)

Lovaas (1966, 1977, 1993) has developed behavioral treatment for autistic children. He focused on strategies to teach social behaviors, eliminate self-stimulatory behaviors, and develop language skills. The behavioral treatment has produced long-lasting effects, and no alternative treatment for autistic children has been shown to be as successful as behavior modification.

5.2 Behavior Analysis in Education

A number of applications have been carried out in several important educational aspects: behavior modifications in special populations (mental retardation, visual and auditory limitations, people with physical limitations, children of superior intelligence, and so forth). Also work has been done in order to maximize the efficiency of teaching techniques, learning in the classroom, and in general academic learning from preschool to university education. The techniques of reinforcement, contingency management, environmental design, token economy, and so forth, previously described in this article, have been applied to the educational area.

5.3 Industrial/Organizational Behavior Analysis

In the early 1970s applied behavior analysis entered the industrial arena. At the heart of this approach lies the belief that most complex human behaviors are learned, and by altering either the conditions preceding the behavior, or especially the consequences following it, that behavior can be altered and new behavior patterns can be learned. A wide variety of industrial-relevant behavior has been successfully altered: teaching the skills required for the job, motivating the performer, reducing absenteeism, reducing turnover, learning to work in groups, improving communication skills in the work setting, reinforcing adequate behavior, extinguishing undesired behavior, increasing productivity, improving morale, overcoming resistance to change, and others (see Hersey et al. 1996).

5.4 Behavioral Community Psychology

As a 'marriage' of the methodology of behaviorism and the strategies and conceptual framework of community psychology, the area of behavioral community psychology (Nietzel et al. 1996) uses classical conditioning, operant conditioning, social learning, and cognitive/self-control procedures. Examples of operant behavior analysis are prompts, feedback, reinforcement and response cost. Examples of social learning and cognitive/self-control procedures are modeling, behavioral rehearsal and role-playing, self-instruction and self-regulation, especially with respect to the development of skills and self-help competences in target populations.

5.5 Forensic Applications

Most applications of behavior analysis to psychology and the law have been in connection with criminal justice. Work has been carried out concerning the behavior of the delinquent individual, including juvenile delinquents and predelinquents; in the prevention of criminal behavior; and in the areas of legal processing, the courts, the jury, witnessess, and so forth. Special importance has been given to the behavior modification of delinquents using behavior analysis procedures.

5.6 Sport Psychology

In this area the contribution of applied behavior analysis has been centered on motivation of athletes, athletic performance, leadership, optimal coaching strategies, audience effects, sport violence, and other similar issues. The main behavioral technology procedures used in sport psychology are positive reinforcement, shaping, chaining, extinction, time out, response cost, fading, prompting, performance feedback, self-monitoring, self-instructions, deep muscle relaxation, modeling, imaginal rehearsal, behavioral rehearsal, thought stopping, and response-induced aids (see Goldstein and Krasner 1987).

5.7 Larger Sociocultural Applications

A number of 'big issues' have been addressed with the procedures of behavior analysis: youth violence,

racism, sexism, poverty, health problems, destruction of the environment, the breakdown of schools, lack of productivity in the workplace, child maltreatment. According to Mattaini and Thyer 1996) these behavioral problems 'could ultimately threaten the survival of the human race and other species' (p. 1)

Behavior, Hierarchical Organization of

The analysis of most complex objects of scientific study reveals a hierarchical structure. At the bottom are elementary units (e.g., the elementary substances in chemistry), which are combined to form complex units (e.g., radicals in chemistry), which are themselves combined to form still more complex units (e.g., amino acids), and so on. The bodily movements that we call behavior are no exception. Complex behavior is created by coordinating elementary units of behavior to form units of modest complexity, then coordinating these units to form more complex units, and so on, up the scale of complexity. The extraordinarily protean character of behavior—the ability of even a basic behavior like locomotion to take on a seemingly infinite variety of forms—makes the existence of units of control and their hierarchical arrangement hard to recognize. This protean character of behavior is itself a consequence of this hierarchical structure and of the control principles that operate within it.

1. The Underlying Neurobiological Elements of a Unit of Behavior

Sherrington (1947/1906) defined a unit of behavior as an assemblage of neuromuscular and neuroendocrine elements sufficient to explain a naturally occurring pattern of movement or exocrine secretion. He recognized three necessary categories of neurobiological elements in any such assemblage—initiator elements, conducting elements, and effector elements. The neural signals that lead to movements originate in initiator elements. They are translated into movements or secretions by effector elements. Conductor elements convey them from the initiator elements to the effector elements.

The currently known initiator elements are sensory receptors and pacemakers. Sensory receptors convert stimulus energy into neural signals. Pacemakers generate rhythmic discharges by means of the intrinsic structure of the voltage-dependent ion channels in the membranes of some elements (pacemaker cells) and the structure of the neural circuits in which these elements are embedded. The effector elements are muscles and the exocrine glands, which are glands like tear glands, sweat glands, and salivary glands that secrete substances outside the body—bearing in mind that the alimentary tract is outside the body from a physiological perspective. The conductor elements are the axons of neurons, which conduct electrical impulses over long distances, the synaptic junctions between cells, where signals are conducted across the very short gaps between cells, and endocrine secretions, which are chemical signals conveyed from their release site to their target sites in the blood. Initiators, conductors and effectors are essential components in

any unit of behavior. Thus, for example, the vertebrate skeletal motor unit—a motor neuron together with the striated muscle fibers that it innervates—is not a unit of behavior, because this assemblage lacks an initiator element. The question is whether there are additional neurobiological elements that play essential roles in many units of behavior beyond the simple reflexes that Sherrington largely considered. In the second half of the twentieth century, the information-processing character of the nervous system has become clearer. This has led to the postulation of additional categories of sub-behavioral elements—memory elements, which hold information over time, and computational elements, which combine information-carrying signals in accord with elementary computational operations, such as the additions and multiplications that mediate and coordinate transforms. These elements, whose cellular nature remains undetermined, mediate the computational functions of the central nervous system. As will be seen, the need for such elements is apparent even in simple movements, such as the scratching movements of a hind limb or the smooth pursuit movements of the eyes.

2. *Distinguishing Between Elementary and Complex Units*

An assembly of neurobiological elements sufficient to explain a naturally occurring pattern of movement or glandular action is an elementary unit of behavior if it cannot be broken down into subassemblies that are themselves capable of explaining a component of that pattern. Take, for example, the scratch reflex in which an animal raises a hind limb so as to place the ends of the digits at the site of an irritating stimulus and then rhythmically wipes the digits repeatedly across the irritation. Although this is a very simple behavior, it is not an elementary unit of behavior, because it can be decomposed into experimentally separable movements, which are themselves units of behavior—the movement that brings the digits to the site of irritation and the rhythmic scratching movement (Sherrington 1947/1906). These two units cannot, so far as we know, be themselves decomposed into movements that are also units, so they are elementary units. Their coordination constitutes the complex unit that mediates the scratching of an irritated spot. The neural tissue that effects this coordination belongs to the complex unit, not to the elementary units that compose it. Thus, directed scratching is one level up in the control hierarchy.

Locomotion is an example of a complex unit much higher in the hierarchy (Gallistel 1980). It involves the coordination of the stepping of each of the limbs. The circuitry that controls the stepping of a single limb is itself a complex unit, coordinating the operation of an oscillator, several reflexes, and one or more servomechanisms. The coordination of the stepping movements of different limbs is effected by means of neural tissue that carries timing signals between the pacemakers that set the stepping rhythms for each limb and by command signals descending from higher neural centers to set the periods of these pacemakers. The complex neural circuitry that effects the coordination we see in locomotion constitutes itself a (complex) unit of behavior for two reasons: (a) it imposes a definite structure on the patterns of muscular activation, a structure that appears whenever the animal locomotes (Weiss 1941) and (b) this structure is activated in the course of many different higher level behaviors.

3. *Kinds of Elementary Units*

Just as there are different elementary substances in chemistry, so, too, there are different elementary units of behavior. Figure 1 gives the functional structures of five that have been well characterized (Gallistel 1994).

Figure 1
Functional structures of five elementary units of behavior (after Gallistel 1994)

Figure 2
The scratching motion of the hind limb of the spinal frog (spinal cord separated from brain) varies depending on the position of the forelimb relative to the hind limb. Numbers indicate the sequence of motions (after Fukson et al. 1980)

In a simple reflex, the initiator element is a sensory receptor (R), sensory axons conduct the action potentials into the central nervous system (CNS), where the rise and fall of the resulting motor axon firing is determined (the central transfer function or CTF), and muscles or exocrine gland effectors (E) translate the signal into action. In an oscillator, a pacemaker is the source of the rhythmic signals driving a rhythmic action. Inputs to the pacemaker adjust its period and phase. In a simple servomechanism, like the optokinetic reaction, the proximal stimulus (in this case, the slippage of the image of the visual field across the retina) is jointly determined by the movement of the visual field (distal stimulus) and the rotation of the eyes and head (animal's response). This retinal image motion generates an error signal, which is shaped by the CTF to produce an effector action—rotation of the eyes and head in the direction of visual field movement—which reduces the proximal stimulus (retinal image motion) and hence the error signal. Thus, there is negative feedback from output to input. The parameters of the CTF presuppose the existence of the negative feedback; the unit does not operate properly in its absence (Collewijn 1969).

These three kinds of elementary units were characterized by the late 1960s, if not earlier, before the computational character of the nervous system was widely recognized. Elementary units containing computational elements and memory elements have been identified more recently.

The reflex movement that brings the digits of the hind leg to the site of irritation on the skin of the forearm in vertebrates has been shown to involve a coordinate transformation, which is why the functional structure of this kind of elementary unit includes a stage that performs this computation (Fukson et al. 1980). The transformation is necessitated by the fact that the spatial relation between the skin of the forearm and the joints of the hind limb changes as the position of the forelimb changes (Fig. 2). There is some reason to think that simple directed limb movements in the frog are controlled by four or five different populations of premotor neurons, each premotor population producing a characteristic dynamic force field when activated (Bizzi et al. 1995). Thus, to a first approximation, the endpoint of the movement may be thought of as being specified by a neural vector, with four or five dimensions (four or five different neuronal populations, with firing rates varying more or less independently between the populations). The set of all possible combinations of firing rates—hence all possible endpoints—constitutes a vector space. The signal indicating the locus of irritation on the skin of the forelimb may be thought of as coming from a two-dimensional vector space because it takes two dimensions to specify a location on the skin surface. The CNS maps the two-dimensional skin space into the four- or five-dimensional premotor space. This mapping itself varies when the position of the forelimb changes; a stimulus at the same point on the skin elicits a movement of the digits to a different point in space, because that point on the skin is now at that different point in space. The notion of a variable coordinate transformation in simple reflex orienting reactions has been most fully developed in the study of the saccadic orientation of the eyes (Gallistel 1999).

Memory elements are required in more sophisticated negative feedback mechanisms. In a simple error-actuated servomechanism, like the optokinetic reaction, there must always be a small error (in this case, a small amount of image slippage), because it is the error signal that drives the reaction. In more sophisticated negative feedback systems, like the smooth pursuit circuit, which mediates the smooth movement of the eyes in following a small foveated target, there is often no error; the eyes rotate at exactly the rate that keeps the target centered on the fovea. This requires a sample-and-hold mechanism, which is to say a mechanism that has a memory element incorporated in it (Krauzlis and Lisberger 1994). When the movement of the target is first detected, its retinal velocity is measured, the measured value is stored in a memory, and this remembered value drives the smooth rotation of the eyes. The incorporation of the memory element means that the effector action is no longer driven by the ongoing error signal, allowing this signal to become effectively zero.

4. *Selective Potentiation and Depotentiation*

A major principle of coordination, which may be observed at every level of the hierarchy, is the selective potentiation of units whose actions functionally cohere with the other actions going on at a given moment and the depotentiation of the units whose actions would be disruptive (Gallistel 1980). Potentiation

raises the potential for an action, but does not actually trigger that action. The triggering of a potentiated action is controlled by stimuli signaling the exact moment at which it becomes appropriate. There are, for example, two different stumble-preventing reflexes in the hind limb of the cat, one producing flexion of the limb, one producing extension (the exact opposite action). Both of these incompatible actions are triggered by a sudden onset tap on the dorsum of the paw (Forssberg et al. 1975), but they are not in practice both activated together. The flexor reflex is potentiated during the swing phase of each stepping cycle, while the opposing extension reflex is depotentiated. This pattern of selective potentiation and depotentiation reverses during the stance phase, when the paw is planted on the ground. The flexion reflex lifts the paw over an obstacle that would otherwise arrest its forward swing. The extension reflex thrusts the weight rapidly onto other legs, enabling the cat to lift the paw sooner when a moving object (e.g., a stone) threatens to sweep it from beneath the cat. Thus, which of the two reflexes is activated when the stimulus comes is determined by the selective potentiation and depotentiation so as to make the elicited action complement the ongoing phase of the step cycle, rather than hinder it.

At the top of the action hierarchy, the arousal of sexual motivation in a female rat through manipulation of her hormone levels potentiates the many different components of her sexual behavior (Adler 1973) and depotentiates reactions that would interfere with sexually oriented actions. For example, the hormonal state potentiates the lordosis response to a squeeze of her flanks, such as the male makes when he mounts. Her lordosis response firmly roots her to the floor and presents her genitals, facilitating penile entry. This same hormonal state depotentiates her flinch responses to painful stimuli delivered to her paws, presumably because such a reaction interferes with the male's intromission (Gordon and Soliman 1999).

5. *Origins of the Multiformedness of Behavior*

Complex units of behavior often have many different surface manifestations. For example, systems of coupled oscillators, of which the locomotory system is an example, can produce many different rhythmic sequences (in this case, different gaits, that is, sequences of stepping actions), depending on simple control parameters, such as the rate at which the stepping pacemakers are cycling (Wilson 1966). This is one reason why behavior takes on so many different forms. Reliance on coordination by selective potentiation and depotentiation within a hierarchical structure is a second major reason. It means that the actual spectrum of component actions that mediate a complex behavior like copulation vary depending on local circumstances particular to a given occasion, because different circumstances trigger different combinations of the potentiated actions.

Behavior Psychotherapy: Rational and Emotive

Rational emotive behavior therapy (REBT) was originated in January 1955 as a pioneering cognitive-

experiential-behavioral system of psychotherapy. It is heavily cognitive and philosophic, and specifically uncovers clients' irrational or dysfunctional beliefs and actively-directively disputes them. But it also sees people's self-defeating cognitions, emotions, and behaviors as intrinsically and holistically connected, not disparate. People disturb themselves with disordered thoughts, feelings, and actions, all of which importantly interact with each other and with the difficulties they encounter in their environment. Therefore, with emotionally and behaviorally disturbed people, REBT employs a number of thinking, feeling, and action techniques that are designed to help them change their self-defeating and socially sabotaging conduct to self-helping and socially effective ways (Ellis 1994, 1998, Ellis and Dryden 1997, Walen et al. 1992).

REBT theorizes that virtually all humans consciously and unconsciously train themselves to be to some degree neurotic; and that, with the help of an effective therapist and/or with self-help materials, they can teach themselves to lead more satisfying lives—if they choose to do so and work hard at modifying their thinking, feeling, and behaving.

1. *Philosophical Background*

Albert Ellis, the originator of REBT, was trained in Rogerian person-centered therapy in graduate school in clinical psychology (1942–7), found it too passive and abandoned it for psychoanalytic training and practice (1947–53). But psychoanalysis, too, he found ineffective because it was too much insight-oriented and too little action-oriented. His clients often saw how they originally became disturbed—supposedly because of their family history. But when he stayed with typical psychoanalytic methods, he failed to show them specifically how to think and act differently and to thus make themselves more functional.

So Ellis went back to philosophy, which had been his hobby since the age of 16, and reread the teachings of the ancient philosophers (especially Epicurus, Epictetus, Marcus Aurelius, and Gautama Buddha) and some of the moderns (especially Dewey, Russell, and Heidegger) and found that they were largely constructivists rather than excavationists. They held that people do not merely get upset by adverse life conditions, but instead often choose to disturb themselves about these adversities. Fortunately, a number of philosophers also said, people could choose to 'unupset' themselves about minor and major difficulties; and, if they made themselves anxious and depressed, they could reduce their dysfunctional feelings and behaviors by acquiring a core philosophy that was realistic, logical, and practical.

Following these philosophers, Ellis started to teach his clients that they had a choice of experiencing healthy negative emotions about the misfortunes they countered—such as feelings of sorrow, disappointment, and frustration; or they could choose to experience unhealthy negative reactions—such as panic, depression, rage, and self-pity. By using rational philosophy with troubled clients, he saw that when they faced adversities with self-helping attitudes they made themselves feel better and functioned more productively. But when they faced similar adversities with irrational (self-defeating) philosophies they made themselves miserable and acted ineffectively. When he convinced them that they almost always had the choice of helping or hindering themselves, even when their desires and goals were seriously blocked, they often were able to make that choice.

2. *The ABCs of Rational Emotive Behavior Therapy*

During the 1950s, Ellis put this constructivist theory into the now well-known ABCs of REBT. This theory states that almost all people try to remain alive and achieve basic goals (G) of being reasonably content by themselves, with other people, productively working, and enjoying recreational pursuits. When their goals are thwarted and they encounter adversities (A) they are then able to construct consequences (C)—mainly feelings and actions—that either help or hinder them satisfying these goals. They largely (though not completely) do this by choosing to follow rational, useful beliefs (B) or to follow irrational, dysfunctional beliefs. Therefore, although the adversities (A) they experience are important contributors to their emotional and behavioral consequences (C), they do not directly or solely cause these consequences. When at C, people feel and act neurotically or self-defeatingly, their irrational beliefs (B) and their experienced adversities (A) bring on their disturbed reactions. So A does not by itself lead to C. A interacts with B to produce C; or $A \times B = C$. However, people tend to be aware that C follows A, but not that B is also included in the process. They therefore think that As automatically lead to disturbed Cs—that their internal reactions are controlled by external events.

Ellis noted in his first paper on REBT, at the Annual Convention of the American Psychological Association in Chicago in August 1956, that when people feel and act disturbedly (C), they have 12 common irrational or dysfunctional beliefs (B) about the undesirable things that happen to them (A). When they change these to rational or functional beliefs (in therapy or on their own) they become significantly less disturbed. Both these hypotheses have been supported by many empirically-based studies, first by followers of REBT (Lyons and Woods 1991), and then by other cognitive behavior therapists who largely follow and have tested the ABC theory of REBT (Barlow and Craske 1994, Hollon and Beck 1994, Meichenbaum

1997). Hundreds of published studies have given much support to this theory.

After using REBT for a few years in the 1950s, Ellis came up with clinical evidence for Karen Horney's (1950) hypothesis about the 'tyranny of the shoulds.' He realized that the many irrational beliefs with which people often disturb themselves can practically always be put under three major headings, all of which include absolutistic shoulds, oughts, and musts. With these three core dysfunctional ideas, people take their strong preferences for success, approval, power, freedom and pleasure, and elevate them to dogmatic, absolutistic demands or commands.

The imperatives that frequently accompany dysfunctional feelings and behaviors seem to be: (a) 'I *absolutely must* perform well at important tasks and be approved by significant others—or else I am an inadequate person!' (b) 'Other people *absolutely must* treat me kindly, considerately, and fairly—or else they are bad individuals!' (3) 'Conditions under which I live *absolutely must* provide me with what I really want—or else my life is *horrible*, I *can't stand* it, and the world's a *rotten place*!'

These three common irrationalities lead to innumerable derivative irrational beliefs and frequently are accompanied by disturbed emotional and behavioral consequences. In fact, REBT hypothesizes that people would find it difficult to make themselves neurotic without taking one or more of their major preferences and transforming them into absolutistic demands. Individuals with severe personality disorders and psychosis also disturb themselves by turning their healthy preferences into unhealthy musturbating, but they often have other biochemical and neurological characteristics that help make them disturbed.

REBT also theorizes that the tendency to elevate healthy preferences to insistent demands, and thereby to think, feel, and act unrealistically and illogically, is innate in humans. People naturally and easily take some of their strong goals and desires and often view them as necessities. This self-defeating propensity is then exacerbated by familial and cultural upbringing, and is solidified by constant practice by those who victimize themselves with it. Therefore, especially with seriously disturbed people, psychotherapy and self-help procedures can, but often only with difficulty, change their dysfunctioning.

Many therapy techniques—such as meditation, relaxation, a close and trusting relationship with a therapist, and distraction with various absorbing activities—can be used to interrupt clients' musturbatory tendencies and help them feel better. But in order for them to get and stay better, REBT holds, they usually have to consciously realize that they are destructively escalating their healthy desires into self-sabotaging demands and then proceed to D: to actively and forcefully dispute the irrational beliefs that are involved in their disturbances. By vigorously and persistently disputing these beliefs—cognitively, emotively, and behaviorally—they can change their self-destructive shoulds and musts into flexible, realistic, and logical preferences. They thereby can make themselves significantly less disturbed.

3. *Rational Emotive Behavior Therapy Techniques*

To help people specifically achieve and maintain a thoroughgoing antimusturbatory basic outlook, REBT teaches them to use a number of cognitive, emotive, and behavioral methods. It helps them gain many insights into their disturbances, but emphasizes three present-oriented ones:

Insight No. 1: People are innate constructivists and by nature, teaching, and, especially, self-training they contribute to their own psychological dysfunctioning. They create as well as acquire their emotional disabilities—as the ABC theory of REBT notes.

Insight No. 2: People usually, with the 'help' and connivance of their family members, first make themselves neurotic when they are young and relatively foolish. But then they actively, though often unconsciously, work hard after their childhood and adolescence is over to habituate themselves to dysfunctional thinking, feeling, and acting. That is mainly why they remain disturbed. They continue to construct dysfunctional beliefs.

Insight No. 3: Because of their natural and acquired propensities to strongly choose major goals and values and to insist, as well as to prefer, that they must achieve them, and because they hold these self-defeating beliefs and feelings for many years, people firmly retain and often resist changing them. Therefore, there usually is no way for them to change but work and practice for a period of time. Heavy work and practice for short periods of time will help; so brief rational emotive behavior therapy can be useful (Ellis 1999). But for long-range gain, and for clients to get better rather than to feel better, they require considerable effort to make cognitive, emotive, and behavioral changes

REBT clients are usually shown how to use these three insights in the first few session of psychotherapy. Thus if they are quite depressed (at point C) about, say, being rejected (at point A) for a very desirable job, they are shown that this rejection by itself did not lead to their depression (C). Instead they mainly upset themselves with their musturbatory beliefs (B) about the adversity (A). The therapist explores the hypothesis that they probably took their desire to get accepted and elevated it into a demand—e.g.,'I *must not* be rejected! This rejection makes me an *inadequate person* who will *continually* lose out on fine jobs!' (Ellis 1998, 1999).

Second, clients are shown—using REBT Insight No. 2—that their remembering past adversities (A),

such as past rejections and failures, do not really make them depressed today (C). Again, it is largely their beliefs (B) about these adversities that now make them prone to depression.

Third, clients are shown that if they work hard and persistently at changing their dysfunctional beliefs (B), their dire needs for success and approval, and return to mere preferences, they can now minimize their depressed feelings—and, better yet, keep warding them off and rarely fall back to them in the future. REBT enables clients to make themselves less disturbed and less disturbable.

4. Multimodal Aspects of Rational Emotive Behavior Therapy

To help clients change their basic self-defeating philosophies, feelings and behaviors, REBT practitioners actively-directively teach and encourage them to use a good many cognitive, experiential, and behavioral techniques, which interact with and reinforce each other. Cognitive methods are particularly emphasized, and often include: (a) *active disputing of clients' irrational beliefs* by both the therapists and the client; (b) *rational coping self-statements* or effective philosophies of living; (c) *modeling* after people who coped well with adversities similar to, or even worse than, those of the clients; (d) *cost–benefit analyses* to reveal how some pleasurable substances and behaviors (e.g., smoking and compulsive gambling) are self-sabotaging and that some onerous tasks (e.g., getting up early to go to work) are unpleasant in the short term but beneficial in the long term; (e) *REBT cognitive homework forms* to practice the uncovering and disputing of dysfunctional beliefs; (f) *psychoeducational materials*, such as books and audiovisual cassettes, to promote self-helping behaviors; (g) *positive visualizations* to practice self-efficacious feelings and actions; (h) *reframing of adversities* so that clients can realize that they are not catastrophic and see that they sometimes have advantages; (i) *practice in resisting overgeneralized, black and white, either/or thinking*; (j) *practical and efficient problem-solving techniques*.

REBT uses many emotive-experiential methods and materials to help clients vigorously, forcefully, and affectively dispute their irrational demands and replace them with healthy preferences (Bernard and Wolfe 2000). Some of its main emotive-expressive techniques include: (a) *forceful and persistent disputing of clients' irrational beliefs*, done in vivo or on a tape recorder; (b) *experiencing a close, trusting, and collaborative relationship* with a therapist and/or therapy group; (c) *steady work at achieving unconditional other-acceptance* (*UOA*), the full acceptance of other people with their failings and misbehaviors; (d) *using visualizations or live experiences to get in touch with intense unhealthy negative* feelings—and to train oneself to feel, instead, healthy negative feelings; (e) *roleplaying difficult emotional situations* and practicing how to handle them; (f) *using REBT's shame-attacking exercises* by doing 'embarrassing' acts in public and working on not denigrating oneself when encountering disapproval; (g) e*ngaging in experiential and encounter exercises* that produce feelings of discomfort and learning how to deal with these feelings.

REBT uses many activity-oriented behavioral methods with clients, such as: (a) *exposure or in vivo desensitization* of dysfunctional phobias and compulsions; (b) *taking deliberate risks of failing at important projects* and refusing to upset oneself about failing; (c) *staying in uncomfortable situations and with disturbed feelings* until one has mastered them; (d) *reinforcing oneself to encourage self-helping behaviors* and penalizing oneself to discourage self-defeating behaviors; (e) *stimulus control* to discourage harmful addictions and compulsions; (f) *relapse prevention* to stop oneself from sliding back to harmful feelings and behaviors; (g) *skill training* to overcome inadequacies in assertion, communication, public speaking, sports, and other desired actions that one is inhibited about.

These are some of the cognitive, emotive, and behavioral techniques that are employed frequently in rational emotive behavior therapy. Many other possible methods are individually tailored and used with individual clients.

The main therapeutic procedure of REBT is to discover how clients think, feel, and act to block their own main desires and goals, and to figure out and experiment with ways of helping them get more of what they desire and less of what they abhor. As they make themselves less disturbed and dysfunctional, they are helped to actualize themselves more—that is, to provide themselves, idiosyncratically, with greater satisfactions. At the same time, clients are helped to stubbornly refuse to define their preferences as dire necessities and thereby tend to reinstitute their disturbances.

When Ellis originated it in 1955, rational emotive therapy was unique. It was followed by somewhat similar forms of cognitive behavior therapy (CBT) in the 1960s and 1970s, particularly the cognitive therapy of Beck (1976), rational behavior therapy of Maultsby (1975), cognitive behavior modification of Meichenbaum (1977), and multimodal therapy of Lazarus (1978). REBT and CBT were soon supported by numerous published studies that showed their effectiveness, with many different types of clients (Hollon and Beck 1994, Lyons and Woods 1991, McGovern and Silverman 1984, Silverman et al. 1992). Consequently, they now are widely employed throughout the Western world. Their use of multimodal methods of therapy has also encouraged the recent movement toward integration in psychotherapy and will most probably continue to do so in the future. It looks likely that rational emotive behavior therapy (REBT) and cognitive behavior therapy (CBT) will continue to thrive in the twenty-first century.

Behavior Therapy: Psychiatric Aspects

Behavior Therapy refers to a range of treatments and techniques which are used to change an individual's maladaptive responses to specific situations. A useful definition is provided by Meyer and Chesser (1970): 'Behaviour therapy aims to modify current symptoms and focuses attention on their behavioural manifestations in terms of observable responses. The techniques used are based on a variety of learning principles. Although behaviour therapists adopt a developmental approach to the genesis of symptoms, they do not think it is always necessary to unravel their origin and subsequent development.'

In psychiatric practice, behavior therapy has been used and demonstrated to be useful in the treatment of anxiety disorders, obsessive-compulsive disorders, habit disorders, and in the modification of challenging or antisocial behaviors. Cognitive Therapy, which examines an individual's thinking patterns and aims to help the person to alter any maladaptive thoughts, can often be used effectively in conjunction with Behavior Therapy. Combination treatment has been shown to be effective in depression, panic, generalized anxiety, posttraumatic stress, and a variety of other psychiatric conditions.

Behavior Therapy works on the premise that, in psychiatric practice, maladaptive behaviors cause and exacerbate psychological distress. Such behaviors can be replaced or unlearned. Although the behaviors may be problematic and result in distress to an individual, initially they are rewarded by a consequence of the behavior. This reward or reinforcement of the behavior strengthens the link between the specific situation or stimulus and the resultant undesirable behavior. This is through Classical Conditioning. Behavior Therapy techniques alter the behavior and the reinforcing feedback of its consequences.

1. History of Behavior Therapy

Although a range of ancient and historical documents can be found which describe treatments of both children and adults with techniques which would now be described as Behavior Therapy, the treatment of anxiety disorders and neuroses was with analytical psychotherapy at the early part of the twentieth century. The prevailing view in psychiatric practice was that such disorders were due to unconscious conflicts which could take years of psychoanalysis to resolve. One of the earliest challenges to this belief was the now famous experiment of Watson and Rayner on Little Albert (Watson and Rayner 1920). Little Albert was a young child who had shown no fear of animals. In their experiment, Watson and Rayner placed the child in a room with a white rat. Any approach of the child towards the rat resulted in a loud aversive noise being made by the researchers. Thus, through this experiment in classical conditioning, the researchers developed a fear of white rats which subsequently generalized to other furry objects and animals in a matter of a few hours. The experimenters then hoped to reverse this experimentally-induced phobia by offering rewards to the boy while in the presence of a rat. Not surprisingly, however, Albert was discharged from hospital before this further research was completed.

A few years later, Jones (1924) tried reinforcement techniques in children with pre-existing phobias. She used food with hungry children and brought the feared object into increasing proximity with the child as it ate. Any fear-response caused her to move the object further away until the child started eating again. This was repeated until the child was happy in close proximity to the feared object.

Despite these clear examples of behavioral principals, behavior therapy was not actually defined as a discipline until the 1950s when Joseph Wolpe was popularizing treatment using systematic desensitization for phobic disorder in the USA. Systematic desensitization is based on the observation that an individual cannot be relaxed and also experience anxiety. The fear response to a phobic stimulus could thus be reduced and eventually extinguished by teaching the patient deep muscular relaxation. A strict hierarchy of fear-provoking stimuli was obtained from the patient and initially, after the patient had induced relaxation, they were asked to imagine the least fear-inducing of these situations. Once this was achieved the patient was asked to move a step at a time with increasingly threatening images. If the patient became anxious the therapist intervened and reintroduced relaxation before asking the patient to imagine a stimulus lower on the hierarchy of fear (Wolpe 1958). Since that time there have been a large number of studies of systematic desensitization. For example, Gelder et al. (1967) compared systematic desensitization with individual psychotherapy and with group psychotherapy in patients with phobic disorders. Systematic desensitization was consistently better than either form of psychotherapy. Although systematic desensitization was shown to be effective in the treatment of specific phobic disorders, it involved a long and laborious process of extremely gradual exposure for both the therapist and the patient.

A more rapid method was found with real life exposure methods which were originally called flooding (Stampfl and Levis 1967). Real-life exposure involves asking the patient to face up to the feared stimulus and without using relaxation or distraction. Even though this causes anxiety, if the patient remains in contact with the stimulus for a length of sufficient time (approximately 1 h), then the anxiety does reduce. Because of the difficulty in encouraging a frightened individual to face up to their worst fear, this is also performed in a hierarchical manner, starting with a situation which causes moderate anxiety before progressing. The hierarchy does not have to be as structured as with systematic desensitization and it was soon found to be effective after only a few hours of therapist time and had the added benefit of teaching the patient how to cope with anxiety which could be used in other anxiety-provoking situations. Real-life exposure methods were pioneered with specific phobias (Watson and Marks 1971) and caused a sensation when first reported. A variety of specific phobics were treated with rapid exposure in real life with great success. Fears by some therapists that anxious patients would be made worse and other symptoms would appear proved unfounded. The great success of these techniques was also criticized because they had not yet been used for the commonest phobia, agoraphobia.

Studies of exposure treatment for agoraphobia were then carried out, for example, Mathews et al. 1976, and the treatment was found to be effective. From 1970 to 1980 exposure treatments for agoraphobia were refined and crucial treatment factors were isolated. For example, the importance of the duration of exposure in treatment of agoraphobia was discovered (Stern and Marks 1973). Real-life exposure was found to be more effective than even very rapid exposure performed in the patient's imagination (Emmelkamp and Wessels 1975).

Over the next few years refinement of psychological treatment factors in agoraphobia continued. It was thought that if treatment could be done in groups it would be more cost effective. Hand et al. (1974) compared 'structured' with 'unstructured' groups, and found progress was greater in the structured group. Only the structured group continued to improve after treatment and to 3-month follow-up. Group exposure required less professional time and so was an advance in treatment. However, in practice it is often difficult to get a group of similar phobic patients together at the same time and the progress of the group as a whole is linked to the speed of progress of it's slowest member.

More recent work in the treatment of anxiety disorders has been in the development of self-exposure where the patient is given detailed instructions about how to perform exposure treatment but the therapist is not present during the exposure therapy. Another development which led to more effective and rapid therapy was the development of home-based treatment where the therapist would carry out the treatment in the patient's home which was subsequently continued by the patient in self-exposure. Marks et al. (1983) showed that brief therapist-aided exposure was a useful adjunct to self-exposure homework instructions, but even self-exposure homework instruction alone is a potent treatment for agoraphobia. Experience to date supports the use of this approach, although involvement of family members in the treatment wherever possible is thought to be beneficial.

The treatment of obsessive-compulsive disorder was developed at the same time as that for agoraphobia. Marks et al. (1975) reported the results over 2 years of 20 patients with chronic obsessive rituals treated by real life exposure. This treatment was as effective for obsessive rituals as it was for agoraphobia. The only difference between the real life exposure used in obsessive-compulsive disorder and phobic disorder is that with the former the patient has to be asked not to perform the anxiety-reducing rituals or compulsions which are a feature of this disorder. These anxiety-

reducing behaviours would otherwise interfere with the natural habituation to anxiety which occurs with prolonged exposure. Although in patients with rituals it was often combined with modeling and response-prevention.

What is at first surprising is that a similar treatment for obsessive-compulsive disorder had been described in the early 1900s. A French psychiatrist, Janet treated a patient with obsessional rituals (1903) and the principles of his treatment are clearly described in the following quotation:

> The person who assists in the performance of these actions, has a very complicated part to play. He must aid in the performance of the action without actually doing it himself, although the latter would be very much easier; and he must do his utmost to conceal his own contribution to the action, for it is essential that the patient should feel he does the action himself and does it unaided. The guide has chosen the action, has overcome the patient's hesitations, and has taken the responsibility … by continual repetition to perform the action; by words of encouragement at every sign of success however insignificant, for encouragement will make the patient realise these little successes, and will stimulate him with the hope aroused by glimpses of greater successes in the future.

The principles outlined by Pierre Janet were refined in a series of studies over the years (Levy and Meyer 1971, Rachman et al. 1971). Until the present time when a truly effective therapy can now be offered to most patients with compulsive rituals.

As well as a treatment for phobic and obsessive-compulsive disorders, behavior therapy has been applied to range of other complaints as varied as schizophrenia and marital/sexual dysfunction. The use of behavior therapy in schizophrenia and learning disability started when Ayllon and Azrin (1968) applied operant reinforcement principles to produce changes in patients with chronic schizophrenia. Nowadays behavior therapy is used to counteract the secondary handicaps of schizophrenia and to assist in patients discharged from hospital to the community.

In 1970 the pioneering work of Masters and Johnson (Masters and Johnson 1966, 1970) led to a range of behavioral techniques for sexual dysfunction.

There are a multitude of other conditions where behavior therapy has been demonstrated to be effective but many of these are outside the realms of this short article. There is a trend now for behavior therapy to be used for an increasing range of disorders, and much progress has been made since the first tentative exposure techniques.

2. *Modern Behavior Therapy*

For the purposes of this article this section will be divided into three main sections. The first will deal with the current use and application of exposure methods of treatment which are used mostly in the anxiety disorders. The second will examine the methods used to teach alternative skills where these have not been learned. Skill training is used in social skills training, treatment of sexual dysfunction, marital therapy, and problem-solving. Third, there will be a description of the use of reinforcement techniques. These techniques are used in learning disability, with chronic patients, and sometimes in child psychiatry.

2.1 *Exposure Treatments*

Exposure treatment has been shown to be effective in 66 percent of agoraphobics (Mathews et al. 1981), between 75 and 85 percent of obsessive-compulsives (Foa and Goldstein 1978, Rachman et al. 1979), and highly effective (Marks 1981) in a mixture of specific and social phobics.

There is often fear of using exposure treatment outside specialist centres. This appears to arise from erroneous views about its applicability, its success rates, the time commitment required by the therapist and also fear of the unknown. In fact, graduated exposure is a remarkably quick and cost-efficient treatment which can be easily applied in many general practice and hospital settings (Marks 1981, 1986, Stern and Drummond 1991). Although some basic training is required, this can easily be obtained by reading about clinical techniques (Hawton et al. 1989, Stern and Drummond 1991) and by obtaining supervision from a trained behavioral psychotherapist.

The most effective exposure has been shown to be:

(a) Prolonged rather than of short duration (Stern and Marks 1973).

(b) In real life rather than in fantasy (Emmelkamp and Wessels 1975).

(c) Regularly practiced with self-exposure homework tasks (McDonald et al. 1978).

One of the concerns about exposure treatment has been that it requires considerable professional input to accompany an anxious patient into fear-provoking situations. Fortunately, it has been demonstrated that instruction in self-exposure techniques can be all that is required for many patients with phobic anxiety and obsessive-compulsive disorder (Ghosh et al. 1988, Marks et al. 1988). The efficacy of self-exposure has led to the development of a number of self-help manuals. However, few patients can complete a treatment program successfully without some professional guidance. The patient needs to be seen initially for education about anxiety and its treatment and for help in devising treatment targets. Subsequent meetings are required to monitor progress, give encouragement and advise on any difficulties which may arise (Ghosh et al. 1988).

Exposure is the cornerstone of treatment of obsessive-compulsive disorder when it is combined with response-prevention. Response-prevention means encouraging the patient not to perform rituals and compulsions. Rituals are overt behaviors or internal

thought patterns which are used to counteract the obsessional fears. Rituals usually can be prevented or reduced substantially by demonstrating to the patient how they interfere with exposure. In exposure treatment, the aim is to produce prolonged periods of contact with the feared situation until the anxiety reduces (habituation). Compulsions or rituals reduce the anxiety and this serves to reinforce the ritual. However, the reduction in anxiety produced by a ritual tends to be small and the effect temporary. In effect rituals prevent therapeutic exposure and instead increase the tendency to ritualize further.

Exposure methods have also been used to treat a variety of other anxiety based disorders to good effect including posttraumatic stress disorder (Keane et al. 1989, Foa et al. 1991) and hypochondriasis (Warwick et al. 1996).

2.2 Teaching New Skills

In a variety of situations some people do not have the appropriate skills to meet the challenges of the environment in which they find themselves. This is, of course, true to some extent for all of us. However with some individuals, specific training can resolve a crisis and remove psychological distress.

Skill training involves the therapist in detailed analysis with the patient to establish what skills are at fault and what effect this defect has. This is followed by sensitive discussion about how the skills could be improved. Frequently the therapist will then demonstrate the skill to be achieved. With a complex skill or where the patient has a very low level of skill in the area, the skill may have to be broken down into a series of stages with the stages being presented one at a time. The patient is then asked to rehearse the new skill and feedback is given by the therapist. It is important that this feedback is encouraging and highlights the positive aspects of the performance as well as making suggestions about any factors which could be improved. In some cases, video or audio tape can also be used to give additional feedback to the patient about progress. The patient is then asked to practice the skill. This continues until the patient is able to incorporate the new skill in everyday life.

These techniques frequently are used in social skills training which is often applied to groups. In couple therapy, they can be used in behavioral exchange therapy to encourage the couple to do positive things for each other using a 'give to get' principle. They may also be used to encourage positive communication between couples. Similar skills are also used in sexual therapy which is based partly on the exposure principle in anxious individuals and also aims to improve basic sexual knowledge and skill. In the case of sexual therapy, the therapist does not demonstrate the skill but describes it using diagrams and the couple are asked to practice at home. In problem-solving techniques, which can be used as an adjunct to other therapies for many patients, the individual is taught how to describe a problem and to weigh up the pros and cons of a decision. A discussion of what is an appropriate response which will produce the best result then follows. This is followed by rehearsal of the required skills.

Due to the diverse nature of the skill-training techniques, there is limited research on outcome. However, studies on sexual skills training have shown it to be an effective treatment for a whole range of sexual problems (Masters and Johnson 1970, Bancroft 1983) and social skills training has variable results depending on the patient mix but many of these are favorable (e.g., Stravynski et al. 1982).

2.3 Applying Operant Techniques to Chronic Problems

In patients with chronic behavior problems, treatment techniques based on operant conditioning are often used. Operant methods can often be more difficult to apply due to confusion about what may be reinforcing or rewarding to a patient. Premack's (1959) principle addresses this finding by observing that high-frequency preferred activity can be used to reinforce lower-frequency, nonpreferred activity. In other words, if a teenage girl spends most of her time surfing the net, this high-frequency preferred activity could be used to reinforce the lower frequency nonpreferred activity of tidying her bedroom.

The role of this type of treatment aimed at reducing undesired behaviors and increasing socially acceptable behavior has increased in the past few years with the increasing closure of many of the older psychiatric institutions and a move towards community care. Discharge to the community or even admission in a psychiatric unit of a district general hospital often means that bizarre or socially unacceptable behavior is not tolerated as well as in the older institutions which were often segregated from the rest of society.

By far the most commonly applied form of reinforcement to be used in positive reinforcement. Negative reinforcement or even punishment are hardly ever used and usually only in dangerous or life-threatening situations due to the obvious ethical dilemmas presented by such methods. Ethical problems may also arise with positive reinforcement, particularly if essential items such as food are used as reinforcers and the patient has not earned a meal that day.

2.3.1 Reinforcers which increase desirable behaviors

Positive reinforcers

(a) Social approval, for example, therapist's approval in phobic who has complied with exposure task.

(b) Higher frequency preferred activities.

(c) Feedback reinforcement, for example, social skills group.

(d) Food reinforcers.

(e) Tokens which are awarded for certain behaviors and can be used by the patient in exchange for a range of rewards.

Negative reinforcement

This means the removal of an aversive event after a specific response is obtained. There are clear ethical problems with such methods and they are rarely used in clinical practice. One exception is when they are used with a consenting adult and applied covertly. For example, a man with illegal sexual preference could be trained to have aversive images following arousing deviant images. He is also taught that he can gain relief from these aversive experiences by switching to neutral thoughts.

2.3.2 Reinforcers which reduce undesirable behaviors

Punishment

(a) Time out, that is, removal of the individual from reinforcing environment for up to 3 minutes.

(b) Overcorrection, for example a patient smashes his cup to the floor, he is asked not only to clear up the mess but then to wash the entire ward floor.

(c) Positive punishment, for example, child puts its finger towards an electric socket and receives a sharp slap on the hand.

Response cost

(a) Penalty involving some time and effort in response to certain behaviors.

(b) A positive reinforcer is removed if certain nondesired activities are indulged in.

3. The Future of Behavior Therapy

Although pure behavior therapy in the form of exposure remains the psychological treatment of choice for uncomplicated phobias and obsessive-compulsive disorder, in many clinical situations it is often combined with cognitive techniques. Many recent studies in a range of conditions as varied as schizophrenia (Tarrier et al. 1993, Kingdon et al. 1994) and hypochondriasis (Warwick et al. 1996), describe such cognitive behavioral treatment. In the future further work needs to identify the specific therapeutic factors of these treatment packages.

The treatment of anxiety disorders has developed rapidly since the 1980s. Anxiety can be treated using behavioral or drug treatments. Unfortunately, there has been a tendency for workers in this field to polarize and confine themselves to their own approach. Both forms of treatment do have difficulties as well as advantages. Similarly criticism can be made of much of the research in this area which has tended to show advantages of drug treatment by those interested psychopharmacology and advantages in behavioral-cognitive therapy by those interested in psychological approaches. This is partly because behavioral-cognitive therapists tend to be more interested in behavioral and cognitive changes, whereas biological therapists are more interested in affective change. Much of the existing research in this area suffers from underpowered studies and poor methodology (Fineberg and Drummond 1995). Despite this, behavior therapy frequently is used in patients who are taking drugs (e.g., Drummond 1993). Future research needs to be done into the effect of combining these two approaches.

Overall, behavior therapy is a proven therapy of known efficacy for a variety of psychiatric and psychological symptoms. It can be usefully combined with cognitive techniques to improve the patient's compliance or to improve the outcome. Drugs may also be used in conjunction with behavior therapy but research in this area has shown conflicting results. Future research needs to examine each aspect of a treatment package and discover which combinations are the most beneficial to patients.

L. M. Drummond

Behavior Therapy: Psychological Perspectives

A new way of treating psychopathology, called behavior therapy, emerged in the 1950s. In its initial form this therapy was restricted to procedures based on classical and operant conditioning. Therapists who employ operant conditioning as means of treatment often prefer the term 'behavior modification.' Over the years many writers have broadened the scope of behavior therapy beyond conditioning to include any attempt to change abnormal behavior, thoughts, and feelings by applying the research methods used and the discoveries made by experimental psychologists in their study of both normal and abnormal behavior.

Over a number of years people in the clinical field —among them Joseph Wolpe and Arnold Lazarus in South Africa, H. J. Eysenck in Great Britain and B. F. Skinner, Albert Bandura, Albert Ellis, and Aaron T. Beck in the United States—began to formulate a new set of assumptions about dealing with clinical problems. Although there are areas of overlap, it is helpful to distinguish four theoretical approaches in behavior therapy—counterconditioning and exposure, operant conditioning, modeling, and cognitive behavior therapy.

1. Counterconditioning and Exposure

Counterconditioning is relearning achieved by eliciting a new response in the presence of a particular stimulus. A response (R_1) to a given stimulus (S) can be eliminated by eliciting a new response (R_2) in the presence of that stimulus. For example, in an early and now famous demonstration in 1924, Mary Cover Jones successfully treated a young boy's fear of rabbits by feeding him in the presence of a rabbit. The animal was at first kept several feet away and then gradually moved closer on successive occasions. In this way the fear (R_1) produced by the rabbit (S) was replaced by the stronger positive feelings evoked by eating (R_2).

The counterconditioning principle, deriving from earlier work by Pavlov and Guthrie, forms the foundation of an important behavior therapy technique, systematic desensitization, developed by Joseph Wolpe (1958). A person who suffers from anxiety works with the therapist to compile a list of feared situations, starting with those that arouse minimal anxiety and progressing to those that are the most frightening. Over a number of sessions and sometimes with the help of taped at-home practice, the person is also taught to relax deeply. Step-by-step, while relaxed, the person imagines the graded series of anxiety-provoking situations. The relaxation tends to inhibit any anxiety that might otherwise be elicited by the imagined scenes. The fearful person becomes able to tolerate increasingly more difficult imagined situations as he or she climbs the hierarchy over a number of therapy sessions. Reduction of fears in real life usually follows.

Wolpe hypothesized that counterconditioning underlies the efficacy of desensitization: a state or response antagonistic to anxiety is substituted for anxiety as the person is exposed gradually to stronger and stronger doses of what he or she fears. Some experiments (Davison 1968) suggest that counterconditioning accounts for the efficacy of the technique, but a number of other explanations are possible (see *Social Cognitive Theory and Clinical Psychology*). Most contemporary theorists attach importance to exposure *per se* to what the person fears; relaxation is then considered a useful strategy to encourage a frightened individual to confront what he or she fears, rather than a response that is substituted for the maladaptive anxiety. Whatever its mechanism of action, systematic desensitization and other exposure techniques have been shown to be effective in reducing a wide variety of fears, from specific phobias like fear of snakes and closed spaces to more complex fears such as social anxiety and agoraphobia (see *Psychological Treatments, Empirically Supported*).

Another type of counterconditioning, aversive conditioning, also played an important historical role in the development of behavior therapy. In aversive conditioning, a stimulus attractive to the patient is paired with an unpleasant event, such as a drug that produces nausea, in the hope of endowing it with negative properties. For example, a problem drinker who wishes to stop drinking might be asked to smell alcohol while he or she is being made nauseous by a drug. Aversive techniques have been employed to reduce smoking and drug use, and the socially inappropriate attraction that objects have for some people, such as the sexual arousal that children produce in pedophiles.

Aversion therapy has been controversial for ethical reasons. A great outcry has been raised about inflicting pain and discomfort on people, even when they ask for it. For example, in its early days, aversion therapy was used to try to change the sexual orientation of homosexuals. But in the late 1960s, gay liberation organizations began to accuse behavior therapists of impeding the acceptance of homosexuality as a legitimate lifestyle. Currently, aversion therapy is rarely used as the only treatment for a particular problem.

2. Operant Conditioning

Several behavioral procedures derive from operant conditioning, an analysis of overt behavior in terms of the conditions under which it occurs and the consequences that it elicits from the environment (see *Autonomic Classical and Operant Conditioning*; *Behavior Analysis, Applied*). Much of this work has been done with children, perhaps because a great deal of their behavior is subject to the oversight and control of others. Treatment typically consists of altering the consequences of problem behavior. For example, if it was established that the problem was motivated by attention seeking, the treatment might be to ignore it. Alternatively, the undesired behavior could be followed by time-out, a procedure wherein the person is banished for a period of time to a dreary location where positive reinforcers are not available.

Making positive reinforcers contingent on behavior is used to increase the frequency of desirable behavior. For example, a socially withdrawn child could be reinforced for playing with others. Similarly, positive reinforcement has been used to help children with autistic disorder develop language, to remediate learning disabilities, and to help children with mental retardation develop necessary living skills. Other problems treated with these methods include bedwetting, aggression, hyperactivity, disruptive classroom behavior, and tantrums (Kazdin and Weisz 1998).

2.1 The Token Economy

An early example of work within the operant tradition is the token economy, a system in which tokens (such as poker chips or stickers) are given for desired

behavior and can later be exchanged for pleasing items and activities. Ayllon and Azrin (1968) set aside an entire ward of a mental hospital for a series of experiments in which rewards were provided for activities such as making beds and combing hair, and were not given when behavior was withdrawn or bizarre. The patients, who averaged 16 years of hospitalization, were systematically rewarded for their ward work and self-care with plastic tokens that could later be exchanged for special privileges, such as listening to records, going to the movies, renting a private room, or enjoying extra visits to the canteen. The life of each patient was as much as possible controlled by this regime.

The rules of a token economy—the medium of exchange, the chores and self-care rewarded and by what number of tokens, the items and privileges that can be purchased and for how many tokens—are carefully established and usually posted so that the patients can understand what the payoff is for behaving in a particular way. These regimes have demonstrated how even markedly regressed adult hospital patients can be significantly helped to achieve more normal functioning by systematic manipulation of reinforcement contingencies. The role of cognitive factors, discussed below, was not formally acknowledged in the early operant conditioning work.

Token economy work demonstrates the positive impact of directing staff attention to rewarding self-care and recreational behaviors, and on the acquisition of social skills, in contrast to the more typical situation in which patients get attention more when they are acting maladaptively and sometimes dangerously. The beneficial effects of carefully constructed token economies have been shown to be markedly superior to routine hospital management, including antipsychotic drugs (Paul et al. 1997).

3. *Modeling*

Modeling has also been used in behavior therapy (see *Social Cognitive Theory and Clinical Psychology*). For example, people can reduce their unrealistic fears by watching both live and filmed encounters in which others gradually approach and successfully confront the things they are afraid of. Modeling is also part of the treatment for children with autistic disorder, helping them develop complex skills. Films depicting actors having pleasurable sex have been used to help sexually inhibited people overcome their discomfort with sexuality and learn sexual techniques (see *Sex Therapy, Clinical Psychology of*).

In an analogous fashion, some behavior therapists use role-playing in the consulting room. Particularly with patients who lack social skills, therapists demonstrate patterns of behaving that might prove more effective than those in which the patients usually engage and then have the patients practice them. In his behavior rehearsal procedures, Lazarus (2000) demonstrates exemplary ways of handling a situation and then encourages patients to imitate them during the therapy session. For example, a student who does not know how to ask a professor for an extension on a term paper might watch the therapist portray a potentially effective way of making the request. The clinician would then help the student practice the new skill. Similar procedures have helped patients with schizophrenia acquire social skills to allow them to deal more effectively with others, and with nonpsychotic patients to encourage greater assertiveness.

4. *Cognitive Behavior Therapy*
