There is nothing either good or bad, but thinking makes it so.

(*Hamlet*, Act II, Scene 2)

The mind is its own place, and in itself
Can make a Heav'n of Hell, a Hell of Heav'n.

(*Paradise Lost*, line 247)

Behavior therapy initially eschewed any appeal to cognitive processes (Wolpe 1958), perhaps as part of efforts to distinguish it from insight-oriented therapies like psychoanalysis and its many variations, as well as humanistic and existential approaches. But it became increasingly apparent in the mid to late 1960s that an empirically-based understanding of therapeutic change would be inadequate without formal inclusion of cognitive variables (Bandura 1969, Davison 1966, London 1964) (see *Social Cognitive Theory and Clinical Psychology*).

One of the ways cognition entered into behavior therapy was via research on modeling. The question was how the observation of a model is translated into changes in overt behavior. In his original writings on modeling, Bandura asserted that an observer could somehow learn new behavior by watching others. Given the emphasis that much of experimental psychology places on learning through doing, this attention to learning without doing was important. But it did not delineate the processes that could be operating. A moment's reflection on the typical modeling experiment suggests the direction that theory and research have taken.

The observer, a child, sits in a chair and watches a film of another child making a number of movements, such as hitting a large, inflated plastic doll in a highly stereotyped manner, and hears the child in the film uttering peculiar sounds. An hour later the youngster is given the opportunity to imitate what was earlier seen and heard. The child is able to do so, as common sense and folk wisdom would predict. How can we understand what happened? Since the child did not do anything of interest in any motoric way while watching the film, except perhaps fidget in the chair, it would not

be fruitful to look at overt behavior for a clue. Obviously, the child's cognitive processes were engaged, including the ability to remember later on what had happened. Data such as these led some behavioral researchers and clinicians to include cognitive variables in their analyses of psychopathology and therapy.

4.1 Approaches to Cognitive Behavior Therapy

Cognitive behavior therapy (CBT) applies theory and research on cognitive processes to alter cognition in the interests of effecting favorable change in emotions and behavior (see *Cognitive Theory: ACT*). CBT has become a blend of the cognitive and behavioral perspectives. Cognitive behavior therapists pay attention to private events—thoughts, perceptions, judgments, self-statements, and even tacit (unconscious) assumptions—and have studied and manipulated these processes in their attempts to understand and modify overt and covert disturbed behavior. But they do not neglect the behavioral factors reviewed above that influence emotion, cognition, and overt behavior (Bandura 1969).

4.1.1 Beck's cognitive therapy. The psychiatrist Aaron Beck is one of the leading cognitive behavior therapists. He developed a cognitive therapy for depression based on the idea that depressed mood is caused by distortions in the way people perceive life experiences (Beck 1976). For example, a depressed person may focus exclusively on negative happenings and ignore positive ones. Beck's therapy aims to persuade patients to change their opinions of themselves and the way in which they interpret life events. For example, when a depressed patient expresses feelings that nothing ever goes right, the therapist uses Socratic strategies to help the person identify counter-examples. The general goal of Beck's therapy is to provide patients with experiences, both inside and outside the consulting room, that will alter their negative schemas, their general beliefs about themselves and their environment. This therapy has shown its value, particularly in alleviating depression (DeRubeis et al. 1999), but elements of Beck's approach can be found as well in effective cognitive–behavioral interventions for such problems as bulimia nervosa, panic disorder (see especially Barlow et al. 2000), social phobia, and generalized anxiety disorder (see *Clinical Psychology: Manual-based Treatment*; *Cognitive Therapy*; *Psychological Treatments, Empirically Supported*).

4.1.2 Ellis's rational–emotive behavior therapy. Albert Ellis is another leading cognitive behavior therapist (see *Behavior Psychotherapy: Rational and Emotive*). His principal thesis is that sustained emotional reactions are caused by internal sentences that people repeat to themselves and that these self-statements reflect sometimes unspoken assumptions—irrational beliefs—about what is necessary to lead a meaningful life. In Ellis's rational–emotive behavior therapy (REBT) (Ellis 1962), the aim is to eliminate self-defeating beliefs through a rational examination of them. Anxious persons, for example, may create their own problems by making unrealistic demands on themselves or others, such as, 'I must win love from everyone.' Ellis proposed that people interpret what is happening around them, that sometimes these interpretations can cause emotional turmoil, and that a therapist's attention should be focused on these beliefs rather than on historical causes or, indeed, on overt behavior.

Ellis used to list a number of irrational beliefs that people can harbor, such as the assumption that they must be thoroughly competent in everything they do. More recently, he has shifted from a cataloguing of specific beliefs to the more general concept of 'demandingness,' that is, the musts or shoulds that people impose on themselves and on others. Thus, instead of wanting something to be a certain way, feeling disappointed, and then perhaps engaging in some behavior that might bring about the desired outcome, the person demands that it be so. It is this unrealistic, unproductive demand, Ellis hypothesizes, that creates the kind of emotional distress and behavioral dysfunction that bring people to therapists, and that should be altered in order to create a more realistic, less absolutistic approach to life's demands. Research supports the value of REBT in alleviating a wide range of anxiety-related problems, including interpersonal performance anxiety, test anxiety, anger, and depression; and it may also be of use in a preventive way by teaching children that their self-worth is not utterly dependent on their endeavors.

4.1.3 Behavioral medicine. A wide range of cognitive–behavioral strategies have been applied with success in a field called 'behavioral medicine,' defined as the study and application of empirically supported techniques for the prevention and amelioration of physical problems (see *Behavioral Medicine*). For example, relaxation training has been found effective in reducing blood pressure in borderline hypertension, possibly by lessening the anger that patients experience when frustrated or provoked (see *Hypertension: Psychosocial Aspects*). Cognitive and behavioral interventions are useful also in encouraging people, even older adults, to alter their lifestyle in ways that contribute to better health and even to help cancer patients cope with their illnesses and with the pain associated with the treatment of them. There is ever-increasing appreciation of the importance of

psychological factors in encouraging people to adopt healthier lifestyles, adhere to sometimes difficult treatment regimens, and to cope with negative emotions that, if unchecked, can exacerbate the course of a physical illness as well as affect the success of a medical intervention (see *Self-efficacy and Health*).

4.2 Conceptual Issues in Cognitive Behavior Therapy

Some criticisms of CBT should be noted. The concepts on which it is based (e.g., schema) are somewhat slippery and not always well-defined. Furthermore, cognitive explanations of psychopathology do not always explain much. For example, that a depressed person has a negative schema tells us that the person has a pessimistic outlook on things. But such a pattern of thinking is actually part of the diagnosis of depression. What is distinctive in the cognitive paradigm is that the thoughts are given casual status; that is, the thoughts are regarded as causing the other features of the disorder, such as profound sadness. Left unanswered is the question of where the negative schema came from in the first place, and to what extent it creates negative emotion and maladaptive behavior rather than being only a correlate of them.

Is the cognitive point of view basically different and separate from the behavioral paradigm? Much of the preceding discussion suggests that it is. But the growing field of cognitive behavior therapy gives one pause, for its workers study the complex interplay of beliefs, expectations, perceptions, and attitudes on the one hand, and overt behavior on the other. For example, Albert Bandura (1977), a leading advocate of the cognitive viewpoint, argues that different therapies produce improvement by increasing people's sense of self-efficacy, a belief that they can achieve desired goals. But, at the same time, he argues that changing behavior through behavioral techniques is the most powerful way to enhance self-efficacy.

Therapists such as Ellis and Beck emphasize direct alteration of cognitions through argument, persuasion, Socratic dialogue, and the like to bring about improvements in emotion and behavior. Complicating matters still further, Ellis, Beck, and their followers also place considerable importance on homework assignments that require clients to behave in ways in which they have been unable to behave because they are hindered by negative thoughts (see *Cognitive Therapy*). Indeed, one study failed to find added benefit from the cognitive components of Beck's cognitive therapy (CT) as compared with the behavioral components alone (Jacobson et al. 1996). Ellis even changed the label for his approach from rational–emotive therapy to rational–emotive behavior therapy in order to highlight the importance of overt behavior. Therapists identified with cognitive behavior therapy work at both the cognitive and behavioral levels, and most of those who use cognitive concepts and try to change beliefs with verbal means also use behavioral procedures to alter behavior directly.

This issue is reflected in the terminology used to refer to people such as Beck and Ellis. Are they cognitive therapists or cognitive behavior therapists? The latter term is preferred by behavior therapists because it denotes both that the therapist regards cognitions as major determinants of emotion and behavior and that he or she maintains the focus on overt behavior that has always characterized behavior therapy. Nonetheless, Beck, even though he assigns many behavioral tasks as part of his therapy, is usually referred to as the founder of cognitive therapy (CT), and Ellis's rational–emotive therapy (RET) used to be spoken of as something separate from behavior therapy.

5. Concluding Comment

Towards the end of the twentieth century, the increasing role of managed care in the United States—entering the picture much later than in other Western countries—made mental health professionals more aware of the need to employ the best-validated and most efficient interventions available. This greater level of accountability is having a revolutionary effect on who gets treated, for how long, and at what cost. Not all patients are helped with behavioral and cognitive-behavioral procedures, and the data are not fully available as to what kinds of problems respond better to such approaches than to others (such as psychoanalytically oriented, humanistic/existential, or drug and other somatic therapies). An advantage of the approaches reviewed in this article is that they possess a high degree of accountability: procedures are clearly spelled out, links to the science of behavior change are a defining characteristic, and evaluations of outcome are routine. These features of behavioral and cognitive therapies would seem to bode well for the continuing development of more and better interventions, to the benefit both of the science and the profession as well as the communities that are served.

Behavior Therapy with Children

Child behavior therapy, including behavior modification and cognitive therapy, consists of a group of diverse but related scientifically-based approaches to the assessment and treatment of children experiencing behavioral and emotional difficulties. Although contemporary behavior therapy with children is characterized by a plurality of viewpoints, techniques, and theoretical rationales, a distillation of these differing perspectives reveals several common features that define the essence of child behavior therapy. These features include '(1) principles of behavioral psychology, most notably principles of learning, (2) use of strategies or procedures that are methodologically sound and empirically validated, and (3) application of such principles and procedures to adjustment problems of children and adolescents' (Ollendick 1986). Presented here is an overview of the historical roots of child behavior therapy, an explication of key concepts underlying the approach, and examples of classic and contemporary uses of behavior therapy with children.

1. Historical Roots

The historical roots of child behavior therapy can be traced to the work of John B. Watson, a key figure in the rise of behaviorism in America during the early 1900s. Watson, who rejected the trends of the time emphasizing mentalistic causes of behavior, maintained that learning processes were the basis of all human behavior. In perhaps the first historical antecedent to modern behavior therapy, one of Watson's students, Mary Cover Jones, applied classical conditioning principles to alleviate a young boy's intense fear of rabbits, by rewarding an incompatible response to fear, and using successive approximations to introduce the rabbit (Jones 1924) (see *Classical Conditioning and Clinical Psychology*).

With the exception of a few isolated examples, such as the classic 'bell and pad' method of treating nocturnal enuresis (bedwetting) (Mowrer and Mowrer 1938), there was a lag of some 30 years before interest in behavioral approaches in the treatment of children re-emerged in psychology. This resurgence was precipitated in large part by discontent with psychoanalysis, the prevailing therapeutic model of the day. Institutional settings in which developmentally delayed children often resided provided the ideal, tightly controlled environments in which to evaluate emergent behavioral treatments. In most cases, early behavioral techniques were developed in animal laboratories by experimental psychologists with the objective of demonstrating the utility of applying specific learning principles to rather circumscribed child behavioral symptoms (Mash 1998).

During the 1960s, behavior therapy relied primarily upon operant conditioning procedures, the principles of which had been pioneered by B. F. Skinner in the 1940s (see *Operant Conditioning and Clinical Psychology*. These approaches were used successfully with developmentally delayed children in institutional settings. Lovaas and Simmons (1969), for example, were able dramatically to improve the behavior of autistic children by applying operant learning principles to manipulate the environmental antecedents and consequences of behavior. In the 1960s and 1970s, behavior therapy was extended to school settings where it was applied to classroom misbehavior. Through this work it was found that ignoring disruptive behavior, while reinforcing positive behavior through praise (or atten-

tion), although the opposite of what many teaching manuals suggested, was useful in reducing the inappropriate classroom behavior (Becker et al. 1967).

Yet, even as behavior modification techniques with children were meeting with initial success, the field was criticized for ignoring some crucial issues, such as whether improvements made in the treatment settings could be maintained across multiple situations over an extended period of time (Abidin 1975). By the middle 1970s, however, the field largely had responded to these shortcomings. Because behavioral changes in response to environmental contingencies tended to be short-lived, the field shifted in emphasis toward the teaching of adaptive behaviors, general problem-solving strategies, and coping skills that generalize more easily across settings. In the 1980s, the behavioral technique of 'time out,' which involves removing children from positively reinforcing situations for a specified period time, became widely used by parents and teachers alike in response to aggressive, destructive, and otherwise unmanageable child behaviors. The modeling of appropriate behavior was also shown to be very effective, and was applied to real world problems for children such as in the use of puppets to demonstrate coping strategies and appropriate behavior for children (Knell 1997).

2. *Principles of Learning and Behavior Change*

Behavior therapists generally hold that both normal and abnormal behavior emanates from the same principles of learning, derived from laboratory studies. These tenets have been extended and applied in a spectrum of strategies to aid in the modification problematic child behaviors. Three types of learning form the building blocks of these techniques and are central to the application of behavior therapy with children. Presented here are brief descriptions of the principles of classical conditioning, operant conditioning, and social learning.

2.1 *Classical Conditioning*

Many are familiar with the pioneering work of Russian scientist Ivan Pavlov (1849–1936) who conditioned dogs to salivate in response to the simple sound of a tone after repeatedly pairing the tone with the presentation of food. In an early example of classical conditioning with children, Watson and Rayner (1920) demonstrated that a fear response could be conditioned in a young boy by repeatedly pairing a loud noise with the presentation of a white rat, of which the child had no naturally occurring fear. After a number of pairings, the presentation of the rat alone became a conditioned stimulus, eliciting a startle response from the boy that had previously only occurred in the presence of the loud noise.

2.2 *Operant Conditioning*

In contrast to classical conditioning, which maintains that behaviors can be *elicited* by preceding conditioned stimuli, operant learning principles hold that behaviors are *emitted* from within, in response to the environmental stimuli that follow them. Operants themselves consist of actions that are performed on the environment that produce some consequence. Operant behaviors that bring about reinforcing environmental changes (i.e., if they provide some reward to the individual or eliminate an aversive stimuli) are likely to be repeated. In the absence of reinforcement, operants are weakened. Removing consequences (ignoring) can decrease or completely eliminate many annoying child behaviors such as whining.

B. F. Skinner, an experimental psychologist considered to be the primary proponent of operant learning theory, distinguished between two important learning processes: reinforcement (both positive and negative) and punishment. Positive reinforcement is the process by which a stimulus or event, occurring after a behavior, increases the future occurrence of a behavior. Negative reinforcement also results in an increase in the frequency of a behavior, but through a process of contingently removing an aversive stimulus following a behavior. Punishment refers to the introduction of an aversive stimulus, or removal of a positive one, following a response, resulting in a decrease in the future probability of that response. Skinner also observed that extinction occurs when the absence of any reinforcement results in a decrease or a reduction in response frequency.

2.3 *Social Learning*

In the 1960s, Albert Bandura defined the process of social learning, in which a learner observes and imitates the behavior of another (known as the model). In contrast to the radical behaviorism of Skinner, Bandura's social learning theory posited that cognitive expectations of reinforcement alone may motivate much of human behavior, resulting in action without the necessity of the actual experience of reinforcement (Bandura 1969) (see *Social Cognitive Theory and Clinical Psychology*). Thus, behavior is the product of a reciprocal interaction between the individual and environmental contingencies. Infants as young as 16 months are known to imitate their peers (Eckerman and Stein 1982), and by the time children reach kindergarten, they are experienced social learners. Modeling can increase negative behavior (e.g., fear of thunderstorms exhibited by parents) or positive responses (e.g., appropriate social skills).

3. *Diagnosis and Behavioral Assessment*

Historically, behavior therapists have eschewed traditional classification schemes used in mental health

diagnosis, maintaining that such systems demonstrate insufficient reliability and validity for many specific disorders to warrant widespread use. Consequently, behavior therapists have developed an alternative set of techniques, known as behavioral assessment strategies, as a means to gather information and precisely delineate behaviors to be targeted for change. These strategies are also used for the collection of data to measure the effectiveness of interventions both during and after treatment. Comprehensive behavioral assessments typically occur along multiple dimensions, which include investigations of children's observable behaviors, cognitive and emotional processes, physiological responses, and the various environmental influences impacting the child.

Three of the most common types of methods employed during behavioral assessments with children are interviews, behavior rating scales and checklists, and direct observation of variables of interest (Van Hasselt and Hersen 1993) (see *Behavioral Assessment*). Multiple informants are utilized, including the child, parents and other family members, teachers, and daycare providers. Interviews are useful in establishing rapport with the child and adults important to historical assessment and treatment, in gaining information about the presenting problems and their maintaining conditions, and in selecting target behaviors to address. Child self-report measures typically utilize a checklist or rating scale format to obtain information about the child's own behaviors, cognitions, and feelings. Parents and teachers may complete behavior checklists or rating scales to provide information about the nature and severity of a problem. Checklists or rating scales can be broad in scope, assessing global problem areas, or may be narrowly focused upon a specific problem behavior. Finally, direct observation of the child and/or family may be conducted by clinicians; frequently, a structured observational coding system is used.

4. *Contemporary Applications of Child Behavior Therapy*

Behavior therapy currently is utilized successfully to treat a variety of behavioral and emotional problems in children that arise in various settings and situations (e.g., in the home, at school, and as a result of medical conditions). Presented next are several examples of childhood problems that can be ameliorated through behavioral techniques. These include fears and phobias, attentional and hyperactivity problems, conduct problems, and various medically-related conditions. For each example, a brief explanation of the problem is provided, followed by a description of typical assessment techniques and discussion of common behavioral treatment approaches. This presentation is by no means a comprehensive catalogue of behavioral interventions; it merely illustrates prototypical applications of basic behavioral principles to the treatment of childhood disorders.

4.1 *School Phobia*

Fears and anxiety disorders are a common occurrence for many young children. However, when a fear of school is involved, the undesirable outcome may be refused attendance on the part of a child. Assessment of this problem involves the use of a child interview, self-report measures, and parent checklists to help distinguish between children whose school refusal stems from difficulty separating from parents, is secondary to conduct problems, or is simply a fearful reaction to school-related stimuli. A typical behavioral approach is to gradually shape children's behavior by rewarding him or her for attending school for progressively longer periods of time. Conversely, punishment in the form of removal of reinforcers and privileges for non-attendance may also be effective.

4.2 *Attentional and Hyperactivity Problems*

Attentional deficits and hyperactive behavior are often most evident in school settings, where children experiencing these difficulties have trouble staying on-task during classroom activities. Behavioral assessment of attention deficits and hyperactivity typically include the completion of parent and teacher rating scales, in combination with a structured interview and direct observation of children's classroom behaviors, plus tests of child attention in the presence of certain distractions. The use of operant conditioning procedures to manage children's behavior has been common in the treatment of attentional and impulse control problems. This procedure, known as contingency management, may include the use of positive reinforcement, in the form of tokens, to increase the frequency of appropriate classroom behaviors, such as working quietly, remaining seated, and paying attention to the teacher. Tokens which can be earned or lost (also known as response cost) in conjunction with social contingencies (e.g., teacher praise) and negative reprimands may be the most effective means of reducing off-task behavior (Rapport et al. 1982). Attention deficit disorders in children are often most effectively treated in combination with psychopharmacological intervention in the form of tranquilizers or more frequently, stimulants, such as Ritalin (Barkley et al. 1984).

4.3 *Oppositional and Defiant Behavior*

Oppositional and defiant behavior involves a collection of disruptive, noncompliant, and negativistic

behaviors that find a child at frequent odds with authority figures. The nature of these behaviors exceeds what would be expected from a 'typical' child at the same developmental stage. Oppositionality and defiance are assessed by means of interviews with the parents (with an emphasis on situational factors) and with the child, as well as behavior checklists completed by the child, parents, and teachers and observation in the typical 'oppositional' settings. Peer relation measures and measures of parental/family functioning may also be utilized. Parent training in effective child behavior management strategies typically is provided and involves provision of immediate, salient, and consistent consequences for appropriate and inappropriate behavior, an explicit rewards program, a proactive, nonemotional approach to misbehavior, and activities to improve the parent–child relationship. A structured didactic approach (e.g., Barkley 1997) or a 'coaching' model may be utilized (Hembree-Kigin and McNeil 1995). Also, reciprocity in negative family interactions is addressed, as families are taught to use effective problem-solving and communication skills.

4.4 Pediatric Medical Issues

Behavior therapy has also been applied to assist medically ill and injured children. In the medical arena, behavior therapists have developed a number of treatments to aid children in coping with the behavioral and emotional components of medical illness and its treatment. Behavioral interventions have targeted children with chronic medical conditions (e.g., asthma, arthritis, cancer) as well as terminal illnesses (e.g., AIDS, cystic fibrosis) and unintentional injuries. The conditions themselves, as well as the aversive treatment regimens they often entail, can negatively impact child and family functioning. Behavior therapists work with children to alleviate symptoms such as chronic pain, to adopt necessary self-care skills, and to increase compliance with prescribed treatments. The modeling of insulin injections for diabetic children, biofeedback techniques to control pain, and the use of relaxation training and distraction procedures to reduce distress during difficult diagnostic procedures, are examples of effective behavioral interventions.

5. New Directions in Child Behavior Therapy

5.1 Prevention

The traditional delivery model utilized by behavior therapists has focused upon the treatment of children with pre-existing behavioral or emotional difficulties. In recent years, however, behavior therapists have expanded the scope of their work by applying behavioral principles to address broader social problems through systemic-level preventive interventions. The concept of intervening with groups of high-risk individuals prior to the onset of a problem is particularly compelling when applied to children who can potentially be spared years of psychological distress through these efforts.

Preventive interventions have targeted a number of problem areas at various points along the developmental continuum. At the earliest stage, prenatal interventions have targeted children indirectly by teaching high-risk mothers about proper care and protection of the developing fetus, in order to prevent prematurity, low birth weight, and specific disabilities and disorders in newborns. In the first years of life, attempts have been made to spare young children from the pervasive harm resulting from child abuse and neglect by identifying those at risk and intervening with parents to prevent the onset and repeated occurrence of maltreatment. Unintentionally occurring injuries, which are the leading cause of death between one and 18 years of age, have also been the focus of successful preventive interventions. Finally, among school aged children, behavioral approaches have targeted the early risk factors signaling the likelihood of poor academic performance, inadequate social skills, as well as stranger abduction and sexual abuse.

5.2 Developmental Issues

In recent years, behavioral therapists have paid increasing attention to developmental issues in the treatment of children. Developmental factors that are of clinical relevance include the use of normative data about child development for the purpose of assessment, and the consideration of age, gender, and ethnic issues in treatment (Van Hasselt and Hersen 1993). There is also increasing recognition that interventions targeting chronic medically related issues occur within and are evaluated against an ever-changing backdrop of growth and development.

6. Summary

Since its inception, the hallmark of behavior therapy has been an adherence to treatment procedures that can be validated scientifically. Thus, behavior therapy with children is a constantly evolving form of treatment, which continually draws upon new findings from empirical research for the development and refinement of therapeutic interventions. In its early incarnations, behavior therapy with children was limited to relatively simplistic applications of basic experimental learning theory to circumscribed behavior problems. However, fueled by increased evidence of its effectiveness, behavior therapy has evolved into a more comprehensive and complex, yet mainstream therapeutic approach, with widespread ap-

plicability to a variety of children's mental health and behavioral problems. Behavior therapy with children continues to expand its purview to encompass broader social problems with a greater sensitivity to developmental processes of youth.

Behavioral Assessment

Behavioral assessment is the identification and measurement of a behavioral problem and its controlling variables (environmental, biological, or personal) for the purposes of manipulating variables relevant to target responses and, ultimately, evaluating and measuring change. From this commonly accepted definition two important characteristics of behavioral assessment arise: it is strongly linked to the clinical context, and it has emerged from a specific theoretical approach of clinical psychology (see *Behavior Therapy: Psychological Perspectives*).

This article deals with the following issues: (a) a historical overview; (b) the nature of behavioral assessment; (c) the process of behavioral assessment, treatment, and evaluation; and (d) the future of behavioral assessment.

1. A Historical Overview

The history of behavioral assessment cannot be separated from behaviorism as a paradigm of scientific psychology and its clinical application. Thus, behavioral assessment began when complex human behaviors were first considered as a subject for scientific study (e.g., Staats 1963, Bandura 1969). Since the 1960s, four main phases have been identified.

1.1 The Starting Point

Although there are several origins of behavioral assessment, it is commonly accepted that Kanfer and Saslow's article *Behavioral Analysis* (1965) represents the foundation stone, with its seven-step guide to behavioral assessment (problematic behaviors and situation, motivational analysis, developmental analysis, self-control analysis, social relationships, and sociocultural and physical environment). This paper introduced behavioral assessment as a main issue—chapters devoted to behavioral assessment were included in books on behavior therapy/behavior modification, and references to it appeared in important behavioral and clinical journals.

1.2 The Period of Growth

In the late 1970s there began what Nelson (1983) called 'the honeymoon' of behavioral assessment. Hundreds of articles, several handbooks, and two journals totally devoted to behavioral assessment (*Behavioral Assessment* and *Journal of Behavioral Assessment*) were published. The main topics covered were: similarities and differences between behavioral and psychological assessment; theoretical supporting models (from radical behaviorist assumptions to the cognitive-behavioral perspective); functional analysis

as the main strategy; idiographism as the principal methodological perspective; the triple response classes of behavior as the basic classification system for operationalizing behavioral problems; the psychometric principle applied to behavioral measurement techniques; the types of method used; and the development of new behavioral assessment measurement devices for assessing clinical problems.

1.3 The Crisis

From the 1980s, we can identify two main profiles of behavioral assessment: the first supports the notion of behavioral assessment as a homogeneous corpus of knowledge, methodological tools and strategies, and a set of techniques; the second paints a diffuse picture of behavioral assessment as merely a 'content' field of psychological assessment, not as a theory-based model within assessment. Indeed, as Bellack and Hersen (1988) pointed out, there was 'neither a single accepted definition of the field, nor a consistent set of methods' (pp. 612–13).

This crisis, referred to by Cone (1993) as a 'schism,' and by Nelson as a period of 'disillusionment,' had several important repercussions, reflected in changes in two important publications: the *Journal of Behavioral Assessment* was renamed *Journal of Psychopathology and Behavioral Assessment*, and *Behavioral Assessment* disappeared in 1992, becoming subsumed as a section in the journal *Behaviour Research and Therapy*.

1.4 Overcoming the Crisis

Crises sometimes have positive net results, and this crisis was overcome. Over the 1990s, linked to the success of the behavioral paradigm, the output of behavioral assessment literature has been stable, and it is even embedded in other general publications of psychological assessment and behavior modification and therapy, and taught in doctoral and clinical practice training programs (Cone 1993, Fernández-Ballesteros 1993, Haynes 1998). Behavioral assessment has expanded its focus and continued its integration within a generic, scientifically based bio-psycho-social model of human behavior and behavior disturbances (Bellack and Hersen 1988).

2. The Nature of Behavioral Assessment

Although, throughout its evolution, the characteristics of behavioral assessment have changed somewhat, it should be emphasized that, at all times, its main goal has been behavioral change. Therefore, all conceptual and methodological features emerge from the attempt to define and measure a particular behavioral problem and its causal or controlling conditions and design the best treatment. The following five traits could be considered the essence of behavioral assessment: functional analysis, triple response modes and multicausality, idiographism, multimethodism, and the experimental method.

2.1 Functional Analysis

The main tool of behavioral assessment is functional analysis. It was defined by Skinner (1953) as '…the (stipulation of) external variables of which behavior is a function provide for what may be called a causal or functional analysis. We undertake to predict and control the behavior of the organism. This is our "dependent variable"—the effect for which we are to find the cause. Our "independent variables"—the cause of behavior—are the external conditions of which behavior is a function' (p. 35). Over the history of behavioral assessment this definition has been extended, since other behaviors (besides overt behavior as dependent variable) and other sites of causation than external conditions (as independent variable) have been integrated; nevertheless, functional analysis continues to represent the core (see *Behavior Analysis, Applied*).

2.2 Triple Response System and Multicausality

The second characteristic of behavioral assessment arose from the complexity of behavioral problems both in their definition and their causation. Behavioral problems were to be defined through the triple response mode—motor, cognitive, physiological—and diverse potential causes—multicausality—were to be accepted. In other words, behavioral problems require specification through several manifestations, and are usually caused by several conditions that cannot be reduced to those external circumstances, since relevant biological and personal (as well as environmental) conditions also contribute to their explanation.

For example, a person's depression should be defined through cognitive (feelings of loneliness, attention and concentration problems), physiological (sleep disturbance) and motor (low rate of social behaviors and physical activity) behaviors. This problem can be explained functionally by several conditions of the subject, such as a reinforcement system deficit, inadequate motivational system (personal condition), or a dysfunction in biological conditions—and usually by the interaction of all of these factors.

2.3 Idiographism

The object of study of behavioral assessment is the behavior of a given person. This means identifying and defining behavioral problems and their controlling variables idiographically. In other words, psychologists should consider a single case and its specific circumstances.

This position does not mean that there are no general principles applicable to human behavior, but it does mean that every behavioral problem may have specific components and causal conditions that should be considered in order to proceed to behavioral change. Idiographism does not reject general classification systems (for communication purposes) or the administration of standard tests (for comparing our case with a sample of the general population), but it demands the measurement of the subject's particular behavioral problem and its potential causal variables.

2.4 Multimethodism

Since overt behaviors and external conditions were the basis of Skinnerian functional analysis, at the very beginning of behavioral assessment, observational procedures were also the fundamental methods proposed. However, considering the evolution of behavioral psychology, since behavioral problems should be described through the triple response mode—motor, cognitive, physiological—other methods of assessment than observation of overt behavior and other informants (than the subject) should be considered. In sum, multimethodism is one of the most important characteristics of behavioral assessment. This technological change has also, of course, occurred in other social sciences, and today multimethodism is the most widespread approach.

Methods in behavioral assessment are diverse. Nevertheless, observation (by experts or relatives) of motor behavior continues to be a commonly used method of assessment for assessing both overt behavior and its external antecedents and consequences. Other methods, such as self-report, self-monitoring, etc., are also administered for assessing public and private events (feelings of sadness, automatic thoughts, etc.). The most important characteristics in the administration of these techniques are that they usually include environmental antecedents and consequences of these private events, which are not considered as intrapsychic traits. Finally, when physiological responses are involved in a behavioral problem, physiological equipment is used and psychophysiological variables measured. Therefore, we can conclude that in the utilization of instruments and procedures in data collection the only restriction comes not from the method but from the level of inference of the assessed variables; in other words, in behavioral assessment, a lower level of inference is prescribed. In sum, multiple response modes, multiple methods, and multiple informants are the most common measurement devices and strategies for assessing variables with low levels of inference.

2.5 Experimental Approach

Behavioral assessment provides the basis for behavioral change, behavioral change requires treatment, and treatment demands experimental manipulations and evaluation (Hayes and Nelson 1986). This is why, throughout the history of behavioral assessment, the experimental method has been a constant among its basic characteristics.

Psychological assessment has several purposes; a subject can be assessed with the purpose of description in psychological/behavioral terms, or of predicting future behavior (for personnel selection or counseling). However, and mainly in clinical settings, behavioral change through treatment is the most important goal, and one of the features that distinguish behavioral assessment from other types of psychological assessment is, precisely, the use of the experimental method.

3. The Process of Behavioral Change: Assessment, Treatment, and Evaluation

One of the most important features of behavioral assessment is its role in behavior modification or behavioral change. Thus, a person with behavioral problems should be assessed in order to specify and measure behavioral excesses, deficits, and inadequacies, to identify the relevant conditions (biological, social, or personal) that are hypothetically functionally related—causing, controlling, or maintaining—to those deficits or inadequacies, to plan the best treatment for manipulating those relevant conditions (or independent variables), and, during and/or after treatment, to evaluate behavioral change. In sum, one of the hallmarks of behavioral assessment is an interactive relationship between assessment, treatment, and evaluation.

3.1 Assessment

Behavioral assessment begins with the identification of the subject's problematic situation and the identification of its controlling, maintaining, or explaining conditions (Fernández-Ballesteros and Staats 1992).

Thus, the first task is the specification of a person's problematic behaviors in term of deficits, excesses, or inappropriateness parameters (frequency, duration, etc.), and of the circumstances in which the behavior began and has occurred since. This initial task requires the description, operationalization, and measurement of the problematic behavioral functioning, and sometimes its classification. Behavioral assessors should also consider the person's assets as a supporting element of future treatment. In sum, psychologists should make decisions about treatment targets and the subject's positive conditions.

Functional analysis also demands identification of the relevant conditions that, hypothetically, explain, control, or maintain the behavioral problem. These conditions should be assessed, at this stage of the process, in terms of their observed association and/or interaction with the subject's problematic target

behaviors, but are selected because of their well-established relationships with the problematic situation. Thus, assessment begins with a case formulation or the conceptualization of the problem (Haynes and Follette 1993).

3.2 Treatment

Although psychological interventions are usually guided, to some extent, by a preassessment of the client, the behavioral model was the first to claim that selection of treatment should be supported by previous assessment. Thus, the selection of the most appropriate treatment should be based on the relevant conditions observed as being associated with the client's target behaviors.

There are two important decisions related to assessment. As Barrios (1988) indicated, selecting the most appropriate treatment for a problem requires information on both the variables that maintain, control, or explain the problem behavior and the variables that produce the most effective treatment.

3.3 Evaluation

One of the hallmarks of behavioral assessment and therapy is evaluation of the treatment, (both during it and afterwards).

For evaluation, which should be planned at the end of the assessment phase, we need to know which measures of the target behaviors will be selected as outcome or dependent variables, and which design will provide the basis for evaluating the treatment (see *Single-case Experimental Designs in Clinical Settings* and *Clinical Treatment Outcome Research: Control and Comparison Groups*). Depending on the selected design, target behaviors will be assessed during or after treatment.

Several problematic issues arise from this final step of the behavioral assessment process. Various authors have stressed the difficulty of measuring change, the importance of change generalization (through stimuli, situations, persons, and time), the relevance of cost-benefit analysis, and the contribution of assessment to treatment effectiveness (Silva 1993).

4. The Future of Behavioral Assessment

Several challenges can be identified for the forthcoming decades. First, even if at the outset behavioral assessment was claimed to be applicable to all fields, it has remained linked to the clinical field. Although parallel frameworks have developed in counseling or personnel selection (e.g., 'assessment centers'), much more effort should be made to extend behavioral assessment.

Moreover, it is extremely important to proceed to an evaluation of behavioral assessment's reliability in terms of interassessor accuracy, and to make cost-benefit analyses with respect to treatment outcomes (Silva 1993).

Behavioral assessment needs measurement instruments and, although thousands of questionnaires and observational scales have been developed, very few have been adequately evaluated in scientific studies. Several advances in psychometrics and statistics can be applied to behavioral assessment technology, and in the near future we can expect improved measurement devices (Barrios 1988).

Classification has been a contradictory operation for the behavioral assessor and therapist. Staats' (1963) and Bandura's (1969) early behavioral classification systems were not commonly accepted. Psychiatric classification systems have been influenced by the behavioral approach in the sense of arriving at a behavioral description of symptoms and syndromes, but these systems have not been transformed into behavioral functional categories. Progress should be made in this direction (Haynes and Follette 1993).

Assessment involves a process of decision-making that is well known in terms of the operations undertaken. Nevertheless, this process is not prescriptive. We might expect that in future standards or guidelines for the assessment process will be developed and supported by scientific associations; indeed, several steps in this direction have already been taken.

Currently, clinical psychology considers not only dysfunctional behavior but also high behavioral functioning. As pointed out by Haynes (1998), the behavioral model should also be committed to promoting successful living throughout life, which, as always, will require sound assessment.

Behavioral Economics

It says something interesting about the field of economics that there is a subfield called behavioral economics. Surely all of economics is meant to be about the behavior of economic agents, be they firms or consumers, suppliers or demanders, bankers or farmers. So, what is behavioral economics, and how does it differ from the rest of economics?

Economics traditionally conceptualizes a world populated by calculating, unemotional maximizers that have been dubbed *Homo economicus*. In a sense, neoclassical economics has defined itself as explicitly 'antibehavioral.' Indeed, virtually all the behavior studied by cognitive and social psychologists is either ignored or ruled out in a standard economic framework. This unbehavioral economic agent has been defended on numerous grounds: some claimed that the model was 'right'; most others simply argued that the standard model was easier to formalize and practically more relevant.

Behavioral economics blossomed with the realization that neither point of view was correct. Empirical and experimental evidence mounted against the stark predictions of unbounded rationality. Further work made clear that one could formalize psychological ideas and translate them into testable predictions. The behavioral economics research program has consisted of two components: (a) identifying the ways in which behavior differs from the standard model and (b) showing how this behavior matters in economic contexts.

This article gives a flavor of the program. We begin by discussing the most important ways in which the standard economic model needs to be enriched. We then illustrate how behavioral economics has been fruitfully applied to two important fields: finance and savings. However, first, we discuss why the market forces and learning do not eliminate the importance of human actions.

1. *Is Homo Economicus the Only One Who Survives?*

Many economists have argued that a combination of market forces (competition and arbitrage) plus evolution should produce a world similar to that described in an economics textbook: do only the rational agents survive? Or, do the workings of markets at least render the actions of the quasi-rational irrelevant? These are questions that have been much studied since the 1980s, and the early impressions of many economists that markets would wipe out irrationality were optimistic.

Consider a specific example: human capital formation. Suppose that a young economist, named Sam, decides to become a behavioral economist, perhaps because he mistakenly thinks this will lead to riches, or because he thinks it is going to be the next fad, or because he finds it interesting and lacks the willpower to study 'real' economics. Whatever the reason for the choice, let us assume for the sake of argument that this decision was a mistake for Sam by any rational calculation. So, what will market forces do? First, Sam may be poorer because of this choice than if he had sensibly chosen to study corporate finance, but he will not be destitute. Sam might even realize that he could switch to corporate finance and make much more money but is simply unable to resist the temptation to continue wasting his time on behavioral economics. So, markets *per se* do not necessarily solve the problem: they provide an *incentive* to switch, but they cannot force Sam's hand.

What about arbitrage? In this case, like most things we study in economics outside the realm of financial markets, there is simply no arbitrage opportunity available. Suppose a wise arbitrageur is watching Sam's choices, what bet can he or she place? None. The same can be said if Sam saves too little for retirement, picks the wrong wife, or buys the wrong car. None of these irrational acts generates an arbitrage opportunity for anyone else.

Indeed, economists now realize that even in financial markets there are important limits to the workings of arbitrage. First, in the face of irrational traders, the

arbitrageur may privately benefit more from trading that helps push prices in the wrong direction than from trading that pushes prices in the right direction. Put another way, it may often pay 'smart money' to follow 'dumb money' rather than to lean against it (Haltiwanger and Waldman 1985, Russell and Thaler 1985). For example, an extremely smart arbitrageur near the beginning of the tulip mania would have profited more from buying tulips and further destabilizing prices than by shorting them. Second, and slightly related, arbitrage is an inherently risky activity and consequently the supply of arbitrage will be inherently limited (De Long et al. 1990). Arbitrageurs who did decide to short tulips early would probably have been wiped out by the time their bets were proven to be 'right.' Add to this the fact that in practice most arbitrageurs are managing other people's money and therefore judged periodically, one can see the short horizons that an arbitrageur will be forced to take on. This point was made forcefully by Shleifer and Vishny (1997), who essentially foresaw the scenario that ended up closing Long-term Capital Management.

So, markets *per se* cannot be relied upon to make economic agents rational. What about evolution? An old argument was that individuals who failed to maximize should have been weeded out by evolutionary forces, which presumably operated during ancient times. Overconfident hunters, for example, presumably caught less prey, ate less, and died younger. Such reasoning, however, has turned out to be faulty. Evolutionary arguments can just as readily explain over-confidence as they can explain appropriate levels of confidence. For example, consider individuals playing a war of attrition (perhaps in deciding when to back down during combat). Here overconfidence will actually help. Seeing the overconfidence, a rational opponent will actually choose to back down sooner. As can be seen from this example, depending on the initial environment (especially when these environments have a game theoretic component to them), evolution may just as readily weed out rational behavior as it does weed out quasi-rational behavior. The troubling flexibility of evolutionary models means that they can just as readily argue for bounds on rationality.

The final argument is that individuals who systematically and consistently make the same mistake will eventually learn the error of their ways. This kind of argument has also not stood up well under theoretical scrutiny. First, the optimal experimentation literature has shown that there can be a complete lack of learning even in infinite horizons. The intuition here is simple: as long as there are some opportunity costs to learning or to experimenting with a new strategy, even a completely 'rational' learner will choose not to experiment. This player will get stuck in a non-optimal equilibrium, simply because the cost of trying something else is too high. Second, work on learning in games has formally demonstrated Keynes' morbid observation on the 'long run.' The time required to converge to an equilibrium strategy can be extremely long. Add to this a changing environment and one can easily be in a situation of perpetual nonconvergence. In practice, for many of the important decisions we make, both arguments apply with full force. The number of times we get to learn from our retirement decisions is low (and possibly zero). The opportunity cost of experimenting with different ways of choosing a career can be very high.

The upshot of all these theoretical innovations has been clear. One cannot defend unbounded rationality on purely theoretical grounds. Neither arbitrage, competition, evolution, nor learning necessarily guarantees that unbounded rationality must be an effective model. In the end, as some might have expected, it must ultimately be an empirical issue. Does 'behavior' matter? Before evaluating this question in two different fields of application, we explore the ways in which real behavior differs from the stylized neoclassical model.

2. *Three Bounds of Human Nature*

The standard economic model of human behavior includes (at least) three unrealistic traits: unbounded rationality, unbounded willpower, and unbounded selfishness. These three traits are good candidates for modification.

Herbert Simon (1955) was an early critic of modeling economic agents as having unlimited information processing capabilities. He suggested the term 'bounded rationality' to describe a more realistic conception of human problem solving capabilities. As stressed by Conlisk (1996), the failure to incorporate bounded rationality into economic models is just bad economics—the equivalent to presuming the existence of a free lunch. Since we have only so much brainpower, and only so much time, we cannot be expected to solve difficult problems optimally. It is eminently 'rational' for people to adopt rules of thumb as a way to economize on cognitive faculties. Yet the standard model ignores these bounds and hence the heuristics commonly used. As shown by Kahneman and Tversky (1974), this oversight can be important since sensible heuristics can lead to systematic errors.

Departures from rationality emerge both in judgments (beliefs) and in choice. The ways in which judgment diverges from rationality is long and extensive (Kahneman et al. 1982). Some illustrative examples include overconfidence, optimism, anchoring, extrapolation, and making judgments of frequency or likelihood based on salience (the availability heuristic) or similarity (the representativeness heuristic).

Many of the departures from rational choice are captured by prospect theory (Kahneman and Tversky

1979), a purely descriptive theory of how people make choices under uncertainty (see Starmer (2000) for a review of literature on non-EU theories of choice). Prospect theory is an excellent example of a behavioral economic theory in that its key theoretical components incorporate important features of psychology. Consider three features of the prospect theory value function. (a) It is defined over changes to wealth rather than levels of wealth (as in EU) to incorporate the concept of adaptation. (b) The loss function is steeper than the gain function to incorporate the notion of 'loss aversion'; the notion that people are more sensitive to decreases in their well being than to increases. (c) Both the gain and loss function display diminishing sensitivity (the gain function is concave, the loss function convex) to reflect experimental findings. To describe fully choices prospect theory often needs to be combined with an understanding of 'mental accounting' (Thaler 1985). One needs to understand when individuals faced with separate gambles treat them as separate gains and losses and when they treat them as one, pooling them to produce one gain or loss.

A few examples can illustrate how these concepts are used in real economics contexts. Consider overconfidence. If investors are overconfident in their abilities, they will be willing to make trades even in the absence of true information. This insight helps explain a major anomaly of financial markets. In an efficient market when rationality is common knowledge, there is virtually no trading, but in actual markets there are hundreds of millions of shares traded daily and most professionally managed portfolios are turned over once a year or more. Individual investors also trade a lot: they incur transaction costs and yet the stocks they buy subsequently do worse than the stocks they sell.

An example involving loss aversion and mental accounting is Camerer et al.'s (1997) study of New York City cab drivers. These cab drivers pay a fixed fee to rent their cabs for 12 h and then keep all their revenues. They must decide how long to drive each day. A maximizing strategy is to work longer hours on good days (days with high earnings per hour such as rainy days or days with a big convention in town) and to quit early on bad days. However, suppose cabbies set a target earnings level for each day, and treat shortfalls relative to that target as a loss. Then, they will end up quitting early on good days and working longer on bad days, precisely the opposite of the rational strategy. This is exactly what Camerer et al. found in their empirical work.

Having solved for the optimum, *Homo economicus* is next assumed to choose the optimum. Real humans, even when they know what is best, sometimes fail to choose it for self-control reasons. Most of us at some point have eaten, drunk, or spent too much, and exercised, saved, or worked too little: such is human nature. People (even economists) also procrastinate. We are completing this article after the date on which it was due, and we are confident that we are not the only guilty parties. Although people have these self-control problems, the are at least somewhat aware of them: they join diet plans and buy cigarettes by the pack (because having an entire carton around is too tempting). They also pay more withholding taxes than they need to (in 1997, nearly 90 million tax returns paid an average refund of around $1,300) in order to assure themselves a refund, but then file their taxes near midnight on April 15 (at the post office that is being kept open late to accommodate their fellow procrastinators).

Finally, people are boundedly selfish. Although economic theory does not rule out altruism, as a practical matter economists stress self-interest as the primary motive. For example, the free rider problems widely discussed in economics are predicted to occur because individuals cannot be expected to contribute to the public good unless their private welfare is thus improved. In contrast, people often take selfless actions. In 1993, 73.4 percent of all households gave some money to charity, the average dollar amount being 2.1 percent of household income. Also, 47.7 percent of the population does volunteer work with 4.2 h per week being the average time volunteered. Similar selfless behavior is observed in controlled laboratory experiments. Subjects systematically often cooperate in public goods and prisoners dilemma games, and turn down unfair offers in 'ultimatum' games.

3. *Finance*

If economists had been polled around 1980 and asked to name the domain in which bounded rationality was least likely to find useful applications the likely winner would have been finance. The limits of arbitrage arguments were not well understood at that time, and one leading economist had called the efficient markets hypothesis the best established fact in economics. Times change. As we begin the twenty-first century finance is perhaps the branch of economics where behavioral economics has made the greatest contributions. How has this happened?

Two factors contributed to the surprising success of behavioral finance. First, financial economics in general, and the efficient market hypothesis in particular, generated sharp, testable predictions about observable phenomena. Second, there are many data readily available to test these sharp predictions. We briefly summarize here a few examples.

The rational efficient markets hypothesis makes two classes of predictions about stock price behavior. The first is that stock prices are 'correct' in the sense that asset prices reflect the true or rational value of the security. In many cases this tenet of the efficient market hypothesis is untestable because intrinsic values are not observable. However, in some special

cases the hypothesis can be tested by comparing two assets whose relative intrinsic values are known. One class of these is called 'Siamese Twins': two versions of the same stock that trade in different places.

A specific well-known example is the case of Royal Dutch Shell as documented in Froot and Dabora (1999). The facts are that Royal Dutch Petroleum and Shell Transport are independently incorporated in The Netherlands and the UK, respectively. The current firm emerged from a 1907 alliance between Royal Dutch and Shell Transport in which the two companies agreed to merge their interests on a 60:40 basis. Royal Dutch trades primarily in the USA and The Netherlands and Shell trades primarily in London. According to any rational model, the shares of these two components (after adjusting for foreign exchange) should trade in a ratio of 60:40. They do not; the actual price ratio has deviated from the expected one by more than 35 percent. Simple explanations such as taxes and transactions costs cannot explain the disparity (see Froot and Dabora 1999). This example illustrates that prices can diverge from intrinsic value because of limits of arbitrage. Some investors do try to exploit this mispricing, buying the cheaper stock and shorting the more expensive one, but this is not a sure thing, as many hedge funds learned in the summer of 1998 (when, at the time hedge funds were trying to get more liquidity, the pricing disparity widened).

The Royal Dutch Shell anomaly is a violation of one of the most basic principles of economics: the law of one price. Another similar example is the case of closed-end mutual funds (Lee et al. 1991). These funds are much like typical (open-end) mutual funds except that to cash out of the fund, investors must sell their shares on the open market. This means that closed-end funds have market prices that are determined by supply and demand, rather than set equal to the value of their assets by the fund managers as in an open-end fund. Since the holdings of closed-end funds are public, market efficiency would lead one to expect that the price of the fund should match the price of the underlying securities they hold (the net asset value or NAV). Instead, closed-end funds typically trade at substantial discounts relative to their NAV, and occasionally at substantial premiums. Most interesting from a behavioral perspective is that closed-end fund discounts are correlated with one another and appear to reflect individual investor sentiment. (Closed-end funds are owned primarily by individual investors rather than institutions.) Lee et al. found that discounts shrink in months when shares of small companies (also owned primarily by individuals) do well, and in months when there is lots of IPO activity, indicating a 'hot' market. Since these findings were predicted by their theory, they move the research beyond the demonstration of an embarrassing fact (price not equal to NAV) toward a constructive understanding of how markets work.

The second principle of the efficient market hypothesis is 'unpredictability.' In an efficient market it is not possible to predict future stock price movements based on publicly available information. Many early violations of this had no explicit link to behavior. Thus it was reported that small firms, firms with low price–earnings ratios earned higher returns than other stocks with the same risk. Also, stocks in general, but especially stocks of small companies, have done well in January and on Fridays (but poorly on Mondays).

An early study by De Bondt et al. (1985) was explicitly motivated by the psychological finding that individuals tend to over-react to new information. For example, experimental evidence suggests that people tended to underweight base-rate data (or prior information) in incorporating new data. De Bondt et al. hypothesized that if investors displayed this behavior, then stocks that had performed fairly well over a period of years will eventually have prices that are too high. Individuals over-reacting to the good news will drive the prices of these stocks too high. Similarly, poor performers will eventually have prices that are too low. This yields a prediction about future returns: past 'winners' ought to underperform while past 'losers' ought to outperform the market. Using data for stocks traded on the New York Stock Exchange, De Bondt et al. (1985) found that the 35 stocks that had performed the worst over the past 5 years (the losers) outperformed the market over the next 5 years, while the 35 biggest winners over the past 5 years subsequently underperformed. Follow-up studies have shown that these early results cannot be attributed to risk (by some measures the portfolio of losers is actually less risky than the portfolio of winners), and can be extended to other measures of over-reaction such as the ratio of market price to the book value of equity.

More recent studies have found other violations of unpredictability that have the opposite pattern from that found by DeBondt et al., namely under-reaction rather than over-reaction. Over short periods of time, e.g., 6 months to 1 year, stocks display momentum—the stocks that go up the fastest for the first 6 months of the year tend to keep going up. Also, after many corporate announcements such as large earnings changes, dividend initiations and omissions, share repurchases, splits, and seasoned equity offerings, there is an initial price jump on the day of the announcement followed by a slow drift in the same direction for as long as 1 year or more (Shleifer 2000).

These findings of under-reaction are a further challenge to the efficient markets hypothesis, but also to behavioral finance. Do markets sometimes over-react, and sometimes under-react? If so, can *any* pattern be explained, at least *ex post*? Is there a unifying framework that can bring together these apparently opposing facts and ideas?

Work is only now beginning to attack this extremely important question. Several explanations have been

offered recently (Shleifer (2000) summarizes them). All rely on psychological evidence (in one way or another) in unifying the facts. They all explain the anomalies by noting that under-reaction appears at short horizons whereas over-reaction appears at longer horizons, but each paper provides its own distinctive explanation. Which (if any) of these is the best one has yet to be decided. But the facts discovered so far, combined with these models, demonstrate the changing nature of finance. Rigorous empirical work building on psychological phenomena has given us new tools to unearth interesting empirical facts. Rigorous theoretical work, on the other hand, has been trying to address the challenge of incorporating these empirical facts into a psychologically plausible model.

The research discussed so far has been about asset prices and the controversy about the efficient market hypothesis. There is another stream of research that is just about investor behavior, not about prices. One example of this stream is motivated by mental accounting and loss aversion. The issue is whether investors are reluctant to realize capital losses (because they would have to 'declare' the loss to themselves). Shefrin and Statman (1985) dubbed this hypothesis the 'disposition effect.' The prediction that investors will be less willing to sell a loser than a winner is striking since the tax law encourages just the opposite behavior. Nevertheless, Odean (1998) finds evidence of just this behavior. In his sample of the customers of a discount brokerage firm, investors were more likely to sell a stock that had increased in value than one that had decreased in value. While around 15 percent of all gains were realized, only 10 percent of all losses are realized. This hesitancy to realize gains came at a cost. Odean shows that the stocks the loser stocks held under-performed the gainer stocks that were sold.

4. *Savings*

If finance was the field in which a behavioral approach was least likely, *a priori*, to succeed, saving had to be one of the most promising. The standard life-cycle model of savings abstracts from both bounded rationality and bounded willpower, yet saving for retirement is both a difficult cognitive problem and a difficult self-control problem. It is then, perhaps less surprising that a behavioral approach has been fruitful here. As in finance, progress has been helped by the combination of a refined standard theory with testable predictions and many data sources on household saving behavior. One crisp prediction of the life-cycle model is that savings rates are independent of income. Suppose twins Tom and Ray are identical in every respect except that Tom earns most of his money early in his life (e.g., he is a basketball player), whereas Ray earns most of his late in life (e.g., he is a manager). The life-cycle model predicts that Tom the basketball player ought to save his early income to increase consumption later in life, whereas Ray the manager ought to borrow from his future income to increase consumption earlier in life. This prediction is completely unsupported by the data, which show that consumption very closely tracks income over individuals' life cycles. Furthermore, the departures from predicted behavior cannot be explained merely by people's inability to borrow. Banks et al. (1998) show, for example, that consumption drops sharply as individuals retire and their incomes drop. They have simply not saved enough for retirement. Indeed, many low- to middle-income families have essentially no savings whatsoever. The primary cause of this lack of saving appears to be self-control. One piece of evidence supporting this conclusion is that virtually all saving done by Americans is accomplished in vehicles that support what are often called 'forced savings,' e.g., accumulating home equity by paying the mortgage and participation in pension plans. Coming full circle, one 'forced' savings that individuals may choose themselves may be high tax withholdings, so that when the refund comes they can buy something they might not have had the willpower to save up for.

One of the most interesting research areas has been devoted to measuring the effectiveness of tax-subsidized savings programs such as IRAs and 401(k)s. The standard analysis of these programs is fairly simple. Consider the original IRA program from the early 1980s. This program provided tax subsidies for savings up to a threshold, often $2,000 per year; there was no marginal incentive to save for any household that was already saving more than $2,000 per year. Therefore, those saving more than the threshold should not increase their total saving, they will merely switch some money from a taxable account to the IRA for the tax gain. Moreover, everyone who is saving a positive amount should participate in this program for the infra-marginal gain. The actual analysis of these programs has shown that the reality is not so clear. By some accounts at least, these programs appear to have generated considerable new savings. Some argue that almost every dollar of savings in IRAs appears to represent new savings. In other words, people are not simply shifting their savings into IRAs and leaving their total behavior unchanged. Similar results are found for 401(k) plans. The behavioral explanation for these findings is that IRAs and 401(k) plans help solve self-control problems by setting up special mental accounts that are devoted to retirement savings. Households tend to respect the designated use of these accounts, and their self-control is helped by the tax penalty that must be paid if funds are removed prematurely. (Some issues remain controversial. See the debate in the Fall 1996 issue of the *Journal of Economic Perspectives*.)

An interesting flip side to IRA and 401(k) programs is that they also generated far less than the full participation one would have expected. Many eligible

people do not participate, foregoing in effect a cash transfer from the government (and, in some cases, from their employer). O'Donoghue and Rabin (1999) present an explanation based on procrastination and hyperbolic discounting. Individuals typically show very sharp impatience for short-horizon decisions, but much more patience at long horizons. This is often referred to as hyperbolic discounting by contrast with the standard assumption of exponential discounting, in which patience is independent of horizon. In exponential models, people are equally patient at long and short horizons. O'Donoghue and Rabin argue that hyperbolic individuals will show exactly the low IRA participation that we observe. Although hyperbolic people will want eventually to participate in IRAs (because they are patient in the long run), something always comes up in the short run (where they are very impatient) that provides greater immediate reward. Consequently, they may delay joining the IRA indefinitely.

If people procrastinate about joining the savings plan, then it should be possible to increase participation rates simply by lowering the psychic costs of joining. One simple way of accomplishing this is to switch the default option for new workers. In most companies, when employees first become eligible for the 401(k) plan, they receive a form inviting them to join; to join they have to send the form back and make some choices. Several firms have made the seemingly inconsequential change of switching the default: employees are enrolled into the plan unless they explicitly opt out. This change has often produced dramatic increases in savings rates. For example, in one company studied by Madrian and Shea (2000), the employees who joined after switching the default to being in the plan were 50 percent more likely to participate than the workers in the year prior to the change. (They also found that the default asset allocation had a strong effect on workers' choices. The firm had made the default asset allocation 100 percent in a money market account, and the proportion of workers selecting this allocation soared.)

Along with these empirical facts, there has also been substantial theoretical work. To cite a few examples, Laibson (1997) and O'Donoghue and Rabin (1999) both examined the effects of hyperbolic discounting on the savings decisions. They highlighted that hyperbolic individuals will demand commitment devices (savings vehicles which are illiquid) and generally fail to obey the Euler equation.

5. *Other Directions*

We have concentrated on two fields here in order to give a sense of what behavioral economics can do, but we do not want to leave the impression that savings and financial markets are the only domains in which a behavioral approach has been or could be effective. In labor economics, experimental and empirical work has underlined the importance of fairness considerations in setting wages. For example, wages between industries differ dramatically, even for identical workers and, most interestingly, even homogeneous workers (such as janitors) earn higher wages when they work in industries where other occupations earn more. In law and economics, we have seen the importance of 'irrelevant' factors in a jury's decision to sentence or in the magnitude of awards they give. In corporate finance, one can fruitfully interpret a manager's decision to acquire or diversify as resulting from overconfidence. One could go on. There is much to be done.

Behavioral Genetics: Psychological Perspectives

Behavioral genetics, the study of genetic influences on behavior, includes the full gamut of genetic levels of analyses. Increasingly, it includes molecular genetic studies of DNA as it relates to behavior. Most behavioral genetic research focuses on the genetic and environmental origins of differences between individuals—that is, why people differ in psychopathology, personality, and cognitive abilities and disabilities. However, 99.9 percent of the 3.5 billion DNA sequences in the human genome are identical for all individuals. Although this leaves about three million DNA sequences that vary among individuals, many genes, especially those genes which are the most important evolutionarily, do not vary. It is not yet possible to study the effects of nonvarying genes in the human species but in mice differences in such genes can be created that knock out the genes' functioning, which makes it possible to study the effects of such gene knock-outs (Plomin and Crabbe 2000).

Evolutionary psychology also considers universal (nonvarying) genes but in an evolutionary timescale. It seeks to understand the adaptive value of universal aspects of human behavior such as our species' natural use of language, our similar facial expressions of emotion, and cross-cultural similarities in mating strategies (Goldsmith et al. in press). It is especially difficult to pin down the effects of nonvarying genes in an evolutionary timeframe. The main line of evidence for evolutionary psychology is to compare average differences between species. This is a very different level of analysis from most behavioral genetics research, which focuses on differences among individuals within a species rather than aspects of behavior that do not vary within a species.

Although molecular genetic and evolutionary analyses that consider universal aspects of our species represent important directions for behavioral genetic research, the vast majority of behavioral genetic research focuses on variations on these universal themes. Since the 1920s, so-called quantitative genetic methods such as twin and adoption designs have been used to estimate the net effect of genetic and environmental factors on individual differences in behavior. As explained in the following section, quantitative genetic research converges on the conclusion that genetic factors contribute importantly to behavioral differences among individuals across a broad range of behaviors. However, the same research provides the best available evidence for the importance of environmental influences, which can only be clearly demonstrated when genetic factors are taken into account.

The case for genetic influence on individual differences in behavior is so strong that molecular genetic studies are now beginning to identify specific genes responsible for the genetic effects seen in quantitative genetic research. The last section considers molecular genetic research on behavior. Although quantitative genetic and molecular genetic strategies are far more powerful using nonhuman animal models (e.g., Plomin and Crabbe 2000), this article is limited to research on human behavior.

1. *Quantitative Genetics*

The twin and adoption methods were developed in the 1920s as tools to screen for genetic influence on complex traits like behavior. These methods emerged from quantitative genetic theory that worked out the expected genetic relationships among different kinds of relatives for complex quantitative traits that are influenced by many genes and many environmental factors (Plomin et al. 2001). Quantitative genetics always focused on naturally occurring genetic variation, in contrast to early work in molecular genetics that centered on single-gene mutations, especially new mutations created using animal models.

Some caveats and cautions are discussed later. However, because the results of quantitative genetic analyses are often misinterpreted, it should be emphasized at the outset that even if a given attribute is highly heritable in the sense of accounting for a large share of differences between persons, the mechanisms by which that attribute develops could be completely dependent on environmental conditions. Take reading as an example. There are individual differences in reading ability that are associated with genetic differences. However, learning to read clearly requires exposure to reading conditions. Genetic influence in reading ability means that some persons somehow more readily pick up reading skills. Moreover, genetic influence only refers to average results across a population. A particular child's poor reading ability might be entirely due to environmental circumstances

that make it especially difficult to learn to read or other children's excellent reading skills might be entirely due to extraordinary efforts on the part of their parents or teachers.

1.1 The Twin Method

The accident of nature that results in identical (monozygotic, MZ) twins or fraternal (dizygotic, DZ) twins provides one way to address the question of genetic and environmental origins of individual differences in behavior. MZ twins are like clones, genetically identical with each other because they came from the same fertilized egg. DZ twins, on the other hand, develop from two eggs that happen to be fertilized at the same time. Like other siblings, DZ twins are only half as similar genetically as MZ twins. To the extent that behavioral variability is caused by environmental factors, DZ twins should be as similar for the behavioral trait as are MZ twins because both types of twins are reared by the same parents in the same place and at the same time. If the trait is influenced by genes, then DZ twins ought to be less similar than MZ twins.

Possible biases in the twin method have been explored. MZ twins often share the same chorion (the outermost membrane surrounding the fetus) during prenatal development, which might make them more similar than DZ twins, who never share the same chorion. The scanty evidence relevant to this issue is mixed (Sokol et al. 1995). Another possibility is that twins may not be representative of the nontwin population because of adverse intrauterine environments caused by twinning (Phillips 1993). However, the statistical distributions for most behavioral dimensions and disorders for twins and nontwins are generally similar, suggesting that twins are reasonably representative of nontwin populations (e.g., Christensen et al. 1995). A subtle but important issue is that MZ twins might have more similar experiences than DZ twins after birth. The twin method is based on the assumption that the environments of DZ twins reared in the same family are approximately as similar as the environments of MZ twins reared in the same family. This assumption has been tested in several ways and appears reasonable for most traits (Bouchard and Propping 1993). Although the possibility remains that MZ twins may be treated more alike by their parents because they are more similar in appearance and behavior, the twin method provides a rough but useful screen to unpack the 'bottom-line' effects of genes and environment (Martin et al. 1997).

1.2 The Adoption Method

The adoption method is another quasi-experimental design that has a different set of assumptions and potential problems. Because the twin and adoption methods are so different, greater confidence is warranted when results from these two methods converge on the same conclusion—as they usually do. One issue for adoption studies is that adoptees and their adoptive families might not be representative of the population as a whole, either because they have distinctive characteristics or because they span a narrower range. There is also the possibility that adopted children might be selectively placed with adoptive parents matched to the birth parents. These issues can be examined empirically. For example, in a longitudinal prospective adoption study of behavioral development that began in 1975, adoptive families were found who are reasonably representative of the population and in this study selective placement was negligible (Plomin et al. 1997).

2. Genetic Influence on Behavior

Consider schizophrenia. Until the 1960s, schizophrenia was thought to be environmental in origin, with theories putting the blame on poor parenting to account for the fact that schizophrenia clearly runs in families. The idea that schizophrenia could run in families for genetic reasons was not seriously considered. Twin and adoption studies changed this view. Twin studies showed that MZ twins are much more similar than DZ twins, which suggests genetic influence. If one member of an MZ twin pair is schizophrenic, the chances are 45 percent that the other twin is also schizophrenic. For DZ twins, the chances are 17 percent. Adoption studies showed that the risk of schizophrenia is just as great when children are adopted away from their schizophrenic parents at birth as when children are reared by their schizophrenic parents, which provides dramatic evidence for genetic transmission. There are intense efforts to identify some of the specific genes responsible for genetic influence on schizophrenia.

In the 1960s, when schizophrenia was thought to be caused environmentally, it was important to emphasize the evidence for genetic influence such as the concordance of 45 percent for MZ twins. Now that evidence for the importance of genetic influence throughout the social and behavioral sciences has largely been accepted, it is important to make sure that the pendulum stays in the middle, in between nature and nurture. We need to emphasize that MZ twins are *only* 45 percent concordant for schizophrenia, which means that in more than half of the cases these pairs of genetically identical clones are discordant for schizophrenia. This discordance cannot be explained genetically—it must be due to environmental factors.

It should be noted that the word *environment* in genetic research really means *nongenetic*, which is a much broader definition of environment than is usually encountered in the social and behavioral sciences. That is, environment denotes all nonheritable

factors, including possible biological events such as prenatal and postnatal illnesses, not just the psychosocial factors that are usually considered in the social and behavioral sciences. The point is that genetics can often explain half of the variance of behavioral traits but this means that the other half of the variance is *not* due to genetic factors.

For milder behavioral disorders, too, a more balanced view that accepts the role of nature as well as nurture is beginning to prevail, and researchers are making progress in identifying specific genes. Moderate genetic influence has also been found for most behavioral disorders that have been studied, including mood disorders and anxiety (Plomin et al. 2001). Indeed, behavioral disorders tend to show greater genetic influence than common medical disorders such as breast cancer or heart disease (Plomin et al. 1994). The reason for the greater genetic influence for behavioral disorders may be that many different biological pathways can affect behavior. Behavior can be considered as the downstream outcome of many different biological systems; genetic influences can operate on behavior via all of the upstream systems.

Genetic influences are not limited to psychopathology; they also contribute to normal variation in personality (Loehlin 1992) and in cognitive abilities and disabilities. Behavioral genetic research to date has only scratched the surface of possible applications in the social and behavioral sciences, even within the best-studied domains of psychopathology, personality, and cognitive disabilities and abilities. For psychopathology, genetic research has just begun to consider disorders other than schizophrenia and the major mood disorders. Developmental psychopathology has recently become an active area of genetic research (Rutter et al. 1999). Personality is so complex that it can keep researchers busy for decades, especially as they go beyond self-report questionnaires to use other measures such as observations and ratings by others (Riemann et al. 1997). A rich territory for future exploration is the links between psychopathology and personality (Nigg and Goldsmith 1994). New directions for genetic research on cognitive abilities and disabilities include the systematic analysis of psychological theories of cognition (Mackintosh 1998) and the use of information-processing measures (e.g., Deary and Caryl 1997, Deary 2000) and brain-imaging measures.

The vast majority of human genetic research in the social and behavioral sciences has focused on psychopathology, personality, and cognitive disabilities and abilities because these areas have long been the focus of research on individual differences. Three new areas of psychology that are beginning to be explored genetically are psychology and aging, health psychology, and evolutionary psychology (Plomin et al. 2001). Some of the oldest areas of psychology—perception and learning, for example—have not emphasized individual differences and as a result have yet to be explored systematically from a genetic perspective. Entire disciplines within the social and behavioral sciences, such as economics, education, and sociology, are still essentially untouched by genetic research.

Genetic research, and especially heritability, is often misinterpreted. As mentioned earlier, a common mistake is to assume that heritability refers to an individual rather than to individual differences in a population. The heritability of height is 90 percent, but this does not mean that you grew to 90 percent of your height for reasons of heredity and that the few remaining inches were added by the environment. Another caution is that heritability like all other descriptive statistics is limited to a particular population as a particular time. Different cultures or cohorts could yield different results. One of the most common misinterpretations is that finding evidence for heritability implies that environmental factors are not important. This is wrong for several reasons. First, heritability of complex traits is seldom greater than 50 percent, which means that most of the variance is due to environmental rather than genetic factors. Indeed, behavioral genetic research provides the strongest available evidence for the importance of the environment. Furthermore, even if the heritability of a trait were 1.0 (which it never is for complex traits), a new environmental intervention could completely change the behavior. High heritability only means that environmental factors that currently vary for the sample do not make much of a difference. An important corollary of this point is that heritability does not constrain environmental interventions such as psychotherapy. Another mistake is to think that genetic influence means that there is a single gene that determines behavior. Single-gene disorders are deterministic—if you inherit the dominant allele for Huntington's disease you will die from the disease regardless of your other genes or your environment. However, complex traits like behavior are never caused by a single gene. Genetic effects are due to many genes that operate as probabilistic propensities rather than predetermined programming. Genes are not destiny. Finally, finding genetic influence on behavior has no necessary policy implications. Such data do not compromise the value of social equality, for example. Knowledge alone does not account for societal and political decisions because values are just as important in the decision-making process.

Genetic research in the social and behavioral sciences is moving beyond heritability. Asking whether and how much genetic factors affect behavioral dimensions and disorders is an important first step in understanding the origins of individual differences, but such questions are only a beginning. The next steps involve the question 'how'—that is, the study of the mechanisms by which genes have their effects. Avenues for genetic research in the social and behavioral sciences include developmental change and continuity,

links between the normal and abnormal, multivariate genetic analysis of heterogeneity and comorbidity, and the interplay between genes and environment (Plomin et al. 2001). An especially exciting direction for research is identification of some of the specific genes responsible for the heritability of behavioral disorders and dimensions.

3. DNA

Now that the contribution of genetic factors to individual differences in behavior is widely accepted, molecular genetic techniques are being applied that can identify some of the genes responsible for this genetic variation. Associations between DNA and behavioral differences have a unique status in the behavioral sciences because the DNA differences clearly cause the behavioral difference, that is, the DNA differences cannot be caused by the behavioral difference. For other factors associated with behavior, even biological factors such as neurotransmitters, it is always possible that behavior was the cause rather than the effect. For example, a certain neurotransmitter might be at higher levels in individuals with schizophrenia but that does not mean that the neurotransmitter causes schizophrenia. Having disordered thought processes characteristic of schizophrenia might have led to the higher level of the neurotransmitter.

The heritability of complex traits like behavior is likely to be due to multiple genes of varying, but small, effect size rather than one gene or a few genes with major effect. Genes in such multiple-gene systems are inherited in the same way as any other gene but they have been given a different name—quantitative trait loci (QTLs)—in order to highlight some important distinctions. Single-gene effects are necessary and sufficient for the development of a disorder such as phenylketonuria (PKU) that, left untreated, causes mental retardation, or Huntington's disease that causes general neural degeneration later in life. In contrast, QTLs contribute interchangeably and additively, analogous to probabilistic risk factors. If there are multiple genes that affect a trait, it is likely that the trait is distributed quantitatively as a dimension rather than qualitatively as a disorder. From a QTL perspective, there are no disorders, just the extremes of quantitative traits caused by the same genetic and environmental factors responsible for variation throughout the dimension. In other words, the QTL perspective predicts that genes found to be associated with complex disorders will also be associated with normal variation and vice versa (Plomin et al. 1994).

The QTL perspective is the molecular genetic version of the quantitative genetic perspective which assumes that genetic influence on complex traits is due to many genes of varying effect size. The goal is not to find *the* gene for a particular trait, but rather *some* of the many genes that make contributions of varying effect sizes to the variance of the trait. Perhaps one gene will be found that accounts for 5 percent of the variance, five other genes might each account for 2 percent of the variance, and 10 other genes might each account for 1 percent of the variance. If the effects of these QTLs are independent, together these QTLs would account for 25 percent of the variance, or half of the heritable variance for a trait whose heritability is 50 percent. All of the genes that contribute to the heritability of the trait are unlikely to be identified because some of their effects may be too small or complicated to detect. Finding QTLs require powerful genetic designs that can detect genes of small effect. Space does not permit a description of the various methods used to detect QTLs (eg., Plomin and Crabbe 2000).

The memory loss and confusion of dementia called Alzheimer's disease was the first behavioral disorder for which a QTL was found. Although single-gene effects have been identified for rare early-onset cases, late-onset Alzheimer's disorder, which strikes as many as one in five individuals in their eighties, is not caused by a single gene. In 1993, a gene on chromosome 19 called apolipoprotein E was found that predicts risk for the disorder better than any other known risk factor (Corder et al. 1993). If you inherit one copy of a particular form (*allele*) of the gene, your risk for Alzheimer's disorder is about four times greater than if you have another allele. If you inherit two copies of the allele (one from each of your parents), your risk is much greater.

Reading disability was the next common behavioral disorder to which a QTL approach was successfully applied. A linkage between reading disability and DNA markers on the short arm of chromosome 6 (Cardon et al. 1994) has been consistently replicated (Grigorenko et al. 1997, Fisher et al. 1999, Gayán et al. 1999). This QTL appears to be broad in its effect, involving both phonological (auditory) and orthographic (visual) aspects of reading disability (Fisher et al. 1999). Several molecular genetic studies have indicated a role for dopamine genes in the etiology of hyperactivity (Thapar et al. 1999). Genes responsible for the heritability of personality (Hamer and Copeland 1998), and of cognitive abilities (Fisher et al. 1999) are also beginning to be identified.

Although attention is now focused on finding specific genes associated with complex traits, the greatest impact on social and behavioral sciences will come after genes have been identified. Few social and behavioral scientists are likely to join the hunt for genes because it is difficult and expensive, but once genes are found, it is relatively easy and inexpensive to use them. DNA can be obtained inexpensively from cheek swabs rather than blood. One cheek swab yields enough DNA to genotype thousands of genes. Microarrays the size of a postage stamp, called DNA chips, are becoming available that can genotype thousands

of genes in a few minutes at costs that will eventually be very low per individual.

Although some psychology departments already have DNA laboratories, it is likely that most research using DNA in the social and behavioral sciences will be accomplished through collaborations with molecular geneticists or through commercial arrangements. It is critical for the future of the social and behavioral sciences that we be prepared to use DNA in our research. What has happened in the area of dementia in the elderly will be played out in many areas of the social and behavioral sciences. Although the association between the apolipoprotein E gene and late-onset Alzheimer's dementia was only recently identified, most research of any sort on dementia now genotypes subjects for apolipoprotein E in order to ascertain whether the results of interest differ for individuals with and without this genetic risk factor.

Among geneticists, it is generally believed that we will be awash in genes associated with complex traits including behavior in the next few years, especially as the Human Genome Project completes sequencing all 3.5 billion bases of DNA in the human genome and identifies all genes and the several million DNA bases that differ among us. The future of genetic research lies in moving from finding genes (genomics) to finding out how genes work (functional genomics). Functional genomics is usually considered in terms of bottom-up molecular biology at the cellular level of analysis. However, a top-down behavioral level of analysis may be even more valuable in understanding how genes work at the level of the intact organism, in understanding interactions and correlations between genes and environment, and in leading to new treatments and interventions. The phrase 'behavioral genomics' has been suggested to emphasize the importance of top-down levels of analysis in understanding how genes work (Plomin and Crabbe 2000). Bottom-up and top-down levels of analysis of gene-behavior pathways will eventually meet in the brain. The grandest implication for science is that DNA will serve as an integrating force across diverse disciplines.

Social and behavioral scientists should participate constructively in the discussion of scientific, clinical and social implications of the advances brought about by DNA research. Students in the social and behavioral sciences must be taught about genetics in order to prepare them for this future. The search for genes involved in behavior has led to a number of ethical concerns: There is fear that the results will be used to justify social inequality, to select individuals for education or employment, or to enable parents to pick and choose among their fetuses. These concerns are largely based on misunderstandings about how genes affect complex traits (Rutter and Plomin 1997). Otherwise, this opportunity for the social and behavioral sciences will slip away by default to geneticists, and the genetics of behavior is much too important a topic to be left to geneticists!

Behavioral Geography

1. Introduction

1.1 Definition

Behavioral geography includes the study of the processes involved in spatial decision making and the consequent traces of human decisions and movements in the environment. Two components, labeled 'spatial behavior' and 'behavior in space,' are generally recognized. 'Spatial behaviors' are the spatially manifested or overt acts of people performing a range of daily or other episodic activities (e.g., journey to work, shopping, recreation, education, and so on). These acts yield data such as distance and direction of movement, directional bias, trip frequency, episodic interval, and repetitiveness, and are represented and analyzed as occurrences in space. 'Behavior in space' focuses on supplying reasons for these overt acts and requires understanding processes such as decision making and choice, spatial cognition and cognitive mapping, spatial knowledge acquisition, risk aversion, uncertainty, habit, search and learning, emotional state, attitudes, cognitive representations, and values and beliefs.

1.2 The Precursors

Behavioral geography began a critical growth phase in the early 1960s, but isolated researchers in human and physical geography had, during the earlier part of the twentieth century, pointed to the need for linking physical reality and human images of that reality. Gulliver (1908) talked of 'perceived spatial orientation' as an important factor in understanding human activities. Trowbridge (1913) discussed the notion of 'imaginary maps,' making it clear that geography existed not only in the objective physical environment but also in our imagination; that imagination could produce vivid verbal or pictorial descriptions, as were found in numerous novels, poetry, and stories told. A 1997 translation of a book by the Finnish geographer (Granö 1997, first published in 1930) shows that he distinguished between 'proximal' and 'distant' landscapes based on the psychophysics of perception, and urged that geographers concentrate on perceived realities. The worlds of the imagination in the past and the present were emphasized further by Wright (1947) and Kirk (1951). By the early 1960s, therefore, the idea of subjective reality and its distinct geographies had been planted in the discipline.

1.3 History

Geographer Kates and psychologist Wohlwill edited a special issue of the *Journal of Social Issues* in 1966 (Kates and Wohlwill 1966). This publication represented 'an attempt by the issue editors to relate behavioral science to an important societal concern: the quality of the environment' (p. 21). This new emphasis joined the geographer's concern with the physical and built environments and the psychologist's concern for human behavior. In his paper, Kates suggested that a concern for human–environment relations was essential in that it could play a role in mediating between behavioral science and professional participation in environmental protection and conservation programs. Kates suggested that geography could assist in building a bridge between the social and behavioral sciences and the professional disciplines of architecture, design, city planning, and others that were directly concerned with the relations between the environment and human behavior.

Following up on a previously published paper on experience and imagination in geography, Lowenthal

(1967) edited a collection that explored human–environment relations from viewpoints in geography, psychology, and planning. Lowenthal's aim was to show that what he called 'the three realms' of geography could be brought together in common study. These realms included the nature of the environment, what we think and feel about the environment, and how we behave in and alter the environment. Behavioral geography generally has followed Lowenthal's suggestion of integrating these three realms, as well as pursuing more detailed examinations of each of them separately.

A third significant publication, edited by Cox and Golledge (1969), formalized the idea of a behavioral stream in geographic research that emphasized individual rather than aggregate behaviors, and suggested replacing ties to economics with ties to psychology. Together with a Penguin book on *Mental Maps* (Gould and White 1974), and a 1972 review of behavioral research in geography (Golledge et al. 1972), these publications established behavioral geography as a distinct and definable subfield of geography.

The message in each of these publications was that people gave life and meaning to different environments by virtue of their interaction with them and their behaviors in them. It was but a short step to arguing that human transformed environments were the result of deliberated decision-making activities, that the resulting structure of the environment reflected human values, beliefs, wants, and needs, and that human actions in those environments were preserved by immediate perceptions and stored in and recalled from long-term memory. As part of understanding human actions and activities, it was necessary to examine how human–environment relations were mediated by social, economic, cultural, political, psychological, and other constraints, each of which produced a more or less 'hidden' structure, which constrained the world as we knew it and experienced it. The next step simply was to acknowledge that to know an environment required learning about critical subsets of information from the mass of experiences open to each individual. Different people received, stored, and used different sensory input (or 'messages') from the different environments in which humanity lived. This differential access and use of information was translated into perceivable differences in the everyday task of living (Hanson and Hanson 1993).

1.4 International Spread

Behavioral geography emerged in the USA as a cohesive unit in the 1960s, consolidated in the 1970s, fragmented somewhat in the 1980s, and has had resurgent growth in the 1990s. Research in the UK (Downs 1970), which defined cognitive dimensions of people's images of shopping centers, stimulated more research using personal construct theory borrowed from psychiatry on human behavioral processes relating to how images are created. Recent activity has been stimulated by Kitchin's (1994) paper on cognitive maps, and by the place-based work on children's environments by Matthews (1992). In Japan, according to Wakabayashi (1996), the environmental perception component of behavioral geography was first developed, with spatial cognition and cognitive mapping emerging much later. In Spain, Aragonés and Arredondo (1985) summarized the growing behavioral interest by examining how cognitive maps developed and how imagery rather than fact seemed to influence planning policy and its implementation in urban areas. Early behavioral research in Australia emphasized cultural perception of the environment as perceived in various settings (e.g., Brookfield 1969). In Sweden, Hägerstrand's (1957) work on migration and mobility, followed by research on diffusion of innovations, initiated yet another stream of behaviorally based work including research on the process of spatial diffusion and the spatial adoption patterns of new ideas and new products. Again following Hägerstrand's lead, the 1970s saw the emergence of another behavioral stream focused on time–space analysis (Carlstein et al. 1978). Here time paths and space–time budgets were defined for daily activities and summarized in time–space frames called 'prisms.' In India, Singh and Singh Rana (1980) pioneered work on cognitive mapping and influenced research on other developmental and cognitive concepts.

During the 1970s, geographers in the USA strengthened their interdisciplinary links as a means of developing better concepts and research tools and models for behavioral geographic research. Much of this occurred via the multidisciplinary activities of the Environmental Design and Research Association (EDRA) that began publishing the journal *Environment and Behavior* in 1969. There is now an active 250 member Specialty Group of the Association of American Geographers (Environmental Perception and Behavioral Geography Specialty Group) and an average of 25 Masters theses or Ph.D. dissertations are produced in this area each year. Although early work in the USA was concentrated in the research activities of relatively few geographers, in the 1970s there was an escalated search for process based and behaviorally based explanations, particularly drawing on material from perceptual, developmental, and cognitive psychology, and from the work on emotion, affect, and attitudes from social psychology. In 2000, the subdiscipline is more proactive than reactive, reaching out to environmental and cognitive psychology (particularly spatial cognition), cognitive science, artificial intelligence, computer science, robotics, information sciences and technologies, virtual environments, and other newly developing and frontier areas of human science.

2. Major Subdivisions

2.1 Spatial Decision-making and Choice Behavior

The geographic emphasis now known as behavioral geography was prompted in part by a 1960's reaction against the unrealistic assumptions of normative economic–geographic models of human decision-making and choice behavior (Golledge 1967). Assuming perfect information, these theories claimed that humans were spatially and economically 'rational,' invariably selecting least cost and closest place alternatives in economic decision-making situations.

At the time that the theoretical and quantitative revolution was under way in geography, the major theories being investigated and used covered industrial, agricultural, and urban location, where economic models emphasizing perfect information and producing optimal and equilibrium solutions dominated the research domain. A critical assumption of all these models was that of economically rational behavior, usually interpreted in geography as least-effort or distance-minimizing behavior. The theories were geographically appealing because it was possible to hold economic variables such as price, quantity, production costs, labor costs, and so on constant and to focus only on transportation costs—the cost of overcoming distance of shipping raw materials or products—as the critical locating variable. In the geographic domain, the economically rational behavior assumption was translated into a spatially rational behavior assumption, where it was hypothesized that the nearest place of supply or demand would invariably have an advantage (by minimizing transport costs) and thus increase the probability of being chosen. The geographer's dissatisfaction with this as a fundamental assumption arose as empirical evidence showed that spatially rational behavior occurred only in a relatively few specialized cases. For example, Gould's (1963) introduction of game theory to geographers showed that as one changed one's attitude towards risk and uncertainty, the optimal solution to a geographic problem (e.g., which crops to grow in a subsistence economy given different environmental conditions) could also change, while Wolpert (1965) showed that Swedish farmers were far from being economically rational in their annual choice of crop types and land use combinations.

Spatial decision-making and choice behaviors have continued to be an important focus. This interest includes locational decisions (e.g., for new shopping centers, emergency services, group houses, child care centers) and choices that influence activities such as consumer behavior, migration, mobility, recreation, tourism, busing, school closure or expansion, and many others. It has also generated an interest in transportation varying from simple mode choice modeling and the building of computational process models of household activity patterns, to the use of global positioning systems (GPS) to track accurately daily behavior in road networks as inputs for an advanced traveler information component of an intelligent transportation system. Using survey diaries to collect data on attitudes towards and preferences for pretrip and en-route advice, behavioral geographers are contributing to a more complete understanding of today's complex travel patterns (e.g., by showing that, given delay information due to congestion or accident in the morning, people will change departure times rather than change routes of travel, whereas the reverse decision is more common in the evening).

2.2 Hazard Research

Following the lead of Gilbert White, who researched people's attitudes towards and reactions to flood hazards (White 1945), geography researchers at the University of Chicago began examining human attitudes towards and adjustments to extreme environmental events. For example, Kates (1966) examined risk and uncertainty as it influenced human responses to severe coastal storms. He showed that increased exposure to storms changed residents' subjective probabilities of storm occurrence periodicity and intensity. Burton, Kates, and White examined recidivist behavior of persons living on flood plains or other hazardous areas (Burton et al. 1978), showing how inertia brought about by investment in land, inheritance, family history, and experience influenced people's attitudes towards and expectations about future flood events. Research on perceptions of drought (Saarinen 1965) initiated a flurry of work labeled 'environmental perception' that illustrated methods for producing attitudinal data on drought and its acceptance as part of the cycle of human–environment relations. These works had an important impact on the worldwide interest in environmental protection and conservation that continues to stimulate a large part of behavioral research today.

Risk assessment, particularly in the context of human responses to hazardous events, has been a fundamental part of the growth of research in this area. It represents one of the founding pillars of interest (Kasperson and Dow 1993). It emphasizes examining subjective probabilities associated with catastrophic events, occurrences, problems of evacuation at times of risk, and the preferred behavior of persons exposed to environmental risk.

2.3 Spatial Knowledge Acquisition

In the early 1960s, geographers and psychologists at Clark University began joint work on objective and subjective spaces, eventually leading to an emphasis

on children's learning activities in a developmental context (Blaut and Stea 1969). They showed that even preschoolers could interpret aerial photos of places. It was suggested by Hart and Moore (1973) that humans passed through stages of spatial knowledge acquisition ranging from egocentric and topologically structured spaces to abstract and fully metric spaces in a manner similar to that outlined in developmental psychology studies of intellectual development. Much research followed on children's environments ranging from playgrounds to urban and rural neighborhoods. Research illustrated that female children observed and remembered more local details (e.g., landmarks), whereas male children traveled further and developed a better metric understanding of space, producing more exocentric rather than egocentric representations of experienced environments.

2.4 *Travel Activity Analysis*

In the USA, Marble (1967) led behavioral researchers to the study of human movement over transportation networks. Perry Hanson (1977) and Susan Hanson (1984) investigated disaggregate behavior by linking transportation research and activity analysis (i.e., daily movement behavior), while Australia's K. P. Burnett examined spatial choice of shopping centers (Burnett 1973), emphasizing the different criteria used by men and women to select shopping destinations. Other researchers investigated urban movement behavior, defining action and activity spaces which summarized, respectively, the total potential area of daily interaction and the actual pattern of a household's daily travel behavior. Consumers searching for products called 'spatially durable/shopping goods' or 'spatially inflexible convenience goods,' respectively, were shown to generate a variety of trips to different places at varying distances from the home base. Convenience shopping often conformed to minimum distance or closest place assumptions, while the search for places at which to purchase shopping goods resulted in 'variety-seeking behavior' which evinced spatially and economically 'irrational' behavior. The results began undermining the acceptability of the normative theories borrowed from economics and launched a search for more realistic assumptions about human spatial behavior. The result was endorsement of the idea that spatial behavior was best conceived as being 'boundedly rational.'

2.5 *Spatial Cognition and Cognitive Maps*

Research on cognitive maps was initiated in response to the question 'what do individuals know about places?' Cognitive maps were defined as a person's internally stored knowledge of the world and its events and processes. Using tasks ranging from sketch mapping to nonmetric multidimensional scaling, attempts were made to discover what people knew—or could recall—about places. External representations of this knowledge (e.g., sketches, verbal descriptions, photo identification, interpoint distance knowledge) showed that the geographic information stored and recalled by people usually was incomplete, fragmented, and distorted. In turn, this necessitated research on cognitive mapping processes, including encoding, decoding, recall, and internal manipulation of sensed information (e.g., estimating distances between real or imagined places).

Much effort was spent on designing meaningful ways to externalize one's spatial knowledge and to represent it as a spatial product that could be evaluated by others. In particular, geographers used multidimensional methods (e.g., nonmetric scaling) to represent the latent structure of geographical knowledge and developed methods of association (e.g., bidimensional regression) to provide a measure of the matching between objective geographic reality and the spatial product obtained from individuals. In part, this research aimed at answering questions as to why people went to various places to perform selected activities when alternative places seemed to be more rational alternatives (e.g., bypassing one nearby store to shop at a further one). Cognitive map research often showed that the location of the spatially 'nearby' place was not known or was wildly distorted, making a further place 'seem' near and more accessible.

Spatial cognition, spatial knowledge acquisition, environmental perception, and cognitive mapping have all been a primary focus of international attention during the 1980s and 1990s (Portugali 1996, Saarinen 1998). Emphasis has been placed on the use of cognitive maps in human wayfinding. Particular success has been achieved in comprehending the distorting effects on human knowledge of geographic alignment (e.g., is Reno, Nevada east or west of San Diego, California?), map orientation and positioning (e.g., as in determining the optimal facing direction of 'you are here' maps), and in discovering variations in spatial knowledge acquisition (e.g., differences between children's, adults', and disabled persons' environmental learning activities).

2.6 '*Place*' *and* '*Landscape*'

Throughout this period of growth there was continuous attention to the concepts of 'place' and 'landscape.' Related research covered a wide range of situations including examining the place of imagination in geographic experiences, defining both human and environmental personality traits and fostering a renewed interest in concepts of 'place' (Tuan 1977, Relph 1976). Researchers examined 'landscapes of

fear' in institutional and urban environments where criminal activity was perceived to endanger normal person–environment interactions. Behavioral geographers defined the sets of environmental features whose presence gave criminals (e.g., residential burglars or street drug sellers) a sense of security when carrying out their trade. Researchers also investigated how places developed images that encouraged or discouraged human visitation (e.g., places of beauty vs. places of fear), which in turn were incorporated into explanations of recreational park use and tourist destination choice.

The geographic study of variations in emotional reactions to different environments continues to play a key part in the practice of behavioral geography and remains significant (Amedeo 1993). In particular, emphasis on place stereotypes and the role of emotional appeal in residential site selection and neighborhood choice stands out. In association with these emphases, there has been a concurrent rethinking of the role of attitudes as a factor influencing human behavior, and an examination of fundamental belief and value systems that mediated human behaviors and which gave meaning to different environments. The latter has been an important part of the study of the ethics of environmental degradation.

2.7 *Adoption and Diffusion of Innovations*

Of perhaps equal importance has been the concern with information processing and the diffusion of both information and innovations. This has generated a strong tie with medical geography, as the spatial and temporal spread of phenomena (e.g. HIV/AIDS, influenza, and other communicable diseases) have been mapped and analyzed to highlight and explain their underlying geography (e.g., Gould 1993).

2.8 *Spatial Behavior of Special Groups*

Since the early 1980s, a growing interest in the behavioral problems of particular social groups has emerged. These groups include underrepresented minorities, the elderly, the homeless, and disabled people (Dear 1991, Golledge 1993). Outstanding in this area is the research on the NIMBY ('not in my back yard') syndrome used to explain negative reactions to local government policy decisions related to the location of what are perceived to be 'noxious' facilities such as group home and rehabilitation centers for drug users, sex offenders, and developmentally disadvantaged people.

Another new and powerful interest is in the geography of female roles and activities, in particular clarifying questions of 'spatial mismatch' between female home and work locations (Hanson and Pratt 1995). Analysis of distances traveled by ethnic and socioeconomic disadvantaged groups has effectively shown that poor female ethnic workers typically have to travel further to their jobs than do other group members.

2.9 *Cognitive and Behavioral Geography and Geographic Information Science*

Cognitive behavioral researchers have joined with researchers in geographic information science (GISc) to study visualization, cognitive cartography, scale, frames of reference, spatial language, verbal protocols for communicating with computers, and multimedia representational formats for digitized data. For example, investigations of whether verbal or mapped representations of geographic information facilitate environmental learning clearly indicate the superiority of maps or graphics wherever possible to impart spatial information, and these results have contributed to the growth of graphic user interfaces (GUI) as the primary human–computer interface.

2.10 *Residential Movement*

Mobility and migration research has been strongly influenced by behavioral research concepts relating to neighborhood preference, destination images, and perceived dimensions of environmental quality (Clark 1986). In particular, human reactions to segregation of housing, ethnic neighborhood growth, and busing of ethnic schoolchildren have been dominant themes for behavioral inquiry.

3. *Promising Future Research Directions*

As the world surges into the twenty-first century—hailed as the Age of Information Technology—behavioral geography is surging with it, no longer being pulled along by other fields of interest. One of the more promising areas of relevance to society at large includes a growing interest in geographic education. This is in part stimulated by the need to investigate spatial knowledge acquisition and new teaching practices tied to gender-free methods and computer-based distance learning technologies. As part of the twenty-first century educational scene, behavioral geographers are beginning to explore virtual environments, particularly the similarities and differences involved in undertaking spatial behavior in real and virtual worlds (e.g., comparing the effectiveness of learning an environment via an immersed virtual trip or a real world experience).

A promising area of future research is the further development of behavior-friendly digitized spatial databases together with analytical tools that explicitly assist in human understanding of data visualization processes. This exploration (via the perceptual and cognitive processes) of the significance of visualiza-

tion, audition and haptics as modes for expressing and representing spatial behavioral activities links behavioral research with cartography and geographic information systems (GIS). Behavioral and cognitive research is providing an important theoretical and analytical component of the emerging field of GISc. For example, exploring the nature of place cells for the neurophysiological evidence that will help decide if there is an understandable geography that the brain uses to store spatial information is becoming a multidisciplinary effort in which behavioral geographers are participating. A tie with spatial linguistics has also developed as researchers examine how language structures thought about space, how verbal interactions influence the way we understand space, and how natural language interfaces can be developed to communicate with computers that access geocoded data and use digital earth database metaphors.

In essence, much of tomorrow's behavioral geography will focus on an examination of the geography of everyday life, including comprehension of individual and group movements. For example, research involved with unpacking the implications of individual and household activity scheduling is promoting the development of intelligent transportation systems. This work has played a major part in establishing the International Association of Travel Behavior Researchers (IATBR). In this context, traditional behavioral research on travel and activities is being complemented by research on human navigation and wayfinding processes in different environments and their relationship to the design and building of artificial intelligences and robots.

A final area of fruitful research includes discovering the structure and influence on spatial behavior of the various realities in which groups of disabled and disenfranchised people must live out their lives. This area assesses the impact on travel of environmental obstacles (e.g., lack of ramps or curb cuts for wheelchairs) that inhibit movement and cause lengthy detours between otherwise easily accessible origins and destinations.

4. *Summary*

Behavioral geographers introduced a number of important changes to the discipline. These included (a) the introduction of new models of human behavior that went far beyond the assumptions of economically and spatially rational behavior to include beings who develop attitudes, emote, are more or less risk averse, have values and beliefs, and are part of sociocultural systems; (b) the expansion of the term 'environment' to include not only the objectively observable natural, biotic and built environments, but also the many hidden environments of human social, economic, physical, linguistic, religious, and other systems that were embedded in human existence; (c) the introduction of the notions of perceptual and cognitive environments which mediated processes of human–environment interaction and provided reference frames for knowing about places; (d) a changed emphasis from the aggregate macroscale focus to disaggregate microscale focus in which individual differences and personal characteristics and habits were seen to be important explanatory factors; (e) the development of new data based on human responses rather than simple counts or objective measures of the quantity of behavior occurring at places; (f) the introduction of different research designs (e.g., ethnomethodology, phenomenology, semiotics, and case studies) that facilitated the collection of behavioral data with reduced fear of experimenter contamination; (g) the importation and development of new methods of analysis (both quantitative and qualitative) that were suited to the subjective, individual, and disaggregate data that was being generated by interview, survey, observation, and focus group discussion; (h) the adoption of multimedia approaches that combined subjective and objective data collection and analysis procedures; (i) the emphasis on the need for valid and reliable research results; (j) the fostering of a growing suspicion that results of behavioral research cannot easily be logically connected into the axioms, theorems, laws, and deductive theories more typical of traditional scientific method as practiced in the natural and physical sciences; and (k) the suggestion of developing integrated place-based science that went beyond mere 'location' in geographic domains.

In sum, behavioral geography has a wide avenue to follow and, if followed successfully, can significantly impact the discipline of geography and enhance the quality of life of those who inhabit this world. Behavioral geographers in the twenty-first century are recognized outside their own discipline for work on cognitive mapping and spatial cognition, environmental learning, preference modeling, discrete choice and decompositional preference modeling, space–time geography, understanding place, contextual analysis, environmental risk assessment, responses to hazards, and many other areas of human–environment relations.

Behavioral Medicine

Behavioral medicine is the interdisciplinary field of research and practice that integrates behavioral, biological, and medical science in order to understand, prevent, and treat a broad range of physical health problems. Although behavioral medicine is a relatively new field, its research and clinical programs are now established in most major universities and medical

centers. This article will trace the evolution of behavioral medicine, describe its theoretical foundations, and review its clinical applications.

1. The Evolution of the Concept of Medicine

Traditionally, Western conceptions of the term 'medicine' refer to a substance that is administered into the body that carries out disease-fighting activities autonomously, acting without patient volition or even awareness of its activities. In a broader sense, medicine refers to a field or group of caregivers who heal the sick and injured, again largely beyond the active involvement of the patient. Underlying these conventional views are basic assumptions that medicine and disease processes operate on strictly biological levels, independent of thoughts, emotions, or behaviors. Medicine and health have not always been viewed in this way, but over the past two centuries the emergence of biological models of health and illness have contributed to highly mechanistic and biologically-oriented perspectives on health and well-being. This perspective is exemplified by passive patients who believe that they are made ill by pathogens or imbalances in their bodies and that they can be made well by treatments that are applied by health professionals. In this view, the sick individual bears little responsibility for the etiology of their malady or for getting well.

It is now clear that these notions of medicine and patient roles in health and illness processes are limited. This does not mean that the massive research and technological revolutions in medicine have been for naught; physicians are better prepared to maintain and restore human health than ever before. However, the emergence of behavioral medicine reflects the scientific recognition that health and disease are not just biological phenomena—that how people act, think, and feel are critical in determining who gets sick, how sick they become, and how well they can be treated. To some extent this reflects a return to doctrine that characterized the early history of medicine, before the biomedical revolution. Ancient Greek physicians and philosophers believed that the mind and body were mutually interdependent, and this interactionist approach was evident in medical practice as late as the Renaissance. Greek physicians prescribed such treatments as relaxation-inducing baths and massages, and medieval remedies included listening to music and thinking comforting thoughts, with objectives resembling modern approaches to relaxation and stress management.

1.1 The Emergence of the Biomedical Model

Despite the predominance of these early holistic approaches, Western philosophical traditions later embraced a radical and categorical separation of mind and body. By the seventeenth century, scholars such as French philosopher Rene Descartes argued that mental events and the physical body were independent of one another, overlapping only occasionally. By this account, bodily disease was properly understood as a biological event, and physicians of the day concentrated on this realm when attempting to understand or treat disease. This reductionist approach found strong empirical support in the scientific revolutions of the nineteenth and early twentieth centuries, marked by discoveries of disease-causing pathogens and the development of vaccines and antibiotic medications. A biologically focused biomedical model of health and disease emerged, and has dominated contemporary thinking about disease origin and healing.

It is probably best to view this enduring biological bias in medicine as an overcorrection, a response to centuries of unfounded dogma guiding medical theory and practice. Prior to the nineteenth century, medical authority was saturated with superstition and guesswork. Theories of the origins of disease had centered on curses, sins, or imbalances of bodily humors, and physicians had touted specious interventions such as leeches, purgatives, bloodletting, pouring boiling oil over wounds, and mixing precious stones with wine. As recently as the mid-nineteenth century, physicians did not know to wash their hands and instruments before performing surgery. But the dramatic advances in biological medicine that ensued were remarkable. Agostino Bassi and Robert Koch demonstrated that infectious diseases were caused by pathogens that could spread; Edward Jenner and Louis Pasteur exploited biological derivatives of these pathogens to produce the first vaccines; and Alexander Fleming discovered the antibiotic properties of penicillin. With these advances, physicians became increasingly able to base their authority on empirical evidence and reason. The medical model that emerged from these and other discoveries was received as a welcomed alternative to more primitive models, and as advances in biological sciences revolutionized medicine, it is not surprising that medicine embraced a strongly biologically oriented model.

1.2 The Emergence of Behavioral Models of Health and Illness

Regardless of the reasons for its pre-eminence, the biomedical model is too narrow and simply cannot explain a panoply of diseases that have replaced infectious illness as the major public health problems over the course of the twentieth century. A number of nineteenth century physicians, including Henry Holland, Benjamin Rush, Claude Bernard, and Sir William Osler, recognized these limitations and reintroduced the idea that psychological or behavioral

influences were also important for health and disease. However, these urgings were largely ignored until well into the twentieth century. First, it became apparent that pathogen models of disease were ill suited to address modern health challenges. At the dawn of the twentieth century, microorganisms were the principal sources of disease and mortality—tuberculosis, cholera, diphtheria, influenza, and other major infectious diseases were caused by viral or bacterial invaders and were best treated with medicines that attacked these pathogens or prepared the body to attack them. As these diseases were conquered, heart disease, stroke, cancer, HIV disease, diabetes, and arthritis emerged as the major public health challenges. At the same time, research from the fields of psychosomatic medicine and behavioral and experimental psychology began to provide compelling evidence of mind–body, or psychophysiological, interactions. For example, Pavlov's (1927) classical conditioning paradigm demonstrated that physiological responses could be influenced by non-biological cues. This important work was continued and broadened by Miller's (1978) seminal work on conditioning and control of autonomic functions such as heart rate, brain waves, or body temperature, as well as by Cohen and Ader (1988) who demonstrated that immune system functions could also be conditioned to neutral stimuli. By advocating a rigorous scientific approach to the simultaneous measurement of physiological and psychological indices, Wolff (1953) made important advances in the area of stress and adaptation in disease. Alexander (1950), Graham (1972), and Mason (1975) also achieved important insights into the relationship between emotional, psychological, and physiological responses. Finally, major epidemiological studies were completed that indicated significant associations between certain behavioral or psychosocial factors and health status (e.g., Berkman and Syme 1979).

Towards the latter part of the twentieth century, this evidence made it clear that biological states and disease processes are multidetermined—caused by a confluence of genetic, biological, environmental, behavioral, and psychosocial factors. This spawned more inclusive, sophisticated, integrative theories of health and illness, culminating in the advent of biobehavioral models of health and disease, which represent an expansion of biomedical models to include psychosocial and behavioral components.

2. *Behavioral and Psychosocial Influences on Health*

The significance of behavior in the field of behavioral medicine is apparent in two related principles about the relationship between behavior and disease, each of which is distinct from more traditional biomedical models of disease. First, behavior and other psychosocial factors contribute to disease etiology. Second, behavior and other psychosocial factors can be used for disease treatment and prevention. The first of these principles has been a primary focus of behavioral medicine research; the second is the basis for behavioral medicine clinical applications.

Prevention and treatment approaches in behavioral medicine are generally based on substantive empirical literatures. These investigations have defined three general pathways through which behavioral or psychosocial factors may influence the etiology, progression, treatment, or prevention of disease: (a) direct effects of cognitive, emotional, or behavioral processes on bodily systems (e.g., nervous, endocrine, or immune systems); (b) health-enhancing or health-impairing behaviors, such as diet, exercise, or smoking; and (c) responses to perceived or actual illness, such as screening behaviors or adherence with treatment recommendations. Each of these pathways will be examined in turn.

2.1 *Biobehavioral Influences in Disease Processes*

Research on the biological correlates of emotional or psychological processes has shown that the nervous, immune, and endocrine systems interact in a reciprocal fashion and regulate a variety of states and conditions. The recent development of the fields of psychoneuroendocrinology and psychoneuroimmunology are evidence of the growing recognition of these bidirectional relationships. Moreover, it has become increasingly clear that these pathways can directly or indirectly affect the etiology or progression of disease and affect disease resistance or vulnerability (e.g., see *Emotions and Health*).

The biological effects of stress in particular have been the focus of considerable research. Although the definition of 'stress' and its usefulness as a construct have been the subject of much debate (e.g., see *Stress: Measurement by Self-report and Interview*), it generally refers to a characteristic pattern of physiological, affective, cognitive, and behavioral changes that mobilize resources and support adaptation to environmental threat. Stress involves appraisal of threat, harm/loss, or challenge (Lazarus 1966), and is associated with a cascade of biological changes including activation of two major neuroendocrine systems: the sympathetic adrenome dullary (SAM) and the hypothalamic–pituitary–adrenocortical (HPA) axes. This activation is manifested by alterations in cardiovascular and respiratory function, digestion, metabolism, and skeletal muscle tone, which are coordinated to mobilize or liberate stored energy in preparation for behavioral response to threat.

Most theorists believe that these systemic changes are adaptive and facilitate immediate survival. This value is most apparent in acute stress situations, particularly those where strength and/or speed are critical coping elements. In situations in which activation of these systems is prolonged or unusually

intense, the value of arousal and activation is less clear and may instead exert a toll on health. The pathophysiology of cardiovascular disease serves as an example.

Cardiovascular disease is the leading cause of death in industrialized countries during this century. In the US, it has been the leading cause of death every year except one since 1900. A primary type of cardiovascular disease is coronary artery disease (CAD), which results from atherosclerosis, the accumulation of hardened deposits or plaque on the inner lining of coronary arteries. When enough plaque forms, blood to the heart is restricted or cut off, resulting in clinical manifestations of CAD including heart attack and sudden cardiac death. Although the pathogenesis of atherosclerosis is not completely understood, a number of lines of evidence suggest that sustained or frequent stress-related neuroendocrine activation is involved. Research suggests that individuals whose personalities are marked by impatience, hostility, and antagonism appear to be at risk for CAD (e.g., see *Coronary-prone Behavior, Type A*), as are individuals who have recently undergone stressful life events. In experimental studies with nonhuman primates, Manuck et al. (1995) demonstrated that disruption of the social environment, heightened cardiovascular reactivity, and behavioral factors such as dominance promoted atherosclerosis. Further, these researchers found that neuroendocrine pathways likely mediated this effect. Sustained or frequent increases in endocrine activity may foster atherosclerosis by damaging arteries and coronary vessels as well as by promoting the formation of blood clots. The physiological consequences of stress and some negative emotional processes appear to contribute significantly to the development of cardiovascular disease (e.g., see *Coronary Heart Disease (CHD): Psychosocial Aspects*).

Immune system activity also appears to be altered by behavioral and emotional processes (e.g., see *Psychoneuroimmunology*). Human and animal studies have demonstrated that the immune system is regulated by the central nervous system, by way of a broad array of nervous and endocrine system pathways (Ader et al. 1991). Several psychosocial factors have been related to changes in immune function, although the complexity and plurality of the immune system make it difficult to generalize or interpret these changes. These factors include loneliness, poor social support, negative mood, disruption of marital relationships, bereavement, and various other forms of pre-existing or new acute and chronic stress (reviewed in Cohen and Herbert 1996). These findings suggest that social and interpersonal support and contact are important in the stability or maintenance of immune functioning (e.g., see *Social Support and Health*).

Although the implications of stress-related immune changes for disease vulnerability have generally not been established, there are some empirical and theoretical reasons to suspect that these changes influence the incidence or progression of infectious disease (Cohen et al. 1991) (see *Infectious Diseases: Psychosocial Aspects*), HIV (Leserman et al. 1997) (see *Sexually Transmitted Diseases: Psychosocial Aspects*), and cancer (Andersen et al. 1994) (see *Cancer: Psychosocial Aspects*). Stress-related changes in immune cells known as natural killer (NK) cells may be particularly relevant for some of these conditions since NK cells have the ability to spontaneously destroy virally infected cells and cancer cells. Psychosocial factors, such as social support, have been linked to better NK activity as well as to cancer survival. Stress-related changes in immune function represent a plausible biobehavioral pathway through which psychosocial factors may influence the development or spread of cancer or other illnesses. Other immune-mediated illnesses such as asthma, arthritis, irritable bowel syndrome, and psoriasis may be influenced through similar biobehavioral pathways.

2.2 Health-protective and Health-impairing Behaviors

In addition to the direct biological effects of stress or other psychosocial factors, a number of health-protective or health-impairing behaviors can influence physical health and disease processes (see *Health Behaviors*; *Health Behavior: Psychosocial Theories*). Diet and obesity have been implicated in several major health problems, including cardiovascular disease, stroke, cancer, and adult onset diabetes. Atherosclerosis appears to be influenced by dietary behavior; the effects of obesity, substantial weight gain, or loss, and caloric restriction on atherosclerosis have been studied. The consumption of saturated fat and trans fatty acids contributes to low-density lipoprotein (LDL) cholesterol and triglyceride levels that promote atherosclerosis. Conversely, some dietary components may confer protection against the incidence or progression of cardiovascular disease. Studies suggest that consumption of antioxidant supplements, fruits and vegetables, and substances containing omega-3 fatty acids or other types of unsaturated fats may be beneficial in this regard. Dietary behavior appears to be important in both the pathophysiology and progression of cardiovascular disease.

There is a growing body of research that suggests that diet also affects the development of cancer. Epidemiological evidence suggests that diets that are rich in plant foods (i.e., fruits, vegetables, legumes, and grains) are associated with lower incidence of several types of cancers (reviewed in Potter and Steinmetz 1996). Laboratory and animal research suggests that constituents of plant foods, including vitamins and phytochemicals, have the capacity to inhibit the initiation, promotion, and/or progression of cancer, which may account for some of the epidemiological associations. On the other hand, a

number of dietary factors may promote the development of certain cancers, notably the consumption of total fat, saturated fat, and total calories.

Exercise appears to be important as a source of physical fitness, as a stress management strategy, and as a source of direct effects on health or disease (see *Physical Activity and Health*). A sedentary lifestyle is a risk factor for a number of diseases, including cardiovascular disease and cancer. Exercise may reduce the risk of cardiovascular disease by reducing stress or physiological reactivity to stress.

Tobacco use is perhaps the best-studied and most notorious health-impairing behavior (see *Smoking and Health*). It is the number one cause of preventable premature death and illness in industrialized nations; approximately half a billion people worldwide who are alive today will likely die from diseases related to tobacco use, which include cardiovascular disease, stroke, hypertension, pulmonary disease, kidney disease, and several different types of cancers. Psychological, behavioral, social, and biological factors are known to contribute to the initiation, maintenance, and relapse of cigarette smoking behavior. Modeling, social reinforcement, perceived cigarette availability, cost, and mental health all contribute to the initiation of smoking behavior, while maintenance of this behavior is largely due to the addictive properties of nicotine. The processes involved in nicotine addiction are similar to that of other drugs such as heroin and cocaine, and involve complex pharmacological, behavioral, and psychological components.

Sun exposure is another behavior that has major health consequences (see *Sun Exposure and Skin Cancer Prevention*). Basal-cell and squamous-cell skin cancers are associated with cumulative sun exposure, while melanomas are more closely associated with infrequent, periodic sunburn. Although the majority of skin cancers could have been prevented by regular sunscreen use or other management of sun exposure, better educational or prevention efforts are needed to bring about the lasting behavioral changes necessary to reduce skin cancer morbidity.

These and other behaviors represent potential contributors to illness and health, and they may interact to form an important level of analysis in the prediction of health and disease outcomes. Stress likely plays a role in many of these behaviors. Stress can also alter cognitive functioning, mood, problem-solving ability, social relationships, task performance, attention, and quality of life, which can in turn affect a number of health-related decisions or behaviors. Stress may thus act through a number of direct and indirect pathways to influence maintenance of health and susceptibility to disease.

2.3 Responses to Actual or Perceived Illness

A third general pathway through which behavior affects health is reflected in how people behave when they are ill, suspect they are ill, or learn that they are at risk for a serious illness. Obviously, early disease detection depends upon appropriate and timely human behavior. For cancer, the time at which the disease is detected can be the most crucial factor in determining treatment outcomes and disease prognosis (see *Cancer Screening*). Screening and self-detection practices are particularly relevant for breast cancer. Considerable research has been aimed at identifying and decreasing barriers to appropriate surveillance. Socioeconomic factors, quality of physician support, risk perceptions, health beliefs, and emotional responses to disease risk appear to influence screening behaviors.

Delays in seeking medical attention after symptoms are detected are also critical aspects of patient care and recovery (see *Symptom Awareness and Interpretation*). Similarly, adherence to medical recommendations and treatment regimens is another important way in which this category of behavior affects health (see *Patient Adherence to Health Care Regimens*). Nonadherence can disrupt treatment, affecting outcomes and interfering with future assessment and diagnosis. Unintentional nonadherence may occur when the patient fails to understand or remember the prescribed treatment. Cases of intentional nonadherence may reflect choices to pursue alternate forms of treatment, naïve theories of illness, or poor satisfaction (Morris and Schulz 1993). The quality of provider-patient interactions, supervision of adherence behaviors, and reminders to comply are among the factors that appear to influence adherence.

3. Behavioral Medicine Applications

The discovery of behavioral and biobehavioral pathways to disease has given rise to behavioral interventions for the treatment and prevention of medical illness and has increased the role of psychologists and behavioral specialists in medical settings. Behavioral medicine interventions generally are aimed at reducing stress or altering health-related behaviors.

3.1 Relaxation and Stress Reduction

One major emphasis of behavioral medicine interventions is the alleviation of stress and the promotion of relaxation. Techniques to achieve physical and mental relaxation have existed for thousands of years. Because of the broad impact of stress on disease pathogenesis, resistance to disease, and health behaviors, the reduction of stress may work in a variety of ways to prevent or delay disease onset or progression. Relaxation and stress reduction interventions consist of an array of techniques. Progressive muscle relaxation is one common method, and involves training the individual to recognize and reduce muscular tension, promoting cognitive and somatic relaxation. Biofeed-

back is the most technical of the relaxation methods, and consists of procedures that increase a person's ability to control physiological activities by providing information, or feedback, about these activities. Other procedures used to reduce stress or induce relaxation include autogenic training, diaphragmatic breathing training, physical exercise, guided imagery, meditation, and cognitive behavioral strategies such as coping skills and problem-solving training (see *Stress Management Programs*). Such interventions can result in the antithesis of the stress response; whereas stress elicits physiological changes that prepare the body for action, stress reduction procedures can elicit nervous and endocrine system changes that induce a state of relaxation, calmness, and decreased arousal and activity.

Stress reduction interventions have been useful in preventing or minimizing a variety of conditions (e.g., cardiovascular disease, arthritis, postsurgical outcomes, bowel disorders, ulcers, headache, and various pain conditions) (see also *Pain, Health Psychology of*). Stress reduction interventions have also been shown to reduce smoking relapse, and to reduce the number of physician visits among a healthy adult sample. The utility of stress reduction interventions is further established by studies that have documented reduced health care costs associated with these interventions (Friedman et al. 1996).

Psychosocial group interventions that provide education and social support may reduce stress or buffer the physical effects of stress (Helgeson and Cohen 1996). For example, individuals at risk for stress-related immune system changes have exhibited more favorable immune outcomes following various psychosocial interventions (e.g., Fawzy et al. 1990). The possibility that such interventions may favorably influence the course of cancer has been suggested by two provocative studies (Fawzy et al. 1993, Spiegel et al. 1989). Although the efficacy of behavioral medicine interventions for delaying cancer progression remains unknown and must await further investigation, the importance of behavioral medicine interventions as adjunct treatments for people with cancer, AIDS, or other serious life-threatening illnesses seems clear (see *Social Support and Recovery from Disease and Medical Procedures*). Providing information about coping, helping to build social support, and other behavioral or psychological strategies for stress and disease management are important in helping patients and family members adjust to the various challenges associated with these diseases.

3.2 Changing Unhealthy Behaviors

Given the deleterious health effects of behaviors such as smoking, physical inactivity, and poor diet, behavior change and modification of unhealthy behaviors is another important focus of behavioral medicine interventions. Behavioral medicine programs use a variety of techniques to promote behavior change. Self-monitoring is a straightforward technique that entails keeping a written record of specified health behaviors as a means of changing the frequency of the behavior. Stimulus control is a technique used to reduce the likelihood of an undesirable behavior by preventing or controlling antecedents of that behavior. Contingency management is a procedure that aims to change the frequency of a health behavior by carefully managing the consequences of that behavior, including rewards or punishments. These and other behaviorally-oriented procedures have been effective in increasing health promoting behaviors, such as exercise or adherence with medical treatment, and decreasing health impairing behaviors, such as smoking or alcohol consumption.

As noted, several different behaviors have been associated with the development or progression of major diseases such as cardiovascular disease and cancer. Consequently, behavioral medicine intervention programs often simultaneously target several different behavioral risk factors. For example, comprehensive behavioral change programs that promote changes in diet, exercise, smoking, social support, and stress management have achieved success in reducing modifiable risk factors for cardiovascular disease, slowing or reversing pathogenic signs of cardiovascular disease, and reducing cardiovascular disease mortality (e.g., Ornish et al. 1998).

Reduction of smoking is itself a frequent target of behavioral medicine intervention programs, because of the often-severe consequences of tobacco use. The same psychological and pharmacological properties that are responsible for the maintenance of smoking behavior are thought to be important considerations when attempting to achieve smoking cessation (see *Smoking Prevention and Smoking Cessation*). Unstated in such strategies and often overlooked are factors that bring people to the point that they want to quit smoking. Smoking cessation procedures are relatively ineffective when applied in situations where smokers do not intend to quit, and considerable effort should be directed towards motivation and contemplation of real cessation attempts. Achieving cessation is extremely difficult for many individuals; research suggests that up to 75 percent of smokers relapse within one year (Shumaker and Grunberg 1986). Because tobacco use is so difficult to stop once it has started, prevention efforts are often considered a more effective strategy to reduce smoking. However, a recent meta-analysis suggests that such programs have only a modest impact (Rooney and Murray 1996). Clearly, the reduction or prevention of tobacco use continues to represent an important challenge for behavioral medicine.

Eating behavior is another consequential health behavior that is addressed by behavioral medicine programs that target specific food consumption or

overall weight gain or loss. Such programs have been successful in reducing consumption of dietary carcinogens and increasing consumption of cancer-protective foods. Dietary change recommendations for decreasing cancer risk are more likely to be adhered to when people believe that what they eat does actually influence the development of cancer, when they understand what recommendations to follow, and when these changes are supported by others.

4. Summary and Conclusions

Behavioral medicine is an interdisciplinary scientific and medical specialty that is based on holistic notions of mind–body interactions and that seeks to prevent, treat, and overcome disease and disability by minimizing biobehavioral conditions that threaten good health. It assumes that the brain, together with the various sensory systems of the body, integrates and regulates physical and psychological events and that many of these events are so intertwined that separation of their elemental properties is impossible. Emotions, for example, consist of both thoughts and visceral events; fear is associated with feelings of fear as well as with changes in heart rate and other autonomic functions. Historically, theorists have argued about whether the cognitive or somatic components of emotions come first. For behavioral medicine, such distinctions are not particularly important or productive; consistent with its holistic approach, behavioral medicine views emotional states as simultaneous changes associated with learned or innate action patterns, and seeks to understand the health-related physiological and behavioral aspects of such experiences. Behavioral medicine is a true hybrid of many life and behavioral sciences, bringing together several disciplines and blending their approaches into something entirely new. The potential of this new science to help solve major public health problems is potentially great, and the early success of interventions derived from behavioral medicine is consistent with the recognition that many of the most pressing modern health problems are largely behavioral in nature, born of genetic and lifestyle origins rather than of microorganisms that invade the human body.

Behavioral Neuroscience

Behavioral and cognitive neuroscience are two sides of the same coin. The field as a whole is concerned with the neuronal and biological bases of behavior and experience, that is to say, psychology. Indeed, the distinction between 'behavioral' and 'cognitive' is rather arbitrary. Operationally, behavioral neuroscience might be defined by the kinds of papers published in the journal *Behavioral Neuroscience* and like journals. The emphasis is on biological studies of such basic phenomena as sensation and perception, motivation, learning, and memory, phenomena that occur similarly in humans and other animals. Most studies are done on infrahuman animals, including non-human primates. By the same token, most of the papers in the journal *Cognitive Neuroscience* and like journals are on humans, with imaging studies predominating. But many behavioral neuroscientists study basic psychological processes in humans, and many who consider themselves cognitive neuroscientists study such processes in animals.

The field of neuroscience is relatively recent as a 'unified' discipline; the first meeting of the Society for Neuroscience was held in 1971. The goal was to merge the disparate fields concerned with the study of the nervous system, e.g., neuroanatomy, neurophysiology, neurochemistry, neuropharmacology, neuroendocrinology, physiological psychology, clinical neurology, etc., into one interdisciplinary field.

There was a very long tradition in psychology of the study of animal behavior and its biological bases, initially termed comparative psychology. For many years the flagship journal devoted to comparative behavior and its biological bases was the *Journal of Comparative and Physiological Psychology*, published by the American Psychological Association. But increasingly the fields of comparative studies of behavior and physiological analysis of behavioral phenomena went separate ways. Consequently, in 1983 the journal was divided in two separate journals. Following is a portion of the editorial justifying this action by the then editor:

> The separation of the *Journal of Comparative and Physiological Psychology* into two companion journals, *Behavioral Neuroscience* and the *Journal of Comparative Psychology*, acknowledges the current state of the sciences concerned with biology and behavior. Behavioral neuroscience is the broader contemporary development of physiological psychology. In all animals above the level of the sponge, the nervous system is the organ of behavior. All biological and behavioral variables that exert any influence on behavior must do so by acting on and through the nervous system.
>
> Traditionally, physiological psychology emphasized certain approaches and techniques, particularly lesions, electrical stimulation, and electrophysiological recording. Study of the biological bases of behavior is now much broader and includes genetic factors, hormonal influences, neurotransmitter and chemical factors, neuroanatomical substrates, effects of drugs, developmental processes, and environmental factors, in addition to more traditional approaches. All these variables act ultimately through the nervous system. All these areas of investigation are entirely appropriate for *Behavioral Neuroscience* – all studies in which biological variables are manipulated or measured and relate to behavior, either directly or by implication.
>
> The contemporary meaning of the term 'behavioral neuroscience' is almost as broad as 'behavior' itself. Behavioral neuroscience is the field concerned with the biological substrates of behavior. Judging by its current rate of development, behavioral neuroscience could well become a dominant field of science in the future (Thompson 1983, p. 3).

By the time this occurred, the term 'behavioral neuroscience' was increasingly used to describe that aspect of the interdisciplinary field of neuroscience concerned with the biological basis of behavior. By the same token, 'cognitive neuroscience' was adapted more recently to emphasize that aspect of neuroscience concerned with the more complex phenomena of the 'mind.'

1. *Historical Developments*

The development of the two aspects of the study of 'brain, mind and behavior' is best viewed historically. As noted above 'behavioral neuroscience,' the subject of this article, is the modern equivalent of 'physiological psychology.' Since Wilhem Wundt, the founder of the modern field of psychology in the 1870s and himself a physiologist, titled his epoch making text *Grundzüge der Physiologische Psychologie* (1874), we

begin with his era. Wundt insisted on the experimental approach to all questions of psychology: the challenge was to find experimental methods to understand psychological processes. The most appropriate methods, e.g., measures of brain activity, did not of course exist in his day. Indeed, the only methods available were simple measurements of behavior like reaction time, and verbal descriptions of experience by introspection, both of which were used in Wundt's laboratory.

Wundt's career illustrates well the roots of the developing field of physiological psychology. After a year of study at Heidelberg in basic medical sciences, he moved to Berlin and worked for two years with Johannes Müller, a founder of modern, experimental physiology. Müller, incidentally, was a vitalist and believed that it would never be possible to measure the speed of the nerve impulse; his own student Helmoltz proved him wrong. Wundt then took his doctorate in medicine and was appointed Dozent in physiology at Heidelberg. Helmholtz then joined the same institute and they were colleagues, but not collaborators, for a period of 13 years. Wundt later moved to Leipzig and established the first formal psychological laboratory, in 1879.

Wundt's text and research at Leipzig represented a brilliant experimental physiologist grappling with problems of the mind and mental events, applying the experimental methods of science as best he could. In fact, the bulk of the research done in the Leipzig laboratory was on sensation and perception, and on reaction time.

Another laboratory of physiological psychology was founded at about the same time, that of William James. James went to Harvard and Harvard Medical School and studied with the great naturalist, Louis Agassiz. James was then, after a year of study abroad, appointed an instructor in physiology at Harvard College in 1872. He actually established an informal physiological psychology laboratory there in 1877 and taught a graduate course on the relations between physiology and psychology.

In sum, the two founders of modern psychology, Wundt in Germany and James in America, were both physiologists by training. More than a third of William James' extraordinary and influential text, *Principles of Psychology* (1890), was devoted to the nervous system. However, this does not necessarily mean that Wundt and James attempted to reduce psychology to physiology; rather they proposed that the subject matter of psychology should be studied scientifically, as in physiology. This view could equally apply to behavioral and cognitive neuroscience as it exists today.

There were powerful intellectual pressures moving bright young physiologically inclined psychologists at the turn of the century. The theory of evolution was a major force. The field of physiology, in particular neurophysiology, in the work of Sir Charles Sherrington and then Lord Adrian, together with clinical neurology and neuroanatomy, were vigorous and exciting fields at the beginning of the twentieth century.

The development of instrumentation was still another very important factor. The human EEG was rediscovered in 1929 (Berger) and the method applied to animal research in the 1930s. At the turn of the century the major experimental techniques for the study of brain function were ablation and electrical stimulation. Neuroanatomy was in its descriptive phase; the monumental work of Ramon y Cajal was published over a period of several decades beginning near the end of the nineteenth century. Neurochemistry was in its purely descriptive phase.

Merely because techniques and basic knowledge were limited does not mean that the field was quiescent. On the contrary, there was ferment over a number of basic issues ranging from the mind-brain problem to localization of function and the nature of neuronal interactions. Add to this the ferment developing in psychology as John Watson took on the older establishment and behaviorism began to dominate. This is the background from which modern physiological psychology developed.

2. *Lashley and the Engram*

Karl S. Lashley is the most important figure in the development of physiological psychology in America (see *Lashley, Karl Spencer (1890–1958)*). He obtained his Ph.D. in zoology at Johns Hopkins University. At Hopkins he studied with John Watson and was heavily influenced by Watson's developing notions of behaviorism. While there he also worked with Shepherd Franz at a government hospital in Washington; they published a paper together in 1917 on the effects of cortical lesions on learning and retention in the rat. Lashley then held teaching and research positions at the University of Minnesota (1917–26), the University of Chicago (1929–35) and then at Harvard from 1935 until his death in 1958. During the Harvard years he spent much of his time at the Yerkes Primate Laboratory in Orange Park, Florida.

Lashley devoted many years to an analysis of brain mechanisms of learning, using the lesion-behavior method, which he developed and elaborated from the work with Franz. During this period, Lashley's theoretical view of learning was heavily influenced by two congruent ideas: localization of function in neurology and behaviorism in psychology.

Localization of function was the major intellectual issue concerning brain organization at the turn of the century. An extreme form of localization was popular at the beginning of the nineteenth century with Gall and phrenology. The neurologist Flourens moved away from that position by arguing for no specific localization within the cerebrum. However, Broca's discovery of a speech center in 1861 began to move the

pendulum back. The critical and classic study on localization was that of Fritsch and Hitzig (1870). They stimulated the cerebral cortex electrically and defined the motor area: not only was it localized to a particular region of the cortex but there were specific organization and localization within it.

In Watson's behaviorism, the learning of a particular response was held to be the formation of a particular set of connections, a series set. Consequently, Lashley argued, it should be possible to localize the place in the cerebral cortex where that learned change in brain organization was stored: the engram. (It was believed at the time that learning occurred in the cerebral cortex). Thus, behaviorism and localization of function were beautifully consistent: they supported the notion of an elaborate and complex switchboard where specific and localized changes occurred when specific habits were learned.

Lashley set about systematically to find these learning locations—the engrams—in a series of studies culminating in his 1929 monograph *Brain Mechanisms of Intelligence*. In this study he used mazes differing in difficulty, and made lesions of varying sizes in all different regions of the cerebral cortex of the rat. The results of this study profoundly altered Lashley's view of the brain organization and had an extraordinary impact on the young field of physiological psychology. The locus of the lesion is unimportant; the size is critically important, particularly for the more difficult mazes. These findings led to Lashley's two theoretical notions of equipotentiality and mass action, i.e., all areas of the cerebral cortex are equally important (at least in maze learning), what is critical is the amount removed.

Lashley's interpretations stirred vigorous debate in the field. Walter Hunter, an important figure in physiological-experimental psychology at Brown University who developed the delayed response task, argued that in fact the rat was using a variety of sensory cues: as more of the sensory regions of cortex were destroyed, fewer and fewer cues became available. Lashley and his associates countered by showing that removing the eyes has much less effect on maze learning than removing the visual area of the cortex. Others argued that Lashley removed more than the visual cortex. Out of this came the long series of lesion-behavior studies analyzing behavioral 'functions' of the cerebral cortex. Initially, studies focused on sensory areas of the cerebral cortex. Beginning in the 1940s several laboratories, including Lashley's and those of Harry Harlow at the University of Wisconsin and Karl Pribram at Yale, took up the search for the more complex functions of association cortex using monkeys. Lashley's interests were not limited to brain mechanisms of learning. His influence is felt strongly through the many eminent contemporary behavioral neuroscientists who worked or had contact with him; Austin Riesen, Donald O. Hebb, Roger W. Sperry and Karl Pribram are examples. Hebb's book *The Organization of Behavior* (1949) is a landmark, as is Sperry's work on consciousness.

We now treat the development of the major areas of research that characterize modern behavioral neuroscience, namely neural and biological substrates of learning and memory, motivated behaviors, and sensory processes.

3. Learning and Memory

3.1 Pavlov

Lashley's pessimistic conclusions in his 1929 monograph put a real damper on the field concerned with brain substrates of memory. But there were other major traditions developing. Perhaps the most important of these was the influence of Pavlov. His writings were not readily available to Western scientists, particularly Americans, until the publication of the English translation of his monumental work *Conditioned Reflexes* in 1927. It is probably fair to say this is the most important single book ever published in the field of behavioral neuroscience. Pavlov developed a vast and coherent body of empirical results characterizing the phenomena of conditioned responses, what he termed 'psychic reflexes.' He argued that the mind could be fully understood by analysis of the higher order learned reflexes and their brain substrates.

W. Horsley Gantt, an American physician, worked with Pavlov for several years and then established a Pavlovian laboratory at Johns Hopkins. He trained several young psychologists, e.g., Roger Loucks and Wolf Brogden, who became very influential in the field. Perhaps the most important modern behavioral analyses of Pavlovian conditioning are the work of Robert Rescorla and Allan Wagner.

Although Pavlov worked with salivary secretion, most studies of classical conditioning in the West tended to utilize skeletal muscle responses, à la Bechterev. Particularly productive have been Pavlovian conditioning of discrete skeletal reflexes (e.g., the eyeblink response) characterized behaviorally by Isadore Gormezano and Allan Wagner and analyzed neuronally by Richard Thompson and his many students; and fear conditioning, first characterized behaviorally by Neal Miller and analyzed neuronally by several investigators (see Sect. 3.6).

3.2 Consolidation

Carl Duncan's discovery of the effects of electroconvulsive shock on retention of simple habits in the rat, in 1949, began the modern field of memory consolidation. Hebb and Gerard were quick to point out the implication of two memory processes, one

transient and fragile and the other more permanent and impervious. James McGaugh and his associates have done the classic work on the psychobiology of memory consolidation. McGaugh and his colleagues (see McGaugh 2000) demonstrated memory facilitation with drugs and showed that these effects were direct and not due to possible reinforcement effects of the drugs (and similarly for ECS impairment).

Chemical approaches to learning and memory are recent. The possibility that protein molecules and RNA might serve to code memory was suggested some years ago by such pioneers as Gerard and Halstead. The RNA hypothesis was taken up by Hyden and associates in Sweden and by several groups in America. An unfortunate byproduct of this approach was the 'transfer of memory' by RNA. These experiments, done by investigators who shall remain nameless, in the end could not be replicated.

At the same time, several very productive lines of investigation of neurochemical and neuroanatomical substrates of learning were developing. In 1953, Krech and Rosenzweig began a collaborative study on relationships between brain chemistry and behavior. Their initial studies concerned brain levels of AChE in relation to the hypothesis behavior and included analysis of strain differences (see, e.g., Krech et al. 1954). More recently, they and their collaborators, Bennett and Diamond, discovered the striking differences in the brains of rats raised in 'rich' vs. 'poor' environments. William Greenough, at the University of Illinois, replicated and extended this work to demonstrate dramatic morphological changes in the structures of synapses and neurons as a result of experience.

3.3 Model Systems

The use of model biological systems has been an important tradition in the study of neural mechanisms of learning. This approach has been particularly successful in the analysis of habituation, itself a very simple form or model of learning (see *Habituation*). Sherrington did important work on flexion reflex 'fatigue' in the spinal animal at the turn of the century. Sharpless and Jasper (1956) established habituation as an important process in EEG activity. Modern Russian influences have been important in this field: the key studies of Evgeny Sokolov, first on habituation of the orienting response in humans and more recently on mechanisms of habituation of responses in the simplified nervous system of the snail (see Sokolov 1963).

The defining properties of habituation were clearly established by Thompson and Spencer in 1966, and the analysis of mechanisms began. Several laboratories using different preparations (Aplysia withdrawal reflex: Kandel and associates, see Kandel 1976; vertebrate spinal reflexes: Thompson and Spencer; crayfish tail flip escape: Krasne, Kennedy, see Krasne and Bryan 1973) have all arrived at the same underlying synaptic mechanism: a decrease in the probability of transmitter release from presynaptic terminals of the habituating pathway. Habituation is thus a very satisfying field: agreement ranges from defining behavioral properties to synaptic mechanisms. In a sense, the problem has been solved. Habituation also provides a most successful example of the use of the model biological systems approach to analysis of neural mechanisms of behavioral plasticity (see Groves and Thompson 1970).

3.4 Hippocampus

Study of the role of the hippocampus in learning and memory has become an entire field. It began with Brenda Milner's extraordinary studies of patient H. M., who following bilateral temporal lobectomy lost the ability to remember his own life experiences, dating to a year or so before his operation and continuing to the present (see Milner 1966). However he is able to learn motor and even complex sensory-motor skills normally. A large animal literature grew in unsuccessful attempts to develop animal models of H. M.'s syndrome. In 1978 Mortimer Mishkin, at NIMH, developed a striking analogue of H. M's syndrome in monkeys by removing the hippocampus and amygdala bilaterally. The animals still had normal visual pattern discriminations but were markedly impaired in recognition memory (delayed non matching to sample task). From recent work, e.g., by Mishkin, Larry Squire, Stuart Zola and others, it is clear that the most extreme form of the syndrome in both monkeys and humans involves the hippocampus and related cortical areas but not the amygdala. Study of hippocampal function, particularly in humans in the context of declarative or 'what' memory is a major topic in cognitive neuroscience today.

Another facet of hippocampal study in the context of behavioral neuroscience is long-term potentiation (LTP), discovered by Bliss and Lomo in 1970. Brief tetanic stimulation of monosynaptic inputs to the hippocampus causes a profound increase in synaptic excitability that can persist for hours or days. Many view it as a leading candidate for a mechanism of memory storage, although direct evidence is still lacking.

Yet another major impetus to study of the hippocampus is the remarkable discovery of 'place cells' by John O'Keefe (1976). When recording from single neurons in the hippocampus of the behaving rat, a given neuron may respond only when the animal is in a particular place in the environment (i.e., in a box or maze) reliably and repeatedly. There is great interest now in the possibility that LTP may be the mechanism forming place cells. A number of laboratories are

making use of genetically altered mice to test this possibility.

3.5 Cerebellum

Yet another brain structure that has become a minor industry in brain substrates of learning and memory is the cerebellum. Masao Ito and his associates in Tokyo discovered the phenomenon of long-term depression (LTD) in cerebellar cortex in 1982. Repeated conjunctive stimulation of the two major projection systems to the cerebellum, mossy-parallel fibers and climbing fibers, yields long-lasting decreases in excitability of parallel fiber-Purkinje neuron synapses. Ito developed considerable evidence that this process underlies plasticity of the vestibulo-ocular reflex. Thompson and associates and others showed that the memory traces for classical conditioning of discrete responses (e.g., eyeblink conditioning) are stored in the cerebellum (Thompson 1986). LTD appears to be a critical process of such memory formation in the cerebellar cortex. The output of the cerebellum to other brain structures is from the cerebellar nuclei and Purkinje neurons inhibit nuclear neurons; hence cortical LTD would decrease inhibition on nuclear neurons.

3.6 Amygdala

Still another structure to assume a major role in the behavioral neuroscience of learning and memory is the amygdala. It was known for some time that electrical stimulation of the amygdala could elicit autonomic and emotional responses. An elegant literature developed by, e.g., Michael Davis, Joseph Le Doux, Michael Fanselow and others demonstrated clearly that the amygdala was the key structure in conditioned fear (see Davis 1992). Indeed, this literature is at least consistent with the view that the essential memory traces for classical fear conditioning are established in the amygdala.

The amygdala is also critical for instrumental learning of fear. James McGaugh and his associates demonstrated that for both passive and active avoidance learning (animals must either not respond, or respond quickly, to avoid shock) amygdala lesions made immediately after training abolished the learned fear (see McGaugh 1989). Surprisingly, if these same lesions were made a week after training, learned fear was not abolished, consistent with a process of consolidation. The apparent differences in the role of the amygdala in aspects of learned fear is an interesting issue.

4. Motivation and Learning

Physiological and neural mechanisms of motivation and emotion have been a particular province of physiological psychology since the 1930s. In recent years, the fields of 'motivation' and 'emotion' have tended to go separate ways. However, motivation and emotion have a common historical origin. In the seventeenth and eighteenth centuries, instinct doctrine served as the explanation for why organisms were driven to behave (at least infrahuman organisms without souls). Darwin's emphasis on the role of adaptive behavior in evolutionary survival resulted in the extension of instinct doctrine to human behavior. Watson rebelled violently against the notion of instinct and rejected it out of hand, together with biological mechanisms of motivation.

In 1928, Bard showed that the hypothalamus was responsible for 'sham rage.' In the 1930s, Ranson and his associates at Northwestern, particularly Magoun and Ingram, published a classic series of papers on the hypothalamus and its role in emotional behavior. Somewhat later, Hess and his collaborators in Switzerland were studying effects of stimulating the hypothalamus in freely moving cats.

4.1 Motivated Behaviors

It is against this backdrop that the modern field of psychobiology of motivation developed (the term 'motivated behaviors' is now preferred to 'motivation'). Karl Lashley was again the prime mover. His paper on *The experimental analysis of instinctive behavior* in 1938 was the key. In it, he argued that motivated behavior varies, and is not simply a chain of instinctive or reflex acts, that it is not dependent upon any one stimulus, and that it involves central state. His conclusions, that 'physiologically, all drives are no more than expressions of the activity of specific mechanisms' and that hormones 'activate some central mechanism which maintains excitability and activity' have a very modern ring.

A most important series of studies was originated in a paper by Klüver and Bucy on *Psychic blindness and other symptoms following bilateral temporal lobectomy in rhesus monkeys* in 1937. This came to be known as the Klüver–Bucy syndrome. The animals exhibited marked changes in motivation and aggressive behavior. The Klüver–Bucy syndrome, together with the suggestion of Papez (1937) that the structures of the limbic system formed a basic circuit for motivation and emotion, led to the extensive field concerned with the behavioral functions of the 'limbic system' (see Isaacson 1982).

Lashley's general notion of a central mechanism that maintains activity was developed by Beach in an important series of papers in the 1940s into a central excitatory mechanism and ultimately a central theory of drive. This view was given a solid physiological basis by Donald Lindsley from the work he and Magoun and associates were doing on the ascending reticular activating system. Lindsley sketched his activation theory of emotion in his important chapter in the *Stevens Handbook* (1951). D. O. Hebb and Elliot

Stellar pulled all these threads together into a general and influential central theory of motivation.

In his empirical work, Beach focused on brain mechanisms of sexual behavior. As the study of sexual behavior developed, hormonal factors came to the fore and the modern field of hormones and behavior developed. Beach played a critical role in the development of this field. Even within the field of hormones and behavior, several fields have developed. Sexual behavior has become a field unto itself. Another important field today is the general area of stress. The endocrinologist Hans Selye was an important intellectual influence. Kurt Richter is the pioneering figure in this field in physiological psychology. Richter took his Ph.D. from Johns Hopkins in 1921 and established his laboratory there. He worked in several areas, including the role of the adrenal gland in stress. The modern field of stress focuses on hormonal-behavioral interactions, e.g., the work of Seymore Levine.

Neal Miller represents a uniquely important tradition in behavioral neuroscience. From the beginning of his career, Miller was interested in physiological mechanisms of both motivation and learning. He took his Ph.D. from Yale in 1935 and stayed on at Yale for many years, with a year out in 1936 at the Vienna Psychoanalytic Institute. Miller was a pioneer in early studies of punishing and rewarding brain stimulation and their roles in learning. He was the first to demonstrate conditioned fear. In more recent years, his work focused on mechanisms of instrumental conditioning of autonomic responses. The impact of his work is much wider than physiological psychology, influencing psychiatry and clinical medicine as well.

4.1.1 Electrical self-stimulation of the brain. James Olds, whose untimely death in 1976 cut short an extraordinary career, made perhaps the most important discovery yet made in the field of behavioral neuroscience: rewarding electrical self-stimulation of the brain. He got his Ph.D. at Harvard and worked with Richard Solomon. Solomon, incidentally, although primarily a behavioral student of learning, had great impact on physiological psychology through his theoretical-experimental analysis of hypothetical central factors in learning. As a graduate student Olds read and was much influenced by Hebb's *The Organization of Behavior* and obtained a postdoctoral with Hebb at McGill in 1953. He began work with Peter Milner and they discovered electrical self-stimulation of the brain. The recent history of this field is well known to everyone. The brain reward system now appears closely similar if not coextensive with the 'addiction' system in the brain: the medial forebrain bundle dopamine projection system to the nucleus accumbens, prefrontal cortex, and other structures.

5. *Sensory Processes*

A major topic area in physiological psychology has been the study of sensory processes: sensation and perception. Indeed, this is perhaps the original field of psychology, dating back at least to Newton. Although specialization has resulted in separation between the fields of psychophysics and sensory physiology, in the sense that few individual scientists do research in both fields, they remain closely interlocked. From the beginning, explorations of sensory and perceptual phenomena have always involved hypothetical physiological mechanisms, e.g., the Young–Helmholtz 3 receptor theory of color vision and the Hering opponent process theory (see Hurvich and Jameson 1974).

This has been a field of extraordinary progress in the twentieth century. Techniques have been critically important. Early in the century there were really no tools, other than rather crude anatomical methods, for analyzing the organization of sensory systems in the brain. The pioneering studies of Adrian (1940) in England and Marshall, Woolsey and Bard (1941) at Johns Hopkins were the first to record electrical evoked potentials from the somatic sensory cortex in response to tactile stimulation. Woolsey and his associates developed the detailed methodology for evoked potential mapping of the cerebral cortex. In an extraordinary series of studies, Woolsey and his colleagues determined the localization and organization of the somatic sensory areas, the visual areas and the auditory areas of the cerebral cortex in a comparative series of mammals. They initially defined two areas (I and II) for each sensory field.

5.1 *Organization of the Sensory Systems*

In the 1940s and 1950s the evoked potential method was used to analyze the organization of sensory systems at all levels from the first order neurons to the cerebral cortex. The principle that emerged was strikingly clear and simple; in every sensory system the nervous system maintained a receptotopic map or projection at all levels from receptors to cerebral cortex: skin surface, retina, basilar membrane. The same organization held for the second sensory areas. The receptor maps in the brain were not one-to-one, rather they reflected the functional organization of each system: fingers, lips, and tongue areas were much enlarged in primate somatic cortex, half the primary visual cortex represented the forea, and so on.

The evoked potential method was very well suited to analysis of the overall organization of sensory systems in the brain. However, it could reveal nothing about what the individual neurons were doing. This had to wait development of the microelectrode. Indeed, the microelectrode has been the key to analysis of the fine-

grained organization and feature detector properties of sensory neurons. Metal microelectrodes were developed in the early 1950s: Davies at Hopkins developed the platinum-iridium glass coated microelectrode, Hubel and Wiesel at Harvard developed the tungsten microelectrode, and the search for feature detectors was on. The pioneering studies were those of Mountcastle and associates at Hopkins on the organization of the somatic-sensory system, those of Hubel and Wiesel at Harvard on visual system and Rose, Hind, Woolsey and associates at Wisconsin on the auditory system. Thanks to the microelectrode and to modern pathway tracing techniques, we now know that each sensory modality is represented multiply in the cerebral cortex.

Meanwhile, pioneering work was being done on receptors. Hartline and Ratliff analyzed receptor responses in a simple visual system, Limulus (horseshoe crab), and discovered lateral inhibition. Von Bekesy discovered the standing wave patterns in the cochlea (working in the psychology department at Harvard). Dark adaptation was explained in biochemical terms by Wald at Harvard. The role of eye movements in visual perception was elucidated by Riggs and associates at Brown.

In the recent past, progress in analysis of sensory processes has been quite remarkable. The ability to measure, with the microelectrode, the activity of single receptors or sensory neurons precisely, with tight stimulus control, has been matched by the great precision of psychophysical methods and results in humans and animals.

Analysis of the physiological properties of neurons in sensory systems, and their psychophysical concomitants, has become highly productive, sophisticated, and elegant. It is without question the most advanced field in behavioral neuroscience. Many would claim it as a separate field, or more precisely, a separate set of fields, i.e., the hearing sciences and the vision sciences. This, by the way, seems characteristic of behavioral neuroscience. The great questions are first raised within the field. As techniques develop and answers begin to appear, separate fields may be created.

6. Conclusion

Several earlier aspects of behavioral neuroscience have developed into separate fields in their own right. We noted the vision sciences and the hearing sciences (see Sect. 5.1). Study of physiological responses in humans has become the field of psychophysiology, with its own society and journal. Another example is the study of human brain damage, particularly in terms of higher functions. This field is now termed neuropsychology and is a part of modern cognitive neuroscience. Yet another example is the field of behavioral genetics, which grew from early studies of selective breeding of behavioral properties. Thanks to the extraordinary developments in genetics and molecular biology, behavioral genetics has become a component of neurogenetics.

The field of behavioral neuroscience (physiological psychology) has a long history of asking fundamental questions about biology, behavior, and experience and developing approaches to deal with these questions. The consequence is often that entire new fields of scientific endeavor develop and became distinct subspecialties in their own right. Perhaps in a more general sense the same can be said of psychology.

Behavioralism: Political

Behavioralism is a current or approach within the discipline of political science. In very general terms, it can be described as theory-led empiricism which aims at the establishment of laws, using as its epistemological model the methodology of the natural sciences. Its goal is the description, explanation, and prediction of political processes based on quantifiable data. Despite initial bitter resistance, behavioralism infiltrated most of the major American political science departments during the 1950s. From the early 1960s, it significantly molded the character of American political science for the next 15–20 years. Since then, there have been hardly any self-declared behavioralists, but the spirit of empiricism and methodical professionalism has shaped the discipline of political science within and outside of the United States to this day.

1. Historical Background

Viewed as an academic movement intended to reorient political science, behavioralism mainly represents a phenomenon of the 1950s and 1960s. As an intellectual school of thought, it can be traced back to the New Science of Politics movement of the 1920s and the Chicago School of Charles E. Merriam and Harold D. Lasswell. Both advocated a political science discipline modeled after empirical sociology, behavioristic psychology and modern economics. The New Science of Politics movement began as a reaction to the then-dominant institutionalist approach, known as 'institutional realism' or 'realist institutionalism.' The realist approach centered on the analysis of the actual (as opposed to simply the legal) relationships between branches of government, political parties, and interest groups. In general, the analysis of political institutions was oriented less toward theory-building than toward fact-finding, and a strict distinction between factual statements and value judgments was rare.

Improved collaboration between political scientists and administrators and politicians during the time of the New Deal and especially during World War II revealed the shortcomings of the realist approach. The gulf seemed too wide between what was required for effective political consulting and what political scientists were able to provide. In particular, the limited predictive capabilities were considered a major shortcoming (Dahl 1961). For example, realists fell short in explaining the success of European fascism through institutional analysis only. To many political scientists, the insights taken from neighboring disciplines, especially from psychology, sociology, and the economics, seemed theoretically and methodologically more sophisticated than those taken from political science.

Primarily younger political scientists became sharp critics of the realist approach but none formulated it with more urgency than David Easton. In programmatic writings dating back to the early 1950s, he criticized the theoretical deficit of the research at that time, the lack of methodological reflection and of

conceptual clarity, the absence of modern methods of data collection and evaluation, as well as the one-sided emphasis on institutional data. Owing to its lack of theoretical orientation and of a standard terminology, political science with its one-sided concentration on facts had failed in keeping pace with the development of sociology and psychology. Indeed, it had not established a canon of empirically sound knowledge that would allow the explanation and prediction of political events (Easton 1953).

Important sociological and socio-psychological studies such as *The People's Choice* (Lazarsfeld et al. 1944), the four volumes of *The American Soldier* (Stouffer et al. 1949) and *The Authoritarian Personality* (Adorno et al. 1950) proved to be important stimuli for those who criticized the institutional approach. Using newly developed data collection methods such as random sampling, attitude measurement based on psychometric scales, panel analysis, and sophisticated statistical methods, those books paved the way for successful behavioral research in the field of political science. Concurrently, a small group of researchers associated with the University of Chicago published several works along the lines of the emerging behavioralism approach. For example, in *Administrative Behavior* Herbert A. Simon (1947) advocated an administrative science based on Max Weber's postulate of value-free judgment and the spirit of logical empiricism. In 1949, V. O. Key Jr. published *Southern Politics*, soon to assume the status of a classic. In 1950, Gabriel Almond's empirical study of US attitudes towards foreign policy, *The American People and Foreign Policy*, followed. 1951 saw the publication of David Truman's analysis of politics as a process of group conflicts, entitled *The Governmental Process* (Truman 1951). In these studies, which were closely based upon methodological individualism, an alternative to the still dominant realistic institutionalism of traditional political science was developed. To many within the rising generation of academics these studies served as a paradigm of further research.

2. *The 'Behavioralist Revolution'*

In the early 1950s, the adherents of behavioralism were a small, scattered band of lone fighters, not held together by any organization, but loosely connected through their understanding of science. They met at seminars and gathered in conjunction with meetings of the American Political Science Association (APSA) to discuss new methods of empirical political science. The restructuring of the entire discipline of political science along the lines of behavioralism and not simply the addition of one more subdiscipline was the goal of these 'young Turks.' Not surprisingly, the demand for such a fundamental reorientation of political science met with stiff opposition from many established political scientists.

The supporters of the behavioralist approach increased steadily in number. They enjoyed early notable successes with the elections of Harald D. Lasswell, perhaps the most important intellectual pioneer of behavioralism, as President of APSA in 1955–6, and of V. O. Key Jr. as his successor in 1957–8. Under Lasswell, the APSA for the first time established a working group of its own concerned with issues of political behavior. By 1960, the number of behavioralist-oriented working groups at APSA conventions had grown substantially. At the same time, a series of important research studies tailored to behavioralism was published. In addition to the electoral studies conducted at Columbia University and at the University of Michigan (*Voting* and *The Voter Decides*, respectively), several programmatic and empirical studies were aimed at revamping the subfields of Comparative Politics and International Relations. After 1956, the profile of the *American Political Science Review* began to change fundamentally, a sign of the gradual transformation of the discipline. The quantitative element was slowly pushing itself to the fore. Practically all of the major American universities appointed behavioralists to their political science departments, starting a sort of chain reaction that accelerated the spread of the behavioralist conviction. After 1960, studies written in the spirit of behavioralist research began to shape the profile of the leading political science publications and the institutional policies within APSA. With only a very few exceptions, all Presidents of the APSA after 1964 were elected from the ranks of the behavioralist movement. Within a decade and a half, behavioralism had succeeded in remodeling the field of political science in the United States.

The rise of behavioralism was also evident in the dramatic increase in research output after 1960. Not a single area of political science was left untouched by the behavioralist wave, although the extent to which behavioralist thought penetrated the various subdisciplines differed. At the center was the study of decision-making and behavioral patterns. In behavioralist research, the individual served as the basis for data collection, and the individual actor, the group, the institution, or even the political system in its entirety formed the basis upon which statements were made. The core concepts of behavioralist research were *political decisions* (Simon 1947), *roles* (Eulau 1963), *interest groups* (Truman 1951), the *political system* (Easton 1965), or *power* itself (Lasswell and Kaplan 1950).

Thus, theoretical concepts and not any longer the analysis of day-to-day-politics as promoted by many institutional realists became the core of intensive discussion. That its main representatives were renowned scientists gave credence to behavioralism. Their research helped to promote the behavioralist approach probably more effectively than all programmatic studies combined that had preceded them.

Among the most renowned studies are *The American Voter* (Campbell et al. 1960), *The Civic Culture* (Almond and Verba 1963) and *The Nerves of Government* (Deutsch 1963). The financial assistance of major scientific foundations and corporations such as Carnegie, Ford, and Rockefeller proved crucial to the success of behavioralist studies that are often time consuming and expensive in their implementation.

3. *The Behavioralist Research Program*

The most important aims and assumptions of behavioralism are summarized and discussed below. Largely owing to the split between a more theoretical branch and a more empirical one, few behavioralists would have agreed with every one of these statements, but the catalogue of behavioralist principles intends to capture the theoretical and epistemological nucleus of the various behavioral science branches within American political science.

(a) In general terms, behavioralism can be defined as *theory-oriented empiricism*. Its aim is not the pure description of political processes, but their explanation and prediction through empirical laws that postulate political and social regularities.

(b) *A systematic and cumulative method*. Empirical investigations should build upon the findings of earlier studies, thereby increasing the range of theoretical statements.

(c) *A focus on the social and psychological determinants of political behavior*. The latter determinants include all types of personality traits such as attitudes or behavioral intentions. The use of mental concepts and the acceptance of introspectively obtained information differentiates behavioralism from psychological Behaviorism. Thus, treating both currents as equivalent seems unwarranted.

(d) *The inductive method*, i.e., the establishment of scientific laws by generalizing from observed social regularities.

(e) *Interdisciplinarity*, i.e., the use of approaches, theoretical concepts and results from other social sciences; this is one of the central elements of the behavioralist research program.

(f) *Orientation toward basic research*. A demand for applied research that is either too forceful or untimely leads according to the 'behavioral creed' to a theoretical abstinence that obstructs cognitive progress.

(g) *The demand for verification*. According to behavioralism, all statements in political science must be in principle verifiable.

(h) *Strict operationalism*. All theoretical terms must be translatable into an observational language. In order to meet the demand for empirical verification, all statements must therefore be attributable to observable behavior.

(i) *A focus on the behavior of individuals as the basic empirical unit of analysis*. Behavioralist research centers more on the informal aspects of the political process and the behavior of individual actors and political groups than on institutions and formal rules. In contrast to psychological behaviorism, the behavioralistic notion of behavior includes not only directly observable behavioral acts but also the attitudinal antecedents and the products of behavior as well as speech acts.

(j) *The use of empirical methods of data collection and evaluation*. In order to meet the demand for verification, suitable collection and evaluation methods should be used, such as attitude scales or complex statistical techniques. Quantitative concepts should be employed wherever possible. According to the research program (although not always to behavioralistic research practice), when a numerical description is not possible, one should turn to qualitative methods. Quantification should not be conducted to the detriment of the substance or of the relevance of the subject matter.

(k) *Adherence to scientific quality criteria*. For reasons of precision and of verification, the instruments of measurement employed must meet the demands of reliability, validity, and objectivity (understood as independence of results from the individual researcher). Furthermore, the representativeness of data is precondition for generalizations. Finally, to avoid contradictions, the concepts employed should be clearly and unequivocally defined and used consistently.

(l) *The principle of value neutrality*. In empirical research, value judgments cannot be justified by scientific method. Owing to their normative character, they interfere with the cognitive content of empirical statements. Thus, such statements should not contain any value judgments.

Over these propositions, the so-called behavioralism controversy erupted during the 1960s. Adherents of normative–philosophical and neo-Marxist standpoints attacked the basic tenets of behavioralism Most self-proclaimed behavioralists, however, opted to stay out of the dispute in favor of concrete, empirical research. Thus, the debate was somewhat lopsided. As for behavioralism itself, it survived this dispute about methods relatively unscathed (Waldo 1975, Falter 1982).

4. *The Imprint of Behavioralism*

In practice, the goals of the behavioralism research agenda have been implemented to differing degrees. For example, the principle of interdisciplinarity has been adopted widely and successfully. As far as the theoretical foundation or the value neutrality was concerned, however, some of the research fell short of its goals. Despite earlier efforts by David Easton (1953, 1965) and Karl W. Deutsch (1963), and exceptions notwithstanding, the development of termino-

logical frameworks with theoretical relevance have remained largely without consequence for empirical research. With regard to verificationism, behavioralism opposes modern analytical theory of science that—in view of the logical shortcomings of the verification principle—only insists on the indirect falsification or confirmation of statements. The same is true for the behavioralistic postulate of strict operationalism; modern analytical theory of science allows as well the indirect empirical interpretation of theoretical concepts.

Even if hardly any modern political scientists see themselves as behavioralists in the narrow sense, American political science, and in its wake major sections of the discipline worldwide, were shaped and permeated by behavioralism. Therefore, one can indeed speak, to use Thomas Kuhn's expression, of a scientific revolution (Kuhn 1962). Contemporary electoral and attitudinal research, policy analysis, and numerous representatives of the rational choice approach owe their convictions to behavioralism.

Behaviorism

Historically, behaviorism was the 'school' of psychology, associated with the name of John Broadus Watson, that rejected mental states and treated all psychological phenomena in terms of stimuli, responses, and stimulus–response associations. Watson launched the system in 1913, with his behavioristic manifesto, *Psychology as the Behaviorist Views It*. He spelled out implications and applications in his 1924 book, *Behaviorism*. This article describes behaviorism as Watson conceived it and presents the criticisms and reactions that led to revisions and a collection contemporary behaviorisms that have replaced Watson's version.

1. Classical Behaviorism

Watsonian behaviorism came into psychology as a protest against structural psychology ('structuralism'), the dominant theory of the time. Structuralism asserted that the purpose of psychology is to understand the mind and consciousness and that the road to such understanding is the introspective method. Watson (1924, p. 3) rejected both of these ideas: 'Consciousness is neither a definable nor a usable concept … it is merely another word for "soul."' As for introspection, 'we find as many introspections as there are individual psychologists. There is no way of experimentally attacking and solving psychological problems and standardizing methods' (Watson 1924, pp. 5–6).

One way to introduce the substantive ideas in classical behaviorism is to organize them around what, for Watson, were the hallmarks of the scientific method: empiricism, determinism, and analysis.

1.1 Empiricism

Instead of consciousness, Watson asked psychology to limit its inquiry to observables: 'Why don't we make

what we can observe the real field of psychology? Now what can we observe? Well, we can observe behavior (responses)—what the organism says or does [and the situations (stimuli) in which behavior occurs'] (Watson 1924, pp. 6–7). This insistence on observation had consequences that often were unpopular.

1.1.1 Rejection of mental states. The psychology of Watson's time often analyzed the contents of the mind into Plato's three human talents: knowing, feeling and doing, which modern psychology calls cognition, affect, and reaction tendencies (Kimble 1996). Watson objected to such mentalistic concepts and translated them into conditioned reflexes: 'laryngeal (language) reflexes' for cognition, 'visceral (emotional) reflexes' for affect, and 'manual (motor) reflexes' for reaction tendencies.

1.1.2 Rejection of physiological states. Watson put physiological mechanisms in the same category of unobservables as mental states. He had little hope that behavior can be reduced to physiology and blamed the structuralists for the promotion of the fiction that it can be: '[For a structuralist] the nervous system … has always been a mystery box—whatever he couldn't explain in "mental" terms he pushed over into the brain' (Watson 1924, p. 43). 'Until [the physiologist has reduced the various phenomena of psychology] to electrical and chemical processes … he cannot help us very much' (p. 169).

1.1.3 Radical environmentalism. Watson's methodological empiricism led naturally to the conclusion that most human traits are learned. He expressed this sentiment in his famous statement:

> Give me a dozen infants, well-formed, and my own specified world to bring them up in and I'll guarantee to take any one at random and to train him to become any type of specialist I might select—doctor, lawyer, merchant-chief and yes, even beggar-man and thief, regardless of his talents, penchants, tendencies, abilities, vocations, and the race of his ancestors' (Watson 1924, p. 82).

1.2 Determinism

Watson came to his position from an interest in animal research, a fact that had two major consequences for his treatment of psychology: First, it accounts for his preference for laboratory experimentation over introspection, which becomes undisciplined anthropomorphism in the study of animal behavior. Second, it emphasized the fact that human beings are animals: 'The behaviorist, in his attempts to get a unitary scheme of animal response, recognizes no dividing line between man and brute' (1924, p. 16). As is true of other animals, human behavior is determined: 'the child or adult has to do what he does' (p. 144).

1.3 Analysis

Watson was explicit on the point that analysis is inherent in the behavioristic position: 'All through our study of behavior [we will have] to dissect the individual. My excuse is that it [is] necessary to look at the wheels before we [can] understand what the whole machine is good for' (1924, p. 216).

2. Criticism and Revision

Even in Watson's time, many psychologists objected to behaviorism, because it seemed to dehumanize humanity, to make the individual a robot, and to ignore the personal realities of consciousness, will, and sense of self. Later, in the middle of the twentieth century, some members of the scientific community (particularly those who fought against behaviorism in the 'cognitive revolution') criticized the position in other terms: as merely scientistic, a mimicry of science. Because it concentrates on laboratory investigation with white rats, it produces knowledge that is superficial, oversimplified, and irrelevant to human behavior.

Such criticism led psychologists who leaned toward behaviorism to the development of several more liberal behaviorisms, which revised Watson's theory in ways that can be presented by revisiting the topics of empiricism, determinism, and analysis.

2.1 Empiricism

Beginning in the 1920s psychology came under the influence of the philosophy of science called logical positivism, which insisted that the basic data of science reside in public observation, and that to be acceptable to science concepts must have what came to be called operational definitions. In the words of Kenneth Spence some years later:

> Accepting the requirement that all terms employed by the scientist, no matter how abstract, must ultimately be referable back to some primitive or basic set of terms that have direct experiential reference, [the logical positivists] suggested that such a basic ['observable thing-language'] for science is provided by the terms designating directly observable physi-

> cal objects such as tables, chairs, and cats, their properties, e.g., green, hard and loud, and the relations [among] them such as between, before, and below (Spence 1956, p. 13).

Operationism allowed acceptance of most of what Watson had rejected along with the subjectivity of structural psychology.

2.1.1 Mental states. As early as 1922, Edward C. Tolman offered a 'new formula for behaviorism' which encouraged psychology to treat mental states as intervening variables that are tied to observation by operational definitions. Later on (1925), for example, he defined one such state for a nonhuman organism—a rat's 'purpose' to obtain food at the end of the maze that the animal is learning—in terms of observable quality of the animal's behavior that one might call 'persistence until' the goal is reached. Once it honors its commitment to base its science on stimuli and responses, psychology can use those data to define concepts that are as biological, cognitive, or humanistic as it chooses.

2.1.2 Physiological states. Since Watson's time, advances in neuroscience (PET scans, MRI imaging, computerized electroencephalography) have provided ways of determining whether behavioral concepts have representations in the brain. When they do, most psychologists take these representations as evidence of the physiological reality of their concepts. A minority, with Watson, believe that this is all they are, that the final determiner of the value of a concept for psychology is its relevance to behavior. All that physiology can contribute is the comfort provided by any confirmation of a theoretical idea.

2.1.3 Biological–environmental interaction. Also since Watson, advances in the study of animal behavior (ethology) and behavioral genetics have tempered the behaviorists' radical environmentalism. Now, the standard position is that behavior results from an interaction between environmental and biological influences. The relative importance of environment and biology vary. For instinctive acts, biology makes the stronger contribution; in social behavior environment is more important.

2.2 Determinism

This interpretation of human behavior as the consequence of interactions between external forces leaves some psychologists, along with ordinary people, uncomfortable because it violates the notion that behavior is caused by resident agents with tangible reality. For those who take this point of view, to explain behavior is to identify those causal agents. Many experimental psychologists find causality in the new-found biological mechanisms mentioned earlier. For many cognitive psychologists, causality is in some mental agent who is busily constructing perceptions, searching memory, parsing text, and using algorithms and heuristics to solve problems. Other psychologists, including many behaviorists, question both conceptions because, in science, explanation is not in terms of indwelling physiological—much less mental—causes, but in terms of laws relating the dependent variables of that science (behavior for psychology) to independent variables.

2.3 Analysis

Although Watson accepted the scientific principle of analysis, contrary to common opinion, he was also recognized that the responses resulting from this analysis are responses of a total individual:

> Some psychologists seem to have the notion that the behaviorist is interested only in the recording of minute muscular responses. Nothing could be further from the truth. The behaviorist is … interested in the behavior of the whole man. … When [a man] reacts he reacts with each and every part of his body (Watson 1924, pp. 14, 75).

What was missing in Watson's theorizing were the overarching organizing mechanisms that, later on, Lashley (1951) called a 'syntax of behavior' and Miller et al. (1960) referred to as 'plans.' That omission is a flaw that remains in most modern versions of behaviorism.

3. Current Behaviorism

For Watson, behaviorism was 'a natural science that takes the whole field of human adjustments as it own' (Watson 1924, p. 11). He gave behavioristic interpretations of child rearing, education, business management, social programs, psychopathology, and psychotherapy. Throughout his long career, B. F. Skinner made similar claims for widespread relevance of behaviorism. He applied behaviorism to education, verbal behavior, psychotherapy, and even an imagined utopian society, Walden Two (Skinner 1948).

However, most psychologists with behavioristic sympathies abandoned comprehensive theory and turned to narrower applications, often in the field of learning. In that context, it is possible to identify a

family of behaviorisms that accept Watson's insistence that scientific psychology is stimulus–response psychology but differ on several other such points.

Radical behaviorism (Skinner 1938) places a strong emphasis on the environmental control of action. It rejects both mental states and physiology as determiners of behavior, and asserts that theories of learning are unnecessary.

Operational behaviorism (Tolman 1922, Spence 1956) accepts mental states when they are defined operationally. It recommends deductive theory and underemphasizes physiology.

Physiological behaviorism (Hull 1943, and most modern behaviorists) combines operational behaviorism with a preference for concepts identified with physiological processes and taken as effective causes of behavior.

Functional behaviorism (Thorndike 1911, Skinner 1981, Kimble 1996) treats behavior as a product of evolution. Both the behavior that has been preserved in evolution and the behavior that is acquired by learning have adaptive value.

Theoretical behaviorism (Staats, 1999, Staddon, 1999) treats internal states as theoretical constructions which may or may not be causal agents.

Only a few psychologists (Kimble, 1996, Staats, 1999) carry on the Watsonian tradition of behaviorism as a general theory of behavior.

G. A. Kimble

Behaviorism, History of

Behaviorism was gradually developed by some psychologists during the first decade of the twentieth century. There were several streams that motivated this. One was the effort to introduce methods of 'objective' natural science into psychology. The second was the effort to make explicit the argument against introspectionism. In fact, for many, behaviorism was akin to an intellectual war against introspective methods. The need for an objective, more scientific psychology was expressed in several countries: V. Bechterev in Russia, H. Piéron in France and J. B. Watson in USA called for a 'new psychology,' closely related to physiology. Their success depended on the historical, religious and scientific context in each country. But soon supporters of mentalism tried to crowd the psychological laboratories again, producing such a muddle that B. F. Skinner engaged in a crusade to restore the purity of behaviorism, conceived of as the philosophy of the science of behavior. Unfortunately, he encountered a prominent champion of mentalism, Noam Chomsky. The psycholinguist took advantage of the troubled times of the Vietnam War and the students' protest against the establishment to provide an alternative look at human beings, that was apparently much richer and deeper.

1. The Contexts of Emergence

1.1 The Nature of Voluntary Acts

At the end of the nineteenth century, psychology was deeply influenced by philosophical issues such as will or intelligence. Most psychologists tried to encompass these complex issues by using introspection, asking subjects to report their feelings or mental operations during some experimental task. In the context of an increasing appeal to scientificity, the subjectivity inherent in such a method soon turned into an obstacle hard to overcome. At the same time, evolutionary ideas, and particularly those of Darwin, exerted a

considerable pressure on the conception of natural beings. As Darwin proposed, the distinction between animal and human intelligence was one of degree, not of kind. Thus, the study of human intelligence or of human learning faculties may begin with animals. Several researchers, such as G. Romanes (one of Darwin's students) and C. Lloyd Morgan (one of Huxley's students), devoted their work to understanding the instinctive capacities of animals, and particularly their learning capacities. Emphasis was put on imitation and on trial and error learning, as discovered by A. Bain, professor of logic in Aberdeen. The question Bain raised was a decisive one and concerned the basis of the voluntary act: when someone performs an action for the first time, does he or she do it in response to an exterior solicitation, or because he or she wants it? For the time, Bain's answer was highly original: it is by accident. If that accident is followed by a benefit, the individual will repeat that response whenever the solicitation occurs again. If the 'sanction' is painful, he or she will not. According to Bain, it is through this process that a spontaneous act becomes a voluntary one (Bain 1855). Of course, Bain's conceptions evoke the Darwinian selection of types as well as the utilitarianism of his friend Stuart Mill. In just the same way that biological types emerge, an act is evaluated from the perspective of its usefulness, in terms of the pleasure or pain it engenders.

1.2 The Beginnings of Animal Psychology in the United States

The works of these first British psychologists did not receive a real response in Great Britain. However, they considerably influenced American psychology and the birth of behaviorism. One man in the United States was especially receptive to the beginnings of animal psychology: E. L. Thorndike. Thorndike was a student of William James at Harvard and was inevitably influenced by the pragmatism and the functionalism of James. After reading the works of Morgan, Thorndike decided to study the mechanisms of learning for some kinds of animal behavior that were not included in their instinctive endowment. In James' cellar, he built some strange boxes, hard to open (the device to exit included, for instance, a simple rotating catch), in which he put a hungry animal and then observed the animal's behavior. These puzzle boxes marked the beginning of American behaviorist psychology. Thorndike studied trial and error learning in a systematic and quantitative manner (he quoted the number of trials necessary to open the door and the response latency for each trial, and thus provided the first learning curves). On the basis of several experiments, he was convinced that the animal learned to solve the problem by connecting the visual perception of the opening mechanism with what he called the successful motor impulse. The implication of this 'stimulus–response,' or S–R, view of learning is that animals learn what to do without in any sense knowing the consequence of the action. The sole effect of reward (something to eat) was to 'stamp in' the S–R connection. Thorndike called this phenomenon the 'Law of Effect' (Thorndike 1898).

1.3 Psychology in Russia and France

But the works of Thorndike did not initially receive a significant response in the United States. He wrote about his researches to a physiologist who was also working on animal learning, far from the United States: I. Pavlov. At the end of the nineteenth century, Pavlov studied the gastric secretion and conditional reflex in dogs. The study of conditioning began during a period of dramatic political developments in Russia, and universities were at the center of political strife. The medical school of St. Petersburg diffused materialistic ideas. In this school, a psychiatrist colleague of Pavlov, V. Bechterev, proposed to stop asking patients to report their feelings and subjective experience in the study of mental diseases. He was convinced that an objective study of the changes occurring during mental diseases would be more instructive. He presented a synthetic report of his convictions in a famous paper of 1906 called 'La psychologie objective,' in which he expressed a radical rejection of introspection. He asserted that introspection had no contribution whatsoever to make to the wider range of problems which psychology should be concerned with (such as mental testing, psychiatric disorders, and animal behavior). Following Sechenov and Pavlov, Bechterev considered the reflex as a key concept of this new objective psychology.

This trend towards an objective point of view in psychological studies was also important in France. In 1908, a psycho-physiologist, H. Piéron, asserted that, to be scientific, psychology had to be centered on behavior and had to ignore consciousness. Piéron was very influential, and founded many institutions and psychological reviews. His objective psychology remained, however, too physiological to change the French way of considering human conduct significantly. Psychoanalysis and the clinical psychology of P. Janet were much more influential and French psychology never became truly 'behavioristic.' Powerful obstacles towards a materialistic conception of man included questions of philosophical context (such as spiritualism), biological choices (Piéron, for example, was a neo-Lamarckian), and religious background (Catholicism remained silently important).

Meanwhile, comparative aspects entered into the battle for objective psychology in the United States. American psychology expanded rapidly around the turn of the century, becoming a prominent aspect of the general growth of higher education and scientific research. Thorndike had stopped working with ani-

mals soon after completing his thesis, and animal psychologists were not receiving financial support, in contrast to Pavlov's school in Russia. Animal psychologists studied first the sensory abilities of animals. Most of them went to Germany to learn the strict methodological rules of experimentation. It was first in France, then in Germany, that a strange but decisive debate concerning invertebrates' behavior took place.

2. *The Psychology of Microorganisms and 'Behavior Man'*

2.1 *A New Object to Study: Protozoa*

Although most psychologists believed that their subject was, or should be, a science, they continued to debate questions dealing with the mind–body problem. As a consequence, psychology here and there still appeared more as a branch of philosophy. The question of where mind and inner life appear on the evolutionary scale became of interest when A. Binet, a French psychologist, published in 1889 a book entitled *La Vie Psychique des Micro-organismes*. He suggested that single-celled animals could perceive and discriminate objects and perform purposive actions. Binet agreed with the rather romantic assertion of E. Haeckel, the German evolutionist, that 'all nature was ensoulled.'

Jacques Loeb, a young German student, imported such preoccupations to the United States. The year Binet's book was published, Loeb proposed a general theory of tropism, first concerning plants, then lower animals. He carried out experiments in the new University of Chicago, and a lively group of young experimentalists did the same at Harvard, recording reactions to systematic changes in various forms of stimulation (chemical, electrical, and by temperature change, for example). Loeb's aim was to explain behavior along purely mechanistic lines, according to a rather reductionist viewpoint. His conceptions were strongly attacked by H. S. Jennings, who asserted that the life of protozoa was far more complicated than Loeb maintained. Jennings joined the biology department of Johns Hopkins University two years after J. M. Baldwin had been appointed to revive psychology at this university. Some of Jennings' ideas about evolution were based on the 'principle of organic selection' that Baldwin and Lloyd Morgan had proposed in 1890.

2.2 *The 'Crisis' in American Psychology*

It is in such a paradoxical context of interest in the evolution of the mind, on the one hand, and in the study of mindless creatures, on the other, that J. B. Watson came to animal psychology and then founded behaviorism. At this time, American psychology was characterized by a lack of strong direction. It had to find a way of reconciling three conflicting aims: (a) to explain the nature of subjective experience and study the mind; (b) to be scientific and objective and use the kind of empirical methods employed in other sciences; (c) to be interesting for questions in everyday life or to make significant practical contributions (specially in education or mental health). When Watson defended the inclusion of animal studies within psychology, he presented the analysis of behavior as promising a combination of usefulness and scientific respectability that the previous alternative, the psychology of consciousness, had failed to provide.

Watson was an atypical American scientist. He came from a small farm in South Carolina and had a wild adolescence. Unexpectedly, he developed a strong interest in philosophy. At 22, after having written to John Dewey, he went to the University of Chicago where a psychological laboratory, included in the philosophy department, was directed by James Angell. There he began working on the process of myelinization of nerve fibers in the brain of rats. He became a close friend of R. Yerkes, who had been one of Thorndike's assistants and then championed comparative psychology as the field capable of providing criteria for the objective scientific verifiability necessary to imbue the whole discipline with sustained faith. Yerkes tried to resolve the disciplinary 'crisis' which affected psychology. He studied discrimination in 'dancing mice' in Harvard and embarked on a collaborative project with Watson on methods for studying vision in animals. Soon, Watson became much more radical and confident than Yerkes, especially concerning the rejection of mentalism. For several reasons, Watson had rapidly attained institutional and professional security: at the age of 31, he replaced J. M. Baldwin both as the head of the journal, *Psychological Review*, and as the chairman of the department of psychology at Johns Hopkins University. To be placed in this professional position was rather strange: Watson was not really well informed about human psychology, and he pursued a line of research which most of his colleagues believed to belong to biology, far from central issues of psychology. 'It is not up to the behavior man to say anything about consciousness,' Watson wrote to Yerkes in 1909. Nevertheless, the 'behavior man' was going to use that key position in American psychology to promote his standpoint.

3. *Watson's Manifesto of Behaviorism*

3.1 *'Psychology as the behaviorist views it'*

In 1913, Watson had the fortunate occasion to make explicit his numerous convictions about psychology. J. McKeen Cattell offered him a forum for their dissemination by inviting him to give a series of eight public lectures at Columbia University, the American center of applied psychology. First of all, Watson

announced that psychology should become an objective experimental science of the prediction and control of behavior. A behaviorist is a psychologist who asserts that there is no dividing line between man and brute, and who strives to arrive at a unitary scheme of animal response, including the behavior of man, with all its refinement and complexity. According to him, the introspective method was to be discarded and to be replaced by the observation of stimulus-response connections, which influence behavior without resort to consciousness. If psychologists followed the plan he suggested, the physician, the jurist and the businessman could utilize psychological data for practical purposes. Watson expressed optimism about the benefits psychology would obtain from taking the behaviorist standpoint. He knew that his conceptions had to confront very complex aspects of human psychology, such as imagination, judgment or reasoning, but he showed himself confident that behaviorism would succeed. A year later, his book *Behavior: An Introduction to Comparative Psychology* presented a central Watsonian conviction: 'there are no centrally initiated processes.' Implicit behavior consists of word movements and thought is a sub-vocal speech according to Watson.

If his colleagues at Johns Hopkins University, A. Meyer, H. Jennings, K. Dunlap, or K. Lashley, shared most of the opinions Watson expressed in 1913, they did not follow Watson on these new elements of behaviorism. First of all, they were Darwinians. But Watson, in contrast, and like Loeb, saw no interest in placing psychology within any evolutionary context. They rejected the search for any single principle, such as tropism or habit, to explain every aspect of behavior. And they did not share his faith in the peripheral origins of all psychological events. Moreover, Watson considered that science had to predict and control, when other psychologists claimed that the goal of science was to understand phenomena. Not all the 'behavior men' were Watsonian behaviorists.

Watson devoted a large part of his subsequent career to human behavior, and especially to the behavior therapy of some disorders that Freudians then called 'neurosis.' His most famous experiment in the field of emotional conditioning was conducted with an eleven-month-old infant, named Albert, whom Watson taught by conditioning to fear white rats (see Sect. 6.1). The case became widely cited as an early piece of evidence in support of conditioning theories of phobias. It was an occasion for Watson to criticize Freudian concepts and to begin a series of studies about children presented in a book he wrote with his assistant and wife, R. R. Watson, *The Psychological Care of an Infant Child*, published in 1928. In the long run, this book probably had a more profound effect on more people than anything else Watson did. The book was dedicated to the first mother of a happy child, the latter being described as a child educated by the behaviorist method. It was probably this book that encouraged the trend towards inflexible patterns of childcare that appeared in North America and Britain during the 1930s, until the publication of B. Spock's book, *Baby and Child Care*, in 1946.

3.2 *The Response to Watsonian Behaviorism*

E. Boring declared that, in the 1920s, it seemed as if all America had gone behaviorist. Even the 'behavior men' like Yerkes declared that, in spite of many criticisms of Watson's radicalism, they were still behaviorists. The manifesto changed the attitudes of human psychologists, in particular about objectivity, the rejection of introspection, and the need to experiment. The applicability of Thorndike's and Watson's theories to human educational psychology or to the therapy of human mental disorders supported the tendency to define psychology as the science of behavior. Behaviorism entered the real world and the term was widely employed to signify a practical attitude towards human problems.

4. *Neo-Behaviorism*

4.1 *Purposive Behavior*

During the second quarter of the twentieth century, a handful of second-generation behaviorists developed a new version of the science of behavior. The evolution of their conceptions was the result of some discord within behaviorism: reading Thorndike's and Watson's books, students were confronted with opposing views on how habits are formed. Thorndike was convinced that habits are entirely based on S–R connections and that such connections are strengthened by the occurrence of a satisfying award. Watson denied the Law of Effect and the role of reward because of its mysterious retroactive effect. This disagreement between the two founders of behaviorism stimulated further experimental work with animals, particularly in the University of California at Berkeley where Zing Yang Kuo and E. G. Tolman arrived in 1918. They studied the influence of reward or punishment on the learning behavior of rats in mazes. But Tolman's real aim was not to evaluate the relative merits of Thorndike's and Watson's conceptions, but to propose another approach to the problem of learning. He asserts that behavior has to be studied from a molar point of view rather than a molecular one (as a series of physiological events).

Tolman was very influenced by Gestalt theoreticians, such as W. Köhler, who went to Berkeley in 1925 and whose detour experiments bore a strong resemblance to Tolman's study of insight in a maze. The experiments run at Berkeley led Tolman to his most significant book, *Purposive Behavior in Animals*

and Men (1932), in which he proposed to reintroduce some inner elements, such as the organization and anticipation of behavior, into the conception of action towards an end. Tolman suggested that his rats constructed a cognitive map of the maze. According to him, behavior was not governed by simple one-to-one S-R bonds, but by complicated patterns of adjustment. These patterns of adjustment constituted purposes, and the organism had to be conceptualized as a functional process. In so doing, Tolman reintroduced into psychology mental concepts that Watson had wanted to eliminate from science. Tolman asserted that purpose was a descriptive feature, not a mentalistic entity supposed to exist parallel to, and to run along side with, behavior, but was out there in the behavior. But when Tolman introduced into behaviorism the concept of intervening variables lying between the stimulus and the response, such variables undoubtedly corresponded to what ordinary people called 'mind.'

4.2 *Psychology as a Hypothetico-Deductive Science*

A decade after Tolman's innovative arguments, methods of statistical inference became standard procedure in the analysis of data from psychological experiments. Then, scientific papers expressed an extreme formalism, such as can be found in C. L. Hull's works. By the mid-1930s, a group of learning theorists at Yale University became a powerful force in American psychology. They benefited from the Behavior Research Fund, which was launched in 1926 and sustained by contributions from private citizens. It was based at the University of Chicago where J. Angell had directed the psychology department. When Angell became president of Yale University in 1921, he also benefited from the Rockefeller Foundation. These flows of money into Yale supported the creation of the Institute of Human Relations of which C. L. Hull became an appointed member in 1929. There he developed a learning theory based on a conditioning model and on research on maze-running rats. Like Pavlov, whose work was translated into English in 1927, Hull conceived of thought as habits and of conditioning experiments as the way to study all aspects of thought.

Hull argued that psychologists had to construct a systematic theory of learning by integrating the two sources of certainty: observed facts and deduction. Psychology had to postulate provisional axioms from facts, to deduce consequences from these axioms and to test these consequences by experiments. Psychology as a science must be a hypothetico-deductive activity. Of course, the hypothetical constructs Hull introduced in his theory looked like Tolman's intervening variables. For Hull, they consisted in inferred states of the organism or nervous system, like 'strength of habit' or 'drive,' whose reduction produces a reinforcing effect on behavior. His behaviorism was then different from the strictly descriptive one of Watson. Hull's aim, to transform the science of man into a mathematical science, (expressed in *The Principles of Behavior: An Introduction to Behavior Theory* in 1943), led him to a very formalistic theory, although one which called for a great number of experiments at the same time. Hull's theory was certainly the most famous behaviorist approach. Neo-behaviorism slowly began to falter in the 1940s, because of the numerous problems it failed to resolve, and because of the increasing influence of operationism and of Gestalt theory in the United States. These factors contributed to the development of studies of problem-solving and to the restoration of interest for what happens inside the 'black box.'

5. *The Skinnerian Crusade*

5.1 *Return to Pure Objectivism*

In 1927, B. Russell published a brisk and readable book called *Philosophy*, devoted to the basic conceptual issues arising in contemporary physics and psychology, and particularly in behaviorism. Russell was generally favorable to Watson's ideas. Being an eminent philosopher, he thus gave behaviorism considerable prestige and deeply influenced a young dilettante student, who promised to have a great future in behaviorism: B. F. Skinner. In 1928, at the age of 24, Skinner entered the Department of Psychology at Harvard University, headed by E. G. Boring who remained an opponent to Watsonianism. In 1936 Skinner was offered a teaching position at the University of Minnesota. In this university, by World War I, applied interests had grown so steadily that separate departments of educational psychology and child welfare had been established. Learning theories provided models for education and childcare. On the basis of numerous experiments with rats and pigeons, Skinner diverged from mainstream learning theories. He rejected the notion of trial-and-error learning and argued instead that all behavior involves one basic principle of reinforcement: an organism makes movements some of which are followed by a reward and will be repeated and others are not and will not be repeated. Thus, Skinner argued, it is possible to devise schedules of reinforcement, to construct circumstances that lead to one pattern of behavior rather than to another. His approach became known as operant conditioning, which he defined as 'the making of a piece of behavior more probable.' Skinner never referred to mind, drives, habits, or any intervening variable: his behaviorism was radical. It was underwritten by four major principles: (a) science needs only systematic observations and does not need theory; (b) the physiological factors which initiate animal behaviors do not concern psychology, i.e., psychology is the science of observable consequences; (c) behaviorism must not refer to mental states or ethical concepts; (d)

behavioral evolution during the life of an organism obeys the same laws as phylogenetic evolution because behavior is a form of biological adaptation (Skinner 1938, 1969).

5.2 Victory and Decline of Skinnerianism

Skinner returned to Harvard in 1948, where he remained for the rest of his career. The same year he wrote a utopian novel, *Walden Two*, inspired by the community described by H. D. Thoreau in the late nineteenth century. The Skinnerian community lives according to the principles of operant conditioning, without any negative reinforcement, positively reinforced each day, and purely programmed. In this utopia as well as in his scientific books, Skinner appeared as a combatant. He fought against the slow resurgence of mental entities or constructs in the description of human action. According to him, such concepts had the perverse effect of obstructing the way to the analysis of what goes on, in assigning a causal status to inferred inner states. He accused 'methodological behaviorists' like Watson but above all he accused Tolman of using experimental and objective principles to describe behavior, while at the same time resorting to inner states to explain behavior. They did so because they admitted that mental life was out of the reach of psychology. Skinnerian radical behaviorism contended that mental life, 'the world inside the skin,' is not very different from observable behavior, that mental life is made up of internal events, and is a behavior.

The gate methodological behaviorism opened was used by cognitivism, that is to say, by a branch of psychology which tried to explain what happens in the black box by resorting to inner, inferred states or operations. Of course, the rise of this psychology triggered frequent and firm reactions by Skinner, who was a provocative and formidable debater. He fought, for instance, against N. Chomsky who defended Cartesian convictions concerning language and attacked the Skinnerian reduction of language to an inner behavior, obeying the same contingencies of reinforcement as any other behavior (Chomsky 1957). Chomsky played a decisive role in the rise of cognitivism and in dismissing behaviorism among the ranks of university psychologists. For many years, in the departments of psychology of several universities in the United States and in Europe, the decay of behaviorism was frequently asserted. It seemed that Chomsky had the last word. But behaviorism was far from extinct: it remained alive in 'the real world.'

6. The Triumph of Applied Behaviorism

To this day, behaviorism remains a decisive source of social methods of control of behavior, even if the scientific indices of the activity of this psychological movement became, above all in Europe, less obvious. Since the beginnings of behaviorism, mental health and education are its main fields of application. The different conceptions of learning and of behavior conditioning led to various techniques of behavior modification and control. As well as Pavlovian conditioning, Watsonian or Skinnerian behaviorisms engendered several kinds of behavioral technologies. All of them were dedicated to the modification of human conduct, especially of abnormal or undesirable forms of such conduct. They were also designed to construct socially desirable behavior.

6.1 Behavior Therapies

Pavlov was probably the first psycho-physiologist to understand the social interest in conditioning. He conceived the normal cortical functioning as based on a precarious equilibrium between the mechanisms of inhibition and of excitation. Pathological behavior results from a disruption of this equilibrium, which is produced by the lack of some substance. Consequently, for example, a deficiency in physiological inhibition processes may be treated by an injection of caffeine or bromide. The administration of such substances obviously constitutes a way of behavior control, and Pavlov was the first to study the activity of such psychotropics on learning. Pavlov also proposed a model of 'experimental neurosis' in animals, induced by a conflict between two excitation processes and leading to animal agitation, aggression, and decline. During the twentieth century, the Soviet School would develop Pavlovian concepts and behavior therapies.

Watson's manifesto was soon followed by preoccupations with the role of conditioning in the construction of habits in childhood. In 1920, Watson and Rayner carried out phobia experiments on an eleven-month-old baby named Albert: they 'taught' Albert to avoid a white rat by associating this animal (which a baby spontaneously does not fear) with a metallic noise (that babies find very frightening). After several associations, the baby was afraid of the rat, and the experimenters generalized that fear to any fur-coated object. This experiment became largely cited as an early piece of evidence in support of conditioning theories of phobias. It was followed by numerous other such experiments; all used as arguments against Freudian theory, which was becoming famous in the West. The opposition between the behaviorist model of neurosis and the psychoanalytic one was much deeper in Europe than in the United States. Behavior therapists considerably developed their techniques (flooding, reciprocal inhibition, aversion, and token economy, for example,) which were used to modify antisocial as well as pathological behavior, or to fight obesity or drug addiction for example. Because they looked like the imposition of constraints on the self, they were frequently criticized and denounced as a

danger for freedom. In spite of such criticism, however, behavior therapies developed fast, even in France or Italy where Freudian conceptions remained very influential.

6.2 Educational Concerns

Since the first formulation of the S–R Law and of the Law of Effect by Thorndike, the field of education has been a key concern for 'behavior men'. Just after the publication of his thesis in 1898, Thorndike concentrated on the American educational system. At this time, in the United States, school learning was being turned into a professional activity; teachers were to be viewed as people possessing special skills and scientifically proven methods. All psychologists, and not only in the United States, were confronted with that social demand from teachers, but behaviorists were then able to furnish some simple formulas to resolve teaching problems.

Whatever the first behaviorists' contribution to education may have been, Skinner's work remains the more decisive and the best-known one. His concern for educational problems has been persistent, and consistent with his wider conceptions of culture and society. In 1954, he developed the principles of programmed teaching, made of linear sequences in the construction of correct answers. According to the principles of operant conditioning, the correct answer has to be reinforced. Teaching machines have considerably developed with computers, which offered unforeseen possibilities.

F. Parot

Belief, Anthropology of

'Belief,' along with 'believe, beliefs' and 'belief systems,' has served as a kind of 'odd job' word for anthropologists: a word commonly used for the analysis of a society's culture, religion, or ideas about the world, but seldom defined or explicitly theorized. Belief is often included in omnibus definitions of culture, such as Tylor's classic 'Culture, or civilization, … is that complex whole, which includes knowledge, belief, art, law, morals, custom, and any other capabilities and habits acquired by man as a member of society' (1871, from Kroeber and Kluckhohn 1952 p. 43) or Sapir's 'culture, that is, … the socially inherited assemblage of practices and beliefs that determines the texture of our lives … (1921, Kroeber and Kluckhohn 1952 p. 47). The term often refers explicitly to religion, as in Tylor's 'minimum definition of religion' as 'the belief in Spiritual Beings' (1873), but is used equally for claims people make about the empirical world or their social institutions.

Accounts of central tenets of culture or world-view in a society are often reported as beliefs. Lawrence's (1964) discussion of cargo cults in New Guinea is typical: 'The Ngaing believed that their world was brought into being by their deities' (p. 16); 'all these peoples believed in a creator God' (p. 21); 'the natives believed they could obtain cargo … largely by ritual' (p. 235). As Needham (1972 p. 3) points out, Lawrence did not find it necessary to define belief or describe how he knows 'that men in New Guinea believe what they say'; he simply assumed that this 'psychological category in the English language denotes a common human capacity.' This is typical of anthropological writing. Despite its ubiquity, 'belief' seldom appears in the Index of ethnographies, and the *International*

Encyclopedia of the Social Sciences (Sills 1968) has no entry for Belief, simply referring the reader to '*See* Attitudes; Ideology; Myth and Symbol; Religion; Values.'

Although there is a long history of analyzing other societies through a systematic description of their 'beliefs and behaviors,' recent ethnographic accounts have reflected ironically on the meaning of belief. 'Take an ethnographer,' writes Jean Favret-Saada (1980 p. 4):

> She has spent more than thirty months in the Bocage in Mayenne, studying witchcraft … 'Tell us about the witches,' she is asked again and again when she gets back to the city … confirm that *out there* there are some people who can bend the laws of causality and morality, who can kill by magic and not be punished; but remember to end by saying that they do not really have that power: they only believe it because they are credulous, backward peasants … No wonder that country people in the West are not in any hurry to step forward and be taken for idiots …

Favret-Saada concludes: 'To say that one is studying beliefs about witchcraft is automatically to deny them any truth: it is just a belief, it is not true.'

'Belief' is thus a ubiquitous term in much of anthropology, a common sense category used for the analysis of the tenets of culture or religion, but a term that is increasingly contested. A review of the meaning and history of the term belief is needed to make sense of this change in its anthropological usage.

1. *Defining 'Belief'*

The Oxford English Dictionary (1989) defines 'belief' as:

(a) The mental action, condition, or habit, of trusting to or confiding in a person or thing; trust, dependence, reliance, confidence, faith.

(b) Mental acceptance of a proposition, statement, or fact, as true, on the ground of authority or evidence …

(c) The thing believed; the proposition or set of propositions held true …

Hahn (1973 p. 208) attempts to clarify anthropological understandings of belief, defining beliefs as 'general propositions about the world (consciously) held to be true.' Tooker (1992 p. 808) points out that such anthropological conceptions of belief typically have two elements: 'propositionality' ('a mental state or conviction in which a doctrine or proposition concerning one's world-view is affirmed as true as opposed to false') and an assumption that such a 'prepositional relationship to tradition is an 'interiorized' one because of its reference to mental states.'

The *OED* indicates that the definition of belief as a proposition held to be true, a definition apparently taken over by anthropologists, rests on an older definition of belief as the condition of trusting in a person or thing, as 'faith.' At the same time, while a 'belief' is defined as a 'mental acceptance of a proposition … as true,' Favret-Saada and others suggest that labeling a proposition a 'belief' implies doubt or even falsehood, that 'studying beliefs about witchcraft is automatically to deny them any truth.' A review of the history of the semantics of 'belief' suggests that this complexity is grounded in changes in the meaning and use of the terms 'believe' and 'belief' in English (and their counterparts in other European languages).

2. *A History of 'Belief' in Euroamerican Language Use*

Anthropologists often talk with members of other societies about some aspect of 'their' world which does not exist in 'ours' and which anthropologists are comfortable asserting is not part of empirical reality. An examination of anthropological texts suggests that such phenomena—the witches of the Bocage or the Azande, the 'cargo' of the Papua New Guinea cults—are discussed in the language of belief, and that the beliefs of others are juxtaposed to 'our' knowledge of the empirical world (see Good 1994 Chap.1). Western civilization has long given great importance to 'beliefs,' with wars, church schisms, persecutions, and martyrdom revolving around Credos and demands for the renunciation of false beliefs. How is it that this same term, 'belief,' came to be so central to anthropological analysis, and what is implied by the juxtaposition of belief and knowledge?

The richest discussion of the history of the concept belief is to be found in two books by Wilfred Cantwell Smith, the historian of religion, which explore the relation between 'belief' and 'faith' historically and across religious traditions. Through historical and linguistic analysis, Smith comes to the startling conclusion that 'the idea that believing is religiously important turns out to be a modern idea,' and that the meaning of the English words 'to believe' and 'belief' have changed dramatically. Since around 1700, leading to misunderstanding of both the Christian tradition and the religious faith of others.

Smith demonstrates that the Old English words which evolved into the modern 'believe' (*geleofan*, *geliefan*) meant 'to belove,' 'to hold dear,' 'to cherish,' 'to regard as lief,' and reflect the Latin root *libet*, 'it pleases,' or *libido*, 'pleasure' (Smith 1977 pp. 41–6; Smith 1979 pp. 105–27). In Chaucer's Canterbury Tales, the words 'accepted by bileve' mean simply 'accept my loyalty; receive me as one who submits himself to you.' Thus Smith argues that 'belief in God' originally meant 'a loyal pledging of oneself to God, a decision and commitment to live one's life in His service' (Smith 1977 p. 42). Its counterpart in the medieval language of the Church and in the Credo was

'I renounce the Devil,' belief and renunciation being parallel and contrasting performatives or actions, rather than states of mind. Today, however, Smith argues, the ritual acclamation 'I believe in God' means for many people 'Given the uncertainty as to whether there be a God or not, as a fact of modern life, I announce that my opinion is 'yes, I judge God to be existent' (1977 p. 44).

Smith argues that this change in the language of belief can be traced in the grammar and semantics of English literature and philosophy, as well as popular usage. Three changes serve as indicators of the changing semantics of the verb 'to believe.' First, Smith finds that grammatically, the *object* of the verb 'to believe' shifted from a person (whom one trusted or had faith in), to a person and his word (his virtue accruing to the trustworthiness of his word), to a proposition. This latter shift began to occur by the end of the seventeenth century, with Locke and was firmly represented by the mid-nineteenth century in John Stuart Mills' philosophy (Smith 1977 p. 48). The twentieth century has seen a further shift, as beliefs have come to mean 'presuppositions,' and it was in this sense that 'belief systems' became nearly synonymous with 'culture' in some strands of anthropology (see Black 1973).

A second shift has occurred in the *subject* of the verb 'to believe,' from an almost exclusive use of the first person—'I believe'—to the predominant use of the third person, 'he believes' or 'they believe.' In anthropology, the impersonal 'it is believed that' parallels the discussion of culture as belief system or system of thought. This change in subject subtly shifts the nature of the speech act involved—from existential or performative ('I believe') to descriptive ('the Ngaing believe that').

Third, Smith observes that an important and often unrecognized change has occurred in 'the relation of belief to truth and knowledge,' as these are historically conceived. Bacon wrote in 1625 of 'the belief of truth,' which he defined as the 'enjoyment of it.' Belief maintains its sense here of holding dear, of appropriating to oneself that which is recognized as true. By the nineteenth century, however, 'to believe' had come to connote doubt, and today it suggests outright error or falsehood. Knowledge requires both certitude and correctness; belief implies uncertainty, error, or both. Smith's favorite illustration of the juxtaposition of belief and knowledge is an entry in the Random House dictionary which defines 'belief' as 'an opinion or conviction,' and at once illustrates this with 'the belief that the earth is flat'! It is virtually unacceptable in popular English usage to say that members of some society 'believe' the earth is round; if this is part of their world-view, then it is knowledge, not belief.

Smith goes on to argue that failure to recognize this shift in meaning has led to mistranslation of texts in the Christian tradition and ultimately to 'the heresy of believing,' the deeply mistaken view that belief in this modern sense is the essence of the religious life rather than faith. *Credo*, in the Latin, is literally 'I set my heart' (from Latin *cordis* or heart). *Credo in unum Deum* was correctly translated in the sixteenth century as 'I believe in one God,' when it meant 'I formally pledge my allegiance to God,' Whom we of course all acknowledge to be present in the world. Today, it is a mistranslation, suggesting that the Credo consists of propositions the veracity of which we assert. This is historically inaccurate and profoundly misrepresents the traditional ritual acclamation. Equally importantly, for Smith, the misplaced focus on belief as the primary dimension of religious life has led to mistranslations and misunderstandings of other religious traditions. It is this claim that has special relevance for anthropology.

3. *'Beliefs' and 'Believing' in Diverse Anthropological Traditions*

The term 'belief' functions quite differently in diverse anthropological traditions. A brief review of several traditions will indicate why 'belief' has emerged as a contested term in recent anthropological writing.

3.1 *The Intellectualist Tradition and Rationality Debates*

'Beliefs' and 'rationality' are central terms in the Intellectualist tradition most closely associated with E. B. Taylor and J. G. Frazer, as well as a series of 'Neo-Tylorians' and a set of rationality debates in the 1970s and 1980s. Tylor and Frazer set out to trace the evolution of beliefs from our 'rude forefathers' to the present, investigating forms of rationality, errors in reasoning, and the history of the evolution of culture from magic to religion and the emergence of science. An example from Frazer's Gifford Lectures, published as *The Belief in Immortality* (Frazer 1913), will illustrate the logic of this program, as well as the evolutionist language that led to its rejection.

> … the question of the validity or truth of religious creeds cannot, perhaps be wholly dissociated from the question of their origin. If, for example, we discover that doctrines which we had accepted with implicit faith from tradition have their close analogies in the barbarous superstitions of ignorant savages, we can hardly help suspecting that our own cherished doctrines may have originated in the similar superstitions of our rude forefathers; … The doubt thus cast on our old creed is perhaps illogical, since even if we should discover that the creed did originate in more superstition, … this discovery would not really disprove the beliefs themselves, for it is perfectly possible that a belief may be true, though the reasons alleged in favor of it are false and absurd …

Beliefs in this tradition were investigated as rational propositions and forms of explanation for natural and

religious phenomena. The intellectualist paradigm was grounded in philosophical empiricism, and judgements concerning validity of propositions and the evolution of explanatory frames from those which were false, even absurd, to those which correctly represent the natural world were essential to the analysis.

British structural-functionalism explicitly rejected the search for origins, the evolutionary claims, and the focus on individual beliefs and their rationality as a basis for social analysis. Nonetheless, classic texts, such as Evans-Pritchards' *Witchcraft, Oracles and Magic among the Azande* (1937) maintained the basic structure of inquiry, investigating witchcraft as a form of rational explanation for misfortune and distinguishing those explanations which attribute 'supra-sensible qualities' to phenomena (described as beliefs) from those which accord to contemporary science (described as knowledge) (cf. Good 1994 pp. 11–3).

In the 1970s and 1980s, the intellectualist tradition was revived in British anthropology under the rubric of Neo-Tylorianism and the rationality debates (e.g., Wilson 1970, Hollis and Lukes 1982). Reacting to the perceived vacuousness of functionalist explanations, a group of anthropologists returned to investigations of the rational structure of non-Western religious systems and their similarities to science as systems of explanation for the natural world. At the heart of these debates was a central question: 'when I come across a set of beliefs which appear *prima facie* irrational, what should be my attitude toward them?' (Lukes 1970 p. 194). For example, 'what does one do with the exotic utterances of primitives, who may say such things as "my brother is a cockatoo,"' asks Turner (1979 p. 401). 'Some things, such as a flat contradiction, could not be "believed,"' in any useful sense of "believe." … Can the fact that these utterances cannot be translated into anything that we would call "rational" warrant a claim that, e.g., these primitives possess a non-logical mentality?' 'Beliefs' in this paradigm were understood as rational propositions, held to be true by members of a society, and analysis focused on the identification, translation, and rational structure of belief systems, examining characteristics of systems 'open' to falsification and thus to change, in contrast to 'closed systems,' Which remain impervious to contradictory data that would lead to change and evolution in the direction of more rational explanation.

3.2 Structural Functionalism

Reacting against intellectualists' search for origins and focus on individual states of minds, Radcliffe-Brown and generations of British anthropologists placed investigations of the structure of social institutions at the center of anthropological theorizing. In this context, individual beliefs are of little interest, and a focus on the relationship between rational propositions and the natural world is replaced by an interest in the structural relation between the symbolic and the social order. Leach made this explicit: 'To ask questions about the content of beliefs which are not contained in the content of ritual is nonsense … Ritual action, and belief are alike to be understood as forms of symbolic statement about the social order' (1954 p. 14).

3.3 The Boasian Tradition

Inheritors of the German philosophical romantics' theorizing about culture and its *Geist*, American anthropologists of the Boasian tradition were more interested in the 'spiritual possessions of the group rather than the individual' (Sapir 1924), in the role of language and culture in constituting phenomenal experience and the 'behavioral environment' (Hallowell 1955) of members of a society. Though the term belief appears in this tradition, it has little theoretical salience. Sapir notes this explicitly: ' … the cultural conception we are now trying to grasp aims to embrace in a single term those general attitudes, views of life, and specific manifestations of civilization that give a particular people its distinctive place in the world. Emphasis is put not so much on what is done and believed by a people as on how what is done and believed functions in the whole life of that people, on what significance it has for them' ([1924] 1970 p. 83).

3.4 Cognitive Anthropology

The term 'belief' appeared as a core analytic category in American anthropology beginning in the 1950s among anthropologists intent on creating a new, more scientific paradigm for studying culture, who gathered under the banner of 'The New Ethnography,' ethnosemantics, or cognitive anthropology. For cognitivists, 'cultures … are not material phenomena; they are cognitive organization of material phenomena. … The object of study is not these material phenomena but the way they are organized in the minds of men (Tyler 1969 p. 3). In this tradition, culture is conceived as generative models, and beliefs are those cognitive structures which take propositional form: 'Beliefs are propositions about the relations among things to which those who believe have made some kind of commitment … for pragmatic or emotional reasons' (Goodenough 1990 p. 597). Although 'beliefs' assume a core analytic function in this tradition, many cognitivists share more with the Boasian tradition than with the intellectualist tradition, in that they are interested in investigating how semantic categories and linguistic structures shape perception of the phenomenal world rather than in normative claims about rationality. (They differ sharply in methodology and forms of ethnographic writing.) 'Beliefs' and 'knowledge' are often used interchangeably in this

tradition, rather than explicitly juxtaposed (see Black 1973). Nonetheless, the term 'belief' often subtly connotes counter-factuality in this tradition as in others.

3.5 Medical Anthropology, Public Health, Health Psychology

Studies of health beliefs was a key element of early forms of medical anthropology, particularly those devoted to applied work in the public health field, though this has not been true in recent years (see Good 1994). However, analyses of beliefs about illness etiologies, the risks of particular behaviors, or the benefits of particular treatments are still ubiquitous in public health work and health psychology. Popular or folk health beliefs are explicitly juxtaposed to medical knowledge, and educational campaigns are devoted to correcting mistaken ideas with the hope this will produce more rational behavior.

4. Critical Reflections

The language of belief has been widely used for ethnographic descriptions of culture, dating back to at least nineteenth century. In some anthropological traditions it has been a key analytic concept; in others, it has been used infrequently and in a common sense way. In some of the behavioral sciences, 'beliefs' continues to be used with little self-consciousness. However, in each of these domains, 'beliefs' are explicitly or implicitly juxtaposed to 'knowledge,' and the use of 'believe' or 'beliefs' connotes assertions to be counter to what is 'known' about empirical reality. This is particularly true in fields such as medicine, where the knowledge claims of the natural sciences run headlong into the historicist convictions of anthropology (Good 1994).

In recent years, the claims implicit in this formulation have been sharply challenged. The representation of others' culture as 'beliefs' ('their' beliefs and 'our' knowledge) authorizes the position and knowledge claims of the anthropological observer. Such authority has been challenged by a variety of forms of critical theory—post-structuralism, feminist writing, post-colonial theorizing, and subaltern studies. The place of the ethnographer as objective scientific observer, both in research and in ethnographic texts, is increasingly contested, and along with it, the use of the language of 'belief.' At the same time, developments in the history, philosophy, and sociology of sciences challenges any views of science as a progressive, normative 'mirror of nature,' the arbiter between belief and knowledge. As a consequence, the labeling of others' assertions about the world as 'beliefs' is increasingly challenged as pejorative, as failing to recognize the 'local' character of knowledge, and as hegemonic. The very use of the term is thus increasingly contested.

Benedict, Ruth (1887–1948)

A US cultural anthropologist, Ruth Fulton Benedict is best known for two books, the 1934 *Patterns of Culture* and the 1946 *The Chrysanthemum and the*

Sword. Each contributes importantly to the central premises of 'culture and personality' studies in US anthropology. Both books demonstrate the close connection between descriptive intensity and ethnographic reliability. Both, too, treat the theories and methods of a science in terms of their significance for ensuring human rights in any society. *Patterns of Culture* gave a wide audience a new concept of culture: an integrated and distinctive whole that molds the temperaments and talents of individuals. *The Chrysanthemum and the Sword* penetrated into the mechanisms through which 'culture' and 'personality' reinforce and replicate a dominant ethos. Both books assert the importance of individual creativity, a bow to the humanitarian impulse Benedict never lost.

1. *The Life*

Ruth Fulton was born on June 5, 1887, in New York City, the daughter of a Vassar graduate and a doctor of medicine. Two years after her birth, her father died and the vision of his lost opportunity for serving humankind haunted her for the rest of her life (Modell 1983). After a childhood spent moving from city to city, in 1905 Ruth and her younger sister Margery entered Vassar College. After graduation, Ruth returned to her mother's house in Buffalo, where she worked for the Charity Organization Society of New York. The experience increased her sensitivity about her partial deafness and exposed her to the struggles of immigrant families in an industrial city. Dissatisfaction persisted, unresolved by teaching in a private school and living with Margery and her husband Robert Freeman in Pasadena, California. A marriage proposal from Stanley Rossiter Benedict seemed to solve all problems; like other women of her generation, Ruth hoped the role of wife would fulfill her ambitions.

A month after their marriage, World War I broke out. The crisis accentuated Benedict's despair at the limitations set for women, nonconformists, and outsiders in her milieu. She tackled the problem through essays on three 'rebellious' women, Mary Wollstonecraft, Margaret Fuller, and Olive Schreiner; never published, the manuscript reveals the writer's impatience with the conventions that restricted her own options. In 1919, Ruth Benedict enrolled in courses at the New School for Social Research, where encounters with sociologist Elsie Clews Parsons and anthropologist Alexander Goldenweiser transformed her thinking. A meeting with Franz Boas at Columbia University completed the process, and in 1921 Benedict enrolled in his anthropology program. A remarkable two years later, she received her Ph.D. for a dissertation on 'The Concept of the Guardian Spirit in North America.'

During the 1920s, Ruth Benedict viewed her commitment to the discipline in the light of her quest for identity as a woman in US society. Personal concerns provided an impetus for anthropological inquiries, while at the same time detouring her from a conventional academic career path. During this period, too, the strains between her and Stanley increased, and in 1930 they agreed on a formal separation. By then Benedict had formed strong bonds with her student Margaret Mead and with Edward Sapir, her colleague. Conversations about the poetry all three wrote prompted Benedict to prove that anthropology could incorporate the voice she had developed as a poet. Her esthetic principles contributed as much to her anthropology as the advice about culture and person offered by Boas.

Ruth Benedict took on teaching duties at Columbia, trained students for the field, and in 1924 assumed editorship of the *Journal of American Folk-Lore*, a position she held until 1940. Her marginality to success in academia became apparent when, after Boas retired in 1937, she did not receive the headship of Columbia's Anthropology Department. The appointment of the anthropologist, Ralph Linton, surprised her colleagues, seeming to many to indicate the continued discrimination against women in US society. In reaction to Linton's appointment, to her abiding restlessness, and to her equally abiding belief in the scientist's duty as citizen, Ruth Benedict moved to Washington to serve her government during the war. She died on September 17, 1948, in New York City, where she had returned. She was 61 years old and in the midst of formulating a major theory of self and society.

2. *The Anthropolosy*

The 1934 publication of *Patterns of Culture* placed Ruth Benedict in the forefront of American anthropology. The book pulled together ideas she had developed in earlier pieces: the significance of coherence and of integrating customs, the social construction of marginality and deviance, the uses of a comparative method for establishing a relativistic stance. In the book's five discursive and three ethnographic chapters, the anthropologist set the foundation for her theoretical and methodological contribution to contemporary social sciences.

The book is best remembered for the notion that 'culture is personality writ large.' The theoretical claim receives support in the ethnographic chapters, which treat three distinct cultures as unitary, integrated, and patterned entities with characteristic personalities. Benedict's concept of culture did not exclude individuals, but explained the links between person and group. The links, she wrote, could be harmonious, leading to the 'successful' individual, or they could be rough, driving an individual into nonconformity, marginality, or madness. Three cultures form the triptych for an application of her theory, the Pueblos

of the American South West, the Dobu Islanders, and the northwest coast Kwakiutl. Each of these cultures receives a 'tag,' the famous Apollonian, paranoiac, and megalomaniac designations that for many readers obscured Benedict's concern with the processes by which a cultural configuration comes into being, persists over generations, bends to change, or collapses under crisis.

Methodologically *Patterns of Culture* introduces interpretive techniques that remain significant to anthropological analysis today. Ruth Benedict's reluctance to spend time in the field went hand in hand with an imaginative reading of available evidence from disparate details of behavior reported to her by informants, stored in ethnographies, or enshrined in items of material culture. Constant reference to US culture further extends her method, drawing comparison away from a simple juxtaposition of traits and towards the assessment of diverse 'arrangements' that became central to her work of the next two decades. In *Patterns of Culture*, Benedict shows brilliantly how the social scientist can maintain relativism in description while taking a stand on the implications of an 'arc' of traits (1934, p. 24).

Over the next decade, she published articles on classic anthropological topics in the 1933 *Encyclopedia of the Social Sciences* and simultaneously probed into the causes and consequences of the Great Depression for a general audience. In periodicals like the *American Scholar* and the *Partisan Review*, she brought an anthropological perspective to the subjects of, for example, unemployment, the 'problem of youth,' and the value of freedom of speech. Drawing on her discipline's comparative method, she mounted a stern critique against US culture, where human resources were wasted by narrow-minded institutions and persons whose capacities fell out of the conventional mold shunted aside. Professional and popular pieces preached an enlightened social engineering that drew lessons from cultures in which no individual was denied social participation.

Benedict's inquiry into the patterns of American culture led her to take on issues of race and class—related, in her framework, to democracy and social justice. Consequently, she examined the spread of totalitarianism under the lens of a comparative analysis of institutions and ideologies that deny the humanity of selected groups. From her perspective, understanding the rise of Nazism and Fascism meant discovering the conditions under which individual citizens detect no disjunction between their commonplace assumptions and the dictates of a political ideologue.

On the eve of World War II, Ruth Benedict reconsidered the implications of cultural relativism and its nonjudgmental stance. Like her mentor Franz Boas, she had argued that every culture should be treated in terms of its own values and purposes. By the end of the 1930s, she sought a scheme for evaluating cultures that respected difference while disclosing the danger some arrangements clearly posed. Danger came in terms of the suppression of individual creativity, fulfillment, and satisfaction; danger came, more dramatically, in acts of murder and genocide. Reacting to world events, Benedict fashioned the material for a theory of self and society in three separate endeavors: an article on childrearing, a book on race and racism, and a series of lectures on the theme of 'synergy.'

In 1938 Ruth Benedict published a seminal piece on childrearing, entitled 'Continuities and Discontinuities in Cultural Conditioning.' The article appeared in *Psychiatry*, a journal that fused psychiatry and social science. The piece reveals Benedict's ambivalence towards Freudian theory and her conviction that social conditions provide the basis for individual well-being. Her argument then sounds commonplace now: cultures should foster consistency between childhood and adulthood, so that traits learned early are appropriate to behaviors required later. At every turn, 'Continuities' criticizes US culture where, the anthropologist argued, sharp discontinuities between childhood and adulthood produce the 'neurotic personality' Karen Horney described. Under ideal conditions in any culture, Benedict wrote, children are conditioned into responsible social participation, their capacities fully utilized.

Simultaneously Benedict chafed under an invitation she had accepted to lecture on 'the individual and society' at Bryn Mawr College in February 1941. Right up her alley, the forum challenged her to delineate systematically the relationships between individual capacity, favored temperaments, social institutions, and cultural values. By then, too, the anthropologist explicitly recognized the urgency of calculating 'the consequences for human life of different social inventions' (1970, p. 322).

Only notes remain from these crucial and complicated lectures to show how far Benedict had moved from *Patterns of Culture*. The move took three forms: greater attention to the psychodynamics of personality development; an acute analysis of the institutions through which individual behaviors are organized; an effort to develop a plan for social change that acknowledged the significance of customary beliefs and behaviors. She chose the word 'synergy' to represent the effective working together of parts, and she compared low synergy with high synergy societies. The lecturer praised 'high synergy' societies, in which cooperation is at a maximum and all acts are mutually reinforcing. In such societies, individuals achieve a strong sense of responsibility and well-being. The unanswered question appears as well: what factors produce high synergy, which low synergy in a society? Her wartime writings pushed her closer to an answer.

A third endeavor refined Benedict's theory of self and society. In the 1940 *Race: Science and Politics*, Benedict analyzed discrimination and racism in her own society. She mounted her strongest attack against

a presumed scientific fact of innate endowment, the clothing for prejudices that condemned 'Negroes' (in the language of the times) to marginal participation in US society. Using comparative examples as well as historical references, she accused her country of fostering divisiveness, crushing the will of individuals, and undermining its own stamina.

The book acknowledged a debt to Boas in insisting that anthropology turn its methods and theories to the solution of contemporary problems. War made the obligation crucial for Benedict, and in the winter of 1942 she assumed a position at the Office of War Information. Obituaries she wrote when Boas died, in December 1942, convey the viewpoint that brought her into the government: 'He never understood how it was possible to keep one's scientific knowledge from influencing one's attitudes and actions in the world of affairs' (quoted in Modell 1983, p. 274). In the OWI, Benedict pursued 'national character' studies; the last assignment put on her desk was 'Japan.'

'The Japanese were the most alien enemy the United States had ever fought in an all-out struggle.' So reads the first sentence of Benedict's 1946 publication, *The Chrysanthemum and the Sword*. The wartime study validates the place Benedict already had in her discipline and indicates the directions she would have pursued had she lived longer than two years after the book's publication. The study of Japan continues the themes she raised throughout the 1930s: how to ensure the well-being of members of diverse cultures without violating the integrity of each culture, how to turn anthropology's comparative method to the service of international organizations devoted to peace, how to exercise responsibility as a social scientist without transgressing the rules of evidence and neutrality. The failings of the book, like its strengths, can be attributed to the complexity of Benedict's goals.

Despite thickly textured descriptions, the book is less an ethnography of Japanese culture than an expansion of anthropological method and theory. Benedict turned the impossibility of doing fieldwork into a virtue, stressing the importance of interpretation over immersion. The anthropologist, she wrote, 'can draw up his hypotheses and get his data in any area of life with profit. He can learn to see the demands any nation makes, whether they are phrased in political, economic, or moral terms, as expressions of habits and ways of thinking which are learned in their social experience' (1946, p. 13). Her data are the 'commonplaces' any Japanese would recognize, the behaviors and beliefs an ordinary person deems natural.

The result is a persuasive display of the dominant 'patterns' of Japanese culture without the homogenizing stamp of her earlier efforts. Benedict shuns the isomorphism implied by 'culture and personality,' while recognizing the importance of consistency between 'society' and 'self' for maintaining high synergy. Japan in World War II was notably synergistic: every act and every attitude seemed to the observer-interpreter to flow harmoniously, the Emperor's commands coordinating with the motives and feelings of Japanese citizens. This was Benedict's test case, the high synergy society she had praised in 1941. The book explores the processes through which personal impulses, tightly constructed cultural demands, and the needs of a nation are channeled smoothly together, without frustration or conflict.

Critics of *The Chrysanthemum and the Sword* gloss over Benedict's delineation of process, and mistakenly consider the designation of Japan as a shame culture the book's major thesis. In the study of Japan, however, *emotion* is an analytic concept that allows the anthropologist to link the drives of individuals to the maintenance of social order and cultural consistency. 'Shame' pushed Benedict's ongoing exploration of self and society into its most radical formulation yet, as she demonstrated the delicate and daily ways in which persons internalize the pressures of their surroundings without experiencing lethargy, anger, suffocation, or despair. Chapters display the abundance of reinforcing activities and attitudes that make shame both a powerful sanction and a barely perceptible burden for the Japanese individual.

Ruth Benedict bequeathed to social science a theory of the social construction and the social uses of an emotion. She argues that mechanisms for instituting and fostering an emotional pattern crucially support the contemporaneous conditions in which a society finds itself; change in the conditions can render the emotion useless—a conclusion she reached about Japan, as the nation encountered devastating defeat in the war. She offers, too, the analogous proposition that an emotional pattern may waste the resources and erode the capacity for social action of members of a culture.

A comparison between Japan and the USA runs through the volume, permitting a sophisticated analysis of shame and guilt that anticipates later recognition by social scientists of the twinning of these emotions. At the same time, Benedict's concern with the collapse in Japanese society after the war biases the comparison, so that shame comes to seem an immature and confining emotion. On a theoretical level, however, her discussion of emotion is value free. She does not posit a hierarchy, in terms either of human or social development, but rather assesses the function of an emotional configuration as it releases or represses expression of human creativity—the humanism in her science.

An emphasis on the social construction of emotion for Benedict eliminated the inevitability of a Freudian model; if personal emotions are socially constructed, then they are alterable. Recognizing how much she had left undone, Benedict undertook several projects after the war, including childrearing studies for UNESCO, participation in the navy's 'cultures at a distance' project, and further comparative inquiry into emotional configurations.

3. The Accomplishment

Ruth Benedict's contribution to social science comes from her ability to combine critical theory with cultural relativism. She accomplished this by constructing a scheme for judging cultures that recognized the full scope of their unique purposes and traits. The scheme included inserting the 'human being' into an analysis of social structures in a way that foreshadows late twentieth- century notions of 'actor' and 'agency.' Moreover, Benedict never loses sight of the constituents of actor and agency: as *The Chrysanthemum and the Sword* demonstrates, the individual is composed at once of idiosyncratic drives and the shaping forces of a culture. Her attempts to explore systematically the conditions under which the ensuing tension is productive rather than destructive banished the simplistic 'culture and personality' equation. A founder of that subfield of US anthropology, Benedict pushed the theoretical formulations linking self and society toward the critical social theory of today's humanistic and social scientific disciplines.

Inasmuch as her comparative analyses have at core the human being—creative, cooperative, resistant, rebellious—they impose a rigorous critique on all cultures. The body of her work asks, 'does a particular social arrangement suppress or exploit diverse individual capacities?' The question pushes Ruth Benedict into the vanguard of critical social theory in two respects: she does not abstract the individual from the material conditions that frame social responsibility, and her emphasis on the diversity of purposes and temperaments in any setting anticipates contemporary rejection of the concept of a bounded society with a definable cultural core.

Ruth Benedict embraced cultural relativism while insisting that the anthropologist interpret cultures in terms of their human benefits. The findings of any science had to be devoted to improving the human condition: preventing war, ensuring peace, and, above all, granting anyone in any milieu access to resources and to rights. Stressing the importance of directed change, Benedict did not preach an imperialistic social engineering. She argued instead that the social scientist had unique skills with which to delineate the cultural values and social institutions upon which change must be based in order to last.

In Ruth Benedict's writings, humanism extends from theory to methods of inquiry and styles of presentation. In her view the social scientist had an obligation not only to investigate circumstances in which some were deprived of the means of survival but also to offer findings in an accessible form. Here again she makes a major contribution: writings that appeal to a general audience, to policy makers and to soldiers, to social scientists and to artists, presage a contemporary scholarship that refuses to remain in an ivory tower.

Bentham, Jeremy (1748–1832)

1. Life and Writings

Bentham's father was a prosperous attorney. Hoping that his precocious child would have an illustrious legal career, he had him educated at Westminster, the Queen's College, Oxford, and Lincoln's Inn (called to the Bar in 1769). For Bentham each of these three institutions came to epitomise aspects of the prevailing orthodoxy: conservatism, complacency, hierarchy, superstition, insincerity, and the elevation of authority over reason. As a child, he conceived a passionate antipathy to the inadequacies and injustices of English law and procedure. Later, 'English common law and equity seemed to Bentham archaic, uncodified, incomprehensible, arbitrary, irrational, cruelly vindictive, tortuously dilatory, and so ruinously expensive that nine out of ten men were literally outlawed' (Mack 1968, p. 55). He very soon abandoned legal practice in disgust. Unmarried, and comfortably off, he devoted himself to criticism and reform of legal, political, and social institutions on the basis of utility or 'the greatest happiness principle.'

Bentham's most important diversion from writing was his attempt to lobby the government for a contract to design and manage a model prison, the panopticon. His proposals to William Pitt in 1791 received some

encouragement, but then encountered repeated delay and opposition. The project failed, in the process nearly bankrupting him, alienating him from the establishment, harming his reputation with posterity, and pushing him towards democracy. He was eventually granted a sum in compensation for his efforts and expenses in 1813, but the project was effectively dead by 1803. Thereafter, he stayed mainly at home, or in various retreats, writing, conversing with his friends, acolytes and other visitors, and conducting an extensive international correspondence.

Bentham's life was relatively uneventful, but enormously productive. Nearly 70,000 pages of manuscripts survive, mostly in University College London, the British Library, and Geneva. By January 2000, 20 of a projected 68–70 volumes of the scholarly edition of *The Collected Works of Jeremy Bentham* had been published. Preliminary work had been completed on several more. Many of Bentham's extant writings are not yet accessible in a readable form, including important ones on sex, religion, fallacies, logic, and language, and many specific legal subjects.

The main outlines of Bentham's life and ideas are known and there have been some important specialized studies. However, the unworked manuscripts contain second thoughts, refinements, and new departures which may confirm the view that Bentham was less doctrinaire, more subtle, original, and genuinely radical than has traditionally been supposed. Revisionism in Bentham studies is at an early stage.

Bentham was a secular child of the Enlightenment. The principle of utility came mainly from Helvetius and he owed much to Bacon, David Hume, (see *Hume, David (1711–76)*). John Locke (see *Locke, John (1632–1704)*), Priestley and European thinkers, including Voltaire, Beccaria, and Charles Montesquieu (see *Montesquieu, Charles, the Second Baron of (1689–1755)*). But he differed from his predecessors in several respects. He insisted that 'the art-and-science' of legislation required as preliminaries exhaustive taxonomy based on precise concepts and exact analysis of social facts. He had an acute awareness of the importance and limitations of language as the main instrument for expressing abstract ideas, and applied his version of utility and relentlessly detailed analysis to a remarkably wide range of subjects. He adopted clear, often extreme, positions on some issues. For example, he maintained that the only criterion of good and bad, of right and wrong, is the principle of utility; all other criteria are either meaningless or perversions of utility or utility disguised or pure subjectivism; that it is easier to justify torture than punishment; that talk of natural rights is both nonsensical and dangerous; that no artificial rule of evidence can promote rectitude of decision; that the common law is not really law, but a fiction based on judicial usurpation of power; and that the interests of the legal profession and of those in power are in general opposed to those of the community.

Despite this seeming clarity, many of Bentham's ideas invite conflicting interpretations. 'Benthamic ambiguity' is an important thread in reading Bentham. For example, he is often treated as a forerunner of both *laissez faire* and the modern welfare state, yet he does not fit either; he was a genuine political radical, but he placed a high value on security, and on the protection of existing property entitlements; he favored both strong government and strong democratic control; he virulently rejected most features of the common law, yet defended some salient institutions such as orality and cross-examination; the great codifier opposed all binding rules of evidence and procedure. There is no more ambiguous symbol than 'the auto-icon,' Bentham's skeleton, fully clothed and topped with a wax head, that sits enigmatically in public in a cupboard in University College London, stimulating endless speculation about its possible meanings. Some seeming ambiguities can be resolved textually; some suggest honest and perceptive puzzlement; others hint that behind the benign exterior lay some deep inner conflicts.

2. *Bentham as Jurist*

Bentham explicitly aspired to be to jurisprudence what Luther was to Christianity and Newton was to science. His contributions to philosophy, political theory, and social reform were offshoots of his concern with law. Utility was a tool both for criticizing existing laws and institutions and guiding legislation. His ideas on linguistic analysis, on evidence and inference, and on democracy grew out of specifically juristic concerns.

Jurisprudence is the most extensive, original, and neglected part of Bentham's legacy. Yet he is better known as a philosopher, political theorist, and social reformer, for three reasons: few Bentham scholars have been jurists; many of the legal writings have only recently started to become accessible; and Bentham's disciple, John Austin, was for a century treated as 'the Father of English Jurisprudence.' Austin's command theory of law is inferior to Bentham's, but Austin was preferred because he was more sympathetic to the common law, less critical of the legal profession, and less dangerously radical than his master. His general ideas were also easier to grasp and to criticize.

Bentham's science of legislation is based on five main pillars: the greatest happiness principle, the theory of fictions, his positivist command theory of law, the pannomion, and, as a late but crucial addition, his constitutional and democratic theory.

2.1 *Bentham as Utilitarian: The Greatest Happiness Principle*

Bentham's best-known expositions of utility are in two early works, *A Fragment on Government* (1977, here-

after *Fragment*), first published in 1776, and *An Introduction to the Principles of Morals and Legislation* (1996, hereafter *IPML*), first published in 1789. The former is primarily an attack on the complacency of William Blackstone's idealization of the common law and his espousal of natural law and social contract theory at the start of his *Commentaries*. *IPML* was conceived as a prolegomenon to a penal code dealing especially with the classification of offences and the principles of punishment. The opening words of *IPML* are: 'Nature has placed mankind under two sovereign masters, *pain* and *pleasure*. It is for them alone to point out what we ought to do, as well as to determine what we shall do.'

As a utilitarian Bentham is generally regarded as more representative than original. The rhetorical opening of *IPML* is often treated as epitomizing classical utilitarianism, a vehicle for considering standard criticisms on, for example, promising, punishment of the innocent, torture, and egoism. However, not all such objections apply to Bentham. For example, pleasure refers to all human values, not just to sensual or hedonistic pleasures or to wealth; the felicific calculus was not intended as an exact measure, but rather as providing a checklist of factors relevant to weighing the costs and benefits of any action; every individual equally counts for one, but the ultimate test is aggregate happiness (i.e., the general welfare). 'Extent' ('whose happiness is to be taken into account?') applies not just to humans, but to all sentient beings, for in respect of animals 'the question is not, Can they *reason*?, nor can they *talk*?, but can they *suffer*?' (*IPML* Chap. XVII, pp. 282–6)

The first six chapters of *IPML* are not fully representative of Bentham's utilitarianism, as it developed over time. They are pedagogically convenient, because they are easy to read and to criticize. Here Benthamic ambiguity seems to begin at the very root of his thought: Does pleasure refer to satisfaction or to preference? Was he a direct or an indirect utilitarian? How different was Bentham's utilitarianism from Hume's? Does rooting utility in human nature make Bentham a closet natural lawyer? Do Bentham's utilitarian actors maximize their own pleasure or is every human choice, in individual morality and collective decision making, to be judged by its tendency to maximize the general welfare? Is the primary concern of sovereigns, their subordinates, and individuals rightly confined to one's own community, subject to certain exceptions?

Such questions are much debated. It is dangerous to impose on Bentham ideas that emerged in later debates about utilitarianism, for example, modern distinctions between act-utilitarianism and rule-utilitarianism, between preference and satisfaction, or between aggregate and average utility. Bentham's ideas developed over time and he was not always consistent. He might also have rejected sharp versions of these distinctions as false dichotomies.

Bentham's utility is a principle of both individual psychology and of social and political morality, of morals and legislation. For the jurist the latter is both more important and less vulnerable to criticism. Humans generally seek to maximize their own interests, and the primary task of legislation is to harmonize individual interests with the general welfare by a system of rewards and punishments. Similarly, the interests of the governors need to be harmonized with the interests of the governed, especially through systematic design and implementation of securities against misrule. Bentham rejected any idea of principles independent of utility, but gave an important place to four principles subordinate to utility: security, subsistence, abundance, and equality. Of these security, or settled grounds of expectation, was the principal one because it implies extension in point of time and is a precondition for achieving the other ends of government. Bentham gave a high priority to both property and order, and hence for liberty in the sense of absence of coercion. Security is also the basis for the important motto of the good citizen, 'To obey punctually; to censure freely' (*Fragment*, Preface). But security can be overridden by utility in given circumstances. Security and subsistence generally have a higher priority than equality, but in the calculus each individual counts for one, the idea of diminishing marginal utility serves a distributive function, and Bentham believed that as a psychological fact 'the nearer the actual proportion approaches to equality, the greater will be the total mass of happiness.' (*Civil Code*; Harrison (1983, pp. 243–50)).

The originality and interest of Bentham's utilitarianism lie mostly in his *applications* of the basic ideas. Utility gives coherence and bite to his detailed treatment of evidence, classification of crimes, the rationalization of punishment, and numerous other specific topics. His utilitarianism should be judged as much by its potential for illumination as an analytical and critical tool applied to concrete issues as by its philosophical defensibility.

2.2 Fictions

Bentham's theory of logic and language anticipated key later developments in English analytical philosophy, including the idea that sentences rather than words are the primary unit of meaning. To clarify basic abstract legal conceptions, such as 'obligation,' 'right,' and 'property,' he substituted for the traditional definition *per genus et differentiam* the technique of 'paraphrasis' and 'phraseoplerosis.' Abstract nouns with no direct counterpart in the world of fact are names of fictitious entities. They can be elucidated by placing them in a whole sentence, such as 'X has a right against Y,' and then asking under what conditions this sentence is true. It is true if Y has a duty. 'Y has a duty' is true if the sovereign of an existing legal system has commanded that there shall be a sanction

(pain) for nonperformance in given circumstances, and Y's situation is subsumed under this command. Thus the terms 'right' and 'duty' are linked through 'sovereign' and 'sanction' to pains and pleasures, things that can be directly experienced.

Bentham's theory of fictions contains his basic ideas on ontology, epistemology, and logic. We construct our knowledge of the world through the lens of language, itself a human construct, which is both necessary because it is our window on the world, and dangerous because it is a distorting lens. Language is the best tool we have for knowledge and understanding. This constructivist epistemology based on utility has affinities with later developments in pragmatism and the sociology of knowledge.

Bentham often used 'fiction' pejoratively. He attacked natural law, social contract theories, and technical legal fictions as dangerous mystifications. One example is his famous attack on natural rights as pestilential nonsense: to say that 'X has a right' logically implies some existing general rule or command. 'X has a legal right' presupposes a law commanded by a sovereign and backed by a sanction. Legal rights are creatures of positive laws. But since natural law does not exist nor do natural rights. The idea of natural rights is nonsensical, like the idea of a son without a father. To talk of imprescriptible (i.e., unalterable) rights is also meaningless, 'nonsense upon stilts,' for the sovereign's power cannot be legally limited. Since rights conflict, talk of 'absolute' rights is contradictory. Talk of nonlegal rights is also mischievous, raising expectations that cannot be fulfilled, inviting anarchy. Bentham's objections relate to the mode of discourse rather than to particular values. There may be moral claims and legal rights based on utility. He would not necessarily have opposed all modern legal bills of rights. His objection was to talk of nonlegal rights, not to the enactment into positive law of enforceable legal rights. A modern Benthamite can argue that talk of 'a right to food' or 'a right to work' refers to important aspirations, but begs questions about the allocation of correlative duties, about enforcement if not legally binding, and about the feasibility of implementing such 'rights.' They represent wishful thinking. As Bentham put it: 'Want is not supply, hunger is not bread.' Bentham started a line of analysis of 'rights,' 'powers,' and 'obligations' that was developed by Austin, Hohfeld (see *Hart, Herbert Lionel Adolphus (1907–92)*), Hart, and others. He still poses a challenge to loose rights talk.

2.3 Theory of Law

Bentham's legal theory operates on at least three levels: first, his general theory of law and its philosophical underpinnings; second, subtheories on, for example, codification and nomography, constitutional law, punishment and reward, and adjective law; third, the pannomion, a comprehensive body of codes of general application, subject to particular, essentially minor, modifications according to time, place and social context.

Bentham's jurisprudence starts with a strong positivist distinction between law as it is and law as it ought to be. 'To the province of the *Expositor* it belongs to explain to us what, as he supposes, the Law is: to that of the *Censor*, to observe what he thinks it ought to be' (*Fragment*, 397). Exposition can be particular or general; censorial jurisprudence is general. Bentham's main interest was in universal censorial jurisprudence.

The fullest account of Bentham's general theory of law *Of Laws in General* (1970 hereafter *OLG*), was first published in a definitive edition, edited by H. L. A. Hart, after Hart's *The Concept of Law* had become the leading text of English legal positivism, partly through its critique of Austin's imperative theory. Ironically, Hart conceded in a late essay that Bentham's version contained an important core of truth, 'the notion of a content-independent, peremptory reason for action' as part of the general notion of authority. (Hart 1982, Chap. 10, p. 261). *OLG* involved a deeper exploration of difficulties that he had dimly recognized earlier, especially the distinction between the civil and the penal branches of jurisprudence and individuation (what constitutes a single law?). The outcome was a dense, but incisive work, which includes original ideas on the logic of the will, a precursor of modern deontic logic.

Bentham elaborated his conception of law in terms later made familiar by John Austin: commands backed by threats made by a sovereign who is subject to a habit of obedience. Yet Bentham's ideas were subtly different. Bentham allowed for limited and divisible sovereignty, whereas Austin did not. The habit of obedience might be partial. Commands, such as judicial orders, need not be general; some laws can be backed by moral or religious sanctions, some laws by rewards. The idea of command has a more complex and limited role in Bentham's theory.

Burns, Hart and others have explored aspects of Bentham's jurisprudence in detail, including universal censorial jurisprudence; legal positivism and sovereignty; and his analysis of fundamental legal concepts, such as rights and obligations. Less abstract and less well known, but more extensive, are his theoretical writings on codification, adjective law (evidence and procedure), judicial organization, civil law, criminal law, indirect legislation, international law, and many other topics, whose importance is often underestimated. For example, Bentham's writings on evidence represent the most original and wide-ranging contribution to evidence theory in the Anglo-American tradition.

2.4 Codification and the Pannomion

From the early 1780s Bentham's main aspiration was to produce a complete body of laws—a pannomion—

to rationalize and systematize English law and, indeed, any legal system. At first he thought that the main weaknesses of English law were lack of organization, incompleteness, and inaccessibility, linked to the prejudice that legislation was an inferior form of law to common law—defects that might be remedied by a comprehensive Digest. By 1782 he was convinced of the necessity for a systematic structure of codes based on utility and satisfying the tests of coherence, completeness, and comprehensibility. The pannomion encompassed integrated codes on civil, penal, procedural, and constitutional law, backed by detailed legislation on specific topics.

He started with penal law, but was diverted by theoretical concerns into 'the metaphysical maze' of *OLG*. By the late 1780s he had completed important work on the general theory of law and legislation, but no actual code. Though codification remained his long-term aim, he only returned to the work of actually preparing codes much later. Starting in 1811 he offered his services as a codifier, first for several jurisdictions in the United States, then for Russia, Poland, and Geneva, and latterly for Spain, Portugal, Tripoli, and various Latin American countries. He now prepared some important general works on codification and started drafting several codes. His ideas excited considerable interest, but did not lead to the adoption of a single code. In 1830 he published the first volume of his magisterial *Constitutional Code* (1983). This, together with a procedure code, was only completed after his death by a former amanuensis, Richard Doane. Shortly before his death, Bentham was still 'codifying like any dragon.' He believed strongly that a code should be the product of a single mind, but his failure to complete a single draft reinforced the view that the pannomion was impracticable.

2.5 Constitutional Law and Democratic Theory

Bentham was not an instinctive democrat. When young, he was mainly concerned with how legislators should govern. He was prepared to deal with aristocrats, enlightened despots, revolutionaries, and democrats in promoting his ideas. His constitutional theory was a late development. The timing and reasons for his 'conversion to democracy' have been much debated. He was sympathetic to democratic ideas at the start of the French Revolution, but he only became involved in the movement for parliamentary reform after 1809, stimulated by his experience of general resistance and indifference to reform, especially the panopticon. Bentham firmly located sovereignty in the people. He recognized the problem of the tyranny of the majority, but he never satisfactorily solved it, perhaps because of his virulent antipathy to talk of nonlegal rights.

His elaborate constitutional design is based on three axioms: maximization of the happiness of all as the proper end of government; the maximization of the self-interest of the governors as the actual end of government in every political community; and the harmonization of the interests of the rulers and the ruled. His scheme involves vesting real and sustained power in the sovereign people to locate, monitor, and dislocate officials through a system of securities against misrule, especially publicity.

Several of the constitutional writings have only recently become available. The main elements in his code were 'expense minimized, aptitude maximized,' universal manhood suffrage (subject to a literacy test), secret ballots, frequent elections, a unicameral legislature, limited judicial power, accountability and transparency, and a power of recall of office holders, including the military, vested in the sovereign people. He supported ideas backed by other radical reformers of the time. In principle he favored votes for women, but considered it inexpedient to press for this. Bentham conceived of a constitutional code as a logical and engineered product of a single mind, based on articulated principles, and designed to provide popular control over misrule, patronage, and other forms of corruption.

3. Bentham and Social Science

Bentham did not draw sharp distinctions between jurisprudence, psychology, political economy, and other fields that have since become semiautonomous social sciences. Utilitarianism requires a concern for social facts. Legislation is the social science. To make calculations the legislator needs reliable information about the existing situation, the likely consequences of a given course of action, and causal relations. He emphasized 'the statistic function' of government; his stepbrother, Charles Abbott, played a leading role in the first population census (Population Bill, 1800); and Bentham himself tirelessly argued for better social data, especially regarding the Poor Laws. This Benthamite enthusiasm was satirized in Charles Dickens's *Hard Times* in Mr. Gradgrind, who believed that 'Facts alone are wanted in life.' Bentham believed no such thing. Utility was his guiding principle and he had a sophisticated awareness of the complexities of concepts such as 'fact' and 'causation.' To his credit, he was among those who first recognized and campaigned for the systematic collection of reliable social data as a necessary, but not a sufficient, condition for policy making and legislation.

On 'the art and science of political economy,' Bentham was a follower of Adam Smith, but criticized his defense of usury laws, and on some issues differed from him in either being more averse or more amenable to interventionism. Bentham saw the main role of government as promoting abundance indirectly through ensuring security, the basic presumption being against government involvement in economic affairs 'without some special reason.' But his proposals included provision for many areas later associated with the welfare state, such as public health, education,

and the relief of indigence. He argued for the emancipation of colonies both on economic and constitutional grounds and, rather than being a doctrinaire supporter of *laissez faire*, consistently applied cost–benefit analysis to particular issues. Bentham had some impact on the economic writings of James Mill, John Stuart Mill (see *Mill, John Stuart (1806–73)*, David Ricardo, and later W. S. Jevons, Alfred Marshall (see *Edgeworth, Francis Ysidro (1845–1926)*), and F. Y. Edgeworth (see *Edgeworth, Francis Ysidro (1845–1926)*). There is a useful, but incomplete, edition of Bentham's economic writings (1952–4).

One cannot do justice here to Bentham's psychology, which is regarded by some as his Achilles heel, nor to his extensive and detailed writings on education, poor law, social administration, and other aspects of social policy. There are some interesting affinities with Marx's (see *Marx, Karl (1818–89)*) ideas, for example, the clash between the interests of the few and the many (though with less emphasis on social class), interest-begotten prejudice, and demystification. But Marx, like Foucault, criticized Bentham without having studied him carefully. Marx treated him as the epitome of 'commonplace bourgeois intelligence.' Foucault interpreted the Panopticon as a symbol of repressive authoritarian control, ignoring the fact that Bentham's concern with transparency applied to those with power as well as those subject to it. Both images are, at best, half-truths. Bentham was also a pioneer in the study of bureaucracy. His standing as a social theorist is ripe for reappraisal.

4. *Influence*

Bentham first gained recognition through the efforts of a Genevan, Etienne Dumont (1759–1829) who between 1802 and 1828 produced five elegant French 'recensions' from manuscripts and printed texts. These were more lucid, succinct, and diplomatic than the originals. Some were translated into several languages, including English. The first, *Traité de legislation civile et penale* (1802) made Bentham's reputation in Europe, whence it spread to Latin America and eventually back to Britain.

In the late nineteenth century Bentham was hailed as the most influential reformer in English history. Subsequently there has been a revisionist debate about the relationship between his ideas and particular reforms. Bentham had both committed disciples and more pragmatic followers who became influential, including Romilly, Brougham, Chadwick, James Mill, and John Stuart Mill; his ideas contributed to the climate of reform in the nineteenth century both in Britain and internationally; many changes, for example in the Anglo-American law of evidence, moved in directions he had advocated, but in a more piecemeal fashion than he would have approved. He hated jargon, but coined neologisms. Some—codify, maximize, international—have become part of the language. Others, fortunately, have not. Many of his proposals, for instance on codification, have not yet been implemented. How far responsibility for specific changes should be attributed to him or his followers remains controversial.

Similar questions arise about his contemporary 'significance.' It is anachronistic to apply early nineteenth-century ideas directly to twenty-first-century issues. Yet, Bentham's views are still relevant to topics as varied as human rights, sovereignty, constitutional reform, penal policy, torture, corruption, patronage, transparency and accountability, freedom of information, political rhetoric, the legal profession, access to justice, inheritance, the free market, globalization, and 'the farther uses of the dead to the living.' On these and many other topics he is still worth consulting, not least because he often takes provocatively radical positions. As Herbert Hart (see *Hart, Herbert Lionel Adolphus (1907–92)*) remarked, 'where Bentham fails to persuade, he still forces us to think' (Hart 1982, p. 39).

Bereavement

The term 'bereavement' is derived from the Latin word *rumpere* (to break, to carry, or tear away), and refers to the objective situation of a person who has suffered the loss of someone significant. 'Grief' is derived from the Latin *gravare* (to weigh down), and refers to the emotional experience of a number of psychological, behavioral, social, and physical reactions to one's loss. The word 'mourning' is derived from the Latin word *memor* (mindful). It refers to actions expressive of grief which are shaped by social and cultural mourning practices and expectations. Pointing to the timeless message of the original meanings of these terms, Jeter (1983) commented that 'as the ancients, people today surviving the death of a family member do feel robbed, weighted down, and are mindful of the past, knowing that life will never be the same' (p. 219). But how do individuals cope with such an experience? To address this question, the models and approaches that seem most influential to the current understanding of bereavement and grief are examined. The discussion begins with a review of the traditional views on bereavement, and then turns to the more recent developments in research and theorizing that have changed basic ways of looking at grief.

1. Traditional Views

Several different theoretical formulations have made important contributions to the current state of knowledge about loss and grief (for a more detailed review see Rando 1993). The first major contribution that is generally referred to as a classic in the field of bereavement was Freud's paper, 'Mourning and melancholia.' According to Freud (1957), the psychological function of grief is to withdraw emotional energy (cathexis) and become detached from the loved one (decathexis). The underlying idea of this formulation is that people have a limited amount of energy at their disposal. Consequently, only by freeing up bound energy will the person be able to reinvest in new relationships and activities. Freud believed that the mourner has to work through the grief (grief work hypothesis) by carefully reviewing thoughts and memories of the deceased (hypercathexis). He maintained that although the process of working through causes intense distress, it is necessary in order to achieve detachment from the loved one.

The second theoretical formulation that has been highly influential was advanced by John Bowlby. In his attachment model of grief, Bowlby (1980) integrates ideas from psychoanalysis, ethology, and from the literature on human development. Fundamental to his view is the similarity between the mourning behavior of adults and primates, and children's reaction to early separation from the mother. He considers grief to be a form of separation distress that triggers attachment behavior such as angry protest, crying, and searching for the lost person. The aim of these behaviors is maintenance of the attachment or reunion, rather than withdrawal. However, in the case of a permanent loss the biological function of assuring proximity with attachment figures becomes dysfunctional. Consequently, the bereaved person struggles between the opposing impulses of activated attachment behavior and the need to survive without the loved one. Bowlby believed that in order to deal with these opposing forces, the mourner must go through four stages of grief: initial numbness, disbelief, or shock; yearning or searching for the lost person, accompanied by anger and protest; despair and disorganization as the bereaved gives up the search, accompanied by feelings of depression and lethargy; and reorganization or recovery as the loss is accepted, and an active life is resumed. Emphasizing the survival value of attachment behavior, Bowlby was the first to give a plausible explanation for responses such as searching or anger in grief.

A number of other theorists have proposed that bereaved individuals go through certain stages in coming to terms with the loss. One stage theory that has received a great deal of attention is Kubler-Ross' model, which addresses people's reaction to their own impending death. Kubler-Ross claims that individuals go through stages of denial, anger, bargaining, depression, and ultimately acceptance. It was her model that has popularized stage theories of bereavement. For the past several years, stage models like Kubler-Ross' have been taught in medical, nursing, and social work schools. These models also have appeared in articles in newspapers and magazines written for bereaved persons and their families.

As a result, stage models have strongly influenced the common understanding of grief in Western society. There is evidence that health-care professionals tend to use the stages as a yardstick to assess the appropriateness of a person's grieving. A negative consequence of this, however, is that people who do not follow the expected stages may be labeled as responding deviantly or pathologically. For example, a person who does not reach a state of resolution after a certain time may be accused of 'wallowing in grief.' Also, legitimate feelings such as being angry because one's spouse died of receiving a wrong medication may be discounted as 'just a stage.' Such a rigid application of stage models has the potential of causing harm to bereaved persons. Therefore, many researchers have cautioned against taking any 'staging' too literally. Because of the widespread use and acceptance of stage models, Wortman and Silver (1989) systematically examined all empirical studies that appeared to provide relevant data on the topic of coping with loss. What they found was that the available evidence did not support and in some cases even contradicted the stage approach. In contrast to the notion of an orderly path of universal stages, the reviewed evidence showed that the reaction to loss varies considerably from person to person, and that few people pass through stages in the expected fashion. As a result of this critique of the stage approach, bereavement experts to date at most endorse the idea of grief as a series of flexible phases instead of a set of discrete stages. However, the main weakness of both stage and phase models seems to be that they cannot account for the immense variability in grief response, and that they do not take into consideration outside influences that may shape the course of the grieving process.

2. *Current Understanding of Grief*

Although most grief researchers now agree that the notion of 'stages' is too simplistic, many still hold assumptions about the grieving process that have been influenced by the contributions of Freud and Bowlby. One such assumption is that following a loss, individuals will go through a period of intense distress. Positive emotions, such as happiness, are implicitly assumed to be absent during this period. Second, it is often assumed that failure to experience such distress is an indication that the grieving process is abnormal, and that subsequent mental or physical health problems will occur. Third, it is assumed that successful adjustment to the loss requires that individuals confront and work through their feelings. Fourth, continued attachment to the person who died has generally been viewed as pathological, and the necessity of breaking down the attachment to the loved one is often considered to be a key component of the mourning process. Finally, it is believed that over time, individuals will reach a state of acceptance regarding what has happened and return to prior levels of functioning.

Although these assumptions about the grieving process are widely held among clinicians and the general public, a careful review of the evidence reveals a surprising lack of support for any of them (see Wortman and Silver in press for a review). In one study addressing the notion that most individuals go through a period of intense distress, elderly widows' and widowers' ratings on symptom inventories were used to classify them into *DSM-IV* (*Diagnostic and Statistical Manual of Mental Disorders*) categories of depression. Two months after the loss, 20 percent were classified as showing major depression, 20 percent were classified as exhibiting minor depression, 11 percent were classified as evidencing subsyndromal depression, and 49 percent were classified as evidencing no depression. These findings provide compelling evidence that following the loss of a spouse, a substantial minority of respondents show few signs of depression (see *Depression*).

In direct contradiction to the idea that it is necessary to experience a period of depression, the expression of negative emotion in the first few months following the loss has repeatedly been shown to portend subsequent difficulties. Expressions of positive emotions, in contrast, are quite common among the bereaved and have been consistently associated with less severe and long-lasting symptoms. These findings have emerged whether emotions are assessed through self-report, coded from narratives, or coded from facial expressions. Similarly, many studies have tested the grief work hypothesis, defining the construct in various ways. Most of these studies have produced evidence that flatly contradicts it, with those working through the loss showing worse outcomes over time (see Bonanno and Kaltman 1999, for a more detailed discussion). For example, Bonnano and associates reported from their study on conjugal loss that those bereaved individuals who evidenced emotional avoidance six months after the loss showed low levels of interviewer-rated grief throughout the study, and this response pattern was linked to few symptoms of any kind over a two-year period.

In contrast to the notion of the necessity of breaking down the attachment, numerous studies show that a continuing attachment to the deceased is normal. For example, in their study of how children cope with the loss of a parent, Silverman and Nickman (1996) reported that four months after the death, it was common for children to maintain an active connection to the deceased. The clear majority of children (74 percent) located their parent in heaven, and almost 60 percent of the children reported talking with the deceased. Types of connections identified in other studies include incorporation of virtues of the deceased into one's own character, using the deceased as a role model, and turning to the deceased for guidance regarding a particular problem. Evidence suggests

that in the majority of cases, such continuing bonds are comforting, although some respondents may find them frightening or disturbing. For example, 57 percent of the children in the study by Silverman and Nickman indicated that they were 'scared' by the idea that their parents could watch them from heaven.

It is widely believed that over time, as a result of working through their loss, individuals will achieve a state of acceptance regarding what has happened, move on with their lives, and resume normal functioning. Yet, available evidence suggests that this is not the case. For example, in a study on conjugal bereavement, Parkes and Weiss (1983) found that 61 percent of respondents whose spouses died suddenly, and 29 percent of those who had forewarning were still asking why the event had happened, two to four years postloss. Similarly, in a study on the long-term impact of losing a spouse or child in a motor vehicle accident, Lehman et al. (1987) found little evidence of acceptance even after four to seven years. Despite the amount of time that had elapsed, a majority of the respondents were unable to find any meaning in the loss, had thoughts that the death was unfair, and had painful memories about their spouse or child during the previous month. Furthermore, this study revealed that the bereaved respondents reported higher levels of depression, lower quality of life, and, in case of the loss of a child, more marital problems as well as a higher divorce rate than respondents in the non-bereaved comparison group.

Because the assumptions about the grieving process and recovery discussed above have not been supported by empirical data, we have come to call them myths of coping with loss (e.g., Wortman and Silver 1989). Instead, the available findings demonstrate the enormous variability in response to loss. They also highlight the importance of thinking about the grieving process in frameworks other than those based on breaking down the attachment or working through the loss.

3. *New Directions in Grief Research*

3.1 *The Stress and Coping Paradigm*

At present, much of the research on bereavement is loosely guided by a theoretical approach that might be called the stress and coping approach (e.g., Dohrenwend and Dohrenwend 1981). This paradigm is based on the assumption that once a stressful life event such as loss of a loved one is encountered, the appraisal of the stressor, as well as mental and physical health consequences, will depend on the individual's vulnerability or resistance factors (see *Stress and Coping Theories*). Those factors most reliably associated with adaptation to a major loss include suddenness of the loss, prior mental health problems, concomitant stressors such as ill health, and lack of social support (see Cook and Oltjenbruns 1998 for a more comprehensive review). However, there have been many inconsistencies across studies regarding the most important risk factors for poor outcome. It has been suggested that this inconclusiveness may be due to the interaction of different contextual factors. For example, a sudden death has often been shown to result in more physical and mental health problems for a bereaved individual than an anticipated death. However, the perception of suddenness appears to be related to the age of the deceased, in the sense that even the sudden death of an older person tends to be not as 'unexpected' as the death of a younger person because it constitutes more of an on-time life event. Thus, to understand the role of risk or protective factors, it is important to look at the overall constellation of contextual variables, and at the ways in which they interact.

The stress and coping paradigm not only points to the importance of contextual factors but also adds a perspective that goes beyond the issue of dealing with grief. Keeping in mind that a newly bereaved individual faces a life without the loved one, it becomes obvious that grief itself is only a part of what may be involved in coping with loss. Drawing on the stress and coping literature, Stroebe and Schut (in press) advanced a dual-track model involving two modes of coping that attend to the specific features of the bereavement process: Loss-oriented coping involves an effort to confront feelings of grief and loss itself, while restoration-oriented coping is an attempt to appease pain in some way, or distance oneself from one's grief in order to focus on the demands of daily life and to be able to keep going. This may enable a person to deal with grief in smaller dosages and, at the same time, create some space and save energy to attend to aspects of restructuring life. The idea is that usually both modes are needed and used at some point in the grieving process, and that a certain oscillation (and balance) between them is most likely to constitute an adaptive coping style.

In support of the two coping modes, Stroebe and associates have been able to show that bereaved mothers tended to be more loss-oriented than their husbands, following the death of their child. Another study revealed that men benefited more from interventions 'teaching' them to be more loss-oriented whereas women gained more from improving their restoration-oriented coping skills. Thus, Stroebe and associates provide evidence suggesting that the two coping modes are useful concepts to explain differential bereavement patterns, such as gender differences, and that bereaved individuals benefit from using both loss- and restoration-oriented strategies. What remains to be examined, however, is the process of oscillation and its adaptiveness.

3.2 *Attachment History*

Another innovative line of bereavement research is focusing on the attachment history of the bereaved.

Evidence suggests that some people show an intense and prolonged grief reaction to the loss of their spouse, and that this response is influenced by their attachment history. In an important series of papers, Prigerson and her associates have identified a type of mourning called traumatic grief (Prigerson et al. 1997), and have shown that its symptoms (e.g., preoccupation with thoughts of the deceased) are distinct from the symptoms of bereavement related depression (e.g., apathy). In one study of elderly bereaved respondents, these investigators found that symptoms of traumatic grief, assessed six months post loss, predicted critical health outcomes such as incidences of cancer, high blood pressure, and cardiac events one year later. Based on their research, the authors propose that a background of physical or sexual abuse, neglect, hostile conflict, or early parental loss or separation, typically leads to attachment disturbances such as excessive dependency or compulsive caregiving. In such cases, the loss of a marital relationship that was stabilizing may result in traumatic grief, even if the loss itself did not occur under traumatic circumstances. At present, preliminary research findings support this model.

3.3 Trauma Theory

In recent years, there has been considerable interest in applying concepts from the trauma literature to help understand the diversity of reactions to loss (see Janoff-Bulman 1992). Many theorists have maintained that losses are particularly likely to result in intense and prolonged grief if they shatter the survivor's most basic assumptions about the world. Particularly if the loss is sudden and traumatic, it may lead most mourners to question assumptions that they previously took for granted. These include assumptions that the world is predictable and controllable, that the world is meaningful and operates according to principles of fairness and justice, that one is safe and secure, that the world is benevolent, and that, generally speaking, other people can be trusted. Consistent with these ideas, there is some evidence to suggest that sudden, traumatic deaths pose particular difficulties for the survivor, especially if the death was intentional (i.e., murder). It appears that such deaths are more likely than those brought about by natural causes to result in post-traumatic stress symptoms such as intrusive thoughts and nightmares (see *Post-traumatic Stress Disorder*).

4. Treatment for Grief

Is it worthwhile to seek treatment following a major loss? How do people know whether treatment is warranted in their case? What types of treatment have been found to be effective? It has been suggested that if the acute symptoms of grief subside after a few months, treatment is probably not warranted. However, if a bereaved person continues to experience intense feelings of yearning and depression, anxiety, or post-traumatic stress symptoms beyond the first six months, there is some consensus that it is wise to consider treatment. Jacobs (1993) has reported that during the first year following a loss, approximately 30 percent of the 800,000 who lose a spouse will experience a diagnosable psychiatric problem. However, less than one in five of these individuals seek help. Those who would particularly benefit from professional help include parents who have lost children, people who have experienced the untimely loss of a spouse, those who are experiencing concomitant stressors such as poor health, and those who have little social support available. Help should ideally be sought from a therapist who is experienced in dealing with grief. For those who have experienced a sudden, traumatic loss, it is important that the therapist be knowledgeable about trauma as well. Individuals may also benefit from support groups. Such groups can help the bereaved to understand that their feelings and reactions are normal, and can impart information about how to deal with specific problems. When one's grief is intense or prolonged, support groups are best considered as an ancillary treatment rather than a substitute for psychotherapy.

5. Conclusion and Outlook

Taken together, the ways in which researchers think about bereavement seem to have changed in a number of crucial regards. As pointed out above, a shift can be observed from the idea of a universal pattern of stages towards a recognition of immense variability and the importance of contextual influences; from the breaking bond orientation towards the concept of transforming the connection to the loved one; and from a model that is marked by a unitary focus on grief toward a comprehensive approach that includes the challenges of dealing with daily life after the loss. However, traditional ways of thinking about grief are still surprisingly prevalent among laypeople, practitioners, and some researchers, despite the lack of supportive evidence. It seems that the more recent evidence contradicting the traditional views of grief will have to be replicated in order to further move along the described shift in understanding bereavement, to the point that outdated models and concepts lose their 'myth' character.

In addition, research is needed to examine further and refine the new ways of understanding bereavement that were outlined above. For instance, while the literature is clear in suggesting that it is common for individuals to maintain a connection to the deceased,

it is unclear what kind of connection tends to be more or less adaptive. Second, a further investigation of the impact of a person's attachment history on adaptation to loss could provide helpful insights into the phenomenon of traumatic grief and may give cues for effective interventions. Third, it would be a contribution of future research to investigate further the use and interplay of the restoration- and loss-oriented modes and their adaptiveness in the context of different kinds of loss and outside conditions. In this context, the controversial question of the role of grief work needs to be further assessed. One important question, for example, is to what extent an oscillation or a certain balance between loss- and restoration-orientation is necessary for positive adjustment. Another issue of great interest is how this dynamic coping process may work in families or other social situations. Some families, for example, may show a certain level of synchrony with respect to their balance of coping. Others may have more of a teamwork style, which means that different family members take over different coping tasks, depending on their current resources and state of mind (Baltes and Staudinger 1996).

As these thoughts demonstrate, there is still much to be learned and understood about the ways in which people cope with a major loss, and those who suffer from a major loss need and deserve an open-minded attitude toward their plight. After all, the death of a loved one constitutes one of the most challenging experiences that we all encounter at some point in our lives.

Bernard, Jessie (1903–96)

Jessie Bernard's role as an amiable radical perfused both her personal history and sociological *oeuvre*. Her traditional sociological training and her marriage to a major figure in the field originally brought Bernard into the sociological establishment. Subsequently, through a series of personal 'revolutions,' she emerged as a feminist critic of mainstream sociological paradigms, social institutions, and public policy, particularly those concerning women's roles. Nonetheless, by the 1970s, Bernard's work was recognized internationally and honored by the entire field, as well.

In 15 solo books, seven co-authored or edited volumes, 25 book chapters, and 60-plus journal articles, her humane and unpretentious style created a medium in which her increasingly radical message was accepted without raising traditional hackles. Bernard's private history may be read as an amicable, but undaunted, rebellion against the expectations that family and society pressed upon a female who was born shortly after the turn of the century and died four years shy of the millennium.

Her belief in social positivism profoundly shaken by the Nazi Holocaust, Bernard resonated to societal

upheavals—particularly the Women's Movement—that were to mark the second half of the twentieth century and dramatically alter her *Weltanschauung*. She was, by turns, a professional academic woman, a single mother, a revered figure in the field of sociology, a feminist author whose work reached an international audience far beyond academic sociology, and a beloved mentor extraordinaire.

1. *Biography*

Born in Minneapolis, Minnesota on June 8, 1903, to parents of Romanian Jewish heritage, Jessie Bernard was the third of Bessie Kanter and David Solomon Ravitch's four children. In January 1920, Bernard entered the University of Minnesota, where she studied with Pitirim Sorokin, Alvin Hanson, N. S. B. Gras, Karl Lashley, and Luther Lee Bernard. She received both her B.A. (1923) and M.A. (1924) from the University of Minnesota, before marrying Bernard, 21 years her senior, against her family's objections to age and religious differences. The Bernards moved to Washington University, St. Louis, where Jessie completed her Ph.D. in 1935. During a marital separation, she worked for the US Bureau of Labor as a social science analyst. Bernard taught at Lindenwood College for Women, St. Charles, Missouri (1940–7) and served as professor of sociology at Pennsylvania State University (1947–64).

Influenced by L. L. Bernard's social positivism as 'the best way to achieve desired societal ends' (1978), Bernard grew to intellectual maturity trained 'strictly in the measurement tradition' (personal communication 1979). In the mid-1940s, the shock of the Nazi Holocaust led her to reject that social positivist paradigm. She moved squarely into the functionalist school, where she was to remain until her feminist epiphany.

L. L. Bernard's death in 1951 left Jessie Bernard responsible for three young children. Bernard's personal life as widow and female family head provided the experiential background for empathic insight into a major emerging sociological problem. By the fall of 1953, Bernard left for Europe to study postwar trends in sociological research and to heal her emotional wounds.

After her year abroad, Bernard returned to Pennsylvania State to work on two new volumes: *Remarriage: A Study of Marriage* (1957a/1971) and *Social Problems at Mid-century: Role, Status, and Stress in a Context of Abundance* (1957b). She spent 1959–60 as a visiting professor at Princeton University, which had just allowed women to enter the front door of the university library. By 1964, Bernard decided to leave academia, where she sensed it was necessary to 'censor (her) ideas to fit the pattern of ideas surrounding (her)' (personal communication 1979). Bernard moved to Washington, DC, where she maintained an active scholarly and professional life as a participant in local and international conferences and policy debates through the late 1980s. She died on October 6, 1996 in Washington, DC.

2. *Major Contributions*

Bernard's scholarship is eclectic, covering a wide range of ideas and using a complex palette of methodologies. Bernard's earliest works, such as *American Family Behavior* (1942a/1973), through *The Future of Marriage* (1972), utilize macrodata, including macrostatistics, to compare sociological patterns and to gauge the strength and trends of sociological phenomena. Later, she turned to microdata in the form of the letters she and her children exchanged over more than 25 years. In *Self-Portrait of a Family* (1978), a courageously self-revealing effort, she chronicled the intimate infrastructure of family life. In her last two volumes, *The Female World* (1981) and *The Female World from a Global Perspective* (1987), Bernard combined macro- and microanalysis to provide a rich texture to her work.

In 1942 Bernard published her first solo book *American Family Behavior* (1942a/1973). In the early years at Penn State, she wrote *American Community Behavior* (1949/1962). Both volumes foreshadowed later work in which Bernard measured the American family's performance, success in marriage, and the 'institutionalization' of marriage and family norms. Despite her defection from social positivism to functionalism, Bernard's reliance on research findings as the best, or only available, evidence remained a hallmark of her later analyses.

Bernard's break from academia came almost simultaneously with the publication of her most significant work to that time, *Academic Women* (1964/1974). Although *Academic Women* received both the Pennsylvania State University Bell award and the Kappa Gamma honorary award, the larger academic establishment, according to Bernard, responded initially with 'a great big yawn' (1964/1974).

Academic Women explored the condition of women in academe, dispassionately examining the evidence for and against discrimination. That book presaged Bernard's later attempts to deal with significant social issues—abortion, battered women, child abuse, the culture of poverty, female-headed families, and sexism—long before they became incendiary social questions. Widely influential, both despite and because of the feminist criticism leveled against it, *Academic Women* scrutinized the factors that accounted for women's subordinate role in academia. Bernard concluded that sex was more salient than role as a determinant of status. She attributed women's unequal condition to their propensity to teach in colleges rather than universities, to teach rather than undertake research, to act as transmitters of established knowledge rather than 'men of knowledge,' and to follow patiently rather than innovate boldly.

Bernard recognized that scientific productivity was a function of a researcher's position in the communication system. She depicted the 'stag effect' as a subtle process excluding women from the informal communication system along which emerging scientific knowledge is disseminated. Although Bernard described the palpable procedures and processes of sexism (a term not yet coined), she stopped short of recognizing them as the informal underpinnings of discrimination. Bernard did not yet perceive, as she later did, the crippling relationship between the informal practices and attitudes of sexism and the structural manifestations of discrimination.

Academic Women touched the beachhead of concern about women's condition in society just ahead of the swelling wave of feminism. Radical feminists railed against Bernard's conclusion that no formal discrimination existed. Later, after her own feminist 'revolution,' Bernard applauded her critics' analyses. Nonetheless, *Academic Women* was the beginning of a new surge of intellectual strength, which even the male-dominated academic establishment could no longer ignore.

Over the next 14 years, Bernard broke through the functionalist paradigm that had held mainstream sociology in its thrall. She entered the unexplored terrain of the feminist perspective. Beginning in her sixth decade, Bernard began to mine a new, richer multidisciplinary vein—feminism—that would later fuel her strongest and most prodigious intellectual contributions.

The most basic theme that snakes through Bernard's work is biculturality, first discussed in terms of Jewish immigrants in America (1942b) and later expanded in *Marriage and Family among Negroes* (1966). Bernard developed the notion of two black cultures—one externally adapted, the other acculturated—within the larger white context. Over her remaining career, Bernard would apply this theme to the female world, as well.

The Sex Game (1968) elaborated biculturality by depicting the sexes as two large, relatively unstructured collectivities living in sexual apartheid. In *Women and the Public Interest: An Essay on Policy and Protest* (1971), Bernard introduced the concept of 'women's sphere' and the pervasive influence of women's 'stroking' function. Bernard marshaled evidence to show that women's specialization in stroking throughout the world contributes to their subordinate position. Through this behavior, the stroker shows solidarity, raises the status of others, gives help, rewards, agrees, concurs, complies, understands, passively accepts (1971). Such stroking behavior, Bernard argued, is incompatible with high-level occupational roles, in which instrumental, aggressive, and, often, competitive behavior is required.

The theme of biculturality is further explored in *The Future of Marriage* (1972), probably her most widely read work. There, Bernard conceptualized each marital union as two different, noncoinciding marriages or worlds (his and hers). With Durkheimian precision, Bernard used census data to demonstrate that marriage benefited men more than women.

Other major themes texture the fabric of Bernard's work: formal vs. informal discrimination; power; women as a subordinate, dependent group; 'stroking' as a fundamental unit of social action; the conflict between women's family and work roles; sexism and power relationships; the deteriorating effect of housework and total responsibility for childcare on women's mental health; homosociality, that is, the preference for social interaction with people like oneself; sex differences, including typical vs. characteristic differences between males and females; biological sex roles vs. cultural gender roles; the function of stereotypes as mechanisms for papering over the lack of fit between gender roles and individual differences; tipping points and turning points; social policy as an instrument for alleviating the disadvantages women face; and the historical youthfulness of the nuclear family.

In the late 1960s, Bernard moved agonizingly, but irrevocably, from a functionalist to a feminist perspective. Surveying sociological phenomena through a feminist prism cast a different, more vivid spectrum of colors than Bernard had seen before. The cool 'objectivity' of social science could now be perceived as a rationalization for remaining emotionally uninvolved in the inequities and moral dilemmas of social life. Until the feminist perspective emerged, male and female researchers alike had to refract society's ills through a single distorting male lens. Missing was the female lens, essential for the social stereoscope through which the two worlds could be seen together in their true dimensionality.

The Female World, Bernard's (1981) *magnum opus*, is arguably the most complex, in-depth, multidisciplinary analysis of women's separate world that has ever been undertaken. *The Female World* includes a complex assessment of women's station. Not only do women live in different marriages than their husbands, they live in different families, educational systems, social strata, occupational structures, and political and cultural realms. Bernard does not deny that women also live in the world of men, but argues that they are not of that world, in much the same way that Americans living in Paris are not bona fide Parisians.

In *The Female World*, Bernard probed the anatomy of that world's unique class structure. She concluded that the very subconcepts underlying the notion of social class (long accepted in mainstream sociology) failed to reflect the complex class structure of the female world. Bernard reported many new feminist historical discoveries, boldly endorsing the emerging options that would reduce the loss of women to meaningless lives. Until then, the female world had been mostly ignored. When it was not completely *terra incognita*, the female world has been analyzed as a by-

product of the male world, using male concepts, male methodologies, and male values. Bernard's goal in *The Female World* was to redress this intellectual inequity. Here, Bernard conceptualized the female world *sui generis*, as an autonomous entity, rather than one created from the rib of male sociological analysis.

The volume, spanning prehistoric times to the late twentieth century, is monumental in scope. It reports on previously ignored female worlds: from the third and fourth century convents to the beguinages, their lay analogue in the thirteenth and fourteenth centuries, to the female vagabonds of the Middle Ages, to the Lowell girls in the nineteenth century, to the twentieth century's institutionalized and homeless women. Bernard moves seamlessly from subhuman primates to humans, from sociology to anthropology, history, psychology, and economics with a breathtaking grasp of concepts, methodologies, central themes, ideological underpinnings, and weaknesses.

To describe the class structure of the female world, Bernard relied in part upon the traditional sociological tripartite model of education, income, and occupation. Where those components were not applicable (e.g., for women who were not in the paid labor force), however, she supplemented them with 'subjective behavioral criteria of status,' such as social climbing, influence, modeling (i.e., who want to be like whom), and even husband's income. The classes Bernard derived were 'society, media-created celebrities, intellectuals, white-collar and pink-collar workers, unpaid housewives, blue-collar and service workers, welfare recipients, and demoralized, broken, homeless, outcast women.'

In *The Female World*, Bernard built upon the bicultural perspective which informed much of her earlier work, using several conceptual polarities to identify the structured differences between these worlds. Following Tönnies, she described the *Gemeinschaft* of the female world, based on kinship and locale. It stands in sharp contrast to the *Gesellschaft* ethos of the male world, structured by money and politics. The *Gemeinschaft*, according to Bernard, unfits women for living in the *Gesellschaft*. The *Gesellschaft*, however, is permeated by a male ethos that Bernard concludes is maladaptive for men as well as women.

The second polarity is that between the integry and the economy, originally described by Kenneth E. Boulding. The integry/economy dichotomy parallels *Gemeinschaft*/*Gesellschaft*. The integry forms that segment of the social system that attends to community, identity, love, trust, altruism, intimacy, and loyalty. The integry belongs to women, encompassing a set of compassionate activities and norms that holds the social structure together.

By contrast, in the economy, monetary exchanges create the context for relationships. The economy, built and governed primarily by men, is based on rationality, self-interest, competition, aggression, and impersonality. Bernard catalogued the costs to women of living in their own world colored by an ethos of agape, that is, of social activism or humanitarianism. She argued that only women who derive their economic support from others—fathers or husbands—can afford to devote themselves to the humanitarian needs of society. Although the total society may benefit from their contributions, the personal price women pay, ranging from guilt to dependency, is heavy.

The Female World is a serious, documentary celebration of women's unique strengths on which Bernard rests the chances for the future salvation of both sexes in a postindustrial society. She offers no apologia for women or for the sex differences whose irreducibility she insisted upon both before and after her feminist conversion. Earlier, Bernard politely predicted that sex role transcendence and shared roles might be the wave of the future (Bernard 1972, 1974, 1975, Lipman-Blumen and Bernard 1979). In this volume, however, Bernard analyzed the entire female world with its complicated structure and ethos, past and present, in still well mannered, but now clearly forceful, tones.

In her final work, *The Female World from a Global Perspective*, Bernard posed two integrating metaphors: the Feminist Enlightenment and equitable integration. Bernard perceived the Feminist Enlightenment, beginning in the 1960s, as an analogue to the eighteenth century French Enlightenment: an intellectual and political movement that redefined history, rejected the authoritarian status quo, and created a new basis for understanding the world. The Feminist Enlightenment, according to Bernard, ground a fresh and sharper scalpel than 'objective' science had provided two centuries before. Feminism offered a laser-hot tool to cut through the stereotypes, sexism, ghettoization, and blindness to the 'racism, classism, and status impediments' that women around the globe still experienced in mid-twentieth century. Bernard apprehended the importance of Women's Studies, a new multidisciplinary field within higher education, as a critical mainspring of the Feminist Enlightenment.

The reconceptualization of equitable integration is the second organizing metaphor of *Global* (as Bernard referred to this volume). Bernard unflinchingly analyzed the political and geographic separations among the segments of the female world no less rigorously than the partitioning of the male and female worlds. She also fathomed the serious difficulties in bridging the chasm between Western feminism and feminism in other parts of the globe. Nonetheless, Bernard worked toward a conceptualization of equitable integration that would allow for solidarity *cum* diversity. Equitable integration would be bolstered by strategies yet to be developed and implemented through realistic policies for reducing, if not totally eradicating, racism, classism, and status impediments.

Communication and technologies for promoting all forms of communication among women loomed large to Bernard. She welcomed enthusiastically the new

possibilities for communication among women, through newsletters, films, TV, and videos. Long before the Internet had become the *modus communicandi*, she understood the importance of electronic communication in breaking down the ideological and cultural barriers among women. Bernard also recognized both the significance and the difficulties of face-to-face meetings among women, particularly the three International Conferences on the Status of Women, sponsored by the United Nations during the Decade of Women, 1975–85. Even when results were disappointing, even when these conferences were nearly capsized by the tsunamis of international politics, Bernard remained clear-eyed but optimistic. She based her optimism on the scholarship and ferment that were sure to flow from the developing Feminist Enlightenment.

3. *Influence, Impact, and Current Significance*

Recognition of Jessie Bernard as a major contributor to the discipline, as well as to the education of the broader public, has come from every quarter. One review of Bernard's work concluded that she was 'one of the most important sociologists of the twentieth century' (Howe and Cantor 1994). Bannister's (1991) less positive evaluation has been rejected uniformly by numerous scholars as too error-ridden to be taken seriously. Ironically, Bernard's ability to speak lucidly and incisively, without academic pretensions, to a larger public probably delayed the enormous outpouring of professional acclaim until her later years.

Bernard's influence is evident in contemporary work on female/male relationships. Her considerable contributions to the field were analyzed in two posthumous panels at the annual meetings of the Eastern Sociological Society and the American Sociological Association. From 1966 to 2000, *The Social Sciences Citations Index* listed 2,994 citations to Bernard's work. Her concepts and insights so widely permeate scholarly thinking that they often appear unacknowledged in the work of contemporary researchers. Many years after Bernard concluded that men benefit more than women from marriage, this topic continues to be debated by contemporary scholars, another sign of the amiable radical's impact. Her work is required reading on current syllabi in sociology, psychology, and women's studies courses, many of which appear on the Internet.

Bernard's influence is not limited to the scholarly world. For example, the central idea of the best seller *Women Are From Venus*, *Men Are From Mars*, by John Gray is vintage Bernard. Various searches of the Internet reveal approximately 450 websites with re ferences to Bernard.

Although she served as president of the Society for the Study of Social Problems (SSSP) (1963–4), after leaving academia Bernard declined nominations to various professional offices, including the presidency of the American Sociological Association. Nonetheless, she received the merit award from the Eastern Sociological Society and the Burgess award from the National Council of Family Relations (1973), the Kurt Lewin award from Pennsylvania State University (1976), the outstanding achievement award from the American Association of University Women (1976), and honorary doctorates from 10 major universities. In 1989, she received the American Sociological Association's (ASA) Distinguished Career Award.

Several awards have been established in Bernard's name to honor those who similarly have contributed intellectually, professionally, and humanely to the world of scholarship and feminism: the Jessie Bernard awards, created by the American Sociological Association (1976), the District of Columbia Sociologists for Women in Society (1978), and the Wise Woman Award by the Institute for Women Policy Studies. These reflect the esteem in which her intellectual brilliance and eclecticism, personal courage, amiable radicalism, unpretentious humanity, and feminist sisterhood are held.

Bernoulli, Jacob I (1654–1705)

Jacob I. Bernoulli, born December 27, 1654 in Basel, died 1705 August 16, in Basel, Swiss mathematician and first scholar of the famous Bernoulli family with important contributions to the infinitesimal calculus, mechanics, theories of variation and probability.

Jacob Bernoulli was born into a family of bankers and merchants from Amsterdam who later moved to Basel. In 1671 he finished his studies in philosophy with a master (Magister) degree, 1676, in theology with a liscentiat. During 1676–80 and 1681–82, he visited France, the Netherlands, and England, and started his studies in applied mathematics, inspired by the philosophical and mathematical works of R. Descartes and N. Malebranche and the physical theories of R. Boyle and R. Hooke. In 1682 he refused an offer to become a preacher in Strasbourg in order to continue his mathematical studies. His brother Johann I. Bernoulli (1667–1748) was instructed by him in mathematics. Johann became also a famous mathematician who later on competed with him in the solution of several mathematical problems. Initially, Jacob gave lectures in experimental physics at the university of Basel. From 1687 he was professor of mathematics at his home university. His '*Opera omnia*' (1744 posthum published) contains scientific articles published by himself and 32 edited treatises.

Since 1677, Jacob Bernoulli wrote a scientific diary, called 'Meditationes.' His first articles were a (false) theory of comets and a treatise on the gravity of the ether. In physics he started with inquiries about the atmospheric density and the perpetuum mobile of D. Papin. During 1684–86, he also worked about logic. In mathematics he started with Descartes' geometry and published algebraic and geometric articles in the '*Acta Eruditorum*.' In competition with J. Wallis he constituted the principle of complete induction in 1686. In 1687, Jacob Bernoulli proved that the area of a triangle can be divided into four parts by two orthogonal straight lines. The work of J. Wallis, I. Barrow, and G. W. Leibniz on the infinitesimal calculus had a great impact on Jacob Bernoulli. As young professor of mathematics, he asked Leibniz to explain to him the foundations of the infinitesimal methods. Behreen 1684 and 1704, he wrote several treatises concerning the theory of mathematical series. Exponential series were considered as the inverse of logarithmic series. In a paper on the divergence of harmonic series he independently repeated the so-called Bernoulli inequality $(1+x)^n \geqslant nx$ $(x \geqslant 0)$, which had already been introduced by I. Barrow in 1670.

In 1691 he published papers about problems in infinitesimal mathematics (e.g., the slope of a tangent line, quadratures, rectifications). Jacob Bernoulli applied infinitesimal methods systematically to geometric problems. For example in 1692, he solved the so-called Florentine problem which means the quadrature of a certain part of the semi-sphere. He analyzed several curves such as the parabolic and logarithmic spiral and introduced the Bernoulli differential equation

$$y' + f(x)y + g(x)y^n = 0.$$

For these problems, he found a formula for the radius of curvature at a point of a curve and used polar coordinates. In 1690 Jacob Bernoulli solved a problem of Leibniz (1686) to determinate the curve along which a body falls with uniform velocity (isochrone). He introduced the word 'integral' when suggesting the name '*calculus integralis*' instead of Leibniz's original '*calculus summatorius*' for the inverse of '*calculus differentialis*.'

In 1696, Johann I. Bernoulli stated his famous problem of the Brachystochrone: along which curve does a mass point move on a vertical plane from a point to a deeper one in the shortest time only by its gravity? Johann I. Bernoulli himself only delivered a restricted solution. His brother and rival Jacob solved the problem in a general way. His main idea was the following: one has to find a curve with an extremum property (i.e., maximum or minimum) from a set of curves. Therefore Jacob Bernoulli assumed that every part and especially every element of the curve also has the extremum property. Bernoulli's postulate inspired L. Euler in a new mathematical discipline which is now called the theory of variations. In his famous inquiry '*Methodus* inveniendi lineas curves maximi minimive proprietate gaudentes' (1744), he reduced problems of variation to problems of maxima and minima. The calculus of variation considers a new kind of problem in infinitesimal calculus: one has not only to find the solution of a function (curve) with an extremum property, but of a functional with real functions as arguments (set of curves). In 'Analysis magni problematis isoperimetrici' (1701), Jacob analyzed isoperimetric curves of a given length enclosing a maximal area. In the analytical mechanics of the eighteenth century (e.g., J. L. Lagrange's *Mécanique analytique* 1788), the calculus of variation became an important procedure for solving mechanical equations of motion.

Today, problems of variation are analyzed in the more general framework of functional analysis. Although it was Jacob Bernoulli who recognized the general concept of variation in the problem of the Brachystochrone, Johann acknowledged his brother's merit only after his death.

In physics, Jacob I. Bernoulli found important results in the mechanics of solid and elastic bodies. In 1691 he started a series of theorems on an elastic beam which is bent by an external force. The problem had already been analyzed by G. Galilei, E. Mariotte, G. W. Leibniz, and others. So, it was a challenge for Jacob to criticize the false or restricted assumption of his famous forerunners and to apply and test his infinitesimal methods. Leibniz praised Bernoulli's approach because of its generality. Some months before his death in 1705, Jacob I. Bernoulli finished his last work about the curvature of a bent beam. He foresaw that his solution was the beginning of a general theory on the elastic continuum. In 1704, he also anticipated D'Alembert's famous principle of virtual velocities by an own version.

Since 1685, Jacob I. Bernoulli had been interested in the theory of probabilities. This early interest is documented in his correspondence with Leibniz. Jacob I. Bernoulli was influenced by the studies of C. Huygens on games of hazard (1657) which he enlarged to a theory with the name '*ars conjectandi*' (art of conjecturing). The *ars conjectandi* which was published post-1713 by Jacob's nephew Niklaus I. Bernoulli had a great impact on the development of the theory of probability (e.g., A. de Moivres' *Doctrine of Chances* 1718). Jacob I. Bernoulli generalized Huygen's examples of numbers and derived general formulas of combinatorics with skillful notations. Referring to Leibniz's combinatorics, he analyzed the so-called Bernoulli polynoms

$$B_m(z) = \sum_{k=0}^{m} \binom{m}{k} B_k \cdot z^{m-k}$$

with $m \geqslant 0$ (integer) and coefficients B_k which can recursively be calculated as so-called Bernoulli numbers

$$B_0 = 1, \quad \sum_{k=0}^{m-1} \binom{m}{k} B_k = 0 \quad \text{where } m \geqslant 2.$$

They are used for solving difference equations of the form

$$u(z+1) - u(z) = m \cdot z^{m-1} \quad \text{where } m \geqslant 1.$$

In some hints of the *ars conjectandi*, one can even find the transition to statistics. The famous law of large numbers can also be found in the *ars conjectandi*. Let us consider a Bernoulli sequence of tests, i.e., a sequence of independent tests by random which always have the constant probability p for the occurrence of an event A. An example is the repeated throw of a coin with probability $p = 0.5$ for the occurrence of the event face side. According to Bernoulli's theorem, the probability that the relative frequency r_n of the occurrence of A after n tests is arbitrarily near to p converges to 1 with increasing p, i.e.

$$\lim_{n \to \infty} P(|r_n - p| < \varepsilon) = 1 \quad \text{for all } \varepsilon > 0.$$

E. Borel (1881–1956) introduced a stronger version of the law of large numbers. The probability that r_n converges to p is 1, i.e.

$$P(\lim_{n \to 0} r_n = p) = 1.$$

Borel's version is stronger than Bernoulli's one, because Borel's version follows from Bernoulli's one, but not vice versa. In the modern theory of probability which is no longer restricted to Bernoulli sequences of tests, Bernoulli's and Borel's laws are special cases of more general theorems about random variables according to certain conditions. Therefore, we prefer to speak of laws of large numbers. In this mathematical tradition, R. von Mises (1883–1953) tried to reduce the concept of statistical probability to sequences of relative frequencies. But from a modern point of view, Bernoulli's and Borel's laws are only probabilistic propositions referring to a measure P of probability. Thus, they presuppose a concept of probability. Besides probability, the *ars conjectandi* also contains reflections about certainty, necessity, random, moral, and caculable expectation.

The work of Jacob I. Bernoulli is distinguished by great algorithmic skills and conceptual depth. In cooperation and competition with famous mathematical contemporaries, he developed the infinitesimal calculus with great mastership. His lifetime is a mathematical period of consolidation and exploitation of the great discoveries of the seventeenth century and of their application to the investigation of scientific problems, for instance, in mechanics. With his brother Johann he realized the transition from the mathematical pioneer Leibniz to the age of L. Euler who became the dominant mathematical figure of the eighteenth century. But Jacob's mathematical contributions are not only restricted to the mathematical fundaments of the eighteenth century. The theory of variation also has great importance in the twentieth century physics of quantum theory and theory of relativity and in the twentieth century mathematics of functional analysis. With his *ars conjectandi*, Jacob I. Bernoulli even founded a mathematical theory with interdisciplinary application in the natural and social sciences. As son of a banking and merchant family, he was aware of the monetary, economic, and social developments of his age, as general interest increased in problems of mathematical expectations, decision, random, probability, interest rate, and statistics,

characterizing human society. Contrary to the indeterminism of human society, the natural science of the seventeenth and eighteenth centuries assumed a completely mathematical determinism of nature which was successfully computable in analytical mechanics. The infinitesimal calculus delivered the mathematical fundament of the new mathematical disciplines. Philosophically, the concept of nature and society in the eighteenth century was discussed later on by Immanuel Kant. In what way is acting and deciding on the basis of free will in a completely determined nature possible? The strict distinction between a completely determined nature and a human world of random, expectation and probability has been overcome in the twentieth century when quantum mechanics with its probabilistic quantum effects became the new fundamental of physics.

Big Man, Anthropology of

Referring to achieved leadership, the term 'big man' has come to stand for a type of polity (distinguished, e.g., from types identified with inherited rank). It is associated closely with, though not limited to, the ethnography of Melanesia. While prominent in ethnography and in developmental theories from the 1950s through the 1980s, this ethnographic construct has become less important in recent years. Contemporary work reflects a methodological turn away from typology building (and the functional and developmental theories it served). Emphasis has shifted instead towards historically and culturally situated understandings of power and agency, attentive to gender and emergent class relations, and to national and transnational processes.

1. Early Work and Developing Analyses

Big man is the Anglicization of a descriptive phrase *bikpela man*—meaning 'prominent man'—common in some variants of *Tok Pisin* (an important Melanesian *lingua franca*). The term was adopted widely in post-World War II Melanesian ethnography (e.g., Oliver 1955, Read 1959, Strathern 1971) to refer to male leaders whose political influence is achieved by means of public oratory, informal persuasion, and the skillful conduct of both private and public wealth exchange. The anthropology of big men comprises both regional ethnography (the sociocultural interpretation of case materials derived from extended field research) and—as this ethnography is puzzling from a comparative perspective—theoretical debate.

1.1 Ethnography

While a variety of political systems have been observed in Melanesia from the early colonial period to the present day, the big man is a notable feature of political life in highland regions of Papua New Guinea and Irian Jaya. These regions are distinctive for high population densities and settled, loosely kin-centered communities (e.g., 'clans' associated with named 'places'). Their horticultural economies characteristically are based on intensive tuber (sweet potato, taro) cultivation and pig raising.

Big man leadership has intrigued anthropologists as a vantage for understanding how economic intensification might be possible in the absence of institutionalized political structures. As it has been observed ethnographically, highland Melanesian sociopolitical life is decentralized, informal, and participatory in spirit. That is, access to garden land is universal (a flexible concomitant of kin relationships), and systematic differences in access to subsistence means, spouses (and other household labor resources), and valuables are muted or absent. While direct participation in clan events is a more or less exclusively male prerogative and affects male social standing, it is not obligatory. Even for men, clan interests do not take precedence necessarily over personal relationships with kin and other exchange partners, in which women are also involved. Finally, in many communities, leadership is a personal achievement associated with organizing events held in the names of clans and tribal alliances. Leaders neither inherit their status by virtue of seniority, lineage membership, or ritual sanction, nor are they formally elected or instated. Communities do not typically institutionalize decision-making councils or offices that must be filled.

Despite the lack of institutionalized political structures, during precolonial and early colonial times communities did affiliate themselves regionally for warfare and ritual performances (e.g., initiations and fertility cults). People also came together frequently to sponsor competitive exchanges of indigenous valuables (e.g., pigs and pearlshells), events in which thousands participated as recipients and donors. Periodic exchange festivals of different scales and degrees of social and political complexity have driven intensive garden production for generations in the highlands. During the colonial period and nowadays, exchanges also involve money and introduced valuables (e.g., cows, trucks), and may partially motivate participation in wage-work and commercial endeavors. Held to mark important events like deaths, and to constitute or reorder regional alliances between groups, these festivals require skillful organizing and long-term planning, as well as an intensive production base.

Early in Highlands research Read (1959) noted a tension between culturally sanctioned assertions of personal autonomy and of collective purpose. Western constructs resolve an apparently analogous relation by subsuming naturalized 'individual' interests within institutionalized social structures (like the state). In contrast, Melanesian cultures implicate both differentiating and collectivizing interests as social possibilities in a distinctive concept of personhood. Autonomy is enacted in the elaboration of personal networks of kin and exchange partners (affines, friends). More or less idiosyncratic, each person's social network embodies interests that converge partially—but may regularly conflict—with the collective projects of clans.

Big men make their names by successfully orienting their clansmen to collective ends. While the means they use varies in different parts of highland Melanesia, their power is personal and ephemeral relative to leadership power in societies with inherited rank or with formal councils. This absence of structurally reproduced power gives Melanesian communities a reputation for 'egalitarianism' (among men, if not between men and women). Men with leadership ambitions work to develop personal access to resources within and outside their communities. They achieve fame and influence by using local and regional social networks as bases for organizing collective wealth prestations: events that make and remake clans and tribal alliances. By means both of public oratory and private persuasion, big men work to add a collective significance to their own and other's actions, which would otherwise be construed only as diversely personal.

1.2 Political Typologies and Developmental Puzzles

In post-World War II anthropology, ethnographic accounts from Melanesia and Polynesia were influential in the modeling of sociopolitical ideal types (respectively exemplifying 'tribes' and 'chieftainships'). Such typologies were central to theories of cultural evolution (development), of special interest to archeologists but also prominent over the past century both within and outside of sociocultural anthropology. Developmental theories assumed that less economically productive, less socially differentiated and politically centralized social types give way, over time, to more productive, more centralized ones. They posited a series of functional interdependencies among variables like population density, technology, the organization of production, 'surplus' production, and sociopolitical stratification.

Sahlins's (1963) typological comparison of the Polynesian chief and Melanesian big man—perhaps the single most influential argument concerning Pacific polities—established the figure of the leader as key to arguments concerning their historical fortunes. With Polynesian chiefs as a standard, Sahlins emphasized the limited coercive power of the big man in mobilizing wealth for public prestations, and identified these limits in the refusal of his clansmen (understood as his political supporters in regional inter-clan prestations) to put up with his increasingly unreciprocal behavior.

Viewed from this perspective, evidence of regular, large-scale prestations of pigs, pearl shells, and other wealth in highland Melanesia was puzzling. Ethnographic arguments by Mervyn Meggitt, Andrew Strathern, and others subsequently demonstrated that—while relations between men (dominant in wealth exchange) and women (mainstays of food and pig production) were conflictual—relations between leaders and their fellow clansmen were not predominantly extractive, but were mitigated by big men's ability to tap labor and other resources in groups other their own by means of exchange networks.

Meanwhile, a convergent line of research—bent more on understanding economic change than sociopolitical systems—developed a comparison between Melanesian exchanges and capitalist markets. Dubbing Melanesians 'primitive capitalists,' this work emphasized apparent similarities between local orientations and Euro-American cultural values like individual achievement, competition, material wealth, and investment. For example, Finney (1973) argued that the similarities culturally and psychologically 'preadapted' the big man, in particular, for capitalist development. Indeed, during the colonial period, highland Papua New Guineans were notably entrepreneurial (rather than simply spending cash incomes on consumer goods).

1.3 Big Man on the Margins

These lines of research came to an ambivalent resolution in the late 1980s (e.g., Godelier and Strathern 1991). Most prominently, Maurice Godelier centered

attention on the structure of marriage exchanges in an argument meant to suggest that the big man type—with its emphasis on the manipulation of wealth—is not as typical of highland Melanesia as earlier ethnography implied it was. In communities where marriage conventions de-emphasize bridewealth (transfers of wealth for persons or their capacities) in favor of 'sister exchange' (transfers of persons for persons), Godelier proposed that one observes 'Great Men' not big men: varieties of male prominence (notably initiation cult leadership) founded on ritual expertise.

Godelier's position followed the classic pattern of using ethnographic cases to construct political economic types as elements in a hypothetical developmental sequence. It made diverse cases comparable (capable of being organized as a progression) by assuming their common commitment to the maintenance of male collective (clan) interests. Also like earlier work, it placed the big man type structurally on the frontier of market capitalism. However, these approaches were already under siege, ethnographically and theoretically, as they were articulated in the mid/late 1980s.

2. Recent Trends

The progressive decline in research on big manship since the mid-1980s echoes a now long-standing disciplinary trend away from typological, developmental/functional comparison and toward nuanced cultural interpretation in the context of historical and ethnographic analyses of intra- and intercultural engagements. On the whole, Melanesian anthropology has not only reflected but also spearheaded these transformations in the 'culture' concept and its uses. In this reworked arena, the rich lines of research that the puzzles of big manship stimulated have been absorbed into other projects.

These projects include, for example, increasingly serious attention to gender relations and meanings and to political economic transformations. Melanesian gender studies direct attention to divergent perspectives and relations within and between communities. They render the male-centered (not to say leader-centered) typification of cultures analytically unusable and big manship a decidedly qualified value (e.g., Lederman 1986, 1990, Godelier and Strathern 1991).

Complementary work seeks insight into the contradictory engagements of men and women, differently positioned in emerging class relations, as Melanesians situate themselves in a roiling global economy (e.g., Gewertz and Errington 1999).

Attention to the adoption of unfamiliar class and national identities has in turn sharpened understanding of the reinvention of culturally familiar relations, values, and meanings. Thus, studies of the articulation of market and gift exchange relations, and their associated political cultures, have clarified their differences even as their mutual entanglements have elaborated over the past generation. For example, one highlands Papua New Guinea people personify the state as a big man to insist on a relationship of equivalence, not hierarchy, between the 'local' and 'national' (Clark 1992). Ethnographic observations like this show what is at stake for Melanesians as the intramale egalitarianism associated with big manship confronts—ambivalently, unevenly, and contingently—structural inequalities associated with state and global involvement, as well as new versions of familiar alternatives and conflicts (notably those between men and women: Sexton 1993).

These studies no longer identify themselves as contributions to the anthropology of the big man or functional/developmental typology building. Instead, they aim to contribute to a more thoroughly historical perspective on the politics of shifting contexts for meaningful action. The rise and ultimate dispersion of big man studies was characteristic of Melanesian anthropology over the past century. A similar interplay of local interpretive ethnography and comparative cultural analysis will continue around political values well into the twenty-first century.

Bilingual Education: International Perspectives

The majority of the world's population speaks more than one language. Given the human cognitive capacity of managing multiple linguistic systems, curricula employing two or more languages of instruction and drawing on the linguistic and cultural resources of bilingual or multilingual individuals should find wide acceptance. In reality, the situation is more complicated. After a definition of bilingual education, an overview of the objectives and major types of programs is offered, and parameters determining success are identified. Throughout, L1 refers to the child's first language(s) and L2 to any languages acquired after age 3 years.

1. *Definition*

For educational programs to qualify as 'bilingual,' two conditions should be met: (a) more than one language serves as medium of instruction and (b) bilingualism and biliteracy are explicit goals. In practice, however, discussions of bilingual education often relax these conditions and include policies considering bilingualism a transitional state.

2. *Settings and Objectives*

Since the 1960s, bilingual curricula have been developed all over the world (see the comprehensive overview in Baker and Jones (1998) and García (1997)). Sometimes, as in Asia and Africa, more than two languages are involved. Besides globalization and the need for intercultural communicative competence, the following factors can be singled out as most conducive to this development: (a) co-existence of two or more official languages, as in Belgium, Canada, Luxembourg, and Switzerland; (b) co-existence of different local languages with a non-indigenous (colonial) language functioning as a neutral official language, such as English in Ghana or French in the Ivory Coast; (c) in-migration and high drop-out rates of minority children; and (d) revival of interest in ethnic cultures and languages.

Against this background, at least three educational objectives can be identified:

(a) assimilation of the child of in-migrant or indigenous minority groups into mainstream society;

(b) maintenance and development of the first language of minority children; and

(c) enrichment and empowerment of minority and majority children.

3. *Types of Bilingual Education*

Baker (1996) (see also Baker and Jones 1998) distinguishes 'strong' and 'weak' educational policies, with only the former satisfying both conditions mentioned in the definition.

3.1 *Strong Forms of Bilingual Education*

An intensively researched program is the *immersion* of groups of majority children in a second language, such as English speakers in French programs in Canada, which may begin in kindergarten or at later grade levels, and be partial in the beginning (with only some subjects taught in L2) or total, with a shift of some contents to L1 in later years.

In *maintenance* or *heritage* programs, minority children are taught in their L1 at least 50 percent of the time. Successful programs have led to the strengthening of Navajo in the USA, of Catalan, Gaelic, Finnish, and Welsh in Europe, of Maori in New Zealand, and of aboriginal languages in Australia.

In *two-way* or *dual-language* programs, which teach through both minority and majority languages (or rely on more than one majority language), balanced numbers of native speakers share a classroom. Languages alternate, either by subject, day, or some other consistent principle.

Second-language medium instruction is also an important feature of *International* and *European schools*, which, like the Swiss 'finishing schools,' are typically attended by children of socioeconomic and intellectual elites.

3.2 *Weak Forms of Bilingual Education*

The 'sink or swim' policy of *submersion* is the most widespread way of dealing with minority children, both in-migrant and indigenous. The child is placed in mainstream classrooms, sometimes assisted by additional instruction in the majority language (in withdrawal or pull-out classes). 'Structured immersion' L2 classes, not to be confused with the immersion program for majority children (e.g., in Canada), contain only minority children. *Transitional* bilingual education starts by teaching in the minority child's L1 and as soon as possible moves over to instruction via L2. It is possible to distinguish 'early exit' (after 2–3 years) and 'late-exit' options.

In many countries, in-migrant children may well experience a mix of different methods. Parental initiatives, religious organizations, and consulates often provide additional L1 classes focusing on language development, ethnic history, and culture.

4. Findings and Problems

Bilingual education programs are subject to many interacting variables. Because of differences in expectations and biases, different evaluations of findings come as no surprise. Indeed, it is difficult to decide which dependent variables (such as degree of competence in various language skills, achievements in other subjects, self-esteem, success in mainstream culture, etc.) are crucial and how they should be measured and compared across studies (compare the recent meta-analysis in Greene (1998)). Nevertheless, a number of conclusions can be drawn (Baker 1996, Baker and Jones 1998, Brisk 1998, Crawford 2001, García 1997, Hakuta 1986).

Prestige of the languages involved and majority/minority status of the child appear to be most significant, as shown in French immersion for English-speaking Canadian children. Positive results can also be achieved where the school locally grants equal status to different languages and where the numbers of majority and minority children are balanced, as in American Spanish–English dual-education programs. In addition to highly qualified and committed bilingual teachers, parental and community support has been vital in all successful cases. Of course, in terms of funding, what matters most is a society's attitude. Xenophobia and concerns about social disintegration often taint discussions and sway political decisions against providing the funds needed for quality curricula.

Scientific studies show that successful *immersion* education of majority children is possible without damage to the child's L1 and without deficits in other academic areas taught in L2. Within the spectrum of immersion options (early vs. late, total vs. partial), best results are achieved in early total immersion. *Maintenance* programs also show promising results. However, while they support in-migrant children's L1 and ethnic identity, they may also segregate these children from their majority peers. An advantage of *two-way/dual-language* schools is that they bring together students from both cultural backgrounds and create a forum for interaction.

Submersion is generally viewed critically (e.g., Baker and Jones 1998, Greene 1998). It leaves the average child with limited L2 proficiency and therefore does not provide the resources needed for coping with other academic subjects. Both *submersion* and early-exit *transition* programs may lead to subtractive effects and eventual loss of L1 without compensatory integration into mainstream society. Moreover, shift to L2 at the expense of L1 may result in alienation from the family.

According to Cummins (1991), for additive rather than subtractive effects to become possible, critical thresholds of L1 proficiency and cognitive development have to be attained; the more advanced children's L1, the better is the basis for positive transfer of skills (including literacy) and concepts acquired through L1.

5. From Paranoia to Empowerment Pedagogy

Bilingual education must be seen against the backdrop of conflicting political ideologies and different attitudes towards bilingualism in general. As pointed out by Brisk (1998, p. 1), 'The paradox of bilingual education is that when it is employed in private schools for the children of elites throughout the world it is accepted as educationally valid […]. However, when public schools implemented education for language minority students over the past 50 years, bilingual education became highly controversial.' Opponents of US bilingual education, in particular, view bilingualism not only as 'a costly and confusing bureaucratic nightmare' (Hayakawa 1992, p. 44) but also as likely to lead to political disloyalty and destabilization.

In his overview of the history of bilingual education in the USA, Baker (1996) distinguishes four overlapping periods characterized by (a) permissiveness, (b) restrictiveness, (c) opportunity, and (d) dismissal (see also Baker and Jones 1998, García 1997, Crawford 2001). Before World War I, *tolerance* of linguistic diversity prevailed. Many ethnic communities taught children in languages other than English. But the Nationality Act of 1906 required immigrants to the USA to learn English in order to become naturalized citizens. World War I and increased numbers of immigrants led to calls for assimilation and Americanization (an attitude strongly reinforced by World War II) and to *restriction* of public-school instruction in languages other than English. This attitude relaxed in the wake of the Civil Rights and Equal Education movements and the growing interest in ethnic values and traditions. In addition, the academic failure of limited English proficient children raised the issue of equal *opportunity* and compensatory measures. Courts mandated bilingual education for minority children; amendments to Education Acts made federal funds available. The *dismissive* period starting in the 1980s took another turn in favor of submersion and transition programs, supported by pressure groups such as US English, English First or English for the Children (see respective websites).

From an international perspective, bilingualism and bilingual education have a more promising future, with countries envisioning themselves as global players aware of their need for interculturally competent mediators. Israel, for example, has moved from submersion to a successful multilingual curriculum. Within the European Community, new employment opportunities have led to an increasing demand for internationally accredited degrees and to recognition of the desirability of L2 skills. More and more parents of majority children are seeking bilingual programs at the nursery and primary school levels. While the current focus is on internationally marketable languages (and the languages of immediate neighbors, as along the border of France and Germany), it is to be expected that this interest will reinforce bilingualism in

general and contribute to the development of effective pedagogical concepts of empowerment for majority and minority children alike.

6. Conclusion

Supporters of bilingual education have to contend not just with those who fear that multilingualism and cultural diversity lead to societal disintegration, but also with those who are concerned about negative consequences for children's cognitive, linguistic, and emotional development. Research has shown that under favorable conditions children can thrive in bilingual programs, at no expense to academic excellence in other domains and without risk for their mother tongue. These results are reinforced by research on bilingualism in general and by the successful simultaneous acquisition of two first languages in early childhood (Grosjean 1982, De Houwer 1996). Where problems arise, they should not be blamed on bilingualism *per se* but rather on the conditions under which it develops.

In the past, schools have often not just served as agents of submersion but prohibited and punished the use of minority languages on their grounds (Grosjean 1982, pp. 27ff). Given our changing world, schools are now called upon to meet the challenge of bilingualism not just as an educational objective but as a school ethic, with highly qualified educators as believable role models. This in turn requires institutions of higher education and their researchers to take more active roles in communicating their findings to practitioners, parents, politicians, and the public.

Bilingualism and Multilingualism

1. Introduction

The topic of competence in more than one language is large and complex and—because it is both an individual and a societal phenomenon—it has an extensive literature within sociolinguistics and the sociology of language. The brief overview provided here can do nothing more than alert the reader to the most relevant strands of the subject. Many important matters—growing up bilingual, informal second-language acquisition, formal second-language learning at school—have to be omitted altogether. Matters of definition, degree and assessment are dealt with first: what is bilingualism and how can its strength be assessed? Second, are there different types of bilingualism—if so, how are the varieties best understood? Third, how are bilingual or multilingual fluencies related to personal characteristics such as age and intelligence? Fourth, how are abilities across languages interrelated? Here, questions of cross-variety borrowing and interference, and 'code-switching'—the use of more than one variety in the same context—are considered. Fifth, there is a brief look at how multiple fluencies arise and are sustained at the social level, and at how these necessitate accommodations—the use of translation, or the emergence of lingua francas, for example.

2. Bilingualism and Multilingualism: Definition, Degree and Assessment

Giuseppe Mezzofanti, chief curator in the Vatican Library in the early nineteenth century, was reportedly fluent in 60 languages, and had some translating ability in about twice that number. Georges Schmidt,

head of the terminology division at the United Nations in the 1960s, knew about 20 languages. The contemporary writer George Steiner claims full and equal competence in English, French, and German. Your cousin in Birmingham can say only *c'est la vie* or *guten tag* or *por favor*. How are these fluencies related? Mezzofanti would seem to be more multilingual than Steiner, for instance—but perhaps the latter has a native-like depth in his three varieties that exceeds Mezzofanti's more superficial, if broader, abilities. Would we then situate Schmidt somewhere between these two and, if so, on what grounds? And what of your Birmingham cousin—does she count as bilingual at all?

In his seminal *Language* (1933), Leonard Bloomfield described bilingualism as the addition of a perfectly learned foreign language to one's maternal and undiminished variety (he did acknowledge that 'perfection' was difficult to assess). Uriel Weinreich, in *Languages in Contact* (1953), noted more simply that bilingualism was the alternate use of two languages. In the same year, Einar Haugen suggested that bilingualism involved the ability to produce complete and meaningful utterances in the second medium. These definitions are representative of a much larger collection, and show that bilingualism has labeled fluencies at the Schmidt or Steiner end of the continuum—but also at the *guten tag* level. In general, earlier definitions tended to restrict bilingualism to equal mastery of two languages (or more, in the multilingual individual), while later ones have allowed for greater variations in competence. Since, however, any relaxation of the concept's status—to cover your Birmingham cousin, for instance—can obviously prove as unsatisfactory a guide to some sort of general definition as earlier arguments from perfection, most contemporary scholars acknowledge that any meaningful discussion can only proceed within specific contexts and for specific purposes.

Further complicating the question of where bilingualism may be said to start is the fact that any definitional lines drawn must cross several specific threads of ability—not just one overall language dimension. Consider, first, that there are four basic language skills: listening, speaking, reading, and writing. Consider further the possible subdivisions: speaking skill, for example, includes what may be quite divergent levels of expression in vocabulary, grammar, and pronunciation. Overall, there are at least 20 linguistic dimensions or features which could or should be assessed when determining bilingual proficiency (Mackey 1962, Weinreich 1953).

We have moved here from definition to assessment—and it follows that, if the former is problematic, the latter becomes difficult. Nonetheless, a number of standard measures of bilingualism have emerged; these include rating scales, and tests of fluency, flexibility, and dominance. In the first category are interviews, language-usage measurements and self-assessment procedures. In some ways, relying upon self-ratings has a lot to recommend it, but the strengths here rest upon the capacity of an individual to be able to self-report accurately, a roughly equivalent sense across respondents of what competence means, and (of course) a willingness to reveal proficiency levels. The possibilities of error here are not entirely absent from apparently more objective tests. One type involves asking people to respond to instructions in more than one language, measuring their response times and, on this basis, attempting to ascertain which variety is dominant. As well, subjects can be presented with picture-naming or word-completion tasks, can be requested to read aloud, or can be asked to pronounce a word common to more than one language (*pipe*, for instance). More straightforward assessments involve measuring the extent of vocabulary, or seeing how many synonyms can be produced, and so on. A great deal of research shows that, although the results of such measurements often intercorrelate, the tests are far from perfect.

3. *Varieties of Bilingualism*

Even if it were possible to accurately measure bilingual and multilingual abilities, labeling problems would remain; after all, it is hardly to be expected that individuals would neatly fall into a small number of categories. To complicate matters further, different writers have used different terms in trying to capture degrees and types of linguistic fluency. For example, balanced bilingual, ambilingual, and equilingual have all been used to designate speakers whose bilingual capacities are great. Baetens Beardsmore (1986) described the ambilingual as one who—in all settings—can function equally well in either variety, and who shows no trace of one language while speaking the other. Since, however, such an individual is rare (if not actually nonexistent), then the balanced or equilingual designations become more likely, insofar as they refer to more roughly equivalent abilities—which need not approach perfection. Of course, most bilingual or multilingual speakers do not even warrant the labels balanced or equilingual—far from it, since most bilingual capacities are quite uneven and usually very susceptible to context and topic.

A useful distinction has been made between receptive (or passive) and productive (or active) bilingual competence. Some can understand a language—spoken or written—without being able to produce it themselves (that is, in anything other than the most halting and rudimentary manner); others can do both. Receptive competence alone has also been referred to as semibilingualism, which does have a certain logic. (Unfortunately, however, the term is sometimes confused with another, semilingualism, which means something else entirely: a lack of fluency in either of two languages. That any speaker of normal intel-

ligence should speak 'no language tolerably'—as Bloomfield (1927) famously observed of an Indian informant—is now widely discredited.)

Another important distinction is that between additive and subtractive bilingualism. In some circumstances, for example, learning a new language represents an expansion of the linguistic repertoire; in others, it may lead to a replacement of the first. At the simplest level, additive bilingualism is the outcome when both languages continue to be useful and valued—consider the bilingualism of academics, of social élites, or aristocracies. Subtractive bilingualism, on the other hand, can be expected in social settings in which one variety is more valuable or dominant than the other. There is little need to maintain two languages indefinitely, if one comes more and more to serve all functions in all domains.

A third dichotomy involves primary and secondary bilingualism. The first reflects the acquisition of a dual competence which has come about naturally—through early learning in the bosom of the family, for example, or because of real and obvious social–contextual demands. The second refers to abilities gained through more self-conscious efforts, notably systematic and formal instruction at school. These are not watertight compartments: one could pick up a good conversational command of a second language at work, say, and then add more formal reading and writing skills through education. This is, incidentally, redolent of the process by which a mother tongue is developed, and it is noteworthy that the more enlightened educational language curricula have tried to capture this in their second-language programs. Nonetheless—and especially at the societal level—there are some obvious differences between primary bilinguals (native speakers of Gaelic in the Scottish highlands and islands, for example) and secondary ones (those who have made a formal commitment to learn Gaelic at school in Glasgow or Edinburgh.

4. *Age and Intelligence*

The expansion of linguistic repertoires—either actual or potential—is often seen to be related to age and intelligence. Smart, young people are popularly considered to possess an advantage here, while older and less gifted individuals find things rather more difficult (There is also the view, particularly prevalent in Anglophone societies, that whole groups can be 'poor at languages,' but this is another matter entirely, albeit an interesting one.) There is some neurological justification for the idea that the young brain is more plastic and flexible than the older one, and hence acquiring another language (or anything else, for that matter) is easier. On the other hand, an overemphasis upon early acquisition and brain malleability—and, more pointed still, the idea of a 'critical period' for languages—can be criticized. Older learners, for example, obviously have a wealth of cognitive experience lacking in younger ones and, provided the motivation is sufficient, often prove to be faster and more fluent learners. If one could combine the maturity and necessity of the older with the imitativeness and spontaneity of the young, one would surely have a recipe for proficient bilingualism.

Many have understood brain capacity to be finite. Two implications follow from this: first, the more capacity you have, the more knowledge (of languages, for example) you can develop; second, there is a danger that taking in something new means losing something already there. At the simplest level, this is reminiscent of the old craniometric axioms that crudely linked brain size to intelligence. At a more subtle level, it is now evident that accepting a finite-container model need have no implications for most people—the brain is large enough to eliminate any worries about exceeding its limits. This is a relatively modern notion, however, and one need not go back very far to find prominent scholars expressing reservations about bilingualism. Firth noted, in 1930, that while bilinguals have two strings to their bow, one is slacker than the other; unilinguals, he felt, had the advantage (see Firth 1970). Jespersen, in his *Language* (1922), observed that bilingualism involved considerable cost—a sort of semilingualism could well result, and a brain overly devoted to languages must necessarily become less available for other tasks.

These opinions were once, as already implied, part of the prevailing intellectual discourse. In general, early studies—particularly those that were part of the American intelligence-testing movement during the great waves of European immigration—tended to associate bilingualism with lowered intelligence. These studies were typically crude and methodologically deficient, and were undertaken at a time when fear and prejudice were rampant. There is space here for only one example; in 1926, Goodenough observed that 'the use of a foreign language in the home is one of the chief factors in producing mental retardation.' It was, of course, just as noticeable in the 1920s as it is today that most people in the world are bilingual or multilingual—not perfectly 'balanced,' perhaps, but not retarded, either.

Later and more careful research tended to show essentially no relationship between intelligence and bilingualism, while investigations beginning in the 1960s demonstrated a positive one. An important study here was that of Peal and Lambert (1962), in which bilingual children outperformed their monolingual counterparts on intelligence tests. The authors concluded that bilingualism was associated with greater mental flexibility and superior conceptual skills. Importantly, though, they acknowledge that their work could not illuminate the causal direction of the apparent bilingualism–intelligence link. As well, cogent criticisms have been made of such studies, on methodological grounds and—more commonly—on

the basis of the nonrepresentativeness of the subjects (usually children, and usually more or less 'balanced' bilinguals). A further problem is that both bilingualism (as already noted) and intelligence are hard to define: consequently, trying to establish links between them is even harder. Strong conclusions about such links are obviously not warranted but it is not unfair to suggest that, if marked cognitive advantages do not flow from bilingualism, at least no cognitive price needs to be paid for it. It cannot be denied, however, that expansion of the language repertoire represents another dimension of individual capacity—at the minimum then, linguistic growth means experiential growth, in the same way that any new intellectual acquisition does.

5. *Borrowing, Interference, and Code-switching*

When a person possesses more than one language, there are obvious possibilities for mixing within a single conversation. The term 'interference' suggests unwelcome or unthinking intrusions from one variety into another. However, while this undoubtedly occurs in the speech of bilinguals, switches often take place for more positive reasons: for emphasis, because the *mot juste* is found in only one of languages, or because of the setting in which conversation occurs (where relevant matters include topic differentiation, variable linguistic competences of interlocutors, desired levels of intimacy or formality, and so on). Some, therefore, have felt that the more neutral 'transference' is an apter term. In any event, code-switching is extremely common and is generally a nonrandom occurrence, triggered by factors which—while not always immediately obvious—usually reveal themselves to careful analysis.

'Sometimes I'll start a sentence in English *y termino en español*' (Poplack 1980) is both an example and the title of an article which attempts to categorize code switches.

The situation of languages in contact often leads to more permanent transferences than those which the previous paragraph has implied. At the lexical level, for instance, one might find a Brussels francophone using the Dutch *vogelpik*, rather than the French *fléchettes* for a game of darts. In this context the Dutch term is a loanword, an item borrowed and used in unchanged form (although, of course, it may be given some elements of a French pronunciation). Another variety of lexical transfer involves loan translation—where the English *skyscraper* becomes *wolkenkrabber*, *wolkenkratzer*, *gratte-ciel* and *rascacielos* (in Dutch, German, French, and Spanish, respectively). Sometimes a word is more fully embraced by another language: in morphological transfer, the Dutch *kluts* ('dollop') and *heilbot* ('halibut') become *une clouche* and *un elbot* in Belgian French. It is also common to find syntactic transfer: for instance, a Dutch speaker might say, in French, '*Tu prends ton plus haut chiffre*'—making his adjectives precede the noun, as they would in Dutch (*Je neemt je hoogste cijfer*), but not as they do in French. Extremely common is phonological transfer—think of fluent adult speakers with 'horrible' accents in their nonmaternal variety.

6. *Multilingualism and its Social Consequences*

Simple observations of the number of languages in the world, and their degree of spread and contact, suggest that bilingual and multilingual competences are commonly required. The forces which give rise to these phenomena are, in general, very easily understood. They include migration, imperialist or colonialist expansion, sociopolitical union among different language groups, the long-term existence of linguistic border regions. In these scenarios, language competences expand (or, occasionally, contract) as a consequence of more basic changes. It is also possible for multiple competences to arise on a more purely voluntary basis—cultural and educational motivations, for example, can expand repertoires, even if they are unaccompanied by either the desire or the possibility to use the new acquisition in ordinary conversational ways.

Multilingualism as a social phenomenon implies both heightened and lessened opportunities for interpersonal exchange. Individuals who know each other's languages can obviously converse, but it is equally clear that a world of many languages is a world in which communicative problems abound. Historically speaking, two major methods of bridging language gaps have exited: translation, and the use of lingua francas. The latter can be conveniently divided into three varieties. First, there are existing languages which have achieved regional (or global) power or status—the so-called 'languages of wider communication.' Greek and Latin were the classical lingua francas—mediums which all educated persons knew (in addition, of course, to their own local speech). Other important lingua francas have included Arabic, Italian, French, and English. Indeed, the status of the last has so far outstripped that of all others that it now poses—in many people's eyes—a distinct threat to many other languages.

Second, limited forms of languages have arisen as lingua francas in settings (trading settlements, for instance) in which ease of acquisition and simple communication are the imperatives. A pidgin variety, for example—often reflecting a mixture of some European colonial language and an indigenous form—is one in which vocabulary and grammar are restricted. Many pidgins have a relatively short life, but some achieve considerable longevity and become expanded and enriched themselves; they have then evolved into creoles. Nobody's mother tongue has become somebody's mother tongue.

Third, the idea of an 'artificial' or 'constructed' language has appealed to many as the ideal lingua franca. Esperanto is the most well-known constructed language but, in fact, hundreds have been developed over the centuries. They are usually quite easy to learn—their vocabularies and grammars are typically free of irregularities—and they have logical appeal as more or less neutral universal mediums. None, however, has managed more than a vestigial existence; apart from certain technical criticisms and some unfortunate associations, it would seem that most people have simply not taken them seriously.

The other great bridge over multilingual chasms is translation and, although much can be said about it, it is only its existence which really needs noting here. Translators and their work are indeed a bridge between linguistic solitudes, but perhaps it is not surprising that their obvious usefulness has sometimes occasioned misgivings. The translator necessarily has a foot in more than one camp and, as Steiner (1992) noted, may take 'hoarded dreams [and] patents of life across the frontier.' The old Italian proverb was blunter: *traduttore*, *traditore*.

Bilingualism: Cognitive Aspects

'Bilingualism' is the regular use of two languages, and bilinguals are those people who use two languages. More specifically, bilingualism refers to the individual competence of comprehension and production of two (natural) languages (language variants like dialects included). Balanced full competence in both languages (balanced bilingualism) is less frequent than dominance of one language (imbalanced bilingualism). Balanced imperfect competence in both languages is labeled semibilingualism. The two languages may be acquired together from infancy on (early bilingualism) or may be learned sequentially (late bilingualism or first language, L1, acquisition and second language, L2, learning). The first language is not always the dominant language when viewed over the life span. The first language of childhood tends to be lost when the child has to emerge into a second language environment without a chance to develop and use its first language further. In general, bilingualism also includes cases with one active and one inactive language. Basic cognitive aspects of bilingualism include (a) issues of neural representations of bilingual language processing, (b) simultaneous or successive learning or acquisition processes of the two languages, (c) representations of linguistic forms and meanings in long-term and working memory, (d) language loss and forgetting, (e) metalinguistic awareness associated with L1 and L2 processing, and (f) code-switching and language mixing.

Two major themes have dominated since the early 1980s in these six aspects: Are a bilingual's language systems separate modules, and if not how much interaction is between them? And in what way are language forms (codes) and their meaning (knowledge structures) represented in the cognitive system? Grosjean (1992) distinguishes two fundamental views on bilingualism: a fractional (monolingual) and a holistic (bilingual) view. According to the fractional view a bilingual should have two separate language

competencies, each single competence similar to that of a corresponding monolingual. The holistic view states that the two language systems of a bilingual are processed in an interdependent way. The blending of the two languages creates a speaker with a specific competence of using the languages together or separately.

1. *Multiple Language Processing and Neurophysiological Evidence of Language Representations*

An individual's obvious capacity to process more than one language without constant interferences requires explanations by mechanisms in the cognitive subsystems responsible for language processing in general and for the separation of the languages during processing, more specifically. These cognitive subsystems have specific neuroanatomical bases. The processing of more than one language on the neurophysiological level seems to be indicated by a greater involvement of the right hemisphere when the weaker language is processed as opposed to the stronger first language (Schönpflug 2001). The involvement of deeper (older) structures of the brain for the first language acquired as opposed to the second language learned later is suggested by Paradis (1994).

Fabbro (1999) discusses differential learning mechanisms involved in the acquisition and learning of L1 and L2. Simultaneous recovery of L1 and L2 after brain injuries are cited as evidence for the involvement of the overlapping structures in the brain processing a bilingual's two languages. Differential recovery of first L1 and then L2 or vice versa are equally frequent, but less frequent than simultaneous recovery. These recovery patterns hint at partially differential organizational structures responsible for a bilingual's language processing in the brain.

2. *Acquisition vs. Learning of L1 and L2*

Learning a language without being explicitly taught is referred to as language acquisition. Language acquisition is a case of implicit learning, that is (a) the acquisition of information is casual, with little direct focalization of attention, nor voluntary concentration; (b) the information is memorized by means of implicit strategies, which do not make it available for conscious introspection; (c) information is automatically used independently of conscious control, letting the subject establish the objectives to be reached, but not consciously carry out the program (execution is automatic)—the subjects' attention can thus be focalized on the result, ignoring the process; (d) this type of learning occurs slowly and improves with practice (for procedural knowledge only). Studies have suggested that in their first year of life children have implicit learning, and in the third year there is still preponderance of implicit over explicit learning.

Several researches report a decline of the ability to learn a L2 up to a native-like performance after the age of eight to 10 (Schönpflug 2001). This suggests a biological critical period that is limited at the beginning or in early puberty. Maturational growth of the structures involved in L2 learning is observed up to puberty, followed by a decline of skills for language learning and great variation in learning effects. These findings leave still open the precise nature of such a critical period. Furthermore, in line with neurophysiological evidence, studies involving phonem discrimination in L2 as compared to L1 support the hypothesis that L1 shapes the perceptual system at early stages of development in such a way that it will determine the perception of nonnative phonemic contrasts, even if there is extensive and early exposure to L2 (e.g., Sebastian-Galles and Soto-Faraco 1999). Cutler et al. (1992) found that adult French monolinguals employ a syllable-based speech segmentation, and monolingual English speakers use a stress-based segmentation procedure. French–English bilinguals with French dominance showed syllable segmentation only with French material, whereas the English-dominant group showed no syllable segmentation in either language. However, the English-dominant group showed stress-based segmentation with English language material, whereas the French-dominant group did not. Thus the two approaches to language segmentation are mutually exclusive, as a consequence of which speech segmentation by bilinguals is, in this respect, functionally monolingual.

The parallel learning of two languages from early childhood on should have effects on the cognitive development of children which should still be noticeable in adulthood. A threshold model of bilingual language acquisition predicts that the acquisition of the two languages has to pass a certain threshold level in order to support cognitive development in other areas (e.g., Cummins 1987). A semilingual language competencies below the threshold for both languages are detrimental for the development of other cognitive domains. However, in a recent well-controlled study no relationship was found between degree of bilingualism and nonverbal intelligence, contrary to the level of bilingualism hypothesis. The results suggest that the effects of bilingualism on cognitive development are not solely dependent on the level of second language proficiency (Jarvis et al. 1995).

3. *Bilingual Language Forgetting and Language Loss*

Memory research has contributed little toward understanding maintenance or loss of complex knowledge systems like the two languages of bilinguals. This is so

because such systems are acquired and maintained over long time periods that cannot be accommodated by traditional research methods. Continued maintenance of knowledge depends on periodic access. Bahrick (1984) tested retention of an L2 learned in school over a 50-year period. The degree of language loss is predictable from the intensity and the success of the original L2 training because there is usually little rehearsal over the life span. In the first three to six years retention exponentially declines; after that there is little loss up to a period of 30 years. But maintenance of retention cannot only be reappearance of the same material but should also be seen as a (re)constructive process. This interpretation implies that metaknowledge of L2 in form of a language schema would provide the frame for reconstruction.

Clinical case studies (e.g., Fabbro 1999, Chap. 26) show that when necessary structures of the brain are still intact and language loss is observed, hypnotic treatment may disinhibit activation processes to understand and produce either a lost L1 or L2. Thus, 'lost' language systems seem to be covered or inhibited but not totally erased. Eliciting factors were familiarity, language of the environment, and affective conditions.

4. *Cognitive Processing of L1 and L2*

A central question in theories of cognitive aspects of bilingualism concerns how a bilingual's two languages are stored in long-term memory. Does each language possess its own memory store or do languages share a single representational system? At the lexical level, words in each language appear to be stored independently, but at the conceptual level, words in each language appear to access a common semantic representation. Dufour and Kroll's (1995) hierarchical model of bilingual representation in memory adds a learning component to the single conceptual store: In adults, early stages in the acquisition of second language vocabulary appear to be characterized by reliance on L1. That is, during the initial phase of L2 learning, individuals seem to rely on associations between words in their two languages in order to get access to the meaning. With greater proficiency in the second language, they become able to access concepts directly without L1 involvement. L1 and L2 connections are asymmetrical.

Additional evidence has come from cross-language conditions; they probably promote the activation of both lexical stores, and less fluent bilinguals may not be able to properly inhibit the influence of the dominant language (see also Schönpflug 2000) .

Paivio (1986) forwarded the most elaborate published model of bilingual memory functioning. Paivio's bilingual dual coding model is in one sense a specific version of the independence approach to bilingual cognition, but it also includes a common representational system that provides a basis for interpreting some findings that appear to support the dependence hypothesis. His basic bilingual memory model claims that in long-term memory representations are coded verbally and nonverbally associated with imagery. The representations associated with the two language codes are conceived to be independent on the verbal coding level. The nonverbal representations or images are shared, however. Abstract representations are predominantly verbally coded whereas concrete representations are coded verbally and in an imagery code. The two verbal systems are functionally independent of the imagery system. The assumptions imply that bilinguals can perceive, remember, and think about nonverbal objects and events without the intervention of either verbal system, and conversely, that they can behave or think verbally without constant input from the nonverbal system. Translation equivalents do not necessarily have identical referential or imaginal meanings.

Anderson (1978) has convincingly argued that the issue of representational format cannot be answered independently of the processes used in accessing those representations. Depending on the particular assumptions chosen by a theorist for accessing memory, results often taken to support imaginal coding might equally well be interpreted within a propositional theory, and vice versa. But no need exists to limit coding dimensions to one or two forms.

The notion is akin to that of the transfer-appropriate processing approach in that performance on some test will benefit to the extent that procedures required during the test recapitulate those employed during encoding. Free recall experiments usually show evidence for a single store view of bilingual language representations. It is a 'conceptually driven' retrieval task. In free recall, individuals are presented no overt cues or hints to guide performance and thus must rely on stored concepts to facilitate remembering. On the other hand, the word fragment completion test, priming in perceptual identification, and lexical decision can be considered as tapping data-driven processing. Finding both language-independent and language-dependent patterns in an experiment under identical study conditions, but with different memory tasks, implies that the question of bilingual representation cannot be answered without a model of both storage and retrieval processes (Anderson 1978). Thus the issue of language dependent or independent representations is indeterminate until the tasks are specified for bilinguals' functioning.

An interesting suggestion was made by French and Ohnesorge (1995). In their model, each group of activated language units of either L1 or L2 will be differentially activated according to the amount of activation coming from the languages with which they are associated. If the L1 context is fully active and the L2 context is only weakly active then the L1 units will have higher overall activation than the weaker units of L2. The former will win the competition and determine

the activation of the entire representation. The advantage of this activation-based network model of bilingual memory is that it fits into an established framework of automatic spreading activation between verbal units, in which interlanguage lexical priming could be more easily explained. Just as activation in a monolingual L1 lexicon initially spreads automatically from a word to all of its related items in a context-independent manner, the activation-based description of bilingual lexical access could be used to explain the type of cross-lingual priming reported by some authors (see also de Groot and Comijs 1995).

Working memory (short-term memory) studies involving bilinguals are quite rare. There is, however, evidence that the phonological component of working memory, the phonological loop, plays a crucial role in supporting the long-term learning of the sound patterns of new words of both native and foreign languages (Baddeley et al. 1998). There is also evidence of strong lexical influence on working memory processing of new phonological structures via the phonological loop. Familiarity with L1 appears to have beneficial consequences for short-term storage of material conforming to the phonotactic and lexical properties of that language. The impact observed is on a lexical and a sublexical level (e.g., digit span). These effects are not found when L2 working memory processing was tested. Thus, the phonological loop is more effective in maintaining representations of words and nonwords from highly familiar languages than from languages that are less well known (e.g., Thorn and Gathercole 1999). In addition, Cheung et al. (2000) report support for Baddeley's model of working memory which specifies a phonological loop including an articulatory (rehearsal) control process and a nonarticulatory phonological store for acoustic memory traces left by verbal input. Differential effects of L1 and L2 on recall of pseudowords from L1 and L2 reveal that the language effect is phonological in nature, rather than having to do with the bilinguals' imbalanced proficiencies in the respective languages.

5. *Metacognition and Bilingualism*

Metalinguistic awareness, one type of metacognition, may be defined as an individual's ability to focus attention on language as an object in and of itself, to reflect upon language, and to evaluate it. Types of metalinguistic abilities are: phonological awareness, word awareness, syntactic awarenesss, and pragmatic awareness, or in other words analyses of knowledge and the control of cognitive operations involving language processing (Bialystock 1988). As language develops, the child structures and organizes an implicit body of language and gradually moves toward representations of knowledge that include explicit features for the structure of that knowledge. Bilingual children show accelerated metalinguistic (phonological) awareness in the preschool years when compared to monolingual children.

The development of linguistic awareness may help with learning a second language. As Thomas (1992) demonstrated, the formal training of a second language has a positive impact on the learning of a third language. This might be due to the fact that metalinguistic awareness determines the use of effective language learning strategies, such as relying on 'natural' informal situations for second language acquisition as opposed to formal instructions.

6. *Code-switching and Language Mixing*

It is critical to know in which speech mode a bilingual is in before making any claims about the individual's language processing or language competence. Interferences between languages during speech production may be a perfectly conscious borrowing or code switching in the bilingual speech mode. Rare are the bilingual corpora that clearly indicate the speech mode. In the monolingual speech mode, bilinguals adopt the language of the monolingual interlocutor. They deactivate more or less successfully the other language.

In the bilingual speech mode, both languages are activated. Bilinguals usually choose a base language to use with other bilingual interlocutors, but can within the same conversation switch to the other language. The switches take place at particular locations like at morpheme, word, phrase, or sentence(s) boundaries. Code-switching is an intentional process whereas language-mixing is the consequence of indiscriminative learning and the bilingual's lack of intra-language associations in one or both languages.

This survey of basic issues in bilingualism research reveals that bilingualism is an important competence in times of globalization and as such is worth being carefully analysed, but apart from this applied aspect it holds promises for the advancement of research and theorizing in some areas of cognitive science.

Bill of Rights

1. *Overview*

Bills of rights in the sense of a listing of popular claims and admonitions to rulers and legislators are largely the legacy of late medieval and early modern English constitutional history. Their elevation into robust, court-enforced restrictions often trumping powers clearly assigned to political players is largely the product of twentieth-century America. Many subterranean steps both in the USA and abroad preceded its full-blown emergence in the 1930s. Current worldwide attraction to the new tradition of judicially supervised rights is a product of experience as to their universal appeal, their value in nation building and civic culture, and their efficient underwriting of a participatory political system. Still in contestation is the relationship of the older rights of political expression and protected procedure, and the claims of twentieth century ideologies of rights to economic achievement and/or economic equality.

2. *The English Antecedents*

Although largely a list of maddeningly narrow perquisites, circumscribed in time, space, and, social class, some of the provisions of Magna Carta have a universalistic King James Bible ring to them. Magna Carta has unmistakably been the great precursor of bills of rights both in popular image and legal reality. The other great English instruments—the Petition of Right (1628) and the document that came to be known as the Bill of Rights (1689)—are mainly allegations of kingly violations of Magna Carta, although they add some new claims as well. Besides being political rallying points these documents gave judges leverage in creatively interpreting and limiting statutes and royal actions.

Even before the conflicts that preceded the revolution American colonists were proud and jealous of their rights as Englishmen, as spelled out in the first

charter of Virginia (1609) and claimed in Maryland's Act for the Liberty of the People (1639). The prototype of American claims, however, was the Massachusetts Body of Liberties (1641), with a listing of specific rights culled from English documents and colonial experience. It contains a guarantee of free speech at town meetings and freedom of women from chastisement by husbands among its innovations. Other colonies enacted similar but varied listings. The colonists also effectively used such justifications as cause for dissatisfactions beginning with the Declaration of Rights and Grievances (1765) and culminating in the Declaration of Independence (1776). Among these was the Address to the Inhabitants of Quebec (1774), which vainly sought Canadian support by listing established freedoms in the colonies threatened by English authorities.

3. *The Road to the Bill of Rights*

In the postrevolutionary era, fully nine of the 13 states had bills of rights, usually in constitutional preambles. The others had some major liberties listed as did the Northwest Ordinance (1787). Only the Articles of Confederation avoided such enumerations.

The Philadelphia Convention's rejection of a Bill of Rights was therefore somewhat out of step with prevailing practice. The chief pro-Federalist defenses—that a Bill of Rights was unnecessary in a government of limited powers, and that enumeration of some rights might be seen as derogation of others—seemed lame since the proposed Constitution already included many traditional liberties, some even limiting state power.

As it became clear that the Constitution would be ratified, the anti-Federalists, prodded by Jefferson from his ambassador's post in Paris, accepted ratification in states conventions, but concentrated on proposed amendments. For their part the Federalists in the late-ratifying states worked mainly to limit amendments in the form of nonbinding recommendations to Congress. Six conventions called for amendments (seven if Rhode Island's belated ratification is counted) and in Pennsylvania a minority report did the same (Rutland 1991, Schwartz 1971).

The Bill of Rights has been aptly characterized as the last great compromise of the constitution, and it has served as the legacy of the states-rights anti-Federalists completing the constitutional structure designed by the nationalizing Federalists. The job of drafting fell largely to Madison, uniquely fit for the task. Then the unofficial floor leader of the Federalists, confidante of Jefferson and later an anti-Federalist president, major author of *The Federalist*, and key player at Philadelphia, he presented a set of proposals which deftly combined ratifying convention resolution, states' bills of rights, and creativity of his own. The House made major changes, deciding to affix the amendments as an appendix to the Constitution rather than intersperse them as in Madison's proposals. It also pruned and reworded them judiciously, adding some proposals generally rejected by the Senate. That later body reduced 17 proposals to 12, fusing some and rejecting others. It dropped Madison's pet proposal, which would have prohibited states as well as nation from infringing on rights of conscience and expression.

Ratification was swift but the first two proposed amendments were rejected. (In one of history's oddities the second was confirmed two hundred years later and is now the Twenty-second Amendment.) Despite much blather about the 'firstness of the First Amendment' it was as sent to the states as the third. Essentially Madison succeeded in satisfying most of the anti-Federalists, while only 'true-blue' Federalists dared sneer at the Bill of Rights, mainly in their private journals or correspondence.

4. *The American Application*

Although a showpiece in early US adulation of 'liberty', the Bill of Rights was barely evident as a legal barrier prior to the Civil War. The Marshall Court decisively slammed the door shut on any effort to use the amendments as checks on state government in Barron vs. Baltimore (1833). At the federal level it was congressional not judicial decision making that 'first crystalized the meaning of the rights of free speech and press' by returning fines, assessed under the Alien and Sedition laws. The due process clause of the Fifth Amendment is mentioned in cloudy passage in the Dred Scott case (1857), but it hinges on issues of citizenship and legal standing rather than liberty.

Not until the twentieth century era, in which the Supreme Court began to apply national standards to state regulation of such matters, criminal law, and the rights of freedom of expression, did the Supreme Court seriously implement the Bill of Rights against the national government. This was partly a product of the relatively limited reach of the national government during the nineteenth century, but it also reflected a shift in judicial sensibility in the twentieth. Nineteenth-century adjudication centered its allocation of power between nation and state. The concern for liberty dealt primarily with property and limits on regulation. The twentieth century has witnessed a constitutional sea change with the Bill of Rights providing the impetus. This has been a two-tier development. Under the rubric of 'liberty,' which states under the Fourteenth Amendment must provide, the Supreme Court had required states to meet the standards of most of the Bill of Rights (on some procedural matters, e.g., size of juries, the standard is less rigorous than that applied to the federal government). At the same time, the federal government has also been held to more rigorous

supervision under a concept (best expressed in footnote 5 of *The Carolene Products* decision of 1937) that courts have a special duty to protect those groups and individuals who are disadvantaged politically, especially where the Constitution confers specific rights.

5. *Experience Abroad*

Some liberal theorists have suggested that development from declaratory to enforceable rights has an imperative that unfolds under modern conditions of growing governmental ubiquity and the need to accommodate cultural diversity. So far only Canada has traversed the full path. Partly to placate growing French-Canadian demands for cultural recognition, Canada first promulgated a set of declaratory rights (1960) and later an explicitly justiciable Charter of Rights in its 'expatriated' constitution of 1992.

European developments also paralleled this but, as with much European Community law, the protection of rights is in fact more problematic and complex than it appears. Continental civil law countries in the nineteenth century generally followed the prototype of the French Declaration of Human Rights in their respective constitutions, but also followed the French in treating these rights as exhortatory rather than enforceable. Like the British, the continent rejected 'government by the judiciary.' True democratic rights were best protected—and least endangered—by popular sovereignty and the people's agent, the legislature.

The easy victory of Nazism and fascism in overnight subversion of rights alarmed and puzzled constitution makers after World War II. Several European countries installed constitutional courts—essentially halfway houses having special responsibility to maintain governmental boundaries. But in many instances only governmental agencies could bring cases. This and other restrictions have kept such courts significant but not encroaching on legislative power in important ways.

Another by-product of post-Hitlerian concerns was the promulgation of the European Convention on Human Rights in 1950 and later the European Court of Human Rights to enforce its provisions. The European Court of Justice, noting that all members of the community were signatories of the European Convention, assimilated it and its jurisprudence into European law. The action was presumably part of the court's conscious attempt at community building (giving individuals as well as businesses a stake in the system). But it also thereby undercut the German courts' resistance to the supremacy of European Community law on the asserted grounds that Germany had stronger protection of rights.

In effect the European Community has a Bill of Rights subscribed to by its members and defined mainly by a separate non-Community entity. In Great Britain, Parliament has already incorporated such rights into English law as of October 2000. This simplifies the task of the English judge, but also raises paradoxes that will be resolved only by future litigation or legislation.

While judicial protection would seem to armor-plate rights, libertarians even in the USA have suggested popular support for liberty may be diminished by reliance on judicial enforcement. Critics of the USA are as impressed with failures at crucial points over two centuries—Dred Scott, Red Scares—as by positive achievements such as desegregation. And certainly normative lists of rights have had great impact in Britain, France, and other European countries.

6. *What do Bills of Rights Protect?*

Many bills of rights are cynically promulgated or fall into obsolescence, often in countries where military juntas take over. The most cynical of all were probably the Soviet and other East European efforts, which were often painstakingly crafted by experts, incorporating the most forward-looking thinking, without any intent of implementation, but to stake a claim of progressive leadership to impress external adherents. Even within the Eastern bloc, however, dissidents carefully memorized provisions, acting as if they expected their rights to be respected.

The contents of bills of rights vary, but they generally accentuate rights of expression (including religion) and procedural protection as to criminal proceedings or governmental taking of property. Equal treatment under the law and gender equality are also usual, as are guarantees of rights to participate politically. Some bills of rights guarantee cultural autonomy or preservation of families (Duchacek 1973).

These so-called 'negative freedoms' have for over a century been seen as inadequate by liberal intellectuals and parties who call for guaranteed 'positive' freedoms—economic opportunity, access to medical services, and employment. A right to universal free education is perhaps the least controversial. Not found in the US Constitution, it is standard in most countries and many American state Constitutions. More controversial are such 'rights' as full employment or guaranteed family income. Communist and Socialist societies have contended economic rights are precursors and prerequisites of procedural and participatory rights, which are in a sense luxuries resulting from economic satisfaction (MacPherson 1966). Liberal theorists argue that history has it right: participatory rights and restraints on governmental naked power unleash marked creativity which permits extension of economic rights.

The fall of 'the evil empire' in Eastern Europe, paralleled by governmental deficits in welfare states in

the West has kept those stressing economic equality rights on the defensive. Even communist China has announced that 'iron rice bowl' guarantees are gone and workers must not only work but scurry to gain employment. At the same time protection against arbitrary confinement and rights of expression has been demonstrated to have wider appeal than some have thought, although perhaps still valued most by the middle classes.

Binding Problem, Neural Basis of

For a large part of the twentieth century, the issue of how physical brain states represent mental objects was dominated by one idea, that of single units as elementary symbols of our mind. According to this idea, an individual's mental state is fully described by the ensemble of single units active in a given moment. This symbol system would be most peculiar in having only one composition rule, that of simultaneous activity, whereas all other known symbol systems have flexible means of building hierarchical structures. The mind, meeting place and source of all other symbol systems, surely must possess a mechanism for combining its semantic atoms into molecules and aggregates in a way richer than anything yet contrived on paper or in electronics. Identifying this mechanism is the binding problem.

1. The Binding Problem

One of the solid results of research on brain function is the localization of mental themes in the brain in a hierarchical manner down to the assignment of definite semantic meaning to individual neurons. It is, therefore, a broadly accepted view that neurons can be treated as elementary symbols with fairly fixed meaning. The assignment of meaning to neurons has been a very successful enterprise for decades, and it is probably a permissible extrapolation to apply this picture to every neuron in our cerebrum, if not in our whole nervous system. It has, furthermore, long been an uncontested view that the state of a neuron can be characterized by an activity variable, which in a not very precisely definable way corresponds to its current rate of firing (one speaks of 'rate coding') . Semantic meaning is routinely assigned to neurons by temporally associating their rate of firing with sensory stimuli or motor responses.

A neuron is thus taken as an elementary symbol that is either active or dormant in a given mental state. It is elementary in the sense of having no internal structure in terms of subsymbols (although a neuron's semantic referent invariably is a composite entity). As a rule there seem to be groups of equisemantic neurons. To allow for this possibility, the term 'single unit' will be used instead of 'single neuron.' In spite of all the internal anatomical and physiological structure of single units, the mental symbols associated with them are taken to be elementary, i.e., as having no internal degrees of freedom.

At issue here are the laws by which higher symbols are composed from single units. With rate coding there is only one composition rule: mere additive, unstructured combination of the active units' elementary meanings into one amorphous lump. This is a very poor composition rule, and a somewhat inadequate basis for cognitive and mental operations. A few examples may illustrate this inadequacy. Assume a first mental object (e.g., an imagined hand) to be represented by the set A of single units, and a second mental object (e.g., an apple) by set B (for simplicity let A and B have no units in common). Now assume there is reason to hold both mental objects simultaneously (as, for instance, when the hand is grasping the apple). The above composition rule states that the superset $C = A \cup B$ will be active. This, however, creates a problem in that C doesn't contain any information as to grouping of its elements in terms of its constituents A and B, and there now may be several ways to decompose C into part symbols. This ambiguity has

been termed the 'superposition catastrophe.' In a more concrete example, let a person perceive a blue letter A and a yellow letter B on a sheet of paper, and assume there are units to represent 'A,' 'B,' 'blue' and 'yellow' in the person's brain. The simultaneous activity of all four units represents the situation incompletely, as a yellow A and a blue B would evoke the same situation. This type of 'conjunction errors' are actually committed by human subjects when not given enough time to inspect a situation (for review see Wolfe and Cave 1999). The experimental examples show that the binding of elements into groups can be a real problem for our brain if it is not given sufficient time.

If single units are the mind's 'bricks,' what is the 'mortar' to erect its cognitive edifices—to group features into objects (such as in figure–ground separation), to attach attributes to referents (such as grammatical roles to the words of a sentence), to represent temporal or spatial arrangements of elements such as in a spoken sentence or in a visual scene, or to point out correspondences between structures found to be analogous to each other?

2. *Binding by More Single Units*

Single units can code for (fixed) combinations of other units, and in fact this is true for almost all units. In the above example, the colored letter ambiguity would be dispelled immediately if there were single units encoding blue As and yellow Bs. So why shouldn't the cognitive architecture of the whole brain be based just on combination-coding units? A correct short answer to this question probably is that indeed it is to a very large degree, but that for the purposes of a small but vital subset of operations it cannot. The reason is that whatever a brain's complement of combination-coding units, it is bound to run continuously into situations which call for new combinations and which would only be represented with dangerous ambiguities. Each individual ambiguity could be stopped by more combination-coding units, but those units happen not to be present (yet). Thus, vital flexibility in handling new situations will need a binding mechanism that transcends a code based entirely on single units.

Several serious obstacles stand in the way of achieving anything like completeness in terms of single-unit coding. The number of composite symbols that are required over a lifetime is too large to be covered ahead of time in any combinatorially complete way. To take just one example, there are an infinite variety of feature combinations through which physical objects can manifest themselves in our visual system, and which must be handled as composite mental entities. It is impossible to represent them one by one in terms of single units. Each one of them is new and unforeseeable, and a single unit to represent it would have to be manufactured on the spot. All that can be hoped for is that certain subpatterns are common to many situations, get represented in single units, and collectively reduce by large factors the combinatorial ambiguity the brain has to cope with, by representing a given mental object in terms of relatively few units.

Representing composite entities (like 'my grandmother') by single units is problematic in itself. It is as if a mathematician wanted to replace all composite expressions by single-letter symbols. We can operate with composite objects (especially when they appear for the first time) only with reference to their parts (and their relations) with which we have had previous experience. Consequently, those parts (and relations) have to be explicitly represented themselves! If, for instance, all colored letters were, for the sake of avoiding ambiguity, represented by colored-letter coding cells (blue-A etc.), anything that I have learned in the past about green As would not be available for blue As and I would have to learn it anew. If, on the other hand, all part-representing units were visible along with the units representing the whole (blue, yellow, A, B along with blue-A and yellow-B), the potential confusion would be even bigger than without the combination-coding units. Each client (that is, group of units) would have to learn to pay exclusive attention to the appropriate symbol level, by disconnecting from units on all levels that would cause confusion. For this and other reasons, installing a new unit is a complicated business that is warranted only for representing frequently recurring symbols. Finally, a brain based entirely on single units could not represent explicitly the hierarchical structure of complex symbols and would consequently not be able to discover structural relations between mental entities.

In summary, a nervous system based entirely on a flat symbol system composed of single units would be totally inflexible and uncreative and would not be able to deal with novel situations.

3. *Temporal Binding*

According to this idea sets of units express mutual binding by synchronizing their signals. In the above example, the units 'blue' and 'A' would express their binding by firing in synchrony, or the two sets of units *A* and *B* would avoid the superposition catastrophe by firing with strong positive signal correlations within each set and zero or negative correlation between them. This idea as such does not go beyond the generally accepted fundamental principle, stated above, that the composition rule for unit symbols is simultaneous activity; it extends it, however, down to the millisecond time scale, and it requires the processing of whole signal sequences if complex binding structures are to be expressed. Temporal signal structure is induced by the presence and structure of connections between units, with strong excitatory links generating positive correlations. Temporal signal

structure is interpreted by structured circuits in that the correlation structure of a set of signals may or may not fit the internal connectivity of a circuit upon which it impinges (two units with mutual excitation are easily excited by correlated signals, for instance, but would respond less readily if they inhibited each other).

Random connectivity structures would neither produce clear-cut signal structures nor could they selectively respond to structured signals. Appropriate connectivity patterns can be formed by network self-organization on the basis of (possibly rapid and reversible) synaptic plasticity: an initially random circuit would create correlation patterns, which would act back on the circuit by strengthening or weakening connections in a feed-forward fashion (strong correlations leading to strong connections, for instance), rapidly converging to an attractor state in which signal correlation and circuit structure are optimally reinforcing each other.

The binding problem and its solution by signal synchrony was first discussed as a fundamental issue of brain function by Von der Malsburg (1981) (although the idea of synchrony coding has been briefly mentioned in several earlier references), and the same reference has proposed network self-organization as its basis. Temporal binding has been applied successfully to a range of problems of brain function, as reviewed in Von der Malsburg 1999. Among these are logical reasoning, figure–ground segregation in the visual, auditory and olfactory modalities, and invariant object recognition. Experimental evidence for temporal signal structure relevant for binding and its occurrence under appropriate circumstances is reviewed in Gray 1999 and in Singer 1999. Main objections to the temporal binding hypothesis, reviewed in Shadlen and Movshon 1999, concern still insufficient experimental evidence and doubts about the ability of cortical tissue to process temporal signal structure on an interestingly fast timescale.

A strong limitation on temporal binding is the low bandwidth of neural signals. According to optimistic estimates, the temporal resolution with which correlations are evaluated in the cerebral cortex is one millisecond. This leaves little space for many time slices to be kept separate in typical processing times of 100 milliseconds. Are there other, more efficient means of binding? One possibility that will have to be explored in the future is based on multicellular units: the neurons in a unit may all code for the same elementary symbol but they may differ in their connectivity to other units. By proper control of a unit's internal activity distribution it may be made to dynamically change its connection pattern and thus express selective binding to other units. This will require highly specific connectivity patterns. Before these are installed, temporal binding and rapid reversible synaptic plasticity will have to act as the 'fire brigade' suppressing binding ambiguities as they emerge.

Once the neural community will start to build up momentum and methodology to fully utilize the strengths of a neural-based symbol system with full binding capability, the remaining deep riddles of our cognitive apparatus may be ready for assault.

Binet, Alfred (1857–1911)

1. A Brief Biography

Alfred Binet was born in the French town of Nice on July 11, 1857. According to his daughter Madeleine (Avanzini 1974), Alfred was a bright child who succeeded so well in school that his mother decided to send him away to the capital when he was barely twelve years old, in order that he might study at one of the best schools in France. Upon graduation from high school, he completed a law degree in 1877, but then decided to pursue studies in medicine and biology. Under the supervision of Balbiani, who was later to become his father-in-law, he started writing a dissertation on 'The sub-intestinal nervous system of insects.' At the same time he wrote plays for the theater. He finally managed to combine his different areas of interest in one discipline, psychology. To simplify, one can distinguish three phases in his career as a psychologist, although his publications prove that the stages were overlapping rather than strictly separate (Delay 1958): psychopathology, experimental psychology, and child psychology.

French psychology in the second half of the nineteenth century was focused mainly on psychopath-

ology, and Binet's early interests were no exception. During this first stage of his career, the main influences on Binet were Théodule-Armand Ribot and Jean-Martin Charcot, and Binet's first major writings explored the domains of sensations, hysteria, hypnotism, and personality disorders. Binet worked closely with Ribot between 1880 and 1907, and published over 40 articles in Ribots's *Revue Philosophique*. During this period, he also began to study hypnosis under the famous neurologist Charcot at the Salpetrière hospital in Paris.

In 1891 Binet received tenure at the Physiological Psychology Laboratory at the Sorbonne University in Paris, where his research focus switched from clinical to experimental psychology. The main contemporary influences in psychophysiology and experimental psychology were German, namely Wilhelm Wundt, whose laboratory in Leipzig served as a model for the one Binet created in Paris. Binet completed his thesis in biology in 1895, the same year in which he became the head of the Physiological Psychology Laboratory and published an *Introduction to Experimental Psychology*. It is also the year in which he founded a journal that is still published today, *L'Année Psychologique*. In 1899 Binet met Théodore Simon, who was to become his closest and most constant collaborator, and that same year he joined the *Free Society for Psychological Child Studies*, of which he became the President in 1902. Like many researchers of his time, Binet decided to follow in the footsteps of neurologist Paul Broca. Binet explored intelligence through phrenology, believing that there is a direct relation between the size of the cranium and a person's level of intelligence. Binet's empirical investigations measured the crania of school children considered by their teachers to be bright and compared these measures with the measures obtained from low-achieving children. In 1901 Binet conceded that 'the idea of measuring intelligence by measuring the head … seemed ridiculous' (Binet 1901, p. 403), but he then discovered that there were noticeable differences in the cranial size and shape of children from the contrasted groups. Very bright students had larger skulls than very low-achieving students. Binet himself, in the same 1901 volume, reached the conclusion that the initial measures showing a cranium size difference between low- and high-achieving students were probably due in part to his own suggestibility. With a rare sense of honesty, he admitted that, having looked for differences, he found them where he expected them. His faith in phrenology shaken, he abandoned it. He also discarded hypnosis, and moved to explore the human psyche through new tests and puzzles that he initially developed for, and then tested on, his two daughters (Binet 1890). As was the case with Piaget several years later, most of his ideas on cognitive development sprang from the observation of his own children.

After a first period devoted to psychopathology, and a second centered on experimental psychology, one can distinguish a third period in Binet's life, dedicated primarily to child psychology. The start of this period can be dated to 1905, the year in which Binet and Simon published several articles on the diagnosis of abnormality (Binet and Simon 1905a, 1905b, 1905c) and the year in which Binet opened a laboratory of experimental pedagogy. In this laboratory, Binet worked closely with teachers. It was during this period that Binet made his major contributions to the study of academic underachievement, but also to psychometrics, a term coined by Sir Francis Galton in 1879. Another major contribution of Binet to child psychology was the view that children are not, as generally thought previously, miniature adults, but obey different rules of cognitive functioning (Zazzo 1958). The rest of this essay will focus on Alfred Binet's contributions to the understanding of abnormal children and the development of the cognitive-assessment tools to which this interest led. This historical account will end with a brief discussion of the current state of the field.

On October 28, 1911, Alfred Binet passed away unexpectedly, at the age of 54, and was laid to rest in the Montparnasse cemetery in Paris.

2. *The Study of Abnormal Children*

Starting with the beginning of the nineteenth century, Binet showed great interest in the study of 'abnormal children' (Binet and Simon 1907). His *Free Society for the Psychological Study of Children* pushed the Government to start evaluating children, with the aim of early identification of abnormal children and the provision to them of special education. In 1904, Binet was officially appointed by the French Minister of Public Education to devise a means of identifying retarded school children. It was based on this interest in abnormal children that the Metric Intelligence Scale was developed in 1905 (Avanzini 1974), with the help of Binet's doctoral student Théodore Simon. Through the use of this scale, children with learning impairments, who were nevertheless thought to be able to profit from education, were selected and put into special-education classes. The first 'perfectioning class' was opened in 1907, and two more such classes followed that year. Although Binet himself was fully convinced that abnormality could to some extent be overcome, Binet always stressed the importance of empirically assessing the correctness of his ideas. And although Binet worked primarily on applied problems, he never forgot the importance of strict experimental methodology. He thus clearly stated the need experimentally to assess the usefulness of the special-education classes before any legislative measures for their institutionalization would be taken.

Before further describing the Metric Intelligence Scale and its most widespread adaptation, known as the Stanford–Binet Scale of Intelligence, let us first go

back to Binet's theory of abnormal children and the special-education classes that led Binet to believe in the need for psychometric assessment.

In their 1907 publication *Abnormal Children*, Binet and Simon proposed a new view of mental retardation. The abnormal child is not a normal child that has either stopped or slowed down in development, but rather, a child with a different developmental pattern. This pattern is unbalanced, with some aspects identical to those of normal children, and others, different. It is this lack of balance between the different developmental aspects that constitute the abnormality (Binet and Simon 1907, 1922). Although there might be an important delay in the acquisition of certain aptitudes, the development of other aspects (cognitive and somatic) might be normal.

Binet and Simon argued that the implications and impact of an acquisition are linked to the age at which it is acquired. For example, learning to read at six does not have the same implications as learning to read at twelve. The abnormal child who learns to read at twelve has a wider vocabulary and more extra-scholastic interests than does the normal six-year-old child. Intellectual impairment can be characterized by three major components: a global developmental delay, the imbalance of this delay depending on the aspects measured, and the resulting lack of co-ordination in the functioning of the mind. Because abnormality is a distinctive developmental pattern, not a mere retardation, special education is possible and needed.

3. *The Metric Intelligence Scale*

The Intelligence Scale devised by Binet and Simon was published in 1905. It contained 30 tests, some of which were expressly created for the scale, and some of which were adaptations of already existing cognitive tests, namely, those developed by the French physicists Blin and Damaye. All tests had been piloted on samples of 'normal' and 'retarded' samples of children of ages two through twelve. The different tests measured everything from such basic skills as co-ordination of movement and imitation to such complex processes as comprehension, judgment, and abstract reasoning. The tests were presented in order of increasing difficulty.

The easiest tests distinguished severely and profoundly mentally retarded children (then labeled as 'idiots') from the rest; tests of intermediate difficulty distinguished between the severely retarded and moderately retarded (then labeled as 'imbeciles'); and higher-level tests between mildly retarded (then labeled as 'morons') and normal children of the same age. The tests also distinguished, of course, between younger and older children. As a member of the ministerial committee on education, Binet's main purpose was to identify the mildly retarded children in order to provide them with the special education, which was thought to increase their cognitive functioning.

In the first publication of the Assessment Scale, the authors emphasized that the Scale should be used only as an indication of the child's cognitive level at the time of administration, and that this performance level is subject to change through an appropriate education. A revised version of the Scale was published in 1908, offering the possibility of establishing a child's *mental age*, a notion first introduced by Chaillé in 1887. If 65–75 percent of the children from a given age group succeeded on a test, the test was classified as being appropriate for and measuring mental performance at that age level. A given child can thus succeed on tests that are at a mental age level that is lower, equal to, or higher than that targeted at her or his biological age. Note that the mental age simply corresponds to the performance norm of a given age group. It does not, as was thought by the American adapters of the Scale, provide an indication of the stage in developmental progression reached by the child. Having a given mental age does not imply functioning as a child of that age. It implies only that an individual's performance on a given test corresponds to what the majority of children at a given age will achieve.

Binet explicitly warned against the use of performance on an IQ test as a fixed measure of intelligence. Indeed, by the nature of the test construction, 25–35 percent of children of a given age will not succeed on a test intended for their age (Lippman 1922).

Binet made it clear that the scale was just one assessment tool, and that the observation of the 'global person' and the test taker's reaction to the situation, as well as his or her behavior, was as important as the test results *per se*. More than the end results, it is the paths by which they are reached that interested Binet.

3.1 *Misinterpretations and Misuses of the Metric Intelligence Scale*

To paraphrase the title of an article by Sarason (1976), the fate of Alfred Binet and school psychology was unfortunate. As described above, Binet's aim was to develop an instrument that would contribute to the identification of those children who needed special help in order to make the most of these children's potential. His aim was to prevent further rejection of these children by supplying them with the special education that would eventually enable them to return to the regular school system. But this second aspect of Binet's program was all too often forgotten and his scale used to weed out rather than to select children for special programs.

It is important to remember that Binet did not view intelligence as a given quantity fixed at birth, but rather, as incremental. It is precisely because of the elastic nature of intelligence and the possibility of

developing it through education that children with specific needs needed to be identified and given the special education that would help them develop their intellectual abilities. But the researchers who imported his instrument to the United States and Great Britain had different views. Lewis Terman, who in 1916 introduced a US version of the Metric Intelligence Scale known as the Stanford–Binet, stressed the importance of hereditary factors in explaining performance on intelligence tests. Terman considered this genetic influence too strong to be altered through education, and advocated placing children with low performance scores in special classes, not in order that they get the special attention they needed to progress, but because there was no hope of their being able to integrate into and profit from normal schooling. Terman 1916) believed that the State would have to assume guardianship for those with intelligence levels in the mentally retarded range.

4. *Strengths and Weaknesses of Binet's Contributions*

Binet's strengths and weaknesses are very much the two sides of the same coin: his strength is in the applied nature and the large social-cultural impact of his work, his weakness, in the lack of a complete theory. Binet's research was particularly important for its pragmatic approach and its attempt directly to connect to social and educational concerns. His research on abnormal children and on cognitive assessment started not from a theoretical construct, but rather in response to a concrete problem.

Binet is perhaps to be remembered for two major theoretical contributions. First, he broke with the Galtonian tradition of studying intelligence through psychophysical processing. He suggested instead that intelligence be studied through higher order processing in complex everyday tasks. This viewpoint, evident as it may seem today, was novel, and almost provocative, to many of his contemporaries. Before Binet, most psychologists, following Wundt's example, thought that intelligence was best explored by studying lower order, very simple, processes. Binet not only decided to explore higher order cognitive functions, but to do so with the same experimental rigor that had previously been applied to simpler processes. Second, he introduced a new methodology for studying intelligence.

It is difficult to find what could be called a true theory of intelligence in Binet's work (Reuchlin 1977). Nevertheless, Binet did think in theoretical terms. In his publications, intelligence is sometimes assimilated to judgment, common sense, practical sense, initiative, or faculty to adapt. At other times, intelligence is decomposed into four 'functions': comprehension (understanding), invention, direction, and self-censorship. But neither Binet's heart nor his head was in theorizing about intelligence. He even went so far as to state that he was only interested in understanding the specific facts that he had gathered and not in any general theory of intelligence.

5. *Psychological Assessment Today*

The importance of psychometrically sound assessment scales to measure level of cognitive development was soon generalized beyond the population of abnormal children and constitutes one of Binet's greatest legacies to the field of cognitive evaluation. The high positive correlation between children's scores on the Binet–Simon Metric Intelligence Scale and their school performance, largely due to the very scholastic nature of the test items, was seen as a proof that the scale was indeed measuring intelligence, and contributed to its widespread success. The Stanford–Binet scale is still widely used for testing of intelligence, although its prominence has been somewhat eclipsed by the success of the Wechsler scales.

Binocular Space Perception Models

Human binocular vision gives rise to the perception of a unitary and stable three-dimensional space of compelling phenomenological reality, but in many situations perception is not veridical. Binocular space perception models aim at predicting perceived spatial relations—such as perceived position, shape, or size—under conditions excluding monocular cues and experiential factors, so that only binocular cues are effective. Binocular cues are the vergence position of the eyes and binocular disparity, which is the difference of the retinal projections in the two eyes caused by their lateral separation.

In the traditional experimental setup observers were presented with isolated point-like light sources of low intensity in complete darkness, with the position of the head kept fixed. The stimuli were confined to the horizontal plane at eye level, taking for granted that disparities in the vertical direction do not contribute to perceiving depth. Sect. 2 illustrates the diversity of psychophysical models that have evolved within this tradition.

With the use of random dot stereograms, which were developed in 1960, it has been shown that disparities on their own are sufficient to produce three-dimensional vision. This impression of depth emerging from binocular disparity, which is known as *stereopsis*, has been the focus of much recent research on binocular vision. Howard and Rogers (1995) provide a comprehensive state-of-the-art report, including a treatment of the optical and physiological basis of stereopsis, and an excellent survey of the vast experimental literature (see also Regan 1991). Sect. 3 highlights some theoretical conceptions relevant to modeling stereoscopic surface perception, and Sect. 4 indicates how this approach may be integrated into a psychophysical framework.

1. Distal and Proximal Stimuli

There are various coordinate systems that not only allow the specification of the position of distal stimuli in three-dimensional physical space but also lead to a characterization of proximal stimuli, which are the retinal images (see Howard and Rogers 1995). In a longitudinal-azimuth/latitudinal-elevation system the position of each distal stimulus is determined by angles of azimuth α_h, β_h and elevation α_v, β_v, describing horizontal and vertical directions relative to the rotation centers of the right and the left eye, respectively (see Fig. 1). Idealizing the relevant optics by identifying the center of rotation and the optical node with the center of curvature of a spherical eye, these coordinates directly specify the proximal stimuli.

Figure 1
The coordinates α_h, β_h denote the monocular azimuth of a point with respect to the rotation centers of right and the left eye and relative to the dashed lines parallel to the y-axis. The coordinates α_v, β_v denote its elevation relative to the place $z = 0$

In the horizontal plane $z = 0$ at eye level the locus of stimuli that are projected onto corresponding retinal points (points that are congruent when the two retinas are superimposed) is a circle through the fixation point and the rotation centers of the two eyes (see Fig. 2). This so-called Vieth–Müller circle is the trajectory of constant binocular parallax γ, which is defined as the difference of the monocular azimuth angles. Accordingly, the locus of symmetric retinal points, which deviate to the same extent but in opposite directions from the foveæ, is known as the hyperbola of Hillebrand (see Fig. 2). This hyperbola can be characterized as the trajectory of constant binocular azimuth φ, which is the average of the monocular azimuth angles. Thus, we have

$$\gamma = \alpha_h - \beta_h \quad \text{and} \quad \varphi = \frac{\alpha_h + \beta_h}{2} \tag{1}$$

With these definitions the relative horizontal disparity between two stimuli may be identified with the difference of their respective binocular parallaxes.

In stereopsis the stimuli, like stereoscopic surfaces, are characterized by a two-dimensional disparity vector field that is to be interpreted as the trans-

Figure 2
In the horizontal plane $z = 0$ at eye level the binocular parallax γ is the angle subtended by the visual axes when the eyes coverage on a point, while the binocular azimuth φ describes its eccentricity. The dotted curves are the Vieth–Müller circle and the hyperbola of Hillebrand incident with the point

formation of the respective retinal images from one eye into the other. The horizontal and vertical component of a disparity vector are given by the differences of $\alpha_h - \beta_h$ and $\alpha_v - \beta_v$ to the respective values of the fixation point.

2. *Psychophysical Models*

To allow for a compact presentation of their basic rationale, the discussion of the models is confined to perceived egocentric distance, and to binocular visual direction, both in the horizontal plane at eye level.

A highly sophisticated approach is due to Rudolf K. Luneburg (1903–49), a physicist, who is given credit for achieving the final mathematical identification of optics with electromagnetics. After becoming acquainted with the striking empirical phenomena in binocular space perception known at that time Luneburg (1947) developed a theory in which depth perception is related to a non-Euclidean geometrical structure of binocular visual space through certain psychophysical assumptions. In particular, he assumed that the points lying on a Vieth–Müller circle are perceived as being equidistant from the observer, and that the hyperbolas of Hillebrand are perceived as radial lines of constant direction. The concrete form of the psychophysical function of egocentric distance $\rho_{K,\sigma}$ is given by the metric radial distance

$$\rho_{K,\sigma}(\gamma) = \tan_K^{-1}(2e^{-\sigma\gamma})$$

where

$$\tan_K^{-1}(r) = \begin{cases} \dfrac{2}{\sqrt{K}} \tan^{-1}\left(\dfrac{\sqrt{K}}{2} r\right) & \text{for } K > 0 \\ r & \text{for } K = 0 \\ \dfrac{2}{\sqrt{-K}} \tanh^{-1}\left(\dfrac{\sqrt{-K}}{2} r\right) & \text{for } K < 0 \text{ and } |r| < 2/\sqrt{-K} \end{cases}.$$

Egocentric distance depends on the geometry through the Gaussian curvature K taken to be constant, and on an observer-specific parameter σ indicating depth sensitivity. Veridical perception is assumed for binocular visual direction, i.e., the respective psychophysical function ϕ takes on the form $\phi(\varphi) = \varphi$.

Numerous experimental studies have revealed that, although the Luneburg theory captures many of the qualitative properties of the data, it is less successful at the quantitative level. Moreover, there is ample evidence that the loci of perceived equidistance exhibit systematic deviations from the Vieth–Müller circles, which, in terms of binocular parallax differences, do not remain constant but tend to decrease in size with increasing distance. This finding led to the conclusion that relative egocentric distance depends not only on disparities, but also on binocular parallax.

Foley (1980) obtained a psychophysical function expressing this dependence by utilizing a heuristic principle sometimes called 'vision is inverse optics.' A formal characterization of how the percept emerges from the proximal image is derived from an optical equation relating the proximal image to the distal stimulus simply by replacing the physical magnitudes by corresponding perceptual quantities. For the physical radial distance r from the origin the approximate (physical) relationship $r \approx (i/\gamma) \cos \varphi$ holds, where γ denotes the binocular parallax, φ the binocular azimuth, and i the interocular distance. By substituting the perceived egocentric distance ρ for r, the 'effective binocular parallax' γ_e for γ, and by identifying the binocular visual direction ϕ with its physical counterpart φ as in the Luneburg theory, Foley obtained the equation

$$\rho = \frac{i}{\gamma_e} \cos\varphi$$

He argued that the egocentric distance ρ to a reference point in the stimulus configuration is misperceived,

while differences of binocular parallaxes are veridically perceived. The linear functional dependence $\gamma_e = p + q\gamma$, with parameter values restricted to move in the ranges $0 < p < 2°$ and $0 < q < 1$, is interpreted to reflect a tendency to overestimate short distances and to underestimate large distances. Consequently, the parallax differences of the locus of perceived equidistance to the corresponding Vieth–Müller circle are a linear function of its parameter γ. Although Foley's theory closely predicts experimental data, its derivation deserves some criticism from the viewpoint of representational measurement theory. No justification is offered for replacing the relevant physical quantities by corresponding perceptual quantities and for treating them as extensive magnitudes (see *Memory Models: Quantitative*). This critique applies to a number of approaches (e.g., Wagner 1985) that convert physical equations into psychological theories by employing the same heuristic. Moreover, meaningfulness problems arise whenever physical and perceptual quantities are compared with each other, which is done by stating that distances are over- or underestimated.

Heller (1997) provides a measurement-theoretic approach to account for the empirically observed locus of perceived equidistance. Binary relations $\preccurlyeq_\rho$ and $\preccurlyeq_\phi$ are introduced to describe the perceived ordering with respect to egocentric distance, ρ, from near to far, and direction, ϕ, from left to right. Within the Luneburg theory these orderings are directly induced by the physical orderings with respect to the binocular parallax $\gamma = \alpha_h - \beta_h$, and the binocular azimuth φ (or, equivalently the sum $\alpha_h + \beta_h$). This motivates the assumption that there exist strictly increasing functions f and g, such that for all stimuli (α_h, β_h), (α_h', β_h')

$$(\alpha_h, \beta_h) \preccurlyeq_\rho (\alpha_h', \beta_h') \text{ iff } f(\alpha_h) - g(\beta_h) \geqslant f(\alpha_h') - g(\beta_h')$$
$$(\alpha_h, \beta_h) \preccurlyeq_\phi (\alpha_h', \beta_h') \text{ iff } f(\alpha_h) + g(\beta_h) \geqslant f(\alpha_h') + g(\beta_h'). \quad (2)$$

The functions f, g can be thought of as implementing the optics of a more realistic eye model, but may additionally specify the contribution of nonoptical causes. A set of sufficient conditions to prove the existence of such a representation is provided within a conjoint measurement approach (see *Measurement Theory: Conjoint*). There is empirical evidence speaking to the validity of the basic axioms, and the empirically observed locus of perceived equidistance is closely predicted with an appropriate choice of functions. With

$$\Gamma = f(\alpha_h) - g(\beta_h) \quad \text{and} \quad \Phi = \frac{f(\alpha_h) + g(\beta_h)}{2} \quad (3)$$

we obtain a psychologically significant recoordinatization of physical space that generalizes Eqn. (1), where the coordinates Γ and Φ characterize the loci of perceived egocentric equidistance and constant binocular direction, respectively. Substituting Γ, Φ for γ, φ at each of their occurrences in the Luneburg theory leads to a generalization of that model.

3. *Computational Approach*

There is currently no comprehensive model of binocular space perception based on stereopsis. On the one hand, it is still necessary to experimentally identify those attributes of the two-dimensional disparity vector field which are relevant to the perception of depth, and to determine their impact. On the other hand, there are a number of criteria indicating depth, with perceived slant and inclination of stereoscopic surfaces having received most attention. Much of the modeling is from 'computational vision', which, however, is concerned primarily with the information that in principle can be extracted from a given disparity vector field irrespective of its relevance for human binocular vision. In search for invariants that allow for characterizing slant, inclination, eccentricity, or distance of a stereoscopic surface, among other quantities, the spatial derivatives of the disparity vector field are considered. The decomposition of the first-order derivative into three components (rotation, uniform expansion or contraction, and an area-preserving linear combination of expansion and contraction in orthogonal directions), the invariances of which can easily be interpreted in optical terms, is a celebrated result by Koenderink and van Doorn (1976).

The following example demonstrates that the computational approach may actually be successful in identifying cues that the visual system could possibly exploit. Mayhew and Longuet-Higgins (1982) showed that the vertical disparities of a few nonmeridional points provide information about the distance and direction of the fixation point, which was thought to be available only from oculomotor cues. Rogers and Bradshaw (1995) argue that, at least in the case of large-field stimuli, this visual information is actually used in binocular space perception. They found that vertical disparities together with vergence contribute to a veridical perception of flat and fronto-parallel surfaces.

4. *Future Research*

It is left as an open problem to provide a comprehensive model of binocular perception of complex stimuli in three-dimensional space. Progress may be expected from integrating the computational results into a psychophysical theory. Showing that the identified optical invariances are relevant to binocular vision amounts to nothing else but showing that they actually constitute psychophysical invariances, which

are transformations of the stimuli leaving perception invariant. Within a representational framework as in Eqn. (2), psychophysical invariances induce functional equations that restrict the possible form of the psychophysical function (see Aczél et al. 1999).

Bioarchaeology

Bioarchaeology is the study of human remains from archaeological settings, viewing these remains in relation to biocultural adaptation, life history, lifeway reconstruction, and population and demographic history (after Buikstra 1977). Human remains can include any body tissue, ranging from artificially or naturally preserved bodies—such as mummies from Egypt or bog bodies from Denmark—to fragments of bones and teeth. Because skeletons are preserved far more often than other types of remains, they comprise most of the subject matter of bioarchaeology (Larsen 1997).

1. Origins and Paradigm Shifts: from Racial Classification to Biological Process

Bioarchaeology originated in the field of osteology, the anatomical study of bones and teeth. Much of the history of study of ancient skeletons focused on classification and racial typology. Biological differences between populations from different time periods—such as differences in skull form—were interpreted to represent replacement of one 'race' of people by another. Various lines of evidence reveal the adaptability of bone tissue, especially with regard to influence of physical activity on shape and structure. For example, skulls representing earlier populations who lived exclusively on wild plants and animals tend to be larger and more robust than skulls representing later farmers (e.g., Carlson and Van Gerven 1977). In consideration of the extrinsic factors that influence skull form (e.g., shift from chewing hard- to soft-textured foods), the temporal variation for many settings is best interpreted in light of underlying biological processes that influence musculoskeletal development and not racial history.

The reinterpretation of temporal changes in skull form is emblematic of the paradigmatic shift that took place in bioarchaeology in the last 30 years of the twentieth century (Larsen 1997). Namely, ancient bones and teeth are no longer viewed as objects for classification only. Rather, bioarchaeologists seek to understand ancient skeletons as though the populations they represent are alive today, subject to the myriad of environmental, cultural, and social influences that affect human biology.

Skeletal and dental tissues are remarkably sensitive to a variety of environmental conditions affecting their form and composition. Owing to this sensitivity during life, human remains recovered from archaeological settings are informative about quality of life (health) and life-style (activity and work) in particular, and behavior in general. Skeletons also contain a fund of information about biological relatedness and demographic history.

2. Quality of Life and Health

Quality of life refers to a variety of factors that influence physical well-being—health is the most important. Health is assessed from human remains via chemical, stress, pathological, and morphological indicators.

2.1 Reconstructing Diet and Inferring Nutrition: Stable Isotopes and Bone Chemistry

The food humans eat and the nutrition that it provides is fundamental to health. Until the 1980s, most

knowledge about ancient diets was based on plant and animal remains from archaeological contexts (see *Paleodemography: Demographic Aspects*; *Zooarchaeology*). In the late 1970s, Vogel and Van der Merwe (1977) identified the timing and intensity of the shift from diets based on wild plants to domesticated plants (maize) by analyzing stable isotope ratios of carbon ($^{12}C/^{13}C$) extracted from archaeological human bone samples. This path-breaking study provided a new basis for reconstructing past diet and set the stage for analysis of stable isotopes of other elements (e.g., nitrogen, strontium, oxygen) and drawing inferences about variation in diet, food use, weaning practices, and climate.

2.1.1 Stress and deprivation. The cells responsible for tooth and bone development are easily disrupted if physiological stress caused by malnutrition or disease occurs while these tissues are forming. In teeth, macroscopically visible areas of enamel deficiency (hypoplasia) or microscopically visible defects (accentuated Retzius lines) indicate growth disruption. In bones, growth arrest (Harris) lines are seen in x-ray images of the ends of leg and arm bones. In addition to having elevated frequencies of indicators of growth arrest, populations that experience chronic illness or malnutrition tend to be short in stature and have less bone mass in comparison with healthy, well-nourished populations.

Many human populations experience iron deficiency, caused by iron-poor diet, parasitic infection, or poor living circumstances involving poor sanitation. Anemia often develops, resulting in increased production of a person's red blood cells. The skull bones of anemic persons are often thickened and display porosity (porotic hyperostosis). The incidence of growth arrest indicators, anemia, and other related morbid conditions increased in the last 10,000 years as human populations shifted to agriculture and became sedentary.

2.1.2 Illness and infection. Throughout the entire five million or so years of human evolution, human beings have been exposed to many different microbes, many of which cause disease. Skeletons record the effects of a number of chronic diseases, such as the treponematoses (the disease group that includes the nonvenereal and venereal forms of syphilis), leprosy, and tuberculosis. Identification of deoxyribonucleic acid (DNA) in archaeological skeletons has verified that the lesions found in ancient remains result from the disease-causing microbes (e.g., *Mycobacterium tuberculosis*; cf. Salo et al. 1994).

Leg (tibia) and, to a lesser extent, other bones in archaeological skeletal samples sometimes display periosteal reactions, areas of pathological bone apposition. These lesions are nonspecific because they can be caused by different infectious agents or by trauma to the lower leg. For many settings, these lesions are likely due to population crowding and poor hygiene, conditions conducive to the maintenance and spread of infectious disease. Sedentary, crowded populations in prehistory have generally higher frequencies of nonspecific and specific infectious disease than mobile, dispersed populations.

2.2 Violence and Injury

All human populations experience physical confrontation of one type or another at some point in time. In the Santa Barbara Channel Island region of the southern California Pacific coast, numerous skulls display indentations (depressed fractures) caused by being struck on the head with a club (Lambert and Walker 1991). In late prehistory in this setting, the frequency of cranial fractures increased, and lethal projectile wounds became more common than before. This temporal shift coincides with deterioration in climate and reduced availability of food resources, suggesting that as environmental stress increased, people became more competitive and more violent. The skeletal evidence derived from the victims of violence may be more informative about the causes and consequences of confrontation than other archaeological evidence (e.g., fortifications, iconography, and weaponry).

3. Lifestyle and Activity

Physical activity is a defining characteristic of different human adaptive regimes. Hunter-gatherers are often characterized as highly mobile, living demanding lifestyles that require a great deal of work in order to acquire food. Agriculturalists, on the other hand, are often thought of as being more 'advanced,' leading lives of leisure. Study of ancient skeletons allows us to address these assumptions and to test hypotheses about labor, workload, and physical activity in past societies.

3.1 Activity and Degenerative Pathology

The articular surfaces of the joints of the skeleton are adapted to withstand mechanical stress, such as those that derive from lifting or walking, or a combination of activities. Over the course of a person's lifetime, the cartilage and bone in the articular joints begins to erode in response to mechanical loading (e.g., knees). In addition, spicules of bone form along the joint margins, which may impede movement. These bone changes are part of a disorder called osteoarthritis. In archaeological settings, there is a tendency for skeletons of prehistoric hunter-gatherers to have more osteoarthritis than those of prehistoric farmers, and males generally have more osteoarthritis than females (see Bridges 1992, Larsen 1995). However, the pattern

and frequency of osteoarthritis is highly variable from one region to another, suggesting that the disorder is influenced by local circumstances involving a complex interplay between culture and lifestyle.

3.2 Activity and Bone Structure

Bone tissue remodels itself in response to mechanical stimulation (Wolff 1892/1986). In areas of the skeleton (or a particular bone) that are subjected to high levels of physical demand, more bone tissue is added in order to add strength and to resist forces that would cause fracture. Breadths and circumferences (e.g., for leg and arm bones) can be used to characterize the size of bones, and to infer levels and types of physical activity. Engineers have developed a more precise way of inferring levels or types of physical activity. Civil and mechanical engineers measure the strength of beams that are used in the construction of buildings. The distribution of material in cross-sections of these beams is analyzed in relation to how they are able to resist bending, twisting (torsion), and other loading modes. Similarly, the human skeleton provides the body with a superstructure for the support of body weight and the action of muscles. From cross-sectional measurements of bones (derived from CAT scans or by direct cutting to reveal the cross-sections), bioarchaeologists apply these engineering principles and methods to determine the strength of bones (Ruff 1992). Biomechanical analysis of skeletons from around the world shows a general reduction in bone strength over the course of human evolution, especially in the last 10,000 years, suggesting that physical activity has declined.

3.3 Activity Above the Neck

The size and morphology of the face and jaws is influenced by mechanical loading and activities involving mastication of food, and in the use of teeth in nondietary roles (e.g., use of front teeth for preparing animal hides for clothing). Human faces and jaws have become smaller in recent human evolution, reflecting the increased tendency for eating softer, more processed foods. Consumption of softer foods and more carbohydrates has also contributed to increase in dental caries (cavities) in recent humans. Patterns of tooth wear are informative about how people use their teeth. Scanning electron microscopy of the chewing surfaces of teeth reveals microwear patterns relating to diet and tooth use (Teaford 1991).

4. Estimating Biological Relatedness: Bone Shapes, Tooth Traits, and Ancient DNA

The shapes and structures of bones and teeth contain key information about population history, since these shapes and structures are at least partly genetically determined. There are some 30 different dental (discrete morphological) traits that are especially useful for identifying inter- and intrapopulation biological relatedness (Scott and Turner 1997).

Because bone shape is influenced by environmental factors (see above), and many dental traits are obliterated by wear on chewing surfaces of teeth, identification of biological relatedness is sometimes problematic. A potentially more informative approach to reconstructing biological history came about in the mid-1980s with the discovery that DNA is often preserved in ancient bones. The development of polymerase chain reaction (PCR) made it possible to amplify short segments of DNA into millions of copies that could be used to identify key parts of the genome (O'Rourke et al. 1996). The analysis of DNA has allowed the testing of hypotheses about biological history, such as long-standing issues relating to population origins and continental settlement (e.g., the origin of native Americans and migration to the Americas), in ways not possible by study of morphology and traits in bones and teeth alone.

5. Population Profiles and Demographic History

Physical anthropologists have developed various methods for identifying sex and estimating age at death from skeletons (Ubelaker 1989). Identification of sex (a biological attribute) allows insight into gender (a social/cultural attribute) and its relationship to health, activity, and social and cultural behavior (Grauer and Stuart-Macadam 1998). Mortality and fertility history of a past population can be reconstructed from age composition of collections of skeletons from archaeological cemeteries. In a stable population with minimal in- or out-migration, age composition is especially informative about birth rates of past populations. A skeletal series having many infants and young children and relatively fewer old adults suggests relatively high birth rate. Conversely, a series containing few children and many older adults suggests low birth rate (e.g., Buikstra et al. 1986). In some regions of the world, the increase in population size that accompanied the shift from foraging to farming appears to be related to decreased birth spacing and increased fertility.

6. Challenges

Research results derived from the study of ancient skeletons—once mostly relegated to the appendices of obscure, unpublished archaeological reports—are now viewed as integral to archaeology. Reflecting this increased role is the growing visibility of bioarchaeology in the popular press and in the scientific literature. Past human biology provides an essential context for understanding present-day diseases, health, and life-style. As the discussion of cultural 'repatriation' continues to build in the USA, Canada,

Australia, Israel, and elsewhere, the archaeological community is increasingly called upon to explain to the larger public why ancient remains are important. Public education about bioarchaeology is important and should be pursued if an informed understanding of the past using the human biological component of the archaeological record is to progress.

Bioethics: Examples from the Life Sciences

Bioethics is a relatively new field of learning, drawing on many established academic disciplines, such as philosophy, jurisprudence, psychology, sociology, and others. Though medical ethics is a central part of bioethics, the latter has a broader scope: in addition to the main theme of classical medical ethics—doctor–patient relationship and doctor–doctor relationship—bioethics is concerned with genuine problems in connection with philosophical ethics as well as practical questions arising from the medical and non-medical life-sciences and affecting public policy and the direction and control of science.

1. The History of Bioethics

The main stimuli for the increase of research in bioethics around the 1960s arose from the technical progress in medicine, societal changes in the western world, and a revitalized interest in the discipline of philosophical ethics. Around that time, progress in medical technology—e.g., kidney dialysis, artificial respirators, organ transplantation, medically safe abortions, and the contraceptive pill—radically changed the practice of medicine. In addition, the first steps towards a powerful gene-technology were made. Roughly at the same time, profound changes occurred in western societies. The civil rights movements in the USA and elsewhere, as well as the transformation of traditional institutions such as the family and the church, caused moral questions concerning an individual's rights and duties in modern society.

Finally, the philosophical discipline of ethics received a fresh impetus. For a long time there had been consensus amongst most philosophers that judgments about moral problems could not be rational in principle. In the second half of the twentieth century, much work has been done, however, which successfully aimed at providing scientific methods for moral reasoning (Arrington 1997, Stingl 1997). In combination, these developments formed the basis of the extraordinary rise of bioethics in the second half of the twentieth century. In the meanwhile, bioethics has become institutionalized in academic departments, professional journals, and international associations.

2. The Scope of Bioethics

Though medical ethics forms the core of bioethics, the latter has a broader scope and is understood to encompass questions arising in the context of the life-sciences, i.e., medicine and the biological disciplines, as well as in some fields of the environmental and social sciences.

The scope of bioethics can be divided roughly into three fields of research. First, there is the project of a rational justification of moral norms. It forms the methodological core of bioethics, since it supplies the strategies of moral reasoning that are applied to the respective problems at issue.

Second, there is what might be called clinical ethics; this group encompasses moral problems that individuals, e.g., nurses, physicians, or researchers, are confronted with in their daily practice. Examples of this kind involve decisions about the end of life, e.g., decisions regarding abortion or medically-assisted suicide.

Finally, there is a group of problems that should be dealt with on the regulatory or policy level. Examples of problems of this kind involve the necessity to develop operationalizable juridical guidelines for awarding patents on biological materials, policies for the allocation of medical resources or the protection of biodiversity.

3. The Method of Bioethics

3.1 Morality and Philosophical Ethics

The task of professionalized ethics is not to be seen in gaining insights from some special source of knowledge—insights that would entitle the ethicist to demand a certain course of action or insist on certain conduct being prohibited. Rather the proper task of ethics is the critical assessment of existing moral convictions and norm systems established from them. This assessment should be done by using a method that is in principle accessible to everyone. Moral convictions are subject to such an assessment when they generate conflicts, e.g., when they are incompatible with other moral convictions. In the case of moral conflicts there is a need for an ethical criterion, that allows us to establish which conviction should be followed. A simple example for such a criterion is the 'Golden Rule': 'We should do unto others as we would wish them to do unto us.' This rule does not provide us with a material action-guide but provides a formal criterion that any action guide has to fulfil in order to be morally acceptable.

Traditionally it has been the domain of philosophical ethics to design strategies for the solution of moral conflicts (Gethmann 1989). In this sense bioethics is only a new area because the conflicts to be solved were unknown until progress in medical technology and societal changes directed public attention to the ethical problems of the life sciences.

It should be the role of a philosopher wishing to contribute to the solution of bioethical issues to provide a clarification of the moral concepts involved and to reconstruct the arguments used in the discussion. On this basis he can develop strategies of moral reasoning that help determine which moral convictions one ought to accept.

It should be made clear, however, that these strategies are developed on the basis of an underlying ethical theory and that a variety of different ethical theories has been developed during the history of ethics (for an introduction, see Frankena 1973): consequentialism claims that, if anything determines the moral status of an action, then it is the consequences of that action, whereas deontological theories hold that there are at least some actions that are morally advisable whatever their consequences. In revitalizing ancient approaches, virtue ethics aims at developing action guides that tell agents what they ought to do in concrete situations.

Principle-based approaches hold that some general moral norms are central to moral reasoning; contrary to this, case-oriented approaches advocate starting with the examination of concrete cases and proceeding from that to more general norms. An example of the latter is the ethics of care: it aims at an expressly practice-oriented approach to bioethics by engaging emotionally in the moral problems at issue. The above list of ethical theories is neither complete nor does it present a proper classification of such theories, but it names those theories most relevant in the recent debate on bioethics (see e.g., Beauchamp and Childress 1994).

Such theories often share certain presuppositions, e.g., the demand for 'universalizability' and 'consistency,' but differ in others, so that—depending on the theory applied—different strategies of moral reasoning can be developed in the discussion of a certain moral problem at issue.

It is often used as an argument against the use of moral reasoning for practical questions that there are no indisputable ultimate arguments for moral norms achievable on a rationally understandable basis. Though true, this should lead to modesty, not resignation, concerning the power of moral argumentation, since we should not demand from the field of ethics what is not available in other areas too: for example, in applying the laws, a judge is always left with a degree of discretion within which he has to examine carefully the special circumstances of the case at issue.

The ability to analyze the moral concepts involved and to apply one or the other ethical theory to bioethical problems will help the physician, policy-maker, or whoever else is confronted with these questions to think about them in a sophisticated way and to develop moral convictions acceptable to all parties concerned.

3.2 Bioethics and the Natural and Social Sciences

The methodology supplied by philosophical ethics is only one, albeit essential, component in the attempt to solve bioethical problems. The philosopher is trained in examining the arguments proposed, whether they are valid relative to some standards of rationality or whether they fall back upon metaphysical or emotion-based beliefs. Substantial arguments about bioethical problems should be based, however, on knowledge from those sciences in the domain in which those problems originated. A discussion of the ethical problems of genetic counseling, for example, without the participation of physicians and others involved in this counseling would be futile. Similarly, it would be pointless to establish the impact that the results of a new technique, such as the genetic manipulation of food, will have on society without the participation of those social sciences that have the necessary empirical methods at their disposal. Finally, it would be vain to develop recommendations for societal regulations, e.g., economically effective and juridically sound allocation procedures for medical resources, without the backing of health economics and jurisprudence. Bioethics is, therefore, an auxiliary discipline supporting the discussions of other disciplines.

3.3 The International and Intercultural Aspects of Bioethics

The experience of a conflict between existing moral convictions in view of the consequences of new techniques is not confined to any cultural or geographical frontier: it is a universal experience. The actual object of the conflict, however, may be highly dependent on, for example, the culture in which the conflict arises.

This context-dependency of bioethical problems is often taken as the prime argument against there being a single method of bioethics, since solutions to moral problems are—so it is claimed—valid only relative to the particular situation for which they were developed. But although it is often the case that material moral convictions do differ between cultures, this does not in itself exclude the possibility of there being a formal criterion acceptable in both cultures—in the same way that the differing views of plaintiff and defendant do not in themselves exclude the possibility of an acceptable judgment.

4. Major Issues in Contemporary Bioethics

The great number and variety of issues discussed in contemporary bioethics compels us to make a rigorous selection. The following section throws a spotlight on some topics that were intensely discussed in the recent debate and that furthermore aptly illustrate an interdisciplinary approach to bioethics (see Chadwick 1998, Kuhse and Singer 1999, Reich 1995).

4.1 Medical Ethics

Since the time of Hippocrates and the ancient Greek medico-philosophers, the emphasis of medical ethics has been on the doctor-patient relationship. Since the 1960s, this has been debated mainly in terms of the improvement of patient autonomy in view of an allegedly prevailing paternalism on the physician's side (Faden and Beauchamp 1986). Today the respect for autonomy is widely accepted as an action guide of overriding importance. Topics still controversially debated are moral problems arising at the beginning of life, the end of life, and the allocation of resources in and to the health care system.

4.1.1 Beginning of life. The moral acceptability of abortion as well as the fate of handicapped newborns is one of the most extensively and intensely discussed issues in bioethics. Basic to this discussion is what quality an entity must possess in order to be a moral subject endowed with certain rights, e.g., a right to life, and how we know when an entity actually possesses this quality.

For some authors, this quality is simply that of belonging to the species *homo sapiens*—a position called speciesism and criticized because affiliation to a certain biological class is as morally irrelevant as the affiliation to a certain race, nation, or social class.

According to another position, this quality is that of being a person—where being a person is understood to involve some kind of self-consciousness. A third position claims that being an agent, i.e., causing one's own actions, makes an entity a moral subject. Characteristic for the latter two positions is that according to them there is the possibility that some members of the species *homo sapiens* are not persons or agents (e.g., a human foetus) while some persons or agents are not members of species *homo sapiens* (e.g., gorillas or dolphins). Once what counts as a moral subject has been defined, it still has to be clarified what rights this moral subject is endowed with. It is, for example, not plausible to claim that a foetus is endowed with an absolute right to life, when even adults are usually not awarded such a far-reaching right: e.g., in the event of war and in self-defense (Tooley 1972).

Over and above this, some criterion has to be found which is applicable in practice and which allows us to determine whether an entity belongs to the class of moral subjects or not. Here an interdisciplinary approach is necessary that combines the above moral considerations concerning the quality characterizing a moral subject with state-of-the-art knowledge from the natural sciences about when an entity actually possesses this quality.

4.1.2 End of life. It has long been (and still is) a rule of most professional codes in medicine to forbid active euthanasia whereas passive euthanasia is some-

times allowed. This distinction between a morally reprehensible action (active euthanasia) and a morally acceptable action (passive euthanasia) is based on an alleged moral difference between 'killing' (act) and 'letting die' (omission). There have been numerous attempts to point out the morally relevant difference between these—without much success so far (Steinbock and Norcross 1994). Though active euthanasia seems acceptable from the point of view of ethics, the satisfactory implementation of codes of conduct concerning active euthanasia in medical practice remains difficult. The reason for this might be that both performing (or even only advocating) active euthanasia can not only jeopardize the patient's trust in his doctor, but moreover generate a threat to legal integrity.

Another controversially debated topic in bioethics is the brain-death criterion: modern medical techniques allow us to sustain the blood circulation of patients, who could not breath spontaneously due to the loss of certain basal brain-functions. According to the traditional definition of death—the standstill of the cardiovascular system—these patients are not dead (though they depend on the continuous support of a respirator). But most people's intuitions are at odds with a patient's body not showing any behavior expected from a living human being. Since the traditional death criterion was no longer useful, it was necessary to adopt a new one (Singer 1994). The Ad Hoc Committee of Harvard Medical School to Examine the Definition of Brain Death in 1968 developed the brain-death criterion that has since developed into the standard death criterion. It is important, however, to notice that the brain-death criterion is not the only possible definition of death—indeed the traditional criterion of complete cessation of blood circulation is another one. In a certain sense, death is not naturally given but defined and much of the controversy about bioethical issues at the end of life arises from neglecting this basic insight.

4.1.3 Allocation of resources. Whenever limited resources are allocated (rationing), refraining from taking desirable actions of one kind becomes the price of performing actions of another kind. Health care is no exception to this universal truth. Fixing a budget in the health care sector means that an increase in spending for, say, preventive medicine has to be accompanied necessarily by decreasing spending in another sector, say, transplantation centers or, on another level, higher spending in a state's education or military sector necessitates lower spending in other sectors, e.g., the health system. The lack of even a basic public health care system makes allocation of resources to the health care system an important topic in many developing countries. But increasing costs of health care have brought the topic of allocation of resources in the health care system onto the general agenda even in those countries that are equipped with a public health care system. The moral questions arising from this are among other things: is there a right to health care? If yes, what has to be provided by the state: a decent minimum or optimal provision? Who shall allocate the scarce resources and by what criteria? Is there a moral obligation to redistribute health care resources on a global level?

4.2 Ethics of Genome Research and Manipulation

Human genome research—best known via the International Human Genome Project, but actually consisting of a multitude of different research programs—has experienced an extraordinary boom during the last decades. Though promising unprecedented options for the prevention, diagnosis, and therapy of diseases, this research bears considerable risks. In this context it is useful to differentiate medico-technical problems of human genome research (e.g., the safety of gene therapy protocols) from moral problems (e.g., the moral acceptability of intervening into the human genome). Only the latter will be considered in the following.

4.2.1 Genetic diagnostics. Genetic tests performed before and after birth as well as the genetic screening of populations are debated controversially because of the potential misuse of the information acquired. Even if the test is used only for medical purposes, the results might lead to stigmatization and discrimination of individuals or ethnic groups. Though not based on state-of-the-art knowledge from the biomedical sciences, this geneticization of medicine should be countered by very careful implementation of genetic diagnostics in the medical practice, including a stronger than usual emphasis on the protection of the privacy and autonomy of the tested (Chadwick et al. 1999).

Another possible domain of use of genetic diagnostics is the testing of individuals applying for insurance coverage (Sorell 1998): it is feared that individuals with an increased genetic risk might have to pay higher premiums or, worse, might be unable to obtain insurance coverage at all. From an ethical point of view, the main question to be discussed is whether there is a right to insurance coverage. A right to the provision of elementary health insurance can be legitimated by an argument concerning the necessary conditions required to allow the full exercise of an individual's civil rights. On the other hand, it seems implausible to postulate a right to life insurance—as long as a life insurance is understood as covering needs beyond the basic needs.

Furthermore, genetic tests might be used in pre-employment (employment selection) tests. Though beneficial in some respects, e.g., saving allergic people

from exposure to allergens, this application may end in severe discrimination of prospective employees: not only that employment could be denied in the light of scientifically unsound tests such as genetic markers for intelligence or criminal behavior, moreover, acquiring a DNA sample of a person makes it possible to perform a whole range of genetic tests that fall outside the employer's legitimate interest in hiring healthy persons.

4.2.2 Gene-therapy. It is hoped that the incorporation of human or nonhuman genes in body cells (somatic gene-therapy) or the human germline (germline gene-therapy) will be a major contribution to the therapy of diseases with a genetic component—hereditary as well as non-hereditary. Somatic gene therapy is seen as a relatively unproblematic method from the ethical (not medico-technical) point of view, since the transferred genes are not inherited by the descendent of the treated individual.

In stark contrast to this, germline gene-therapy is controversially debated. Since the transferred genes to germline cells are inherited by all offspring, the question arises whether such an intervention in the genetic constitution of an unborn individual can be legitimated and, on a more general level, whether germline therapy leads to a new form of eugenics or genetic enhancement. Since most authors hold that if germline gene-therapy were to be applied, it could not be exclusively confined in the long run to medical application, the debate therefore centers on the question whether the intervention into the lives of future persons by genetic enhancement is different in any morally relevant way from classic interventions such as education (Agar 1998)

4.2.3 Cloning. The first cloning—i.e., asexual reproduction—of a mammal in 1996 raised moral question concerning the application of this technique to non-human animals and humans (Harris 1997, Wilmut 1998). Animal cloning is debated mainly in view of the legitimation of manipulating the genome of wild-type animals and the effect of a change in the genetic pool of the biosphere that might have considerable effects on biodiversity.

The debate on human cloning has focused on the ethical problems of producing copies of existing human beings (reproductive cloning). Concerning reproductive cloning, the emphasis of the moral debate lies on whether there are morally acceptable aims for the actual application of this technique, whether the genetic identity of a clone and its donor amounts to a morally problematic personal identity, and whether human cloning leads to an infringement of the dignity of the clone or the donor.

The cloning only of parts of humans (cells or organs) is technically still in its infancy but has caused an intense debate concerning the moral status of the embryonic cells that are necessarily consumed in the embryo experimentation needed for a further development of this technique (see Lauritzen 2001).

4.2.4 Genetically modified organisms. An area of application for the results of genome research is the manipulation of organisms. Well established is the introduction of genes in bacteria, plants or animals. The transgenic organisms produced employing this method are used either to perform further research on the transferred gene or with the purpose of producing certain rare substances in a bio-factory, e.g., the generation of insulin in transgenic bacteria. Additionally, it is hoped that transgenic organisms will be helpful in improving food-supply in developing countries.

The moral problems of genetically modified organisms arise from possibly deliberate interventions in the 'natural' biodiversity as well as from alleged infringements of animal rights. The destruction of biodiversity is a controversially discussed problem, which is tightly connected with the development of modern societies. Usually it is presupposed that the description and quantification of biodiversity is scientifically and unambiguously clarified. In contrast to this expectation, neither biology nor other disciplines dealing with corresponding parameterizations, such as economics, have presented uniform concepts which can serve as a basis for measurability and comparability of biodiversity.

4.2.5 Bio-patenting. Genetic research and its commercial use have stimulated a debate on the moral acceptability of patenting human and non-human genes. Though there exists a number of national and international conventions on the patentability of bio-materials there remains considerable uncertainty on exactly what can be patented and what rights are connected to awarded patents.

The moral debate on patents centers around three major questions: are 'patents on life' immoral and is, therefore, the patenting of plants and animals, but in particular of human genes, morally unacceptable? Does the patenting of bio-materials—in particular human genes—lead to a massive hindrance to biomedical research? Does bio-patenting lead to an unfair distribution of resources between the rich, industrialized countries and the developing countries? None of these questions can be said to have been solved at the moment and strong political and economic interests make this issue important well beyond the academic area

Bioethics: Philosophical Aspects

Etymologically, the term 'bioethics' derives from the Greek words *bios* (life) and *ethike* (ethics), and literally means the ethics of life. In practice, however, it denotes a field largely concerned with the ethical analysis of normative problems in the biomedical sciences, medical practices, and health care management. Reflecting this focus, this article addresses the nature and history of bioethics, the dominant ethical theories employed in bioethical reasoning, and their influence in the main areas of bioethical research.

1. Bioethics—Scope and History

Bioethics, both as an academic discipline and as a professional activity, has evolved from the domain of medical ethics. It is a multidisciplinary field that extends far beyond the spheres of healthcare and medical ethics. It encompasses a wide range of ethical problems in the life sciences. These include issues related to genetics, theories of human development, behavioral psychology, and resource allocation in healthcare management.

Bioethical expertise is sought by courts, parliaments, research ethics committees, and is used in clinical consultations to guide the behavior of medical professionals. Despite its practical appeal, however, disagreement exists about the nature and scope of bioethics as a professional/theoretical discipline. Bioethicists come from a diverse range of professional backgrounds, including healthcare professions, philosophy, jurisprudence, sociology, and theology. Debate about the proper relations between the disciplines contributing to bioethical analysis is continuing (Carson and Burns 1997).

1.1 Expanding Issues in Medicine

The reasons for the progression of bioethics as a multidisciplinary activity can perhaps best be understood by considering the societal context in which it began. The rapid developments with regard to both the availability of biomedical technology and dramatically advancing biomedical research required a rethinking of traditional approaches to medical ethics. The 1960s saw not only the first successful organ transplantations, the contraceptive pill, and the arrival of prenatal diagnosis, but also a shift to the deployment of highly technological medicine. Particular people began to demand greater liberties, such as equal rights for those who were non-Caucasian, female, and gay. Medical paternalism, and the attitude that the 'doctor knows best' were no longer considered sacrosanct. The Western world saw the progression

towards civil liberties, and changes in the practices of the biomedical sciences began to reflect the modern emphasis on autonomy. Informed consent, the protection of human subjects, and patient self-determination began to assume paramount importance in both theoretical and legal contexts.

1.2 Bioethics Teaching

Bioethics is currently taught in many diverse forms throughout both the developed and developing world. Bioethicists teach in medical faculties, medical humanities, and philosophy programs, and in one of several hundred research centers in postgraduate degree programs. The socioeconomic and cultural contexts of teaching influence the topics that constitute a given syllabus. For example, in developing countries, issues such as exploitation in organ transplantation or human experimentation feature more prominently than in developed nations. Teachers try to instill heightened sensitivity in their students to ethical issues and values in medicine, as well as provide them with skills in dealing with ethical problems arising in healthcare practice. Courses are often taken as part of obligatory continuing medical education requirements.

2. Theoretical Approaches to Bioethics

Philosophical ethics, the theoretical heart of bioethical analyses, consists of a variety of competing ethical theories. Utilitarians, deontologists, casuists, communitarians, contractarians, virtue ethicists, and ethicists of other persuasions appeal to differing modes of ethical reasoning. This has consequences for bioethical analyses since the type of ethical theory or religious framework to which a given bioethicist subscribes will be reflected in the practical advice advocated.

2.1 Principle-based Bioethics

Principle-based bioethics typically refers to an approach developed by Beauchamp and Childress (1994). They propose a system of bioethics comprised of four major principles: autonomy, beneficence, nonmaleficence, and justice. These *prima facie* principles primarily concern respect for the choices people make, the obligation to help, but not harm, other parties, and the requirement to act in a fair and equitable manner with regard to the distribution of medical burdens and benefits. Critics charge that principle-based bioethics is unsuitable for practical decision making because the lack of hierarchical order of principles renders the ranking in any given situation somewhat arbitrary. Because it is able to be taught in a comprehensive and accessible manner, however, this approach is favored in many bioethics teaching programs.

2.2 Utilitarian Bioethics

Utilitarians have developed a consequentialist type of theory, judging the rightness or wrongness of a given action exclusively by its consequences. Of all the ethical theories, utilitarian modes of reasoning are most easily suited to problem solving in bioethics. This is because their guiding principle is singular and unambiguous, providing a clear procedure for decision making. The basic utilitarian premise is that both individual action and public policy should maximize utility (which is normally defined in terms of happiness or preference-satisfaction) for the greatest number of people. Its patterns of analysis are congruent with traditional forms of reasoning in public policy. Utilitarians have contributed sophisticated works to central problems in bioethics, such as abortion, voluntary euthanasia, embryo experimentation, and resource allocation.

Critics of utilitarianism doubt that it is possible to quantify interest or preference satisfaction, and question the feasibility of the utilitarian calculus as a decision directive. Also controversial is the utilitarian rejection of two distinctions which are central to other approaches in medical ethics: the intention/foresight and acts/omissions distinctions. These distinctions are important in terms of motives and responsibilities for action, both of which utilitarians ignore, focusing exclusively on consequences as criteria of right action.

2.3 Deontological Bioethics

Secular deontological approaches to bioethics tend to be based on Kantian and neo-Kantian ethical theories, and feature most prominently in the areas of resource allocation and general social health policy. Daniels (1985), for example, uses a neo-Kantian form of contractarianism to support his influential argument for a universal right to healthcare. The Kantian moral agent is quite different from the utilitarian agent who acts in order to satisfy interests or desires.

Kant was concerned with the motivation of action, and argued that duty alone should motivate morally adequate action. An 'action done from duty has its moral worth not in the purpose to be attained by it, but in the maxim in accordance with which it is decided upon' (Kant 1976). These maxims are constructed as absolute imperatives of the sort, 'don't kill,' 'don't lie,' etc. Furthermore, Kant developed

Categorical Imperatives, the most influential of which demands that the moral agent never treat other people as mere means to ends (however noble these may be), but rather as ends in themselves.

There are some reasonably clear differences between Kantian and utilitarian bioethical decision making. Utilitarians and Kantians arrive at very different answers to the question of whether it is ethically justifiable to kill one 'innocent' human being in order to save 10 similar others who are in need of organ transplants. All other things being equal, utilitarians would conclude that it is right to kill one person to save the lives of 10 others, while a Kantian would argue that it is unacceptable to kill an innocent person. Kantians are not concerned about the consequences of action, but rather with the question of whether one can consistently wish to be treated by other rational agents in the same manner as one desires to act in a comparable situation. Kantian bioethicists tend to defend absolutist positions, such as the rejection of voluntary euthanasia, irrespective of the suffering this may cause.

2.4 Feminist Bioethics

Feminist approaches to bioethics are unified by a common concern for women's oppression. Feminist bioethics raises the question of unequal distribution of social power, and the subsequent biases that manifest in the life sciences, medical practices, and philosophical ethics. There are numerous feminist approaches to these fields. Feminist projects provide a critique of traditional approaches to bioethics, focusing on the effects that the historical exclusion of women and their experiences have had on theory production. Some feminists aim merely to provide a *corrective* to dominant theories and practices, while others embark on the more radical project of creating positive feminist theories and practices which differ *fundamentally* from those which are the objects of critique. Whether one stops at critique, or progresses to creating novel theories founded on new premises, depends largely on how deep the level of masculine bias is held to be. Bioethics provides fertile ground for feminist analysis, since scientific claims have long been used as tools to justify women's oppression as part of the natural order of things. Feminist interactions with the sciences aim to expose the value-laden nature of scientific practices; how our social context effects the sort of questions asked, the methodologies employed, and the sort of answers that are considered coherent. Feminists have been central to debates on abortion and reproductive technologies. The scope of feminist argument is not, however, limited to those domains explicitly related to women; it spans the entire field of bioethics. Some theorists have demanded that feminist theory also consider the ways in which race, ethnicity, and class bear upon theory construction. For these reasons, many feminists reject the goal of one universal moral theory in favor of a more pluralistic approach to knowledges and their application.

Commonly, feminists take issue with the *sort* of human agent that moral theory assumes. Specifically, it is argued that certain features of this subject (i.e., its participation in an alleged objective, universal human Reason) reflect a mode of reasoning which depends on the exclusion/devaluation of women's experiences. Contemporary models of moral reasoning drawn from experiences in the private sphere (such as mothering, caring for the aged, and preparing and distributing food) are substantially different from those based on hitherto ignored experiences common to the public arena, which has historically been the domain of men. Indeed, care- (Gilligan 1982, Noddings 1984) and maternal- (Ruddick 1995, Held 1993) based are perhaps the main challenges to traditional moral theory produced by Anglo-American feminists. From a utilitarian perspective, their implications have been most thoroughly explored in the domain of nursing (Kuhse 1997).

2.5 Communitarian Bioethics

In the context of bioethics, communitarianism constitutes a critical discourse that challenges dominant approaches which are based on Enlightenment philosophies. The idea of an isolated knowing subject, who defines ethical truth in accordance with the dictates of human reason, is rejected. Communitarians privilege the interests and values *of the community* in negotiating morally optimal courses of action. They argue that any moral theory is determined by socio-historical context, including the traditions, religions, and culture of a community. Within traditional moral theories, these influences are often seen as extraneous, contaminating the goal of objective moral truth. For communitarians, however, attempts to produce an impartial, universal moral theory are not only futile, but represent a mistaken concept of what moral thought *should* involve. They emphasize that certain decisions require a view of the good, of what is worthwhile and valuable for a community.

The goal of defining goods and values that are genuinely shared by any given community is problematic. In increasingly multicultural societies and global communities, identifying shared conceptions of the moral good might only be possible if communities are defined in a narrow sense, resulting in many communities with perhaps competing views of the good life.

2.6 Religious Bioethics

Religious ethics is not a unified ethical theory, like Kantianism. Religious ethical analyses will always

depend on the particular religious scripture that guides the ethicist. Monotheistic religions are traditionally less open-minded with regard to pluralistic views that might be held in secular societies. Still, even within Christianity and Judaism, there is a range of diverse views held by bioethics scholars. Catholic bioethicists tend to be in strict agreement with the teachings of their organization. This is largely due to the fact that Catholicism is the only mainstream religion that has a body of papal ex cathedra teaching. Even here, however, the Biblical commandment 'thou shalt not kill' has undergone some theological reinterpretation. Despite this, there is unanimity among Catholic scholars that active euthanasia and abortion are ethically unacceptable. In many countries, Islamic medical associations have produced their own code of ethical conduct.

3. *Issues in Bioethics*

3.1 *Research Ethics*

Research ethics came about largely because of revelations regarding the gruesome medical experiments conducted by Nazi doctors in German concentration camps during the Third Reich. The most important international normative framework regulating the standards of research clinical trials is the Declaration of Helsinki (WMA [World Medical Association] 1964). In 1993, it was supplemented by international research ethics guidelines produced by the CIOMS (Council of Medical Organisations of Medical Sciences) in collaboration with the WHO (World Health Organisation). This set of documents contains a series of important protections for people participating as research subjects. These are especially important for people in developing countries, where exploitative trials continue to take place. Bioethical analyses of research ask questions such as the following:

(a) Ought researchers be held responsible for the use of their research results by other parties?

(b) What is the appropriate point in time to stop research clinical trials?

(c) Are placebo controls defensible in trials with terminally ill patients?

(d) Are terminally ill patients justified in breaking protocols in placebo controlled trials, given that many only joined the trial in order to access the experimental agent (Schüklenk 1998)?

(e) Ought women of childbearing age be enrolled in research clinical trials?

(f) Ought prisoners be asked to participate in nontherapeutic research?

A key issue in research ethics is informed consent, which is considered a precondition for any ethical research, given that it is voluntary and autonomous. Justifications for this premise derive from the idea that individual autonomy is of intrinsic and/or instrumental value. Neo-Kantians argue that autonomy is of great instrinsic value. Young (1986), for example, understands the value of autonomy as a character ideal, rather than as a means to some further good. Utilitarians also support the idea of respect for informed consent because they, too, value personal autonomy. In this instance, personal autonomy is of instrumental value, necessary to satisfy one's own preferences, desires, and interests. Research ethics protections and standards pertaining to research subjects in developing countries are also issues of paramount importance. AIDS research in particular has led to large numbers of international collaborative research projects. International research ethics guidelines require that every patient (including those in any control group) should be assured of access to the best proven diagnosis and therapeutic method. This requirement was designed to prevent the exploitation of research subjects in developing countries who participate in projects undertaken by Western researchers. Some bioethicists have argued that the enforcement of Western norms in developing countries constitutes cultural imperialism. Utilitarians are most likely to inquire after the consequences of accepting a lower standard of care for research subjects in developing countries. If such a strategy would lead to the development of cheaper, perhaps affordable, drugs for people living in developing nations, utilitarians would accept such a policy change.

Deontologists argue that the primary obligation of physicians is to their research subjects and not to future generations of patients. This makes them more ideal advocates of current research subjects' interests, as opposed to utilitarians who would have to take into account the interests of all concerned, including those of future generations. Principalists would have to balance the duties of nonmaleficence and beneficence against each other in this case. They suggest that we have an absolute duty not to harm anyone, but that we have no absolute duty to do good. This view could be used to justify providing local standards of care in international collaborative research efforts, because providing the highest attainable standards of care would require providing more than what is already available. This is arguably doing good over and above the call of duty.

3.2 *Beginning and End of Life*

The moral status of embryos, fetuses, and infants continues to dominate beginning of life debates. Some ethicists suggest that fetuses deserve moral standing and consideration by virtue of their belonging to the human species. Others reject this proposal as speciesist, arguing that the mere fact of being human does not give fetuses special status (Singer 1990).

Rather, their moral standing ought to depend on their dispositional capacities.

The debates about the moral status of embryos and fetuses primarily affect issues surrounding new reproductive technologies and abortion.

Catholic bioethicists hold that nothing can justify the killing of innocent human beings, irrespective of whether they are fetuses, infants, adults, or people suffering from terminal illnesses. Abortion is considered unethical, even when the mother's life is at stake (Sacred Congregation for the Doctrine of Faith 1980). These bioethicists argue that fetuses are human beings from conception, and ought to be accorded the same moral entitlements to life as other humans. In turn, embryo experimentation is also deemed unacceptable. This view is often supported by deontological ethicists who propose an absolute sanctity of all life. The vast majority of feminists support (and have been crucial in creating and maintaining) the legal right to abortion on the basis of the mother's interest in/right to bodily autonomy and integrity. This interest/right is often seen as overriding any moral status that the fetus might have. Feminists have also argued that maternal–fetal conflict models inaccurately characterize what is at stake in pregnant women's decisions which affect their fetus, and alternate models which do not centralize conflict have been proposed.

Bioethical debates concerning the end of life tend to be preoccupied with the permissibility of physician-assisted suicide and voluntary euthanasia. Many people suffering from terminal illnesses find their quality of life during their last months of life so unbearable that they ask physicians to help them die, either by means of supplying them with lethal doses of drugs, or by killing them actively. The Hippocratic Oath requires doctors to 'neither give a deadly drug to anyone if asked for it, nor make a suggestion to this effect.' Accordingly, medical ethics has traditionally seen doctors' assistance in patients' attempts to die as incompatible with their roles as lifesavers. The sanctity-of-life doctrine in medicine, strongly influenced by religious views, rejects the view that some lives might be so bad that they are not worth living. Utilitarians argue that we ought to abandon the sanctity of life doctrine and substitute it with a quality of life ethics instead (Kuhse 1987).

3.3 The 'New Genetics'

Molecular genetics, and its associated research and engineering techniques, are often called the 'new genetics.' This field facilitates the manipulation of living organisms to a hitherto unimaginable degree. We are able to clone animals, research treatments of diseases with both somatic and germ-line gene therapy, select animal and human embryos and fetuses on the basis of their genotype, create microorganisms of desired genotypes, and have them, as well as plants, express both human and animal genes which code for desired protein products. Questions such as the following are now widely debated:

(a) Is reproductive/therapeutic *human* cloning morally acceptable?

(b) Does selecting against people with disease genes through prenatal screening constitute discrimination?

(c) Can we define disease genes in morally neutral ways?

(d) Does the desire for positive human traits such as physical beauty or intelligence justify the selective abortion of fetuses with 'suboptimal' genotypes?

(e) What ecological effects are likely as we cross species barriers by creating hybrid organisms?

(f) How can we control the creation of genetically engineered pathogens tailored for particular human populations in the service of military or terrorists' agendas?

Human society remains deeply troubled by genocidal wars, and discrimination against people on the basis of race, ethnicity, sex, and sexual orientation is rife. The identification of genetic markers of marginalization opens new possibilites for eugenic programs, racial 'cleansing,' and genetically targeted biological warfare. It is thus clear that the 'new genetics' may be used for malign purposes as well as for the good of humanity. An example of the ways in which the application of moral theories to genetics differs can be found in discussions of prenatal testing and subsequent selective abortion for nonmedical reasons. What constitutes a *medical* reason is itself open to debate, and the question of whether abortion, based on the presence of, say, a gene predisposing to late-onset cancer, is justified, is far from settled. Screening and abortion for nonmedical reasons are far more controversial. A dominant utilitarian approach to this issue would look to individual preferences, and would be likely to endorse a liberal approach, where uptake of such technology would be a matter of individual choice. For as long as fetuses are not considered entities either with interests able to outweigh those of parents, or with the capacity to suffer significantly, there would be no reason against the provision of selective abortion. The only utilitarian argument against such technology would be one which held that the indirect consequences for society in general would be so detrimental that they outweighed the direct preferences of potential users.

A deontologist's approach might oppose the provision of prenatal screening in order to facilitate selective abortion for nonmedical reasons. Motives for action are crucial for a deontologist. Deontologists emphasize respect for human dignity, which entails that all people be treated equally, and that they not be used merely as means to another's ends, but rather, always as ends in themselves. It is possible that abortion *per se* would be opposed on the basis of respect for human potentiality. Differentiating be-

tween people on the basis of sex or hair/eye color would be incompatible with respect for human dignity, and associated selective abortion would certainly be a case of using a potential person for another's, perhaps trivial, ends (Davis 1997).

A liberal feminist bioethicist's response might endorse eugenic technology in accordance with respect for a woman's right to autonomy, and control over the pregnancies with which she chooses to continue (Warren 1985). Feminists would also be concerned with the social conditions in which technology is developed, and the demand for its provision generated. Attentive to the ways in which science might work in the interests of the dominant sex, race, and class, any technology which facilitates discrimination against these markers of marginalization would be viewed with suspicion. Thus, prenatal testing for sex might not be supported in societies where there is entrenched oppression/devaluation of women, and a concomitant preference for male children.

3.4 Healthcare Professional–Patient Relationship

Some writers suggest that the relationship between healthcare professionals (HCPs) and patients is best understood as a contractual agreement, similar to that between a customer and a professional selling service. A contract usually includes protections to the partners such that if the contract is broken by one party (i.e., by providing substandard treatments, or by not paying the due fee), legal recourse can be sought by the wronged other. The advantage of this model is that it breaks with authoritarian models of the physician. Instead it requires respect for the patient's autonomy, usually first-person voluntary informed consent to treatment, and agreement between doctors and patients about a proposed course of action. It has been proposed that medical practice ought to rely on a covenant model instead of the code-based model that it tends to rely on in actuality (May 1975). Others have seen doctors' service provision and associated medical paternalism as an extension of their professional duty of beneficence (Downie 1994). This traditional attitude has been challenged by claims of patients' rights to medical care and doctors' obligations to satisfy these rights.

US bioethicists have attempted to address ethical concerns of the HCP–patient relationship in the context of the principle-based approach. This strategy turned out to be quite problematic because of the conflicts between simultaneously having to respect autonomy, act beneficently, and act justly.

Utilitarians defend upholding patient confidentiality by pointing to the negative consequences for the physician–patient relationship once patients cannot trust that their medical details will be kept confidential. They suggest that maintaining patient confidentiality is necessary for achieving the health and well-being of patients. Deontologists support this conclusion on the basis of a distinctly different rationale. They argue that respect for patient autonomy requires that patients keep control over what type of intimate, private information is available to parties other than those to whom they disclose it.

3.5 Resource Allocation

Determining the optimal means of allocating scarce resources for healthcare is an intractable problem requiring constant negotiation as new technologies and treatments become available. While the UN Declaration of Human Rights states that every person 'has the right to a standard of living adequate for the health and well-being of himself (sic);' defining the criteria of such adequacy is open to debate. As is the case with any limited resource, there are always situations in which the number of people desirous of a particular form of healthcare outweighs what is available. On a macrolevel, decisions must be made regarding the extent to which healthcare should be state-funded, and the way in which such provisions should be distributed between medical research programs, available treatments, and technologies. On a microlevel, medical staff must confront issues such as how to allocate hospital beds, order of, and eligibility for, treatments. Prominent criteria for resource allocation decisions are need, merit, desert, order of demand, social utility, and expected benefit from treatment. Some theorists suggest that it is only when consensus about degree of need cannot be reached that other factors come into play (Harris 1998). Where a maximizing strategy is endorsed, however, it is largely the consequences of treatment that matter, and medical need is not necessarily the primary criterion. Resolving some way of considering these issues is particularly pertinent in the face of an aging population, where healthcare becomes increasingly expensive, and quality of life considerations become pressing. For example, how should funding be distributed between geriatric and newborn-infant care?

Callahan (1990) argues that this question is necessarily linked to the goals of the community. A communitarian approach might articulate the goals of medicine in terms of particular stages of the life cycle, while also thinking about what the goals and virtues of the elderly should be. This entails the possibility that elderly persons might be morally required to forego certain life-prolonging treatments in the interests of providing healthcare for younger generations. A utilitarian method uses quality adjusted life years (QALYs) in order to help determine who has most claim on limited treatments. QALYs provide a means of calculating which individuals, with treatment, can expect to live the longest, where the number of years

are adjusted for quality. Thus a person predicted to live 10 *actual* years after treatment with a very low quality of life would have less than 10 QALY years to live, and would lose out to a patient predicted to live, say, eight actual years with a good quality of life. Similarly, if we imagine an elderly person and a youth, both in need of an organ transplant, and both with similar qualities of life expected postoperation, it is clear that the QALY method would favor the young person. A utilitarian may, of course, choose to include other factors beside QALYs in their calculation of who should get the organ. If the elderly person had, say, a large number of refugees dependant on them for survival, then this may count as a compelling reason to favor their receipt of the organ. Nonetheless, whether or not the initial favoring of youth amounts to ageism is debatable. Indeed, whether or not the QALY method discriminates against disabled people is also questionable, since mental/physical disabilities are generally assumed to reduce quality of life. Any method of assessing quality of life remains controversial. Some argue that quality of life is a subjective concept which can only be meaningfully assessed by the individuals in question. Other theorists who maintain that quality of life can be judged objectively disagree over the relevant criteria in such a decision. Thus it has been suggested that some measure of both subjective and objective evaluations are needed in order to measure health states (Wikler and Marchland 1998).

Biogeography

Biogeography is not easy to be defined precisely and this is for several reasons. Some scientists think that biogeography is a biological discipline, firmly rooted in nothing but the biological sciences. Biogeography, or the two common subdivisions phytogeography and zoogeography, is the field for studying the distribution of plants and animals, respectively. Due especially to the higher diversity and the greater mobility of animals, zoogeography has developed less than plant geography. Moreover, plants are more directly affected by their physical habitat and exert at the same time a greater influence on climatic and edaphic properties than animals. They better indicate visibly the environmental condition they live in.

On the other hand, many geographers claim biogeography to be a geographical discipline and regard it as a most important link between physical and human geography, because man's effects on plants and animals are included. They stick firmly to the ecosystem concept and regard biogeography as a vital part of ecological geography or geoecology. And they underline the often neglected meaning of scales in time and space as well as the dynamics of the ecosystems.

The struggle between biologists, who prefer a more

historical view and underline the importance of evolution, and geographers, who accentuate ecological relations and anthropogenic changes, is not very productive. As the term indicates, biogeography is at the same time a biological and a geographical science. The roots of biogeography lie in the classical 'Natural History.' Probably Alexander von Humboldt was the first biogeographer, a generalist who was able to do research in botany and zoology as well as in geology, geography, climatology, and soil science. He recognized the very complex nature of plant and animal distribution patterns and was aware of the necessity of a broader, interdisciplinary view on the basis of the integration of data and information from numerous disciplines of natural and even social and economic sciences. And for this tremendous diversity of biogeography, a holistic approach is indispensable. Only biologists and geographers together can bridge the gap between the topics involved.

For these reasons a short and comprehensive definition of biogeography is rather impossible. The main contents, tasks, and scientific approaches of biogeography can be summarized as follows.

Biogeography is the science of living organisms in time and space. Biogeographers combine geographical and biological methods in order to discover, to present, and to explain the development of the spatial distribution patterns of single organisms and of organisms associated in phyto-, zoo- and biocenosis. In this approach, evolutional dynamics and historical developments have to be taken into consideration as well as the ecological background with abiotic factors such as temperature, light, water, nutrients, and mechanical influences, which the environment offers in a given quality and quantity, and the demands of plants and animals respectively. Biotic factors, as far as they concern competition and especially human influences, are of outstanding importance as well. Basic knowledge about the dynamics of the area of species/biocenosis is a prerequisite for a better understanding of ecosystem dynamics as well as for treating properly applied problems, e.g., concerning bioindication in a polluted environment, protection of natural reserves, or the maintenance of biodiversity.

In order to understand the distribution patterns of organisms and biocenosis, which is the main objective of biogeography, all relevant historical and ecological factors on all temporal and spatial scales must be integrated. Because of the complex nature of biogeography and the countless interrelations between different elements of different scientific disciplines, it is almost impossible to find a logical order for treating the most important aspects separately. The following subdivision into several sections is highly artificial and is only included for practical reasons. And for reasons of interest and knowledge, attention is primarily given to the study of plants rather than animals.

Evolutional and historical developments and the ecological background of distribution patterns will be treated in the following sections. Aspects of regional biogeography and some general rules and models follow. In a concluding section, topics of applied biogeography are addressed.

1. *Historical Biogeography*

Historical biogeography is concerned with the evolutionary processes which contributed to the actual distribution patterns of plant and animal life. The chorological dynamic is focused over very large temporal and spatial scales. The effects of past events on the present distribution and all the environmental changes that have taken place during the time of origin of a species until today are studied. Evolution for all biota means change, too, and this change—due to environmental changes—can be accomplished by genetical adaptation and/or by spatial adaptation. If changes of the environment are slow and continuous, species adapt and speciation can take place; if they happen too fast, extinction may be the consequence. For some biogeographers this approach is not only important but is the whole content of biogeography. Most important is the perception that biogeography has a vital component that has been often neglected: dynamics in time and space. Distribution patterns can only be explained by understanding the underlying processes.

Basic processes are all dispersal mechanisms. They can be decisive for the migration potential of organisms; the spatial range a species may colonize. Active dispersal (autochory) and different modes of passive dispersal (allochory) are responsible for the distribution of diaspores. Among the latter, anemochory (dispersal by wind) and different types of zoochory (dispersal by animals, especially birds and numerous insects) are most successful. But there are more dispersal modes; more recently, man has an increasing importance (anthropochory).

Not only the dispersal mode but also the actual and the former constellations of the continents and oceans highly influence a more or less successful expansion of the area of a given species. Terrestrial plants may cross marine barriers, where animals did not succeed. Some seeds tolerate salt water, others do not. For climatic and orographic reasons, mountain ridges are sometimes invincible barriers. Species with a successful dispersal mode, which have been able to cross all such barriers by land bridges, stepping stones, long-distance jumps, or special transportation can achieve a cosmopolitan range. Others stay restricted to their area of origin and remain endemics. Also, the area of formerly widespread organisms can be split up by newly opened oceans or other barriers. The result is disjunction and probably vicariance.

Not only dispersal mechanisms but also continental drift, plate tectonics, landmass fragmentation, and marked climatic changes contributed greatly to form-

ing the actual distribution patterns of plants and animals. Geological changes are mainly linked with their large-scale distribution, climatic changes also with finer-scale patterns. Especially important during the Paleozoic has been the initiation of the breakup of the old Pangea. Mesozoic times are marked by the great extinctions of formerly important groups (dinosaurian) and the rise of flowering plants. Partly due to sophisticated research techniques like radiocarbon data and palynological analysis, knowledge about the influence of the Ice Ages on the distribution of plants is rich and detailed. Temperature fluctuations and eustatic changes of the sea level have opened new dispersal pathways for some species or forced others to look for refuges.

Best documented is the dynamics of plant and animal distribution in the last few thousands of years. Nevertheless, there is now one element which is new and complicates the interpretation of a given distribution pattern. This element, which must also be regarded as an ecological factor of growing importance, is man and his manyfold activities and influences. Domestication and Neolithic agriculture have been the impact of early human culture. Now not only all energy and nutrient cycles can be manipulated but also any still-existing geographical barrier can easily be bridged. Man can change the genetic setup of organisms as well as create new site conditions. Pollution in a very large sense is a completely new aspect in biogeography. 'Greenhouse-effects,' 'forest die-back,' 'eutrophisation,' and more are the new keywords. The problems arising with this development show that there are growing challenges for modern biogeography.

Research on historical biogeography has always been accompanied by theoretical and modeling efforts. The best known are linked to the different succession theories and to the idea of a final stage of development ('climax') and to plant-strategy types ('r'- and 'K'-strategists). More recently, vegetation dynamics are discussed on the basis of models, which take the role of competition, biodiversity, and plant functional types more into account. The stability of communities of plants and animals, and finally of complete ecosystems is intensely discussed. Furthermore, the problem of temporal scales is gaining increasing recognition.

2. *Ecological Biogeography*

Ecological biogeography is concerned with ecological processes, which contribute to the distribution of plant and animal life in the biosphere. It is important to distinguish the historical elements within the actual patterns from the ecological ones. After the understanding of the geological history and evolution of life on earth, it is now the present abiotic and biotic environment, the major ecological factors on short temporal and often fine spatial scales, which is focused on. Especially, geographers preferred this ecological concept to the historical concept.

The first and basic ecological approach (autecology) is concerned with relations between organisms and the abiotic complexes like climate, soil, relief forms, or abiotic factors such as light, temperature, water, and chemical and mechanical factors of their habitat. The most important factors affecting the large-scale distribution of plants and animals are climatic factors. Climate is generally considered as the basis for explaining biogeographical patterns since long-standing close relations between climatic parameters and the distribution of large vegetation units such as tropical savannas or boreal forests are known. Timberline studies especially underline these relations. On finer scales, soil chemistry and moisture levels, or mechanical disturbances like fire or avalanches may be more decisive. Autecologists always ask two questions. The first one concerns the quality and quantity of a chosen factor that affects the environment. Geographers often concentrate on this question whereas biologists prefer working on the second one. This concerns the ecological amplitude of plants or animals with respect to the chosen factor; for instance, temperature requirements for seed germination or availability of a minimum amount of water.

Today, the most important ecological factors affecting plant and animal life are certainly the manifold influences of man. As already pointed out in the chapter about historical biogeography, human impact on purpose or by chance often directly changed the close natural relations between organisms and their environment by changing site qualities as well as the genetic constellation of organisms. Man is regarded not only as an integral part of the global biocenosis but also as the ecologically dominant organism in it. Results of recent research prove that the role of man is still of increasing relevance for our future.

A second, more complex and more important approach of ecological biogeography is concerned with the relations between organisms (synecology). Already man's influences may be regarded as synecological processes. In general, synecology concerns all mutualistic relations (e.g., symbiosis, parasitism) and often most complex interactions between individuals or species of plants and animals including the important plant–animal interactions. Inter- and intraspecific competition as well as the responses of plants, animals, and their communities to every kind of stress have to be understood in order to explain distribution patterns. Competition can eliminate those species that are only poorly adapted to their environment and may determine which individuals will survive or fail. Some species may tolerate a broad range of stress factors and can survive; others are unable to colonize in the same situation.

The ecosystem concept, to organize the very complex topic of ecological interactions and functional

relations, which has been developed by geographers as well as by biologists, is a fundamental integrating concept. It shows the interactions between the living and non-living world and helps to understand the way in which the natural environment and its abiotic and biotic components operate. Here, the fluxes of energy, the cycling of nutrients, and the exchanges of information can be demonstrated. It is possible to give an overview on food chains and trophic levels and to show the participating producers, consuments, and destruents in the systems context. So far, the ecosystem concept quite often has been used for modeling ecological processes.

The term 'ecosystem' is also used for spatial entities but is not restricted to a certain scale. This concept can be adapted as well to a complete climatical zone as to the flowerhead of a thistle, where different insects struggle for the same resources. It is often utilized for lower levels of spatial and organizational hierarchies such as biotopes and ecotopes or populations and communities. The most important fact is that ecosystems are open systems. New members may move into such a system and may leave it. Their boundaries are not fixed; there are transitional zones (ecotones) between adjacent ecosystems, no sharp dividing lines.

Today, modern technical equipment and new statistical and mathematical methods for collecting and analyzing data from the field as well as from the laboratories lead to a growing knowledge about ecological relations (e.g., competition, stress reaction, plant–animal interaction) and prove that the ecosystem is still the most valuable conceptional framework in biogeography.

3. *Aspects of Regional Biogeography: Classification and Ordination*

The classification of natural regions has long been an important objective for physical geographers. Decisive criteria for these classifications at a broad scale are climate, soils, and vegetation and their zonal distribution. Biogeography early became the discipline that was concerned with the large world vegetation types. The biosphere was divided into three-dimensional bioms or the large vegetation zones closely related to climate such as 'tropical rain forests' or 'boreal coniferous forests.' Biologists sometimes followed another hierarchical concept that they related to spatial scales, too: the concept of individuals, species, populations, communities, and ecosystems. Here, concepts are proposed, which are commonly accepted and widely used, bearing in mind that the chosen scale is largely responsible for interpretation and explanation of spatial patterns of organisms.

Since the nineteenth century, botanists and geographers contributed to a regional classification that is based on the distribution of species, a so-called floristic classification. The distribution area of a species and of others, which occupy the same or nearly the same area, is regarded as a biogeographical unit. Such a unit may be called, e.g., 'alpine,' 'Atlantic,' 'sub-Mediterranean.' In a hierarchical order these units (area types) form provinces, regions, and finally plant kingdoms, the Holarctic, palaeotropic, Neotropic, Australian, capensian, and Antarctic plant kingdoms. The plant kingdoms, especially, reflect the geological development more than the recent ecological background.

Plant sociology produced a classification on the basis of the composition of plant species, too, but these are ecologically clearly related to one another. The basic unit is the plant association. Species living together in these associations need more or less the same light, temperature, water, and nutrient supply and arrange themselves according to their competitive ability. Associations are characterized by a significant species group combination and character, and differential species, respectively. According to the floristic composition and the environmental conditions, associations are grouped to higher elements in the plant sociological hierarchy, e.g., to alliances and to classes. Examples of the latter are the rock, grassland, or swamp communities of Central Europe.

Physiognomy is the keyword for a vegetation classification that is based on plant life forms. Here, morphological structural characteristics of plants are more important than their taxonomy. Life forms—annuals, perennials, xerophytes, mesophytes—or the components of the traditional concept with phanerophytes, chamaephytes, hemikryptophytes, geophytes, and therophytes, have a clear ecological background which is proved by convergent traits, e.g., succulence, hairy leaves, thin bark. This approach is particularly useful because it facilitates the identification of functional relations between plants and animals. The vegetation units with a characteristic composition of life forms are called formations, such as deserts, forests, and grasslands, dominated by certain life forms (and not species) such as therophytes, grasses, or trees. The advantage of such a classification is obviously the possibility to compare vegetation units under the same macroclimatological conditions from continent to continent, without looking at species composition, and to understand better the functional meaning of morphological plant and vegetation structures, for example, leaf characteristics or stratification.

There is at least one complete method other than the traditional classifications of vegetation as a means for better relating and understanding plant species and their environment: the ordination. Plant sociology and more recently sigma sociology (analyses of vegetation complexes) have mainly developed in Central Europe, ordination—following the continuum concept—like other numerical methods developed in North America. Classification adopts discontinuous models and presumes that discrete units exist. Ordination is a

model for continuous vegetation distribution and needs gradient analysis. The results of an ordination are not discrete units but distribution trends. Today, the character and sharpness of boundaries between vegetation units and the stochastic aspects of plant and animal distribution are intensely discussed.

4. General Rules and Models in Biogeography

Biogeography is not only concerned with historical or ecological questions in particular studies but also with general rules and models, which provide a general framework of understanding patterns and processes, that may later be used for prognostic purposes. One such long-standing generalization is Buffon's law, which says that different regions of the earth that have the same ecological conditions are nevertheless inhabited by different species of plants and animals. Certain biogeographical rules are well known, such as Bergmann's rule, which says that animal species from the same genus are bigger in high latitudes than in lower ones. Allen's rule points out that for the same examples, the extremities in colder regions are smaller than in warmer. And according to Averill's rule, the wings of birds in higher latitudes are narrower than those of birds in lower latitudes. More recently, general rules like the latitudinal diversity gradient or models like the Sloss model ('single large or several small' areas for natural conservation) are discussed.

A special field of research has been dedicated to island biogeography. Life on islands played a vital part in Darwin's ideas about natural selection and adaptive radiation of birds. More recently, a model or theory of island biogeography has been proposed by McArthur and Wilson (1963). This theory says that on each island a state of dynamic equilibrium between species immigration and extinction exists and that the present species number depends largely on island size and distance of the island to the next continent or nearby island. The theory of island biogeography has been very stimulating for research and further modeling, although the results of many studies did not support the predicted relationships. The individual ecological abilities and needs of plant and animal species have been largely neglected as well as the fact that, for example vegetation development is not static and that it is important to choose the right moment for immigration in order to compete successfully with other plant species. Just counting species and calculating species turnover seem to be simple. To reach the main objective of biogeography, the understanding of pattern and processes requires a more comprehensive approach. For such an approach, the existing knowledge and the availability of sound data, however, does not justify mathematical sophistication so much today. It is more important to strengthen the empirical basis.

5. Applied Biogeography

During recent decades there has been a growing awareness of human impact on ecosystems and especially on vegetation. Man not only altered but also often destroyed the plant cover; his activities also had many negative consequences for site conditions. Looking for solutions to restore the plant cover and re-stabilize the whole ecosystem is one example for research in applied biogeography. In this case, plants or the vegetation cover as a whole are regarded as an important ecosystem element. If this element has been destroyed or altered, consequences arise for many other elements of the system, e.g., the soil properties or microclimatological conditions. The most important fields of applied research in this respect are almost all types of environmental degradation (e.g., soil erosion, desertification). Detailed afforestation planning—not necessarily with exotic tree species—can be a result of this research.

Another field for applied research in biogeography is linked with the idea that all biota are humankind's most valuable resource on earth. There is an urgent need to develop plans for a sustainable use of these renewable or non-renewable resources in agriculture, including range management and forestry. Furthermore, resources are both biomass and genetic resources. The topics dealt with thus relate to either land use or protection of plants and animals; and maintenance of biological diversity. Biogeographers contributed a lot, especially in natural conservation planning of reserves of the biosphere as well as of smaller areas of protection, to develop not only special management concepts but also general rules. In this context, the study of rare plants is as important as that of introduced and invasive species.

A last important subject of applied biogeography concerns bioindication. Plants, animals, and microorganisms can be regarded as simple instruments, which show by their mere presence or absence a certain environmental quality or the stress any kind of contamination has on a certain environment. Organisms as indicators may have advantages over chemical analysis, because they indicate more average conditions. Bioindication is already very useful to characterize more or less natural conditions of ecosystems. It has, nevertheless, growing importance in cases of environmental pollution in industrial areas, towns, and in aquatic ecosystems. And bioindication queried earlier—once the chosen organisms have been calibrated with the polluting substances—is certainly a valuable instrument in those countries where more sophisticated data collecting is too expensive.

Biographical Methodology: Psychological Perspectives

Lytton Strachey, the eminent artist of biography, once wryly observed: 'it is perhaps as difficult to write a good life as to live one.' Expressing the same opinion more forcefully, Virginia Woolf remarked of biographical art: 'Writing lives is the devil' (quoted in Edel 1984, p. 17). Scientific counterparts express similar ambivalence toward the biographical enterprise (Mc Adams and West 1997). Indeed, many would concur that 'near anarchy' captures the current state of narrative analysis, including that of biography.

Ironically, the greatest ambivalence may characterize personologists, a subgroup of personality psychologists, who draw systematically from psychological theory and research to write lives. Most personologists continue to endorse the core belief that the 'real business of psychology' concerns the long unit—that is, 'the life cycle of a single individual' (Murray et al. 1938, p. 39)—in principle.

The call has sounded yet again to resume and refine the personological tradition of Henry Murray in practice (McAdams and West 1997). Although personology has progressed considerably since 1990 (Craik 1997, Runyan 1997), scientific writing of individual lives has not kept pace (e.g., McAdams and West 1997, Nasby and Read 1997). Shoda and Mischel (1996) astutely note: 'generally not until the end of papers [do] researchers express the conviction that what we really need now is to return to the basic mission of the field, and to return to the commitment to understand intra-individual functioning and dynamics' (1996, pp. 414–15).

The personological study of life narratives has simply not grown to the potential that methodological and theoretical advances permit. We now hear more and more about the biographical study of individual lives, but only a handful of personologists have actually heeded the call to produce scientific biographies of particular individuals (e.g., Nasby and Read 1997).

A nagging irony arises here, because understanding individual lives constitutes one of the four tasks of personality psychology (Runyan 1997). Nevertheless, the field has not witnessed the optimal use of the scientific biography (e.g., McAdams and West 1997). Despite exhortations to write lives, ambivalence continues to stifle implementation of scientific biography (McAdams and West 1997, Rosenwald 1988). Why, then, does the slim and unacceptable ratio of heat to light persist?

A partial answer simply reflects the fact that academic training to pursue biographical science remains limited (Nasby and Read 1997), which almost further begs the question. Similarly, personality psychology receives a less-than-generous share of available funding, personology even less. Not surprisingly, therefore, the field of personality continues to emphasize individual and group differences, where the limited funds disproportionately flow. Moreover, detailed study of an individual life poses daunting challenges, technical as well as conceptual.

Considering the specific challenges to writing a life from the perspective of personology may also clarify the impediments that other disciplines confront when conducting biography from a scientific vantage point. The potential generalizability of the current analysis owes much to the strategic location of personality (Mayer 1998) vis-à-vis adjoining disciplines (e.g., anthropology, history, psychological subfields other than personology, sociology, and even neurology). Insights from personology may also elucidate the difficulties of biographical endeavors that follow the artistic, rather than scientific, path. A detailed characterization and analysis of the problem follows.

More generally, the problem consists of multiple elements, running the gamut from data, theory, and methodology, to the unit of analysis and the reward structure of academic institutions. However accurate, colorful allusions to demonic impediment and 'near anarchy' serve to identify, but not overcome, the problem. The remainder of this article, therefore, examines the nature and scope of each challenge more extensively. Ultimately, articulating how best to write a life first requires careful examination of the problematic details—where, after all, the devil resides.

1. Nature and Scope of the Problem

1.1 Data

When studying an individual life, data often pose the central difficulty. The challenges of data can prevent a

biographical investigation from exiting the starting gate. Most agree that the single-case study requires a wealth and variety of data, but investigators must typically confront inaccessibility of subjects. To complete the task, psychobiographers often can only consult archival material; the investigator cannot obtain data through interviews or assessments, essentially reducing the project to psychobiography. Given inadequate data, production of psychobiography almost inevitably falls prey to projection and other varieties of countertransference. The consequences of inadequate data partially explain the multiplicity of embarrassing work that plagues the genre.

Biographies that permit creative investigation *in vivo* typically include clinical cases that suffer from other limitations, most notably a pathological focus. Furthermore, studying a life ideally means conducting an investigation over time, which poses practical difficulties that intimidate all too many. Often, investigators come no closer to the ideal than studying college sophomores over a semester.

Recent developments, however, illustrate that the task of gathering adequate data, although difficult, need no longer derail a biographical project. For example, personologists have outlined guidelines according to which a biographer can extract case data from narrative sources and reveal the underlying order therein. Personologists have also profitably applied coding schemes to analyze the content of narrative material. For example, personologists have devised coding systems that yield quantitative measures of important motives, including intimacy, as well as achievement, power, and affiliation-intimacy, and the broader concerns of identity, intimacy, and generativity. One may also reliably evaluate affect or affective tone through ratings of narrative material.

Applying each of the aforementioned techniques, Nasby and Read (1997) reported an integrative case study of the solo circumnavigator, Dodge Morgan. In addition, the investigators applied concomitant time series analysis (CTSA) to the quantitative measures of motives, broader concerns, and affect as well as performance measures of daily progress. CTSA permitted detection, modeling, and removal of statistical artifacts (long-term trends, cycles, and serial dependencies) from each variable over time. Once decomposed, accurate calculation of cross-correlation functions that assessed synchronous and lagged relations between variables occurred, which permitted valid statistical tests of hypotheses about the circumnavigator's functioning throughout the life-defining event of the voyage.

Similarly, Simonton (1998) investigated 'Mad' King George of England, first performing content analyses of the historical record to obtain quantitative measures of stress and health, and then decomposing each series before finally calculating the cross-correlations (synchronous and lagged) between the multiple indices of stress and health. Of considerable importance, the 'historiometric' approach illustrates that a biographer can often derive quantitative indices from the qualitative or narrative sources of information that dominate historical records, and then apply sophisticated statistical techniques, including but not restricted to CTSA, to test explicit hypotheses about historical figures.

1.2 Theory

Many psychologists have now accepted the premise that clarification and elaboration of theory best justifies conducting the case study (and, through extension, the biography). A principal responsibility of psychologists entails generating and testing increasingly powerful theoretical insights. Although theory development and testing may require sustained activities that extend beyond the confines of the case study or the biography, either proves well suited to clarify theory.

The detail and depth of the biography and the case study do much to promote understanding of theoretical foundations. Indeed, the application of theory to the individual means that an individual life becomes text that one must interpret. Inevitably, any comprehensive fund of biographical data will reveal discrepancies from theoretical expectations. One must not avoid or discard inconsistencies, which, disturbingly, occurs often. Effectively, the latter practice distorts evidence and wastes information. Instead, discrepancies and inconsistencies provide opportunities—not only to locate where the theoretical foundation contains cracks, but also to integrate through a higher-order synthesis or dialectic.

More important, but rarely appreciated among biographers, the dividends of applying multiple theories to the same case deserve far more attention. For example, Nasby and Read (1997) illustrated the process of applying two diverse theoretical perspectives—the Five Factor and Life Story Models—to multiple sources of data, qualitative as well as quantitative. In addition, Wiggins (1997), who provided commentary, reinterpreted some of the case data from a third perspective—that of the Interpersonal Circumplex Model. The multiple theories served the role of multiple methods (McAdams and West 1997), each providing a unique perspective from which to construe data from the case. Considering the three accounts jointly, a complex and coherent portrait of the circumnavigator emerged, one far richer than would have resulted from the application of a single perspective.

In addition, applying multiple theories provided explicit bases of deriving hypotheses, some complementary, others contradictory. The approach forced the researchers to consider the full range of available

evidence supporting or refuting each hypothesis, 'rather than foreclosing on a conceptually pleasing but incomplete or possibly erroneous understanding' (Mc Adams and West 1997, p. 758).

1.3 Methodology

That no definitive methodology exists to design and conduct biographical research has led critics to conclude that such endeavors lack scientific rigor. Runyan (1997) has repeatedly and effectively, however, countered each criticism. From an alternative perspective, the richness of methodological choices simply creates distinctive technical challenges (e.g., Nasby and Read 1997). Any biographer can misuse any method; but the expanded degrees of freedom that ensue from the complexity of the endeavor and the flexibility of methods gives single-case studies, including biographies, 'probing and testing power' that can validly disclose unanticipated effects that more structured approaches might very well miss.

Moreover, one can recast the methodological concerns to reveal strengths of the biographical approach. Through integration, the methodological concerns point to utilizing multiple sources of data and multiple strategies of measurement, multi-operationalizing multiple constructs, analyzing the data across varying levels of abstraction, and including both qualitative and quantitative methods (e.g., McAdams and West 1997, Nasby and Read 1997).

2. The Long Unit of Analysis: The Whole Person Over a Lifetime

The underachievement that characterizes the personological agenda of studying the whole person ensues also from improperly appreciating the implications of adopting the *long unit* (Murray et al. 1938). Confusing the two meanings of the rallying cry, one methodological, one conceptual, may have hindered identification of the source of difficulty. The methodological meaning concerns the comprehensive assessment of personality. Few doubt that comprehensive assessment should remain the aspiration of the personologist, even though '[c]apturing the 'whole personality' remains beyond our grasp' (Craik 1997, p. 1095).

The trouble can be accorded to the conceptual meaning. Allport (1937) observed a long while ago that (p. 343):

> [Holistic conceptions of personality] do little more than assert personality to be an 'Indivisible Whole,' 'a total integrated pattern of behavior,' … Personality … is like a symphony. Granted; but does not the comprehension of symphonic unity come only though an understanding of the articulate weaving of motifs, movements, bridge-passages, modulation, contrasts, and codas? Nothing but empty and vague adjectives can be used to characterize the work as a whole. If a totality is not articulated, it is likely to be an incomprehensible blur; it can then be extolled, but not understood.

No less germane today, the critique that Allport (1937) marshaled suggests a solution. Craik (1997), for example, refers to the current revival of the personality system framework (Mayer 1998, Nasby and Read 1997, Shoda and Mischel 1996). Unlike previous efforts, the current revival appreciates that one cannot study the undifferentiated whole. Studying a complex system (e.g., a person) first requires systematically engaging the task of differentiation, a task that specifies both the components of the system and the organization of the components.

Mayer (1998) has considerably advanced the initial and necessary process of differentiation, locating personality amongst adjoining systems (biological, situational, sociological). More specifically, Mayer presents a structural model that not only specifies the components of a personality system, but also accommodates all four tasks of personality psychology (Runyan 1997): general theory, individual and group differences, specific processes and behavior, and individual persons and lives. The structural model achieves inclusive and integrative power through a variety of means, which bridge data, theory, and methodology.

The structural model offers a preliminary specification of how systemic components relate to one another statically. Refining the model, however, will require a treatment of systemic organization from a dynamic perspective (e.g., external control, distributed control, hierarchical control). Articulating how the components function jointly over time awaits further efforts. My colleagues and I have initiated development of a metaperspective that takes us beyond the metaphor of a systems framework to a formal (mathematical) implementation. Interestingly, formalizing a dynamic systems model returns personology full circle to the long unit (Murray et al. 1938): the preferred means of examining and testing a dynamic model tracks the functioning of an individual system (person) over time.

3. Reward and Value Structure of Academic Institutions

The technical challenges of data, theory, and methodology as well as the conceptual obstacles of espousing and pursuing the long unit of 'the whole person' share a common denominator. Each identifies an internal source of impediment to writing a life. Internal factors explain the difficulties of optimally pursuing artistic biography. Beyond internal impediments, however, the institutional context of pursuing biography scientifically presents additional hurdles.

Personality psychologists continue to pay lip service to the personological agenda in principle, and avoid accepting the challenge in practice. Rosenwald (1988)

remarked, 'when tendered an invitation to examine any life in detail, the psychologist usually declines … the case study has come to be regarded as a scholar's trap' (p. 239). Along parallel lines, Carlson (1971) chided much earlier that: 'Personality psychology would seem to be paying an exorbitant price in potential knowledge for the security afforded by preserving norms of convenience and methodological orthodoxy' (p. 207). The situation has not appreciably changed.

Summarizing the current state of personality research, Endler and Speer (1998) concluded that (p. 667):

> Success in an academic climate seems to involve the adoption of methods aimed at publishing a maximum number of articles in a minimum amount of time … [T]he choice of research method in our field is more the product of the academic marketplace than of scientific considerations … The question remains as to whether these constraints have served to compromise the overall quality and scientific contributions of our discipline.

Institutional standards and values of academic reward set stringent criteria that emphasize quantity and speed. Here the internal factors and external factors converge (or collide). Accordingly, most psychologists skirt the 'scholar's trap' of the case study and the scientific biography, opting instead for cost- and time-efficient investigations of group and individual differences or specific processes and classes of behavior.

Realistically, the prospects of reforming university philosophy range between slim and none. A few, therefore, have sought to establish climates more hospitable to the personological agenda. McAdams, for example, has established the Foley Center for the Study of Lives, 'a mini-oasis of personology in the Midwest dust bowl.' (from a personal communication, March 7, 2000). The Foley Center, which exclusively pursues a personological agenda through the financial support of the Foley Family Foundation, nevertheless operates under the auspices of a traditional university. Therefore, the center does not replace the reward structure of mainstream academia. My colleagues and I have adopted a different tack, searching beyond the confines of traditional academia to establish, also through private funding, the California Personological Research Institute (CaPRI). The mission of CaPRI exclusively concerns the personological study of lives, and the reward structure matches the core purpose of the institution accordingly.

4. Conclusion

Through the current analysis, CaPRI has begun to develop a biographical/personological study, one that draws inclusive and integrative strength from the application of dynamic systems theory. The metaperspective may bring personology closer to the goal of more efficiently and satisfactorily addressing the technical challenges to scientific biography that pertain to data, theory, and methodology as well as the conceptual obstacles that surround the adoption of the long unit (Murray et al. 1938). Overcoming institutional obstacles may await the establishment of biographical or personological centers that follow ad hoc missions and reward investigators accordingly.

The current analysis may help to overcome some ambivalence among personologists, thereby generating more heat relative to light, and should extend beyond the boundaries of personology and adjoining disciplines to include biographical artistry. We may never remove the devil from either the art or the science of biography, but we may stand a better chance of overcoming the technical and conceptual impediments to writing a life well. Although the odds of living a good life will remain unchanged, the odds of writing one could improve substantially.

Biography and Society

In 1959 the American sociologist C. Wright Mills wrote in *The Sociological Imagination*: 'Social science deals with problems of biography, of history, and of their intersections within social structures,' adding that 'these three—biography, history, society—are the coordinate points of the proper study of man' (Mills 1959). Indeed in disciplines such as history or ethnography the association between 'biography' and 'society' is taken for granted. Neither historians nor ethnographers need to be reminded that the societies they study have an history which extends up to the present times; nor that each of their members is a 'singular universal' (Sartre 1960), differently embedded in social structures and historical time, but all participating in the constant remaking of their own society.

Sociology, however, as an *institution*, with shared beliefs handed down to younger cohorts through textbooks, and with norms of scientificity, seems to forget this again and again. Within the short history of empirical (sociological) research scholars have organized the more or less systematic production of autobiographies and more recently, of recorded life stories (the 'biographical method'). But the legitimacy of such date has been recurrently denied. Not so long ago, for example, Bourdieu (1986) argued that life history had been 'smuggled' from common sense into sociology. He was echoing a long line of earlier similar statements—the 'common sense' view of sociology as institution—denigrating life stories as subjective and therefore(?), unreliable, data. The dramatic changes of the biographical method's status in the history of empirical sociology cannot be understood without taking into account this background of diffuse hostility. We shall return to this point in the discussion below, after a recall of the main events of the biographical method's history.

1. *A Short History of the Biographical Method in Sociology*

In the history of sociology the use of autobiographies written on request coincides with the beginnings of empirical research at the University of Chicago. The authors of the first major work, *The Polish Peasant in Europe and America* (Thomas and Znaniecki 1918–1920), went as far as stating that the life history provides the best kind of sociological material. Indeed its greatest virtue is to provide access to and knowledge about how people in a given situation; experience that situation (perceive it, evaluate it, feel about it) within the totality of their own life experience; and how they react, interact and act in its context.

The life history allows the expression of lived experience, of the meanings it takes (in retrospect) for the person; of the values and attitudes that shape such subjective meanings; of the affects that go with it; of motives for action. Such an 'insider's view' is rich in hints, clues and insights to the outsider (the researcher) who is trying to understand situations and processes, social milieus and their inner dynamics. While Thomas and Znaniecki used mostly sets of letters exchanged between emigrants and their families back home, they also commissioned an extensive autobiography of a young Polish emigrant to Chicago; finding it so interesting that they published it as one of the four volumes of their work, commenting it by way of numerous footnotes.

While this autobiography itself reads as well today as it did in the 1920s, Thomas and Znaniecki's footnotes, however, sound dated. The authors' sociological theorizing of the processes of cultural disorganization and reorganization which necessarily accompany flows of emigration/immigration were remarkably innovative and proved very influential; but in retrospect they seem to stem much more from the authors' general knowledge of such processes than from the personal documents they used.

In the 1920s and 1930s several Chicago scholars trained by Robert E. Park, who had taken over from Thomas, produced a stream of very valuable studies on various marginal groups living in Chicago. Some of the best ones used autobiographies as one of their main tools (see especially Shaw 1927; for an historical account see Bennett 1981). However a consistent methodological paradigm did not emerge until Lindesmith's (1947) study of heroin addicts. By then it was too late. A new method, the survey, was raising considerable hopes, monopolizing attention, scientific legitimacy and research funds. So-called (by contrast)

'qualitative' methods, including case histories were marginalized. If part of the spirit of the Chicago School survived in symbolic interactionism it was with a focus on direct observation of interaction, which also meant losing sight of the historical, societal and biographical roots of social action.

While after World War II the life history was disappearing from the scene of American sociology, a major work was in the making in American anthropology: Oscar Lewis's *The Children of Sanchez* (1961). Before Lewis, American anthropology had already generated a long list of published life histories, some of them great classics (such as Simmons's *Sun Chief* 1942). To collect the information, however, researchers had either been taking notes while interviewing, or—in Simmons's case—had asked a literate Indian, Don Talayesva, to write his own autobiography. The technological innovation of the tape recorder now allowed researchers to record verbatim the speech of persons who could not write, thus opening immense possibilities.

Lewis was the first to fully use the new technique. Indeed *The Children of Sanchez* became an instant best-seller worldwide. The body of the book is made of the life stories of four siblings who are growing up in a deprived area of Mexico City. Their young lives are already full of dramas and emotion, of adventures and experiences, which they narrate as if they were all born storytellers. Middle-class readers all over the world felt that for the first time they were listening directly to the fresh voices of persons they would normally never meet; persons very distant in geographical and social terms, but who appeared very close psychologically. Reading this book in Paris in 1962, de Beauvoir (1965) (see *Beauvoir, Simone de (1908–86)*) wondered aloud whether there was still some room for fiction writers, since now the characters of Balzac, Dickens, and Zola could speak by themselves. (It must be added, however, that the vividness of *The Children of Sanchez's* narratives owes much, perhaps not in content but certainly in form, to the highly skilled rewriting of Lewis.)

It is in Western Europe that the life history reappeared, partly through the influence of Lewis's volume, in the 1970s. The Italian scholar Franco Ferrarotti was one of the first postwar sociologists to realize that what ordinary people have to say on the basis of their own life experience is worth listening to. His *Storia e storie di vita* (History and life histories) is an all-out effort, deeply inspired by Sartre's humanism, to identify what he calls the *specificity* of the biographical method (Ferrarotti 1981; see also his paper in Bertaux 1981).

In France Catani (1982) inspired by the anthropologist Louis Dumont, was the first to try using one single life history to capture the whole 'cultural model' of a given culture. This was nothing less than the French cultural model, which Catani, as an Italian, was looking at from the outside. His *Tante Suzanne* contains the verbatim transcription of the six interviews through which an aging woman, Suzanne Mazé, tells him her life story. Born in a rural environment, she had worked most of her life as a worker in small shops, had married an artisan and retired as a petty-bourgeois: a rather typical trajectory for her generation. Catani, a precursor of current 'narrativism,' analyses both content and form of her interviews: the *content* yields her core values, which can plausibly be extended to the social milieus of which she had been part. The recurrent *forms* her narrative takes up give access to another kind of implicit meanings. The latter may also be embodied in objects, not words: for instance in her garden Suzanne has purposefully planted the 'same' trees as those which adorned the castle's park where her mother worked as servant when herself was a child.

Another important work is by Abdel Malek Sayad (1991) on the emigration of Kabyles from Algerian villages to French cities in the 1950s and 1960s. Sayad interviewed dozens of such emigrants and published some of their life stories, which—after translation and no doubt some rewriting, as in Lewis's case–are so self-expressive they hardly need commentary. His analysis addresses other levels of reality including directly collective ones, such as the complex chain of myths, dreams, disillusions, and lies through which emigration becomes a self-sustaining process; the secret complicity of French and Algerian governments in organizing such migration flows to the benefit of both States; the collective dilemma of living between two societies while belonging to neither; and the silent drama of ageing emigrants when realizing that their children, growing up in France, are becoming alien to them. While resting on a limited number of cases, Sayad's sociologically dense descriptions of the processes accompanying emigration sound very convincing, all the more so because he was himself part and parcel of the process he was studying.

Bertaux's work exemplifies a third style of research using life stories, the one focusing on a social world: in his case French artisanal bakery (Bertaux and Bertaux-Wiame 1981). His initial focus on the structural relationships of production between artisans and bakers, on their consequences on everyday life and his subjects' respective life chances, came from Marx and Bourdieu; but his decision to collect life stories of aging or retired bakery workers, of bakers and bakers' wives, was inspired by *The Children of Sanchez*. This unlikely combination resulted in the discovery of the hidden mechanisms through which the supposedly obsolete artisanal form of production in France had successfully resisted the recurrent attempts by industrial bakeries to take over the bread market (Bertaux and Bertaux-Wiame 1981). Coupled with data such as historical documents, juridical regulations, and (scarce) statistics, the life stories gave a historical depth and biographical thickness to the sociological inquiry. Also the recurrence, from one life story to the

next, of descriptions of the same situations and actions led the authors to identify, via the phenomenon of 'saturation' emerging after a limited number of case studies, a methodological principle allowing them to put forward plausible generalizations. Saturation has thus become, for case studies, the equivalent of the representative sample for survey research.

Bertaux also took the initiative to organize an *ad hoc* group on life history within the program of the 1978 World Congress of Sociology in Uppsala; a group to which an unexpectedly high number of sociologists turned up. This eventually led to the creation of the Biography and Society Research committee within the International Sociological Association and contributed to the return of life history as a legitimate sociological method. The 20 years that followed have seen a flowering of research projects using this method, particularly in Germany: the German Sociological Association has a *Biographieforschung* Research Committee. Some of its regular debates are devoted to the study of life course, focusing on the issue–framed by Martin Kohli—of whether 'biography' is presently becoming more institutionalized, or less (See *Drugs: International Aspects*; *Age, Sociology of*; *Disability: Sociological Aspects*; *Age Policy*).

For a reflexive overview of recent trends in Germany see Apitzsch and Inowlocki 2000. The case history of whole families, an extension of the biographical method, has also been used by some European scholars in researching specific social mobility processes—for example, on what happened to Russian families expropriated by the October Revolution, or on the very differing fates of descendants of poor peasants and craftsmen in three neighbouring villages in Tuscany: the aim of such research projects being to show that the study of social mobility, long the exclusive province of survey research, can benefit from research based on case histories (Bertaux and Thompson 1997).

One recent trend in Europe is the comparative study across Western Europe of poverty and precariousness by means of case studies and case histories (Chamberlayne et al. 2000, chap. 18). Together with the very dynamic field of European comparative research on Welfare States (see *Welfare*), such studies provide 'views from below.' They usefully complement the statistical surveys of poverty research, which prove inadequate in capturing the complexity of local situations and, especially, the survival tactics and strategies of individuals and households confronted with the precariousness of their conditions of life.

2. Discussion

Contemporary sociology as an institution manifests a reluctance to grant full status to the use of life stories. Why is it so? A short semantic analysis of the expression 'Biography and Society' allows to get at the root of the issue. When the 'revival' of the biographical method took place in the early 1980s, sociology as institution was organized around the hegemony of survey research and, more generally, of a self-conception which borrowed its core elements from the natural sciences and the hypothetico-deductive method (the considerable efficiency of survey research is not to be denied, but the structural similarity between sociology and natural sciences is highly questionable, if only because the controlled experiment, the core method of natural sciences, is out of question for sociology). At the 1978 World Congress of Sociology, an *ad hoc* group on 'the individual and society' would have attracted few sociologists and aroused no expectations. But 'life history' brought to the fore elements which had been forgotten or repressed by the 'natural science' conception of sociology. While 'the individual' is a generic term, 'life history' denotes the *singularity* of destinies: 'biography' in that sense is the biography of one given singular person who exists somewhere in time and space, a person with a gender and embedded in a context.

Biography also immediately refers to time, both biographical time and historical time, and all levels of intermediate temporalities. Biography also speaks, in Sartre's words (1960), of 'what people do of what has been done of them,' hence of action (which radically distinguishes the world of human affairs from the world of inanimate objects). Finally biography includes the sphere of meaning, which Weber has shown to be constitutive of action. Singularity, historicity, action, and meaning (not to mention emotions and feelings) are part of social-historical reality, as Dilthey recognized (and theorized about) long ago; but they do not fit with the view of sociology as a natural science in the making, the view which has long been the core legitimacy resource of the institution of sociology.

Biography: Historical

1. Definition and Parameters

Historical biography (from the Greek *grafein*: writing; *bios*: life; *historia*: inquiry, knowledge) is an individual, historical life in writing, written by someone from a later era. The historical biography as scholarly biography manifests a somewhat contradictory predicament inasmuch as biography places the individual at the center, whereas history focuses on common structures and events. Historical biography is a genre which is characterized by variety and diversity, both in historical outlook and methodology. This article will present the Western, historical biography. In terms of genre, historical biography verges on autobiography, literary biography, the traditional tale, and the biographical novel. In specialist professional terms, the historical biography verges on psychology, sociology, anthropology, history, and literature. In terms of subject, the historical biography is open to everyone and anyone, statesmen and farmers, generals and artists, philosophers and scientists, heroes and villains, women and men. As regards time-scale, historical biography has existed since the first century AD and up to the threshold of the second millennium. All this makes the genre both extremely complex and deeply fascinating. Historical biography diverges from popular biography's interest in the private lives of the famous, but shares the popular genre's interest for getting behind the myth. It diverges from fiction, but shares genre with the modern novel, which has long since broken with linear narrative in recognition that the passage of real life is fragmented.

2. Two Thousand Years of the Historical Biography: Changing Focus

Since antiquity Western historical biography has been regarded as a branch of historiography and has developed from being an ethical-humanistic genre to being a genre consisting of various methodologies, forms, and styles within twentieth-century specialized scholarship. As a genre, biography in the West is considered to have been established by the Greek Plutarch, who published the comparative lives of Greek and Roman statesmen *Bioi Parallelloi* (AD 125). This work, together with Tacitus' *De vita Agricolae* (AD 98) and Diogenes Laërtius' biographies of Greek philosophers (3rd century AD), characterized what has been called *the classical biography*, built upon the fundamental principles of ethics: the central figures were either commended for having fulfilled their duty or censured for falling into the trap of ambition or arrogance. The classical biography-type from antiquity was maintained throughout the Middle Ages. A sidelong consideration must here be given to China's great historian Sima Qian, who, during the period of classical antiquity, developed a biographical form which belongs to a much later Western epoch: *Shiji* (185–45 BC). This work contains biographies, not just of eminent statesmen and soldiers, but also of individuals such as fortune-tellers, courtiers, and murderers. A completely modern approach, in today's terms, was demonstrated by Sima Qian's contemporary, the poet and literary historian Liu Xiang, whose work *Lienü zhuan* (79–78 BC) shows that female personalities in China were already at this stage considered worthy of biographical study.

In accordance with the requirements of the church and spiritual needs, the Middle Ages saw the development of the martyr biography (e.g. John Foxe's *Book of Martyrs*, 1563) or lives of holy men and women, known as hagiographies. The purpose was didactic and the central character was presented as a model of Christian propriety and public virtue: God's creation was portrayed as an individual who, in the course of a lifetime, developed as a moral example to others, or whose destiny was first fulfilled in death. This biographical model was also used for biographies of princes and emperors, with Einhard's *Vita Caroli*

Magni (829) frequently cited as the most important. But until twentieth-century medievalists began producing historical biographies, the Middle Ages essentially lay in biographical darkness. History, seen as the contemporary environment, was of no interest in the Middle Ages, unless contributing to an insight into the central figure's moral attributes.

The approach to historical biography changed during the Italian Renaissance, a change which continued further afield from the seventeenth up to the nineteenth century. This type of biography has been called *romantic-linear development history* and developed from Boccaccio's sense for the specific in *Vita di Dante Alighieri* (1354–5) to a glorification of brilliant individualities in connection with the much later liberal individualism in society. Biographical literature was so extensive in the nineteenth century that E. M. Ottinger's (1854) bibliography of biographical literature was only rudimentary, even though it was wide-ranging. From the turn of that century, James Boswell's *Life of Samuel Johnson* (1791) is still singled out as the pioneering biography of the era, as it was based on empirical material in the form of letters, private papers, conversations, interviews, and personal observation of Samuel Johnson's comportment. This was the first biography to construct a nuanced, candid personality. In the historical biography of the time, the history of human achievement was fundamentally the story of imposing male heroes (e.g., Thomas Carlyle 1841). It was still the exceptional person and the developmental process which characterized the 'life-and-letters' biography at the end of the nineteenth century (e.g., Dilthey 1870, Grimm 1873). Even though ideas from the community at large were incorporated into the biographies via reference to letters, there was no trace of historical reflection on the individual and society.

The modern life story, as twentieth-century historical biography has been called, came about as the result of the crisis for humanism, Christianity, and rationalism which followed in the wake of Darwinism and psychoanalysis as it developed during the twentieth century. This category of biography displays the following characteristics: (a) a multitude of biographical methodologies evolved; (b) the number of published historical biographies increased; (c) historical–biographical literature as a genre became broader, with the emergence of the 'life-and-times' biography in which the individual is presented in the light of contemporary society; (d) male heads of state were, with a few exceptions, the focus of interest throughout the century; (e) biographical critique and the methodology debate intensified at regular intervals, but were not carried out systematically; (f) a new aspect was incorporated into the genre—demythologization, unmasking; (g) historical biography was influenced by both academics and artists. Serious biographical literature thus covered the entire spectrum from not very accessible treatises to stylistically inviting reading.

The sociological and historical professions regarded the biography critically throughout the century. As early as 1898, G. V. Plekhanov published a short tract in which he called to account the perception of the imposing personality as being the only driving force of history and at the same time proposed the dynamics between personality and society as historical transformation factor (Plekhanov 1898). He maintained that an imposing personality only had historical significance if the person in question was possessed of attributes which were necessary at that specific point in history and which gave historical impact to this particular talent. This observation has had profound repercussions for historians' development of the historical biography. Sociologists have used historical biography as methodology in a qualitative analysis of the significance of subjective experience for social reality. Pioneers in this respect were F. Znaniecki and W. Thomas (1918–20) who presented the individual as both creative and created in social evolution. This was followed up theoretically by the Italian sociologist Franco Ferrarotti (1983) who saw the individual as an active pivot in respect of the structures and history of society. Life histories have also been found interesting by late twentieth-century anthropologists wishing to promote subjective experience as a factor in the creation of personal identity (e.g., Crapanzano 1980). Anthropologists have considered biography to be a participant observator in a crosscultural and cross-epochal dialogue with the historical subject. It was the mentalities-historians who influenced the historical biography, especially the French Annales School and its preoccupation with personification and its hermeneutic, mentalities-historical studies. In her innovative study of sixteenth-century *Martin Guerre* (1983), Natalie Zemon Davis used new ideas, concepts and methodologies from anthropology, ethnography, and literary criticism to examine the dilemma of truth and doubt in historical research. Perception of a central figure became the result of a communicative process between two cultures and two people, not an objective description, as Giovanni Levi (1989) has also expressed it. Jean-Paul Sartre's concept of interaction between the life lived and the written text inspired the development of the dialectic biography. In Denmark, the historical figure within this tradition is interpreted as both the bearer of a cultural convention and a cultural agitator (Possing 1992). Sociologists, ethnologists, and historians have all used reminiscence, the oral-history tradition, and private papers as empirical source material through which to understand social action in a wider perspective as a confrontation with the positivist, Marxist, and structuralist thinking which has starved the biography of life. The objective has been to get behind the mythologization of major figures: 'A modern biographer may or may not choose to reveal the intimate, the amorous details of a life, but he must, if he is good at what he does, probe beneath its public, polished self' (Pachter 1979).

The modern life story in literary history was introduced with Lytton Strachey's *Eminent Victorians* (1918), which in the twentieth century came to play the same revolutionary role for historical biographers of all professions as Boswell had for biography in the eighteenth and nineteenth centuries: the introduction of the artistic, interpretative biography, given form via selection, concentration, and interpretation of the sources. The idea was to get behind the myth of the subject of the biography and it became possible to write biographies of both men and women. Leon Edel (1957) published the most influential post-war study of the biography, which he honed throughout his life's work under the motto: 'A writer of lives is allowed the imagination of form but not of fact' (Edel 1984). Owing to, among other factors, the achievement of Edel, literary biography became a well-established genre in its own right. Within this genre, the post-modernists Ira Bruce Nadel (1984) and William H. Epstein (1987) have sought for a poetics of biography by pointing out that definitive life portraits are not to be found.

3. *The Intellectual Position of the Historical Biography on the Eve of the New Millennium: Quest and Ambiguity*

Historical-sociological biographers and literary biographers began to draw a little closer together after the 1930s. This drawing together has continued throughout the rest of the century: literary-framed biography has become more scholarly-framed and historical-, sociological-, anthropological-, and natural science-framed biography has become more literary-framed in recognition that the more objective a biography is, the more lifeless and hollow it becomes (Kendall 1965, Madélenat 1984). On the other hand, the psycho-historical biography has not really established a firm footing within the humanities and the social sciences, primarily because it is generally based on extremely insubstantial source matter.

In the light of a quarter-century's interest in social- and mentalities-history and historical narrative, the historical biography, with its focus on the individual above community, class, and social group, has undergone a renaissance. The role of historical biography as a point of orientation in human life could be one of several reasons for its popularity as a genre at a time when belief in the great utopias has disappeared: it has become the prism for a multitude of preoccupations. The 1990s have seen a desire for images of women and men as creative, reflective, doubting, and determining individuals; a desire to get away from the tendency to reduce specific singularity to social regularity. The French historian Giovanni Levi (1989) has expressed this need for open reflection by pointing out that, more than ever, the ambiguous biography is a central preoccupation for historians. The biography is a sanctuary for dramatic, old-fashioned narrative amidst a deconstructing and fragmented era. It facilitates reflection on the human ideal and the flawed, so that biography does not become eulogy.

The renaissance of biography is a manifestation of a genuine renewal of the genre, with its source in inspiration from advanced literature such as the works of Proust and Joyce, and in the critical question about the extent and manner in which history is created by people and how a life can be decoded. On the one hand, historical biography makes a justifiable demand to set the agenda via a rehumanization of the humanities, which means that passion, irrationality, and human idiosyncrasy are drawn into an understanding of an individual's life work. On the other hand, the genre's respectability is contested time and again, and it has not secured a serious, scholarly profile in those humanities occupied with historical change. Some maintain that biography chose them while they were engaged on other research. Ambivalence in relation to placing the biography within historiography would seem to be the result of opposition to a consideration of single characters. Individual lives, especially the private, are considered by some as irrelevant or inappropriate to the understanding of history, scholarship, or art, because the genius of these individuals has forced them to keep the world at a certain distance. Their significance, maintain the anti-biographers, is to be found in their work(s), not in their person.

That the genre gets left out in the cold, but has still imposed itself, is further illustrated by the reaction of postmodern and poststructuralist critics such as Derrida, Foucault, and Barthes, who have called the historical biography 'impossible to use as reference,' 'spurious,' 'a feature of the exercise of power,' 'profit-mongering in intimacy' or, conversely, a thanatography—an account of a person's death. Pierre Bourdieu has used the expression 'the biographical illusion' (1986), by which is meant that a life story has no direction and cannot be construed in a chronological order. A human individual, meanwhile, is not conceivable without the surrounding society and a biography does not need to present a life as a continuum. A biography can both de- and reconstruct a life. Historical biography will, in any case, easily create new myths in the process of demythologization. This situation is a quandary which historical biography will have to live with when it creates what could be called a kind of authentic fiction.

4. *The Interdisciplinary, Historical Biography: Need for Systematic, Methodical Reflection*

At the year 2000, the historical biography is inherently interdisciplinary. It has developed from a conscious mythologization of prominent, historical figures to a

critical humanization of both well-known and forgotten historical lives. Despite the abundance of publications, certain common features can be detected in historical biography of the 1990s:

The subjects of the great majority of biographies are men living in the twentieth century, most of them being politicians or scientists. Besides statesmen and princes, figures from earlier periods include religious leaders and pilgrims, intellectuals, philosophers and scientists, inventors, adventurers, lawyers, painters, composers, plus a queen or two, and a couple of early feminists.

The familiar gender-imbalance in historiography is pronounced in the historical-biographical genre: less than 4 percent of biographies reviewed in specialized journals have a woman as the central subject and less than 8 percent are written by female biographers.

The scholarly history community's parameter for the evaluation of a historical biography is still the 'life-and-times' model, some biographies having a great deal of 'life' in relation to 'times,' others having little. Most are based on archival material and some even on detective-like research. Some historical biographies skew the individual perspective at the expense of historical analysis, in others the person disappears. Generally, the relationship between the nomothetic and the idiographic is not erased in the historical biography, no more than it is in the rest of historiography.

The target readership for historical biography is often a broad public beyond the specialized forum.

Nevertheless, historical biography has not been the subject of systematic, theoretical-methodological discussion in professional journals in Europe and the USA during the 1990s. Only specialized history journals in the former East Germany have provided the framework for an independent biography-historical discussion. The content of the American journal *Biography*: *An Inter-disciplinary Quarterly*, which has been published since 1977, consists primarily of reviews. In the small Danish-language sphere, a castigation of the historical biography genre proceeded throughout the 1990s (*Historisk Tidsskrift*).

At the beginning of the new millennium a series of primary historical-biographical forms can be identified:

the classical historical biography, in which the perspective concentrates on the central figure's work and in which personalism is irrelevant (e.g., Young-Bruehl 1982).

the existential biography, where the subject is seen in his/her own creative context and the life and work as a coherent, existential whole; where the linear perspective is restored and the personal-public are inseparable (e.g., Söderquist 1998).

the historical biography as historical prism, in which the light of history is refracted and the perspective raises the central figure as representative of a time, a historical situation, a type or social phenomenon. This is often seen as a bridge-builder between research and exposition (e.g., Tuchman 1966, 1986).

the historical biography as a cultural reflector, where a popular culture is analyzed via an exceptional case, by means of which a singular personality can prove to reveal a representative aspect in the historical culture (e.g., Ginzburg 1976).

the historical life-and-times biography, where the portrait painted is colored by society's palette (e.g., Sklar 1973, Fox Keller 1983). In some French and a few Scandinavian biographies, this type has been expanded to:

the historical life-work-times biography, also known as 'the total' or 'the dialectical biography,' in which the dynamic interplay and power structure between the individual, the work and the surroundings becomes a driving force (e.g., Possing 1992, Nilsson 1994, Le Goff 1996).

relational biography, which focuses on the relationship between two or more central figures (e.g., Rose 1983, Haavet 1998).

the historiographical biography, which discusses all the others' ways of writing biographies of the same central figure (e.g., Rosenbaum 1998).

The same methodological criteria apply for the historical biography as for all other historical analysis. But greater caution and ethical awareness are required when writing the biography of a person than when analyzing a theory or a social movement. In other words, there is a difference between the critique of a collective process and that of an individual. The twenty-first century will not just need historical biographies of prominent men and (more) women. There will also be a need for biographies of the grand fiasco, the oddity, the ordinary normal citizen, and the profoundly unoriginal opportunist, because our knowledge of the mentalities of the past will thereby be deepened. The significance of biographical myth in the formation of national and supranational identities will be central to future historical research. Myths have not infrequently proved to be more creative in the view of history than have objective facts, and thus deserve historiographical treatment. The historical biography can redevelop '*l'écriture historique*,' historical writing. The fundamental question for historical biography in the twenty-first century will be if rehumanization of the humanities and social sciences is compatible with clear historical analysis.

Biology's Influence on Sociology: Human Sociobiology

In their early development, sociology and evolutionary biology were complementary. Soon, however, biology was subject to certain controversial issues, and most sociologists became alienated from it. Then, starting a few decades ago, biological theory made compelling strides toward the study of social, including human, behavior. As a result, while sociologists' estrangement is still widespread, a small and growing number have been accepting the challenge. This article begins with a brief statement on the early relationship. It then highlights the following major stages in the growth of evolutionary biology in view of their special relevance to sociological theory: (a) the synthesis of Darwinian theory and genetic science and (b) sociobiology, or the study of evolution and behavior. Underscored are the theory of altruism, the fitness principle, and the theories of parental investment and sexual selection.

1. *Evolutionary Biology and Sociology: The Early Stage*

Both sciences are creatures of the nineteenth century. For several decades they were also mutually influential. For instance, The Division of Labor in Society, sociologist E. Durkheim's classic, argues in a Darwinian key that labor becomes more divided in large part 'because the struggle for existence [Darwin's concept] is more acute.' In the process, Durkheim produces a theory of solidarity that foreshadows the current theory of altruism. Likewise, in 1852 H. Spencer argued, again in Darwinian fashion, that the evolution of human society was a result of competition for scarce resources in which 'the more adapted [prevailed] over the less adapted.' In short, social evolution was the result of the 'survival of the fittest.'

Darwin (1859) liked this expression in preference to his own concept of 'natural selection,' first used in 1838.

1.1 Darwin's Theory of Evolution by Natural Selection

Darwin (1859, p. 75) was at pains to point out that his great discovery (the theory of evolution by natural selection) owed much to another early sociologist, the English demographer T. Malthus. In fact, if we focus on this link of scientific progress, we can grasp immediately the basics of Darwin's theory. In 1798, Malthus had argued that the growth of human population tends to be steeper than the growth of the resources necessary for its sustenance. The inevitable result: competition for scarce resources.

In 1837 Darwin had been on a fact-finding voyage around the world for nearly five years, and had returned to England fully convinced of the fact of evolution or, as he called it, 'descent with modification.' But he had searched in vain for the ultimate, or uniform, mechanism of evolution. A reading of Malthus in the winter of 1837–8 gave him the key, leading him to reason that Malthus' argument applied to all species. Accordingly, he defined his theory as 'the doctrine of Malthus applied with manifold force to the whole animal and vegetable kingdoms; for in this case there can be no artificial increase of food, and no prudential restraint from marriage' (1859, p. 75). In short, life is a 'struggle for existence' in which, given the scarcity of resources and different innate 'variations' (later replaced by 'genes'), some individuals are more likely than others to survive and reproduce. Moreover, such variations are heritable. Natural selection, therefore, refers to a process of differential reproduction in which, through heredity, the genes that are better adapted to the competition, and thus better respond to environmental challenges, are conveyed through the generations, while the less adapted are at the same time discarded. In time, this process, along with genetic novelties later termed 'mutations,' produces descent with modification. Consider, for example, a population of ancestral females. Those who mated with individuals who excelled in the competition for resources were at a reproductive advantage in relation to the mates of less successful males. As a result, today's females are the heirs of the more successful ancestors. To a substantial degree, their reproductive strategy may also be expected to reflect the ancient one.

1.2 Sociologists' Subsequent Estrangement

The revolution in physical science took nearly two centuries to be widely accepted. Darwin's theory fared almost as poorly. It clashed with the theological view of the creation. Moreover, from the beginning there was some equivocation in the concept of natural selection. Equating it with 'survival of the fittest' was an error, both scholarly and human. In fact, as C. Badcock (1994) notes, the use of 'fit' and 'fitness' (though technical terms) invites ideological interpretations. Further, Darwin's revolution coincided with the classical stage of another revolution, and this was accompanied by an ideology that celebrated the rich and mighty: the capitalists. Survival of the fittest came to be the catchword of the new order, and 'social Darwinism' was born.

Few social scientists bothered to read Darwin carefully, if at all. Else they would have known that, for Darwin, the fittest were likely to be the members of the highly reproductive 'lower order.' They fancied Darwin through the errors of such statements as the following by Rockefeller: 'The growth of a large business is merely the survival of the fittest .... the working out of a law of nature and a law of God.' From the pulpit, others attributed the abject conditions of the working masses to the will of God.

Even great scholars were unable to escape the virus of the ideological pestilence, and as a minimum were guilty of careless pronouncements. In his Statics, Spencer, who heavily influenced the great American sociologist, W. G. Sumner among others, wrote such irritants as the following: 'The whole effort of nature is to get rid of [feeble elements], to clear the world of them.' At about the same time, starting around 1883, a movement arose—and soon compromised the IQ test and the rising science of genetics—according to which, as one enthusiast put it, 'human matings could be placed on the same high plane as that of horse breeding.' Capitalist ideology, Darwinian vernacular, and eugenics all wrapped up in one. Sociologists fell under it.

In the meantime, Europe-born sociology was migrating to the United States where the cities were teeming with humble immigrants. Even to many a great professor, these were the unfit, biologically destined to failure. Indeed, as the Great Depression crashed in, not a few of them were reduced to quasi-imbecility by hunger, prejudice, and humiliation. But the children and the grandchildren of these 'failures' soon started filling the halls of the universities. Many of them studied sociology; even today an exceptional percentage of sociology students were raised in relatively poor ethnic groups. The old epithets had stung, and were never forgotten. One of their first acts was to expunge the very word biology from the curriculum on human behavior.

Sociology today faces a marvelous challenge. The many branches of evolutionary biology, e.g., neuroendocrinology, human genetics, and primatology, leave little doubt that a fuller understanding of human behavior requires an opening to biology. The aversion to biology persists, but a small and growing number of sociologists are accepting the challenge, avidly conscious of richer frontiers in behavioral science.

2. *The Modern Synthesis*

Natural selection is one of the two atlantes of evolutionary biology. Genetics is the other. Genetics provides information on the units of heredity, the materia prima of evolution (DNA). It was discovered around 1865 by the botanist Gregor J. Mendel, but it lay dormant until 1900. Indeed, until about 1930, the two pillars of what has become a prodigious scientific revolution developed with near disregard of each other—a grave lesson on the obstacles facing the construction of scientific bridges. By 1930, however, the inevitable happened. A group of great minds formally wedded the evolutionary twins into the 'Synthetic Theory' or 'Modern Synthesis' (Huxley 1942). The particulars are numerous and complex. But T. Dobzhansky and his associates (1977, p. 18) so captured the crucial premise of the momentous synthesis: 'All biological ogranization, down to the level of molecules, has evolved as a result of natural selection acting upon genetic variation.'

Whether natural selection 'acts on' genetic variation is a knotty question that need not be treated here (but see Lopreato 1989). Technically, the action on genes comes from environmental pressures; natural selection 'records and orders' the ensuing effects through the generations. But the proposition is most remarkable, representing a splendid case of scientific inevitability. To grasp the point, we need only glance at some three centuries and behold the cornucopia of laws that constituted physical science. They too have been epitomized by a synthesizing premise, as follows: 'The universe is a system of matter in motion obeying immanent, natural laws' (Kuhn 1957). Returning to the general proposition of the modern synthesis, it is possible to show that it is a sort of corollary of this Newtonian proposition. Suppose we translate the former as follows: the universe of biological organizations is a system of genetic matter in motion obeying the immanent, natural laws of natural selection and genetic variation (Lopreato 1984). We have not disturbed the logical structure. We have merely specified (an avoidable deed) the type of matter and the relevant laws. The modern synthesis was inherent in the scientific revolution.

3. *Sociobiology: The New Synthesis*

The goal above was to exemplify the inherent tendency of sciences to unite, and thus to suggest two other inevitabilities: (a) the expansion of the modern synthesis toward the evolutionary study of behavior (sociobiology) and (b) the 'consilience' (Wilson 1998) of sociobiology and social science, namely the rise of human sociobiology, which to almost imperceptible degrees branches off into 'evolutionary anthropology,' 'evolutionary psychology,' 'evolutionary sociology,' and so forth.

The forging of the modern synthesis gave exceptional impetus to the study of social behavior and organization. By the early 1970s, four zoologists in particular (W. D. Hamilton, R. L. Trivers, G. Williams, and E. O. Wilson) had published compelling discoveries. Pre-eminent was the finding that in evolutionary history organisms, human ancestors included, appear to have behaved in fair harmony with their genetic structure (genotype). Among social scientists, this is a troublesome thought, in part because we have little experience with remote concepts. The problem is, in turn, exacerbated by a tendency to grasp the idea in teleological terms and to reject the unrestrained stress on selfishness and genetic determinism presumably implied in it. In fact, nothing in sociobiology suggests unidirectional biological determinism, or that human beings are obsessed with their 'selfish genes' (Dawkins 1989). In classical scientific mode, sociobiology stresses the heuristic value of a remote (distal, ultimate, relatively constant) explanatory device. Certainly it does not neglect dimensions of sociability. Living in society requires sentiments that act subtly in antagonistically cooperative efforts, such as devotion, a sense of fairness, and the need for vengeance. D. Thiessen (1996, p. 7) has captured the poetry of the seeming paradox as follows: 'We cannot view love, loyalty, and altruism without also seeing hate, abandonment, and selfishness.... We may wish for better, but when we accept one of our sides, we accept the other. This is our bittersweet destiny, to be noble, debased.'

In 1975, the entomologist E. O. Wilson published a hugely influential work that creatively codified the evolutionary knowledge on social behavior and formally launched sociobiology as the 'new synthesis.' For social scientists, the basic theme was the quest for a comprehensive theory of human nature: What are the fundamental forces driving human beings, and how are they expressed in group living? An intuitive quest for a theory of human nature had been central to the work of all founders of sociology; the time had now come to rely on more rigorous techniques.

3.1 *Altruism*

A major step forward was taken by W. D. Hamilton (1964) in a seminal paper on 'the genetical theory of social behaviour.' Among eusocial insects, e.g., ants, only a very small number of individuals are reproductive—a bit of a puzzle in view of Darwin's accent on direct reproduction. Such insects have a peculiar system of reproduction and sex determination (haplodiploidy); the vast majority (females) are diploid (have two parents), while males are haploid (have only a mother). In examining the kinship coefficients (r), Hamilton discovered that the diploids are more than normally related to one another. Accordingly, they have evolved to cater very diligently to the needs of the

queen and the young and, except for rare cases, to forego reproduction. Given the very close kinship, this 'altruism' redounds to their own genetic benefit. In short, eusocial species have evolved according to what is termed kin selection; the genetic fitness of organisms is inclusive of the share accruing to them from reproductive kin.

To varying degrees, kin selection applies to all social species. Hamilton eventually summarized by concluding that the probability of altruism increases (a) as the *r* between benefactor and beneficiary increases, and (b) as the benefit accruing to the beneficiary exceeds the cost incurred by the benefactor. In short, the more kindred two individuals are, and the less it costs to do each other good, the more likely they are to do it. Numberless studies show that this rule covers the typical case. Does it also apply to human beings? The answer is strongly suggested by last wills and testaments, which show that rarely do we bequeath our (fitness-enhancing) resources to others than our kin (Clignet 1992). Facts of great subtlety are even more convincing. For instance, most of us would expect a child's grandparents to be equally caring of the child. On average, they are equally related to the grandchild. But—and here is an evolutionary drama—in our ancient brain the paternity of a child is not so certain as the child's maternity, and 'paternal uncertainty' modifies the probability of altruism. Thus, a recent study shows that the most caring is the mother's mother; second is her husband, not the paternal grandmother. Dad's father comes last (Euler and Weitzel 1996). The difference in altruism between grandmother and grandfather reflects, as we shall presently see, another major theory of sociobiology, namely 'differential parental investment.'

Kin selection and altruism theories are very promising tools for sociologists. Consider briefly ethnic conflict, a phenomenon that time and again has grievously plagued the human peace in all corners of the earth. To explain it, social scientists tend to search for facts peculiar to given times and places. This is not a useless strategy. But if a phenomenon is universal and recurrent, it also requires a universally applicable explanation. We are the descendants of individuals whose social horizon was delimited by a clan of 25–50 souls. Beyond the clan was the 'out-group,' often an enemy. This condition lasted until very recent times. In the meantime our clannish brain has not changed. It is still the product of kin selection and kin altruism. Hence, even in the midst of the megasociety, we are subject to a force that whispers from within: 'they' are like 'us'; the 'others' are the enemy—if not just now, then in the time of the 'Fathers.' J. Piaget's famous studies showed that children grow up with us-vs.-them notions. Ultimately, human beings are 'ethnic' and genocidal because we have an ancient, clannish brain. Its deadliness is touched off by a variety of contextual pretexts. A more mature sociology must consider both types of causes.

Altruistic favoritism is not limited to the kin group, though it reaches its greatest intensity there. It may be observed wherever it serves the selfish needs of its agents. In 1971, Robert Trivers expanded the theory of altruism to account for acts of reciprocity even across species. For instance, a number of species of fish perform a service analogous to that of the dental technician. Their 'customers' have been observed queuing up and, as the occasion arises, defending their health providers from predators. So, the ones profit from having their mouth and gills cleared of parasites. The others receive food and protection from predators. Complex societies are possible largely because of reciprocal altruism.

3.2 The Fitness Principle

Scientific theories are held together by at least one general principle or law. The general principle of sociobiology, often referred to as the fitness or maximization principle, is implicit in the above theories and others that will be sampled below. It may be expressed as a probability statement as follows: *organisms tend to behave so as to maximize their inclusive fitness*. This is shorthand for saying that organisms are, to varying degrees, observed behaving as if they were intent on conveying the maximum possible portion of their genotype to future generations, partly or fully through kin selection. In time, however, purely probabilistic statements typically undergo contingent refinements, as in the form: if X, then Y, provided that Z.... Newton's laws of motion, for example, take this shape. Something of this nature is needed for a more finished fitness principle. A first approximation for human sociobiology is available, and its contingencies are (a) the pursuit of 'creature comforts,' (b) self-deception, and (c) 'autonomization'—as when, e.g., the quest for riches becomes an end in itself and ceases to be a means to reproductive success (Lopreato 1989). Sociology is perfectly suited to improve further.

3.3 Differential Parental Investment and Sexual Selection

The fitness principle is a broad umbrella covering a growing number of theoretical statements. This final section introduces several crucial ones specific to sex differences. It will be helpful to first recall a few widely noted facts. In general, female behavior is more cautious than its male counterpart. Thus, at all ages except the 80s women are subject to far fewer traumas resulting from accidents or agonistic activity. They are less likely to stress 'skin-deep' qualities in their mates. Young women prefer slightly older men who offer the prospects needed to raise successful children. In the market place they suffer various disadvantages. Yet there is evidence that female medical students prefer life partners who will be more successful than they.

Females are more apt to want a commitment before agreeing to sex, have fewer sexual partners, and are less disposed to cheat on them (Laumann et al. 1994). Above all, they devote more time to child care, even when they are employed in the market place.

Sociologists tend to attribute such differences to socialization, and many 'feminists' single out a system of patriarchy as the culprit designed to favor male interests. There is some validity to this view; once such a system is in place, it inevitably abets socialization processes consistent with the feminist criticism. But this strategy takes facts as given. The job of science is to explain them. Socialization is only part of the story; by itself it cannot explain why such 'sex roles' are universal and persistent. It can also result in stupefying absurdities. By its logic, we should be able, for example, to raise boys as girls and girls as boys. In fact, studies show that even 'gender stereotypes' endure unabated, despite recent deep changes in sex roles.

Nobody knows for sure how patriarchy developed. Chances are good that it is millions of years old. Hence, the best bet is that it is wired in a brain that has not changed for at least 30,000 years. What, then, is the complement of socialization? There is a major physio-anatomic difference between males and females, across the creation. Anisogamy, the name given to it, refers to the inequality between female gametes (eggs) and male gametes (sperm). In our species, eggs are about 85,000 times larger than sperm and are responsible for the nutrition of the embryo in its early stage. Produced once in a lifetime, *in utero*, only a tiny number can be promoted into offspring; pregnancy and child rearing are time-consuming. Females, in short, make a greater parental investment from the very beginning, and then continue to contribute disproportionately through lactation and child-care at least during the tender years. It follows that a mistake—mating with one who will contribute little or nothing to the well-being of the offspring—is very costly. Accordingly, evolutionists hold that women have been selected to specialize in the caring, cautious, 'choosy' reproductive strategy that has been encountered above.

The male scenario is quite different. The miniscule sperm contribute only genes. They are also produced in huge quantities continuously from the onset of sexual maturity. The reproductive potential of males is enormous, and some men are known to have sired literally thousands of children (Betzig 1986). It is no mere effect of socialization that, for example, middle-aged men frequently 'play around,' nor that they only too often fail to pay legally required child support. There is a hedonistic streak in the male endocrine system. More than females, on average males have evolved to prefer quantity and to philander. That may be detrimental to abandoned spouses and children. But evolution has not been kind to males. Given anisogamy, there is a prohibitive scarcity of candidates to philander with. The male reproductive system has encouraged polygyny, or marriage with multiple wives, so widespread until very recently. But the other side of polygyny is male celibacy. Even today a study from Sweden (Lindquist Forsberg and Tullberg 1995) shows that there is an overlarge percentace of unskilled men without mates. If we now recall the female preference for relatively rich males (e.g., Buss 1989)—resulting in what is termed 'hypergyny'—it is hard to avoid the conclusion that patriarchy, so hastily taken as a given by some sociologists, most probably evolved with the aid of female complicity. There is no intention here to pass judgment. Understanding certain facts helps to know certain others. At any rate, as Doreen Kimura (1992) has put it, boys and girls enter the world with differently wired brains.

Polygyny, hypergyny, and patriarchy are ultimately the results of the differential parental investment and sexual selection inherent in anisogamy. But these are the landmarks, as it were, of a large landscape of human nature and its rich repertoire of human facts. On sex differences the following are useful guides to such awe-inspiring abundance.

The Law of Anisogamy: the two sexes are endowed with different reproductive strategies, and their behaviors reflect that difference in direct proportion to their relevance to it (Lopreato and Crippen 1999). In other words, the closer we get to the fundamentals of life (e.g., sex, sex roles, courting, family), the more readily observable are the effects of anisogamy.

Corollary 1. Males, the sex investing less in parenting, compete more for mates than females, the sex that invests more (Trivers 1972).

Corollary 2. Females have been selected to specialize in choosy behavior, while males have been selected to specialize in agonistic behavior (Darwin 1871).

Together with a variety of culture and socialization factors, the above propositions explain large classes of behavioral differences between the sexes. But sociology will derive enormous profit from an evolutionary perspective on all its subject matter.

Biomedical Sciences and Technology: History and Sociology

Despite the recent emergence of a few major, unifying themes, the history and sociology of the biomedical sciences and technology (HSBST) can hardly be said to constitute a homogeneous, well-defined field of inquiry. This diversity probably accounts for the vitality of the field. Two reasons explain this state of affairs, namely, the scattered, somewhat twisted (sub)disciplinary origins of the field, and the ambiguities surrounding the nature and identity of its subject matter, biomedicine.

1. *Origins and Definitions of the Field*

As with other interdisciplinary endeavors, HSBST lies at the intersection of several specialized (sub)fields. In this case, the intersection is somewhat tangled. The history and the sociology of medicine can only partly be defined as the field's parent disciplines insofar as they have both experienced serious trouble in dealing with science as a subject matter. In this respect, criticism of the two disciplines' shortcomings has often served as a negative cast for delineating HSBST's programmatic content. As Warner (1985) has noted, during the 1970s and 1980s a new brand of historian of medicine, reacting against narrow internalist histories of medical theories, recentered the domain within the social history of medicine. Unfortunately, the resulting accounts have, more often than not, left out medicine and science, concentrating instead on the role of science as an ideology, a source of authority, or a mere legitimization device. Two consequences followed. The first, more obvious one, was to prevent any investigation or understanding of the actual content of medical practices. The second was to take for granted the dominant, laboratory-based definition of what constitutes medical science, thus disregarding the multiplicity and variety of clinical, laboratory, and public health practices that, at different times and in different locales, have been defined as scientific. A similar situation has characterized the development of medical sociology, insofar as the latter grew out of the distinction between disease and illness, i.e., between the biological and psycho-social aspects of pathological processes, a dichotomy that effectively left a major portion of medical activities outside of the purview of sociological analysis (Lock and Gordon 1988). One of medical sociology's key notions, namely medicalization, a term used to refer to the medical redefinition of previously nonmedical problems and behaviors, rested on the possibility of establishing *a priori*, unproblematic distinctions between social and medical problems, thus missing the opportunity to investigate the actual work that goes into the production of medical (and social) problems *qua* medical (and social) problems.

Before the 1980s, apart from a remarkable, pioneering study by Ludwik Fleck (1935) of the development of the Wassermann test for syphilis, the content of biomedical practices was, from the point of view of the social sciences, largely *terra incognita*. The situation changed with the development of science and technology studies as a semiautonomous field and the ensuing constitution of a rich body of empirical analysis of scientific beliefs and practices. The articles

collected in Wright and Treacher (1982) exemplify early attempts to apply insights from science and technology studies to medicine, by adopting the, by now, largely superseded approach of correlating a specific body of medical knowledge with the social and political interests of professional or ruling groups (see *Strong Program, in Sociology of Scientific Knowledge*). Several of the founding contributions to science and technology studies, especially those providing ethnographic analyses of laboratories (see *Laboratory Studies*: *Historical Perspectives*), took biomedical laboratories as their field site. However, for most of these early studies, biomedical activities acted as examples of (generic) scientific practices, rather than starting points for the investigation of biomedicine.

Moreover, medical practices encompass more than laboratory research: the clinic and its derivatives, including clinical research, are a major part of the picture. The relation between the laboratory and the clinic constitutes, arguably, the essential tension of the biomedical enterprise. As a result, work in HSBST, while unfolding in close relation to developments in science and technology studies, far from severing links with more traditional contributions to the history and sociology of medicine, has continued to draw from their insights, albeit by reinterpreting them. Connections across dividing lines have been made easier by the fact that social scientists in different subfields sometime share theoretical approaches, as was the case, for instance, with symbolic interactionism (compare, e.g., Strauss et al. (1985) with Star (1989)).

At this point, an additional difficulty arises. HSBST could be defined, so to speak, from without, by compiling a list of contributions that, because of their subject matter, can be construed as referring to biomedicine, even in the absence of (strong) co-citation patterns. Or, it could be more cogently characterized by the presence of a core of mutually citing contributions that bear witness to the emergence of a common set of questions. By adopting this latter avenue, it becomes possible to argue that the field's coherence is provided by its focus on the biomedical enterprise as defined by the mutually constitutive relations between the laboratory and the clinic, or, more precisely, between investigations of (normal) biology and investigations of pathological structures and mechanisms. This theme should not to be understood as a purely epistemological one, for, in addition to epistemological issues, it simultaneously raises institutional, economic, and political considerations. To visualize this point fully, a few additional remarks on the nature of biomedicine are needed.

2. *What is Biomedicine?*

Recent dictionary entries define biomedicine as a branch of medicine that is combined with research in biology or, in other words, as the application of the natural sciences, especially the biological and physiological sciences, to clinical medicine. While, indeed, in present-day discourse the term 'biomedicine' (and its adjectival form 'biomedical') generally refers to modern, scientific Western medicine, casual use of the term disguises two important facts, namely that the term itself is of recent origin (its widespread use postdates World War Two) and, more important, that the relation between biology and the clinic is, even in the twenty-first century, far from being as seamless and as unproblematic as the term would lead one to suppose. The term first surfaced, rather idiosyncratically, in the 12th edition (1923) of Dorland's medical dictionary, but its career took off in the 1950s, when users gave it two related, yet distinct meanings. On the one hand, there was the epistemological idea of a crossing over of medicine with biology, with all its institutional consequences. On the other hand, the term referred to a substantive area, namely the study of environmental stresses on the human body—a normal body in a pathological environment—as in the case of space travel (NASA, with its manned space program, was established in 1958) and radioactive fallout from nuclear experiments. Both meanings are, of course, linked, insofar as they are mirror images of the attempt to relate biology to pathology. To speak of biomedicine is to take for granted the claim that the relationship between biology and pathology, rather than a matter of quality, is simply one of quantity, i.e., of bodily mechanisms gone awry by reaching beyond the upper or lower limits of the normal spectrum. As forcefully argued by Canguilhem (1966), such a claim is highly questionable. This is not to say that such a thing as 'biomedicine' is an epistemological monster and thus a practical impossibility. Rather, it is to point to the fact that the relationship between biology and pathology is not a simple one, and that, instead of taking their relationship for granted, one should analyze their practical, ongoing articulation.

But is the biomedical project really that novel? Did not pathology already attempt to model itself on biology since Thomas Sydenham's seventeenth century proposal that diseases be treated as autonomous entities, like plants and animals, and be subjected to similar schemes of description and classification? Is it not the case that contemporary 'biomedicine' goes back to the bacteriological and laboratory revolution of the second half of the nineteenth century, or to Rudolf Virchow's contemporary program of a cellular pathology applying cell biology to pathological processes (Vogel and Rosenberg 1979, Cunningham and Williams 1992)? While the idea that the pathological can be reduced to the normal is indeed a common theme in nineteenth century medicine, at the practical level, the normal and the pathological remained the products of distinct experimental and institutional practices. From this point of view, modern biomedicine constitutes a novel institutional and scientific activity that is incommensurable with the biology and

medicine of, say, a Louis Pasteur or a Robert Koch. Biology and medicine are now tightly intertwined research enterprises. Practitioners of the activity known as biomedicine can no longer say beforehand whether a particular research project, clinical investigation or even clinical intervention will result in biological or medical facts. Somewhat like the distance between pure and applied research, that between biology and medicine has collapsed without, of course, erasing the distinction between the two activities.

3. Socio-historical Accounts of Biomedicine

The exponential rise in public funds made available to university and para-public research since 1945 has put a lot of biology on the market and has generated numerous public and private schemes to translate that knowledge into clinically useful practices. Social scientists have described a number of these large-scale movements of money and personnel, for instance by analyzing the influence of large science-based funding institutions and cancer policy on biomedical research in terms of 'crusades' (Panem 1984), 'bandwagons' (Fujimura 1996), and 'wars' (Proctor 1995). In the same vein, the wave of reform that ran through the Western biomedical world in the post-War period vastly expanded the notion of public health to include funding for basic medical research. In the UK, for example, the creation of the National Health Service in 1948 gave the Ministry of Health the power to fund and conduct research. In the USA, the National Institutes of Health, founded in 1948, quickly became the leading source of continuous federal funding for medical research. The rise in funds was accompanied by a concomitant rise in clinical personnel in university departments of medicine. As clinical departments became more academic, medical schools became increasingly research-oriented to the extent that by 1980, they awarded 42 percent of all PhDs given in the biological sciences. Useful overviews of this post-War institutional expansion can be found in Bynum and Porter (1993) and Krige and Pestre (1997).

Thus, once a handmaiden to pathology, biology has come to count as the ultimate description and account of disease origins and mechanisms. Prediagnostic biological tests for individuals and screens for groups as well as therapeutic monitoring procedures now pervade the practice of medicine. This trend has been analyzed in Reiser's (1978) seminal overview of clinical instruments and machines, that emphasized a number of themes that have since become standard. It is generally held, for example, that new scientific technologies have tended to remove the patient from the clinical picture with clinicians' attention being increasingly led from the bedside to the laboratory. As a consequence, modern medicine can be characterized by its high degree of specialization, often based on new scientific technologies. In addition, it is maintained that scientific technologies have downgraded or eliminated skills embodied in what is termed clinical judgment with the consequence being that diagnosing physicians became more and more subservient to technologies whose development they cannot control (Berg 1997). Although biology, as characterized by the investigation of quantifiable, biological variables, has yet to substitute itself, in the reductionist sense, for pathology, it has to a certain extent encircled medicine. While the qualitative, synthetic judgment of the pathologist or clinician recognizes a specific disease in an individual, biological variables, by definition, vary continuously and thus apply to populations. They consequently open the door to screening and automation in medicine, two practices that bring pathology and biology together within a single space of representation.

In analyzing the institutional and conceptual innovations that have created the dynamic interchange between biology and pathology, historians and sociologists have isolated a series of trends. A major trend is the alignment of biomedical research along molecular and cell biology lines (Moulin 1991, de Chadarevian and Kamminga 1998). The trend predates the meteoric development of molecular biology and molecular genetics during the second part of the twentieth century. The latter, however, is generally regarded as the agent of an epochal transition to a new kind of medicine, 'predictive medicine,' whose full effects have yet to be felt (Wailoo 1997) but that has the potential of extending medical intervention from the sick to the potentially sick person, and from individual to collective patients (families and populations).

One of the consequences but also one of the causes of the use of biological variables in the diagnosis of diseases, and thus of the renewed alignment of the biological and the medical, has been that the technologies for the investigation of the normal and the pathological have become increasingly the same. Historical studies have shown, for example, that an experimental system instituted for the study of cancer can easily become a system for the study of protein synthesis (Rheinberger 1997). As medical problems thus find their solution through biological innovation, the transfer of concepts and techniques from fundamental biology to medical practice has been vastly accelerated. Conversely, medical problems have become the starting point for many fundamental biological investigations (Sinding 1991). Finally, clinical trials, the hallmark of so-called evidence-based medicine, are no longer restricted to the testing of therapies. As a spate of recent histories has shown, since the 1960s, an expanded notion of clinical trial now includes the study of biological markers and etiological research. No longer solely a determination of the efficiency of treatment, clinical trials are sim-

ultaneously an exploration of human biology (Löwy 1996).

While in the early twentieth century several areas of medical diagnostics became routinely based on technologies derived from chemistry and physics (Howell 1995), in the second half of the century, and despite the contributions of nuclear medicine and biophysics (Blume 1992), biomedical technologies have become relatively independent of physics and chemistry. Indeed, the post-War alliance of biology and medicine has made possible a new kind of medical technology that is truly biomedical: generated within biology and medicine, these biotechnologies use fragments of living systems such as cells, enzymes, antibodies, and gene segments. Whether or not genetic engineering techniques, and the results obtained through their application to, say, the study of the human genome, have the potential of transforming biomedicine by collapsing ontological distinctions between nature and society (see the debate between Rheinberger and Rabinow in Lock et al. (2000)) is still an open question. What is undisputed is that, in the absence of outside, physico-chemical, standards, the effective use of biotechnologies requires intensive standardization and new forms of collaboration between biomedical practitioners (Fujimura 1996). In a similar vein, Gaudillière (in de Chadarevian and Kamminga 1998) has suggested that engineering and management practices have played an important role in the spread of a number of experimental models of cancer etiology, and Marks (1997) has shown how clinical research has been transformed by clinical trials and how, during World War Two, standardization and cooperation came to be seen as necessary although not sufficient conditions for the conduct of clinical research. In short, it has become increasingly clear that regulatory interventions—ranging from tacit agreements to the stabilization of practices, the establishment of norms, the setting of *de facto* standards and guidelines, and the promulgation of formal, explicit regulations—have become part and parcel of the biomedical enterprise.

Nonconventional actors such as patient support groups and activist organizations increasingly play a role in these regulatory activities, and thus in the production of biomedical knowledge, insofar as the former are constitutive of the latter (Epstein 1996). Moreover, support group activities are consonant with the development of new group identities based on the sharing of an actual or potential condition, as in the case of hereditary or genetic diseases. These new 'bio-social' identities question traditional distinctions between scientists and lay people or between experts and politicians, thus challenging the regulatory and policy mechanisms to which governmental bodies had grown accustomed (Rabeharisoa and Callon 1999, Rabinow 1999).

In keeping with leading approaches in science and technology studies, much work in HSBST has focused on the *material culture* of biomedicine, that is, on the local, contingent production of biomedical practices and representations, examining in often painstaking detail the various elements and tasks that enter in their constitution. Much of this work, in turn, has gone into the analysis of the (interactive) production of medical talk, images, inscriptions, standards, classifications, and the mobilization of tools, skills, and bodies (e.g., Atkinson 1995, Cambrosio and Keating 1995, Fujimura 1996, Berg 1997, Berg and Mol 1998). Yet it would appear that the emerging coherence of HSBST comes from its focus on biomedicine as a distinctive social, institutional, material, and epistemological configuration.

Biopsychology and Health

In countries and periods of history dominated by war and poverty, the attitude towards health predominantly concentrated on survival, by caring for sufficient food supplies. But in more affluent societies and historical periods, attention to mere alimentation changed into interest in nutrition and its significance for health and disease. In the twentieth century, nutrition turned into a concern of medicine when it became obvious that a deficiency of certain nutrients or the wrong diet could cause disease. Therefore the analysis of food components (for example, artificial preservatives or flavorings) became an important aspect of general programs on risk assessment concerned with a variety of environmental risk factors, for example, exposure to air pollution, radiation, chemicals, or drugs of abuse.

Similarly, at the beginning of the twentieth century, the discovery of bacterial infections by Semmelweis, Koch, and Virchow led to the improvement of public hygiene. Respective laws for protection from bacterial infection as well as for food safety were enacted. They were later followed by regulations on permissible doses of chemicals or radiation at workplaces and the safety of drugs.

Another line in health psychology came from stress research developed from experiments on animals and observations in psychosomatic diseases demonstrating the mechanisms by which mental and physical strain affect somatic processes. At present, however, there is more concern about public health and safety rules than about the doses and biological mechanisms by which environmentally noxious stimuli may affect the organism. Therefore, this article is devoted to illustrating biological mechanisms by which health-related behaviors affect somatic systems involved in the maintenance and restoration of health. Furthermore, the role of personality and the genetic roots of these mechanisms will be discussed.

1. *Classes of Health-related Behaviors and Classes of Somatic Mediators*

There are three major classes of behavior related to health: (a) avoiding exposure to or protecting the organism from noxious influences and environmental risks; (b) the application of drugs, nutrients, or psychological pleasure in order to increase health; and (c) challenging the organism by training techniques. The first two behaviors try to adapt the environment to the organism, while the third behavior adapts the organism to the environment. All the behaviors more or less act via the following somatic mediators: (a) the autonomic nervous system; (b) the endocrine system and its neurotransmitter-related feedback mechanisms; (c) the central nervous system; (d) the musculoskeletal and peripheral nervous system; (e) the immune system; (f) metabolism; and (g) systems of cell biology relevant for genetic information, growth, and repair functions.

Most papers on behavior and health do not communicate details on the somatic systems involved, and those on psychophysiology usually relate behavior to the somatic mediators, but cannot prove that they are directly related to later beneficial or detrimental effects

on health outcome, so that no causal conclusions are possible. Restoring health through behavior can be more validly related to health outcome than preventive behavior, because comparison of treatment is possible in small samples, whereas beneficial effects of preventive behavior are hard to prove and require larger samples and longer observation times for identifying the signal to noise ratio. Furthermore, in questionnaire studies, reported health behavior is highly confounded by personality factors (e.g., neuroticism) that are related to the behavior as well as to reporting symptoms of disease. Therefore the emphasis will be on results obtained from experimental and clinical sources.

2. *Avoiding Noxious Influences*

In order to demonstrate the beneficial influence of avoiding noxious stimuli, their detrimental effects have to be outlined. It must be emphasized, however, that most of the stimuli avoided (like stress, excess calories, certain food components, or even alcohol) can also have beneficial effects, if exposure is moderate.

2.1 *Avoiding Stress*

Exposure to social, psychological, and work-related stress relates to all the mediator systems listed and associated diseases (for a review, see Brown et al. 1991, Krantz et al. 1985).

The major mediator is the *sympathetic nervous system* (*SNS*), with its influence on cardiovascular reactions leading to hypertension and myocardial ischemia or infarction. Constant sympathetic tone leads to constriction of vessels, inadequate perfusion, anaerobic metabolism, and diminished contraction of the heart—and therefore to reduced oxygen supply. Furthermore, the stress-induced increase in adrenaline increases cell metabolism, which requires more oxygen, leading to a discrepancy between supply and demand. In addition, stress-induced increases in cortisol, in combination with increased cholesterol, may increase the danger of infarction by increasing the tendency of blood clotting. Mediating processes for hypertension consist of continuous contraction of vessels and false shifts in feedback mechanisms from baroreceptor signals to the brain (see *Stress and Health Research*).

With respect to the digestive system, the stress-induced sympathetic tone will first suppress parasympathetic secretion of hydrochloric acid with a subsequent rebound effect. Furthermore, adrenaline is known to increase secretion of gastrin, an acid-stimulating peptide in the mucosa. Finally, protective factors like prostaglandines are reduced, and the blood supply of the mucosa in the stomach is decreased due to sympathetic vasoconstriction. This may lead to necrosis of mucosa areas. Moreover, stress-induced gastric ulcers may develop from hemorrhagic erosions facilitated by stress-induced cortisol increase. Furthermore, sympathetically-induced adrenaline increases plasma glucose levels and inhibits insulin, resulting in hyperglycemia. This contributes to the development of diabetes. Also, disturbances in bowel movements (constipation) may result from sympathetic arousal.

All *endocrine systems* respond to physical and psychological stress, in particular if the stressor involves uncertainty (see Brush and Levine 1989, Nemeroff and Loosen 1987). All hormones are organized according to feedback loops: high blood levels lead to reduced release of peptidergic releasing factors in the brain, with subsequent reduced production of respective glandotropic hormones from the pituitary. Therefore, imbalance in the system usually elicits a cascade of disturbances which may also affect other endocrine systems. So, sustained stimulation of the hypothalamo-pituitary-adrenocortical (HPA) axis leads to considerable increases in cortisol. Due to its close interaction with the hypothalamo-pituitary-gonadal axis, hyperstimulation of the HPA axis will result in a suppressed functioning of reproductive hormones and subsequent disturbances of the menstrual cycle and fertility. Due to its antagonistic function to insulin in glucose metabolism, cortisol increase may also lead to insulin resistance and diabetes. Prolonged cortisol increase may lead to a degeneration of hippocampal cells and therefore even to a decline in memory. Furthermore, the corticotropin releasing factor (CRF) of the brain also inhibits gastric and colonal transit time, leading to constipation.

Relations between stress and the *immune system* have been widely described. They are closely related to the SNS as well as to the HPA axis activities (e.g., see Lewis et al. 1994, Glaser and Kiecolt-Glaser 1994). This is due to the fact that immune cells (macrophages, lymphocytes, and natural killer (NK) cells) bear receptors for neurotransmitters, hormones, and neuropeptides, and because the lymphoid tissues for cell storage (e.g., spleen, lymph nodes, and bone marrow) are directly innervated by sympathetic nerves. Although activation of immune cells is mainly directed against antigens discovered as 'nonself' (e.g., viruses, bacteria, neoplastic, or damaged cells), it also occurs upon nonantigen-related stressors. In a very simplified manner, it could be said that the SNS has a primarily activating effect (increasing the number and activity of these cells), as observed in acute stress, whereas the hormones of the HPA axis have more immune-suppressing than activating effects. Immunosuppression is only observed after chronic stress (e.g., hopelessness, helplessness). The reduction in macrophage and NK cell activity diminishes the defense mechanisms, increasing the probability of infection and growth of cancer cells because environmental and internal antigens can no longer be eliminated. More-

over, the capacity of the immune system to discriminate between 'self' and 'nonself' or between harmless and dangerous antigens is reduced by stress factors. In combination with reduced cortisol release as a consequence of chronic stress, this may lead to immunological overreactions, as observed in allergies and autoimmune diseases. In these diseases, the production of soluble mediators of immune cells, like cytokines and growth factors, contribute to the aggravation of symptoms.(see *Psychoneuroimmunology*).

In summary, the relationship between the immune system and stress follows an inverted U-function, which means that avoiding stress as well as exposure to an extremely high stress load (intensity, duration) are both accompanied by low immune functions. The most important issue in immune functioning is therefore to maintain a balance between activation and suppression of immune functions. A disturbed immunological homeostasis is the most serious factor for developing immunological diseases.

The *musculoskeletal system* is affected by physical stressors, like muscular constraint induced by monotonous repetitive physical work. This increases muscular tension by sustained activation of small low-threshold motor units, which leads to degenerative processes. If, in addition, carbon dioxide (CO_2) is increased by hyperventilation, neuronal excitability and muscular tension will develop, a process which has also been shown to result from mental stressors.

Protection from stimuli like *radiation*, *sun exposure*, *or air pollution* aims at reduction of the risk of cancer. These stimuli exert direct damage of DNA in the cells, for instance, in melanomas developing after heavy sun exposure and after involuntary exposure to radiation. Among polluting substances, lead is one of those most thoroughly investigated, since it produces subclinical central nervous disturbances such as attention deficits.

2.2 Avoiding Unhealthy Food

Beliefs about what kind of food is unhealthy refer to an item's calorie, salt, fat, sugar, and chemical food additive content, as well as to its likelihood of being bacterially contaminated.

Restricting calorie intake in general to avoid obesity aims at reducing heart failure, hypertension, and stroke, as well as secondary insulin deficiency and diabetes. It is less known that cancerogens are also reduced by a restricted diet. This results from an increase in the production of enzymes involved in eliminating free radicals from the cell, which play a major role in DNA damage, mutagenic changes, and in the development of cancer (Joannides 1998). Low-calorie supply also supports apoptosis, the death of cells, which is necessary to keep cell numbers constant, to remove DNA-damaged cells, and to protect the organism from toxicants and allergens. Therefore, oncogen formation has been shown to be lower in food-restricted animals.

Salt is accused of contributing to hypertension because of its sensitizing effect on catecholamines and its effect on water retention, both of which are relevant to hypertension. This is supported by intercultural correlations between the consumption of salt and the incidence of hypertension, as well as by effects of salt reduction in the diet of hypertensives.

Fat is avoided not only for its high caloric value, which contributes to obesity, but in particular for its cholesterol content, which leads to precipitation of arteriosclerotic plaques in the arteries, increasing the risk of coronary heart disease, particularly in combination with low density lipoprotein (LDL). Avoiding fat containing saturated fatty acids (e.g., those found in pork) as opposed to unsaturated fatty acids (those found in olive oil) reduces cholesterol formation, which is only increased by saturated fatty acids.

Avoidance of *sugar* aims at reducing calorie intake and preventing bacterial growth, which leads to dental caries. Bleached white sugar in particular is avoided because of its suspected cancerogenic property. According to animal research, this is claimed to develop from the formation of free radicals induced by the hypochlorites used for bleaching. But questionnaire studies relating health problems to consumption of sweet food did not reveal associations, although this food is consumed more in conditions of stress.

Smoked food is also avoided for its possible carcinogenesis. Its consumption leads to formation of nitrosamines and benzpyrines thought to damage DNA function, which again may lead to abnormal cell proliferation. *Food preservatives* like biphenyls (e.g., those sprayed on fruit) may also cause DNA damage. However, international food safety regulations that define the admissible daily intake (ADI) of food additives and the permitted procedures for smoking, radiation, or genetic manipulation of food are so stringent nowadays that food from countries subjected to these laws may be considered as generally safe.

The fear of *food contaminated* by microorganisms is widespread and leads to avoidance of unwashed or uncooked fruit and vegetables or to abstinence from food which is beyond its recommended date of consumption. However, no studies have been conducted to demonstrate noxious consequences to the health of people who neglected these dates, because there are wide safety ranges based on differing national regulations. However, since the discovery of the BSE disease in cows (suspected to lead to the central nervous condition Creutzfeldt-Jakob Disease, or CJD), and after reports of salmonella infections in chickens, avoiding respective sources of beef and eggs was felt to be justified even by government regulations.

Persons with respective experiences will avoid *food causing allergies*, such as fish, shrimps, eggs and other proteins, or fruit (particularly strawberries, tomatoes,

or nuts), but also food additives (such as benzoates or antioxidants, colorants, and flavorings). These allergies are mediated by intensive production of immunoglobulin E antibodies formed against the food allergens, which lead to severe antigen antibody reactions upon reexposure of antigens (for details, see Ziegler and Filer 1996).

2.3 Avoiding Drugs of Abuse

Alcohol is avoided because of several risk factors (see Verschuren 1993). The most prominent is drunken driving, but people are also afraid of developing liver cirrhosis, a degenerative induration of liver cells upon heavy long-term consumption. It results from inhibition of prolinoxidase, which leads to formation of fibrotic tissue. Furthermore, alcohol leads to higher concentrations of free fatty acids and to inhibition of protein synthesis, resulting in accumulation of lipoproteins and fat in liver cells (see *Drug Use and Abuse: Psychosocial Aspects*).

Thirty-two epidemiological studies proved a linear or j-shaped relationship between alcohol intake and blood pressure, even when age, weight, smoking, coffee consumption, and physical activity were partialled out. The regression becomes linear with consumption of 30–40 g of ethanol per day. Although acute alcohol administration and low doses may lower blood pressure by dilation of capillaries and reduced peripheral resistance, chronic intake may reduce the diameter of blood vessels by incorporation of cholesterol. Similar mechanisms are involved in the association between chronic consumption and stroke, whereas the protective effects of lower doses against coronary heart disease may be due to its fibrinolytic (and therefore antithrombotic) properties and its capacity to increase the antisclerotic high density lipoprotein (HDL). A further hypertensiogenic mechanism by higher doses is the activation of the renin-angiotensin system, which, in combination with a reduced venous return of the blood and neurogenic mechanisms, may exert pressor effects on the cardiovascular system. The relationship between alcohol and colonorectal cancer, however, is weak. Cell damage of the central nervous system after long-term exposure is well-known in psychiatry as the Korsakow disease (with symptoms of tremor and amnesia).

There is also a direct effect of ethanol on endocrine functions (decrease of testosterone, but increase of weak androgens and reduction of gonadotropin secretion from the hypothalamus and the pituitary) resulting in reproductive deficits.

Smoking in most cases is not a matter of decision to abstain from a primarily desired activity, because its reinforcing properties have to be learned, but quitting is related to avoiding risks. These are threefold: (a) nicotine induces adrenaline release, leading to vasoconstriction and the danger of coronary and peripheral arterial obstruction; (b) the formation of carbon monoxide-induced methemoglobin reduces oxygen supply, which increases ischemic pain; (c) the numerous carcinogenic substances contained in tobacco smoke, primarily benzyprens, are the major source of lung cancer, the prevalence of which among smokers is 5.2 times higher than in nonsmokers, even when correcting for confounding factors (age, social class, and alcohol consumption) (see *Smoking and Health*).

3. Application of Health-promoting Stimuli

Behavior of this type mainly refers to oral application of '*healthy food*,' vitamins, minerals, or drugs. Fruit and vegetables are considered healthy because of their low calorie and cholesterol content and richness in vitamins and fiber. Fiber promotes the motility of the intestines and protects against cancer. Proteins are preferred because they need more endogenous energy to be metabolized and are therefore less fattening than carbohydrates and fat.

With respect to *vitamins*, both under- and overdosing is related to disease. Therefore, health behavior may also result in symptoms caused by overdosing. *Vitamin A* (retinol) is a major product of rhodopsin necessary for vision. Deficiency not only results in problems adapting to the dark, but also sclerosis of the cornea, skin, and mucous membranes. Hypervitaminosis, among other symptoms, has teratogenic effects (malformations in the offspring). *Vitamins B1* (thiamin), *B2* (riboflavin), *B5* (nicotinamide), pantothenic acid, and *B6* (pyridoxine) are usually combined in vitamin pills and have the common function of serving as cofactors in different enzymes of the intermediate metabolism. Therefore, a multitude of symptoms may results from vitamin deficiencies: neurological (B1, B5, B6) and cardiovascular disturbances (B1), arteriosclerotic (B2) and dermatological/epithelial changes (B5, B6). *Vitamin B12* (cyanocobolamin) in combination with *folic acid* is involved in hematopoesis and nucleotide formation necessary for DNA formation. Therefore deficiency leads to pernicious anemia.

Vitamin C (ascorbic acid) is the most popular vitamin because of its well-known protective effects against scurvy. This is due to its ability to support collagen biosynthesis. The same mechanism is suspected to operate against invasion of microorganisms during infections. This vitamin, therefore, is consumed in large doses in order to avoid infectious diseases.

Vitamin E (tocopherol), by virtue of its antioxydative potential, protects the cells from free radicals and lipid peroxides which cause instability of cell membranes. Therefore, Vitamin E is said to be protective against carcinogenicity, and also against Alzheimer's disease.

Among *minerals and trace metals*, health-minded individuals are best familiar with the necessity of ingesting enough *iron* ions, available in meat and vegetables or medication, because of its central role in formation of hemoglobin, which transports oxygen. A deficiency may result not only from diminished intake, but also from increased need, such as during infections, pregnancy, and cancer; from dysfunction in storage in liver or bone marrow; and from increased loss, such as bleeding. *Fluoride* is known to be beneficial for protection against caries. Many other elements, such as calcium and phosphorus, are basic requirements for maintaining cell function and hence are constituents of diet supplementation. Also, the relevance of trace metals, for example iodine, copper, manganese, cobalt, zinc, and selenium, which fulfil important biochemical functions as cofactors in biotransformation enzymes (selen, zinc) or as components of hormones (iodine in thyroxin), are targets of dietary enrichment in persons concerned about health.

It must be summarized, however, that except for states of deficiency in vitamins, minerals, or trace metals as perhaps in malnutrition, disturbances of internal absorption, pregnancy, or infectious diseases, no health-promoting or disease-prohibiting effects of vitamins have been proven by epidemiological studies.

4. *Challenging the Organism by Training*

Health-minded persons attempt to adapt their organisms to environmental requirements for health reasons. They achieve this through training techniques, such as *somatic exercises*, relaxation, or behavior therapy. Somatic exercise, like sports, act on all the mediator systems listed above. Any isometric or isotonic muscular activity increases heart rate. But long-term training also increases the number and diameter of myocardial muscle fibers and the growth of collaterals of the coronaries. This results in the lowering of blood pressure and increase in stroke volume. The acute effect of running is said to produce short-term euphoria by release of endogenous β-endorphins.

There is a clear negative correlation between amount of exercise a person takes per week and their relative risk of mortality. It is supposed that this is due to production of lower values of LDL cholesterol. However, it must be kept in mind that performing exercise is not only a cause, but also a consequence of better health. Effects of physical exercise on the immune system follow the same inverted U-shape relationship as that of mental stressors. Increases in number and activity of NK cells (Shephard and Shek 1994), mediated by adrenaline and β-endorphin release, result from short-term activity but will be suppressed again upon longer physical strain, mainly by release of cortisol. Long-lasting or extensive sport activities may lead to higher rates of infections (see *Physical Activity and Health*).

Relaxation training and *biofeedback techniques* are usually applied to alleviate rather than to prohibit symptoms. These techniques aim at influencing the autonomic nervous system (blood pressure, thermoregulatory effects, or visceral symptoms) and musculoskeletal pains. Sleep disturbances may be alleviated because feedback loops from the SNS and baroreceptors to the brain may decrease neuronal firing. The effects may be acutely observed, but their enduring effects after cessation of training are never very long-lasting. Also, relaxation-induced effects on the immune system are well documented (e.g., in a review by van Rood et al. 1993), and include an increase in the number and activity of NK cells and macrophages and in immunoglobulin A. The clinical relevance for reduction of cancer or infections, however, has not been shown in the same populations because large prospective epidemiological intervention studies would be required.

Compliance with the physician's recommendations and willingness to take part in *behavior therapy* are, of course, similar active processes suitable to influence somatic functions.

5. *The Genetic Basis for Behavior and Mediator Systems*

As outlined in the introduction, many behaviors are determined by personality traits, and this again is partly of a genetic nature. Thus, risk-taking behaviors, such as seeking dangerous activities, exposing oneself to drugs of abuse (particularly alcohol), careless driving, unsafe sex, and risky dangers in connection with crime, have been clearly shown to have a genetic basis of about up to 56 percent. These behaviors may already be predicted from traits measured at early adolescence. The traits are directly related to lower expectations about the person's beliefs about their susceptibility to health risks, and are negatively associated with the personality dimensions agreeableness and conscientiousness. Traits such as neuroticism, anxiety, conscientiousness, and the coping style of sensitization are associated with cautious, health-minded behavior and avoidance of noxious stimuli. Also, these traits have been shown to have a genetic basis of about 30–50 percent. Undertaking training activities is probably more learned, but is also based on hereditary traits, such as conscientiousness.

On the other hand, somatic mediators are also very much influenced by genetic factors, for instance body weight or dispositions for heart and circulatory diseases. Genes responsible for the development of certain types of cancer have been traced to their location on certain chromosomes; the development of

diabetes, disturbances in lipoprotein formation, and the disposition for allergies and autoimmune diseases, as well as for Alzheimer's disease, have all been proven to have a genetic basis, as demonstrated by twin studies and by molecular genetic methods. Of course, genetic factors are never related to one gene or one chromosome, but result from multiple interactions between different genes.

The major conclusions drawn from above for future concern about health research are threefold:

(a) Health research should focus on the process characterized by the Allostatic Load Model developed by McEwen (1998), which refers to the ability 'to achieve stability through change,' i.e., activation of physiological systems in order first to cope with the stressor and then to shut off the allostatic response as soon as the stress is terminated. This means that not the size of response to a noxious stimulus, but the adaptability of the organism has to be the major concern.

(b) Epidemiological and psychophysiological/biochemical research should become more closely related.

(c) Scientific facts about the pathophysiology of risk factors should be provided by administrative agencies, instead of restrictive rules, in order to prevent health behavior ridden by irrational beliefs.

Biosphere Reserves

1. Definition

Biosphere reserves are natural protected areas included in a global network organized by the United Nations Educational, Scientific, and Cultural Organization (UNESCO). Participating countries propose land and water sites within their boundaries as potential biosphere reserves, and accepted sites are designated at the international level by UNESCO's Man and the Biosphere (MAB) Program. To qualify for acceptance as a biosphere reserve, a protected area must have global or regional significance for biological conservation, one or more inviolate core zones, and one or more surrounding buffer zones or transition zones where human communities utilize natural resources in ecologically sustainable ways.

Approval of a proposed site by the MAB Program morally commits the host country to manage the protected area according to designated standards and to participate in MAB's international biosphere reserve network. On-the-ground management of biosphere reserves continues to be the obligation of the individual countries, according to their national laws. Participation in the MAB biosphere reserve system is voluntary; countries are not required to designate biosphere reserves. UNESCO's role in the biosphere reserve network focuses on facilitating information exchange, providing guidance and technical assistance, encouraging international cooperation, and promoting financial and technical support from governments and international organizations. A small secretariat staffed by professional conservationists coordinates the biosphere reserve program from UNESCO's headquarters in Paris. As of mid-1999, 357 biosphere reserves had been established in 90 countries.

2. The Concept

The central tenet of biosphere reserves is the conservation of natural resources alongside their utilization for human benefit. The overall goal of biosphere reserves is the protection of biological diversity, but they differ from strictly protected areas such as national parks and wilderness areas by accepting

human settlement as a feature of the landscape. Biosphere reserves do not represent an attempt to wall out the external world, but to incorporate human populations into sustainable land-use systems. In most biosphere reserves, land ownership remains unchanged upon acceptance of the reserve into the global network: private landowners retain their holdings, but agree to manage them in ways compatible with the reserve's maintenance. In other biosphere reserves, all land areas are owned and controlled by the nation's government.

Although no single, land-use-zoning system exists for biosphere reserves, most contain three elements: a core zone, a buffer zone, and a transition zone. Valuable ecological resources are preserved in core zones, which are surrounded by buffer zones and transition zones characterized by increasing intensity of human use. These buffer zones and transition zones may include seminatural ecosystems and agricultural systems. Core zones are securely protected land or marine areas designed to conserve biological diversity, provide locations for monitoring minimally-disturbed ecosystems, and serve as sites for nondestructive research and education. A core zone usually represents a major ecosystem of world significance and is large enough to allow *in situ* conservation of the site's biological diversity. A biosphere reserve's core zone serves as a global benchmark of ecological health, setting the standard for comparison with the effects of human uses occurring elsewhere in the reserve. A clearly defined buffer zone, which surrounds or adjoins the core zones, may be used for activities compatible with sound ecological practices, including environmental education, tourism, and applied research. The buffer zone serves to integrate the biosphere reserve into the geographical region it represents.

The buffer zone may be used for education, training, and manipulative research on ecosystem management, and may include traditional land-use practices such as grazing, fishing, and even timber extraction. Where possible, a second form of buffer zone, the transition zone, surrounds the first for experimentation in alternative land-uses, education, training, and recreation, while simultaneously benefiting local human populations. The flexible transition zone may contain human settlements, agriculture, and other uses in which communities, management agencies, scientists, and other stakeholders work together to sustainably develop the area's resources (UNESCO 1996). In some biosphere reserves, human communities exist in both the buffer zone and transition zone. In other reserves, humans occupy only the transition zone.

Although the zoning system of biosphere reserves originally was envisioned as a series of concentric rings with the core zone in the center, zoning systems have been implemented in various ways, according to local conditions. In some countries, for example, a zone designed for sustainable resource extraction lies between core zones. Nonetheless, most biosphere reserves follow the usual model of having one or more well-protected core zones surrounded by a buffer zone and transition zone.

Because biosphere reserves are intended to emerge from a participatory process with local communities and natural resource harvesters, they have social, as well as spatial, components. Interest groups—or stakeholders—affected by the reserve may be invited to participate in planning the biosphere reserve's design and management. This participation is aimed at gaining community support for the reserve and commitment to its long-term success.

Sites selected by MAB for inclusion in the biosphere reserve network are intended to carry out three basic functions: conservation, development, and logistic support for research, education, and monitoring. More specifically, these three functions are designed to:

(a) Contribute to the conservation of landscapes, ecosystems, species, and genetic variation;

(b) Foster ecologically, socially, and culturally sustainable development; and

(c) Provide logistical support for environmental education, training, demonstration projects, monitoring, and research relating to local, regional, national, and global issues of conservation and sustainable development (Gregg 1999).

UNESCO's MAB program maintains a computerized data base, the MAB Information System, which provides details on the geographical, ecological, and administrative characteristics of the global network of biosphere reserves. The database includes relevant publications and information on research projects within the reserves.

3. *Process of Selecting Biosphere Reserves*

Proposals for new biosphere reserves are sent to the Paris office of UNESCO from the participating country's MAB National Committee or MAB focal point, or (if such entities have not been established) from the country's UNESCO National Commission. Formally established in 1971, the MAB is an intergovernmental United Nations program of research and training aimed at developing an interdisciplinary scientific basis for the conservation and rational use of the natural resources of the global biosphere. The MAB program is designed to provide continuous training of professional conservation personnel and to acquire, transfer, and apply the information needed to manage the world's natural resources. The World Network of Biosphere Reserves forms the backbone of the MAB Program.

Countries proposing biosphere reserve status for natural areas within their boundaries are asked by UNESCO's MAB Secretariat to submit maps and to complete a questionnaire about the site. The ques-

tionnaire allows MAB specialists to evaluate the suitability of the site as a biosphere reserve and supplies information for the network's computerized database. The database allows for the interchange of standardized information about accepted biosphere reserves. Data included in the questionnaire include latitude and longitude of the proposed reserve, minimum and maximum altitudes, total size, status of existing protection, land tenure, physical characteristics, vegetation, fauna, scientific research, and human modifications. MAB's International Coordinating Council, comprising representatives from 34 member states, gives final approval of protected areas for biosphere reserve status. The General Conference of UNESCO elects these representatives on a rotating basis. A few countries (e.g., Mexico and Guatemala) have enacted specific legislation declaring new protected areas as national biosphere reserves, which are later submitted to UNESCO for inclusion in the global network. However, most biosphere reserves encompass areas previously protected under other categories, such as national parks or wildlife reserves. Biosphere reserves may also be recognized through other international designations, such as World Heritage Sites and Ramsar wetland sites.

4. *Characteristics*

Michel Batisse, Senior Science Advisor to UNESCO and one of the pioneers of the biosphere reserve concept, defines the primary characteristics of biosphere reserves as follows (Batisse 1982):

(a) Biosphere reserves are protected areas of land and coast environments; together they should constitute a worldwide network linked by international understanding on purposes, standards, and exchange, of scientific information.

The network of biosphere reserves should include significant examples of biomes throughout the world.

(b) Each biosphere reserve should include one or more of the following: representative examples of natural biomes; unique communities or areas with unusual features of exceptional interest; examples of harmonious landscape resulting from traditional patterns of land-use; and/or examples of modified or degraded ecosystems that are capable of being restored to more-or-less natural conditions.

(c) Each biosphere reserve should be large enough to be an effective conservation unit and to accommodate different uses without conflict.

(d) Biosphere reserves should provide opportunities for ecological research, education, and training; they will have particular value as benchmarks or standards for measurement of long-term changes in the global biosphere as a whole.

(e) A biosphere reserve must have adequate long-term legal protection.

(f) In some cases biosphere reserves will coincide with, or incorporate, existing or proposed protected areas, such as national parks, sanctuaries, or nature reserves.

5. *History of Biosphere Reserves*

The term biosphere reserve emerged during a 1969 UNESCO-sponsored gathering of 80 scientists from 30 countries, aimed at coordinating a worldwide network of protected areas to ensure the conservation of genetic resources. The first official definition of biosphere reserves came in 1970 in a plan proposed to the UNESCO General Conference, which launched the Man and the Biosphere Program. A task force organized by UNESCO in Paris in 1974 formulated criteria and guidelines for the selection and establishment of biosphere reserves. In 1976, the MAB Bureau of the MAB Coordinating Council designated the first cohort of 57 biosphere reserves. By the following year, the network had grown to include 118 biosphere reserves in 27 countries.

During a 1981 international conference sponsored by UNESCO to review the MAB program, delegates focused on the need to emphasize the development and integration of the functions of biosphere reserves, rather than the designation of a maximum number of sites. The conference also set the stage for the first International Biosphere Reserve Congress, held in Minsk, Belarus, in 1983. International specialists at the conference produced the first detailed compilation of biosphere reserve case studies and made recommendations for a program framework. UNESCO used these recommendations to publish its first Action Plan for Biosphere Reserves, adopted by the organization in 1984. The plan recommended a minimum set of activities for implementation in each biosphere reserve, including baseline inventories of flora and fauna, preparation of a history of research, establishment of research facilities and research programs, and preparation of a management plan that addresses the three defined biosphere reserve functions of conservation, sustainable development, and logistic support for research, education, and monitoring (UNESCO 1984).

Through time, the concept of biosphere reserves has been elaborated and clarified in international meetings. In 1982, a MAB Scientific Conference celebrating the tenth anniversary of the MAB program added the phrase 'representative ecological area' as a subtitle to the term biosphere reserve. The biosphere reserve network is designed to include ecosystems that are representative of the major biomes of the world, as defined by a global classification of biomes based on 193 biogeographical provinces belonging to 14 types of biomes within 80 biogeographical realms. The biogeographer Udvardy created this classification at

the request of UNESCO and the International Union for the Conservation of Nature (IUCN) in 1975. During its first 10 years of existence, conservationists promoting the biosphere reserve attempted to include at least one biosphere reserve in each biogeographical province. However, the requirement that participating countries must nominate sites within their borders before they can be included in the network has hindered the goal of full coverage.

In 1995, in Seville, Spain, UNESCO sponsored an international conference of experts to recommend a new strategy for developing effective biosphere reserves. The Seville Strategy (1996) establishes goals, objectives, and actions for implementing the biosphere reserve concept at international, national, and biosphere reserve levels. The Strategy includes a checklist of indicators for use in evaluating progress in implementation. The document also presents a statutory framework of the World Network of Biosphere Reserves, setting forth definitions, functions, selection criteria, and designation and review procedures for biosphere reserves. One new provision in the documents requires governments to submit status reviews of each biosphere reserve every 10 years for comments and recommendations by MAB's International Coordinating Council. The Seville Strategy also highlights the role of biosphere reserves in responding to Agenda 21, an agreement that resulted from the United Nations Conference on Environment and Development (the Earth Summit), in Rio de Janeiro, Brazil, in 1992, as well as the contribution of biosphere reserves to implementation of the Convention on Biological Diversity.

6. *Trends and Criticisms*

From its first list of 57 sites in 1976, the biosphere reserve network grew to include 214 reserves in 58 countries by 1982, and by 2000 to 368 biosphere reserves in 91 countries. New biosphere reserves are added to the network each year. More than 110 countries have joined the program and formed national MAB committees. The development of the biosphere reserve concept helped create a new movement in environmental conservation that focuses on combining the protection of biological diversity with sustainable economic development for human benefit. The link between biological diversity conservation and the development needs of human communities is now recognized as a central component in the successful management of protected areas. Because they are designed to be relevant to human needs, biosphere reserves have helped make the conservation of biological diversity more scientific, more systematic, and more socially and economically acceptable to human populations.

Within biosphere reserves themselves, recent innovations include new methodologies for involving stakeholders in decision-making processes and resolving conflicts. New kinds of biosphere reserves are also evolving, such as cluster and transfrontier reserves, which transcend national boundaries (e.g., the La Amistad Biosphere Reserve in Costa Rica and Panama).

During the late 1990s, information exchange emerged as a priority goal for the network of biosphere reserves. New international networks, facilitated by the Internet and expanded access to computers, are improving communication and cooperation between biosphere reserve managers in different countries. Funding from the Global Environmental Facility (GEF) has linked biosphere reserves in five Eastern European countries via the Internet. The technology firms Intel and NEC have joined with UNESCO and Conservation International to provide communications training and equipment for 25 biosphere reserves in Africa, Asia, and Latin America. The EuroMAB Network sponsors workshops that link biosphere reserves in Europe with reserves in North America. Regional networks have been established for Spanish and Portuguese-speaking biosphere reserve managers in Latin America and for French and English-speakers in Africa. These regional efforts are connected to one another through the UNESCO-MABnet Internet site (http://www.unesco.org/mab).

Some conservationists have criticized the sustainable development aspect of biosphere reserves as 'wishful thinking' (e.g., Terborgh 1999). In his view, project managers who try to invigorate the local economy (e.g., in buffer zones) of protected areas, end up attracting new settlers to a reserve's perimeter, thereby increasing external pressure on the protected area's natural resources. Terborgh warns that such projects 'shoot at the wrong target'—local communities rather than the protected area and its resources (Terborgh 1999).

Other researchers have noted that while biosphere reserves 'look like a politically expedient and socially acceptable way of meeting livelihood and conservation needs,' in reality, the management of biosphere reserves is more socially complicated than that of conventional parks (Brandon 1998). To be successful, this perspective holds, biosphere reserves require agreements with local people to stop using the resources of the core zones, to alter use patterns in the buffer zones, and to agree to abide by a new management authority. At the same time, the biosphere reserve concept facilitates conservation efforts in some protected areas precisely because it emphasizes agreements with local populations in the reserve's design and management.

The 1996 Seville Strategy declared that biosphere reserves are now poised to take on a new role. The rapid growth of the human population and increasing consumption of natural resources are forcing conservationists to search for examples of how to merge conservation and sustainable development. According

to the Seville Strategy, 'Biosphere reserves offer such examples,' becoming theaters for reconciling people and nature by showing the way to a more sustainable future. The Seville Conference concluded that the three basic functions of biosphere reserves—conservation, sustainable development, and logistic support for research, education, and monitoring—will be as valid as ever in future years. The primary challenges to biosphere reserves today are adding new sites to improve world coverage and ensuring that biosphere reserves fulfill their designated functions.

Biotechnology

In the closing decades of the twentieth century, biotechnology emerged as a site of rapid change in science and technology and as an arena of social and institutional transformation. The development of new techniques for studying, manipulating, and redesigning living things produced important applications in medicine and agriculture, and generated massive investment. In the world of research, biotechnology was often at the forefront of change in scientific institutions and practices. More broadly, biotechnology—widely perceived as having 'revolutionary' implications—inspired both intense enthusiasm and determined opposition. As an area of science and technology with the explicit goal of intervening in the machinery of life, biotechnology often disrupts traditional ways of distinguishing 'nature' from 'culture,' calling into question settled social arrangements and presenting societies with unfamiliar risks, unprecedented ethical dilemmas, and novel opportunities. As a result, biotechnology poses difficult challenges of governance. This article examines the rise of biotechnology and considers its technological and epistemic structure, its institutional dimensions, and its problematic position in contemporary politics.

1. The Term Biotechnology

Defining biotechnology poses challenges, for the word is less a tightly-defined, technical term than a loose umbrella category, or even a slogan, that conveys—sometimes simultaneously—visions of unbounded progress and unregulated tampering with nature. Many authors have tried to capture biotechnology within their own well-crafted definitions, but these attempts cannot neatly contain this expanding network of activities and its increasingly dense connections to diverse social worlds. Although the word has a long history (Bud 1993), in most contemporary contexts biotechnology refers to a novel and growing collection of techniques, grounded in molecular and cell biology, for analyzing and manipulating the molecular building blocks of life. The term also designates products, such as pharmaceuticals or genetically-modified foods, created using these techniques. At times, it refers not to products or techniques but to an economic sector or area of research. Biotechnology acquired these intertwined meanings toward the end of the 1970s, coming into widespread use in the early 1980s, as molecular biology was increasingly understood not only as a 'science' for learning about nature but also as a 'technology' for altering it.

2. The Biotechnology 'Revolution'

One of the ironies of the rise of biotechnology is that a sense of revolutionary potential energizes both the enthusiasm and the opposition it engenders. Supporters and critics alike often fit biotechnology into a narrative of radical discontinuity (e.g., Conway 1997, Kevles and Hood 1992, Rifkin 1983). Biotechnology advocates claim that it will completely transform medicine, spawn entirely new industries, and supply

adequate food to the growing world population. Critics—who warn of unanticipated consequences and the hazards of altering human identity—also cast the new biology as a revolutionary force, arguing that genetic engineering is ushering in a risky new stage in evolution, as nature itself comes under technological control.

Alongside the notion of revolution, the discourse on biotechnology also features an opposing frame that stresses continuity with the biological and historical past. Thus, supporters of biotechnology sometimes downplay its novelty, defining it inclusively (e.g., as the harnessing of biological agents to provide goods and services) and portraying it as merely the latest twist on age-old methods of plant breeding, animal husbandry, and brewing. Such moves help to make the exotic familiar, to suggest that ancient precedents justify apparently novel practices, and to undermine the notion of an untouched 'natural' order that must be protected from human intervention. Critics of biotechnology, for their part, often contend that predictions of unprecedented progress overstate the benefits, suggesting that biotechnology will perpetuate, rather than eliminate, long-standing inequalities in agricultural and health care systems.

As these observations suggest, narratives of continuity and discontinuity provide opposing frames that participants in debates about biotechnology can selectively deploy to mobilize support for their views. But for social scientists, the relevant question is whether the concept of a biotechnology revolution has analytic utility. Although some might be tempted to dismiss this notion as overheated rhetoric, many people in contemporary societies apprehend biotechnology in precisely these terms. Like information technology and computers, biotechnology seems perpetually to stand at the threshold of the next qualitative transformation (see *Science and Technology, Social Study of: Computers and Information Technology*). Biologists who pause to marvel at the pace of progress, like ordinary citizens who reflect on the stream of announcements from the research front, experience biotechnology as an area of ongoing change where old boundaries are continually broken and the unprecedented rapidly becomes the mundane.

2.1 A New Technological and Epistemic Space

Whether framed as revolutionary change or incremental evolution, biotechnology clearly emerged from a complex constellation of phenomena, among them the development of increasingly powerful tools for representing and manipulating the molecular building blocks of life. The development of such techniques as recombinant DNA technology, monoclonal antibodies, in vitro fertilization, the polymerase chain reaction (PCR), and high-throughput DNA sequencing have dramatically extended human control over living organisms. Although the arrival of each of these techniques was widely heralded as 'revolutionary,' the increasing power of biotechnology cannot be attributed to any single tool, but stems from the ability to combine and recombine such tools, creating new assemblages capable of building and taking apart molecules, rearranging the genetic code of organisms, and reading and writing the 'language' of DNA. No less significantly, such techniques have consolidated and accelerated epistemic change in the life sciences, increasing the centrality of metaphors from information theory and cybernetics (e.g., code, control, and text) for understanding living things (Kay 1999, Keller 1995). More precisely, these tools provide practical means that, quite literally, lend substance to these metaphors, giving them material form and making them into epistemic things embedded in experimental systems (Rheinberger 1997) and sociotechnical networks (see *Experiment, in Science and Technology Studies*).

The field of molecular biology expanded rapidly after World War II, and by 1970, scientists knew how genes specify protein structures and had found enzymes that cut, join, and extend DNA molecules. This set the stage for recombinant DNA technology (rDNA)—the emergence of which is often taken as the starting point for modern biotechnology. Recombinant DNA techniques enabled scientists for the first time to insert or delete genes from the genetic code of living things, for example, by removing a piece of DNA from one organism and splicing it into the DNA of a distantly related species. The development of these methods generated great excitement and provoked controversy (discussed below) about the wisdom and safety of genetic engineering. Beyond opening up a wide range of new research strategies, this technology allowed scientists to design genetically modified organisms to produce commercial products. In the late 1970s, researchers began using genetically engineered bacteria as microscopic manufacturing plants for making valuable proteins, such as human insulin and human growth hormone.

In the last two decades of the twentieth century, the power of the biotechnology tool kit continued to increase. The development of monoclonal antibodies, which permitted scientists to construct extremely accurate assays for detecting specific proteins, yielded applications in research and medical diagnostics (Cambrosio and Keating 1995). New methods for transferring genes into developing embryos allowed scientists to alter the genetic code of animals, thus extending genetic engineering from microorganisms to higher forms of life. Parallel techniques enabled scientists to produce transgenic plants, modifying the genomes of agricultural crops to enhance disease resistance, shelf life, and other properties. Molecular biology and biotechnology also played an increasingly central role in the development of pharmaceuticals, including

vaccines, antibiotics, and drugs used to combat heart disease, cancer, and AIDS.

Tools and practices for representing and analyzing DNA molecules were also rapidly developed (Fujimura 1996). Methods for mapping the location of genes grew increasingly powerful; the polymerase chain reaction (PCR) became important in research, diagnostics, and forensics (Rabinow 1996); and DNA sequencing—a technique for representing the nucleotide sequences of DNA molecules as written inscriptions (strings of the letters A, C, G, and T)—rapidly developed. In the 1990s, the human genome project, along with other concerted mapping and sequencing efforts, produced an exponentially increasing volume of biomolecular data on a variety of organisms of medical and agricultural importance (Cook-Deegan 1994, Fortun 1998, Hilgartner 1998). These data—along with increasingly automated means of producing, standardizing, ordering, and analyzing them—constituted the core of genomics, a field that further united information sciences and biology. In effect, by opening up new computational approaches to biology, genome research created a new technological and epistemic 'space,' allowing researchers to perform 'experiments' *in silico* or in a domain linking computational work to the 'wet lab.'

2.2 New Institutional Spaces

Large infusions of capital, promotional state policies, and novel institutional arrangements played a significant role in spurring these developments (Thackray 1998). By the end of the 1970s, government, industry, and academic elites in both Europe and the United States saw investment in 'high technology'—especially computers and biotechnology—as the long-term prescription for economic growth. On both sides of the Atlantic, policymakers sought to spur innovation and speed the translation of basic science into marketable products. The result: a significant shift in the political economy of research that eased the commodification of knowledge (see *Intellectual Property, Concepts of*). Governments encouraged universities and corporations to form new kinds of academic–industry alliances, and the scope of intellectual property protection grew considerably broader, expanding to encompass, for example, genetically engineered organisms (Boyle 1996, Jasanoff 1995a).

In the United States, significant numbers of academic biologists became entrepreneurs for the first time. The most dramatic institutional innovation was the startup company founded by venture capitalists and university professors—many of whom kept their academic posts (Kenney 1986). Increasingly, biotechnology research took place in spaces that were not neatly lodged in either an academic or a corporate milieu, but in complex hybrids of university and industry, public and private, basic and applied (see *Science and Industry*; *Universities and Science and Technology: United States*). Some observers warned that these hybrids would threaten the independence of academic biologists, compromising their ability to offer a credible, critical voice in public decision-making. Ultimately, however, these institutional innovations proved irresistible, given competitive pressures and the scientific and economic opportunities.

Owing to international variation in research systems (see *National Innovation Systems*), the commercialization of biotechnology followed distinct paths in different nations. In Europe and Japan, the large multinational corporations (MNCs) that control production of pharmaceuticals, chemicals, and agricultural inputs built biotechnology directly into their in-house research operations. But in the United States, with its unique pattern of venture capital financing, a separate 'biotechnology industry' composed of free-standing firms took shape (Kenney 1998). The first major wave of biotechnology firms appeared between 1979 in 1981, and during the following two decades, entrepreneurs founded successive waves of firms, whipping up investor enthusiasm around a series of 'revolutions,' including monoclonal antibodies, gene therapy, and genomics.

Even in the United States, however, MNCs—which have poured huge sums into genetic engineering, rational drug design, and genomics—became the dominant players in efforts to exploit the new biology commercially. Indeed, given the structural connections between the biotechnology firms and the MNCs, the image of a separate biotechnology industry is somewhat misleading: Biotechnology startups often derive the bulk of their revenue from contracts with giant companies; MNCs often acquire successful firms; and many biotechnology firms are best understood as research shops that hope to sell intellectual property to large corporations.

3. The Politics of Biotechnology

New institutional spaces have been important not only to the commercialization of biotechnology but also to its politics. Since the early 1970s, biotechnology has posed difficult problems of governance, confronting societies with a stream of potentially controversial issues. More deeply, because biotechnology often seems to undermine basic categories of social order, such as the 'natural' or the 'human,' it tends to pose problems that do not fit neatly into the cosmologies and routines that guide public action. Democratic societies thus face the challenge of building new discursive regimes, regulatory mechanisms, and forums for public discussion that can produce legitimate settlements in this context. In this respect, the institutionalization of risk management and bioethics

have been particularly important. Although the precise techniques for engineering consent have varied across nations (Gottweis 1998, Jasanoff 1995b), states have consistently responded to opposition in ways that allowed the development of biotechnologies to proceed. Despite a cascade of visible controversies, states have so far managed to convert volatile mixtures of concerns into more stable forms. Unstable blends of technical uncertainties, science fiction scenarios, critiques of corporate power, and misgivings about hubris and slippery-slopes, have been discursively distilled into categories amenable to bureaucratic management and expert decision-making (Jasanoff 1995b).

3.1 Risk Management

The process of 'thinning' multidimensional controversies into manageable technical problems susceptible to rqegulatory solutions is well illustrated by what has come to be known as the recombinant DNA debate (see *Risk, Sociology and Politics of*). During the 1960s and early 1970s, scientists and other observers often construed the arrival of genetic engineering—viewed, once again, through the frame of radical discontinuity—as a portentous development that raised many troubling choices for society. As researchers became convinced that molecular techniques would soon make it possible to modify the genomes of living organisms, a number of prominent scientists warned that developments in biology could be dangerously misapplied, and they called for broad public discussion of such possibilities as genetic engineering of humans. However, soon after researchers began splicing genes into bacteria and viruses, the focus of discussion shifted from broad concerns about the long-term implications of genetic engineering to much narrower and immediate questions about the laboratory hazards of recombinant DNA (rDNA) research (Wright 1994). In particular, scientists familiar with the early gene splicing experiments worried about accidentally creating dangerous microorganisms, resulting in catastrophic epidemics or disrupting ecosystems. The problem of providing credible scientific arguments that rDNA research could be safely conducted posed significant challenges given limited evidence and technical debate about the magnitude of the hazards, and in 1974 ten prominent biologists published a call for a partial moratorium on certain rDNA experiments.

The debate about the 'moratorium' and the physical hazards of rDNA research threw the future of genetic engineering into doubt, but it also allowed broader ethical and political questions to slip into the background (Gottweis 1998, Wright 1994). Moreover, scientific experts soon developed a discursive framework that provided a technical strategy for controlling the laboratory risks. This strategy, which took shape at a famous international meeting in Asilomar, California, relied on a system of classification (experiments would be grouped according to their expected level of hazard) and a gradient of controls (e.g., physical barriers, such as negative air pressure, and biological controls, such as 'disarmed' bacterial strains unable to survive outside the laboratory). On both sides of the Atlantic, the strategy of requiring increasingly stringent containment for increasingly risky experiments formed the basis for guidelines or regulatory controls, designed by expert committees, that allowed research to proceed.

Containing the microbes within the laboratory became a means of containing fears and allowing genetic engineers to pursue the unbounded possibilities they believed to lie before them. As the 1970s progressed, these controls were progressively relaxed as a growing number of scientists concluded that the danger of devastating epidemics was remote. Ultimately, the resolution of the controversy inspired a second-order debate about whether scientists, policymakers, and publics had responded appropriately or excessively to the risks of novel organisms. In contemporary debates over biotechnology, the rDNA debate has acquired an almost mythic status: for some, it serves as a cautionary tale about the dangers of irrational fear of technology; for others, it provides a commendable example of scientists taking responsibility for the social implications of their work.

In the 1980s and 1990s, new regulatory challenges emerged as agricultural biotechnologists sought to move genetically modified organisms (GMOs) from the laboratory to the field—first on an experimental basis and later in full-scale production (see *Agricultural Sciences and Technology*). In this context, risk management shifted from containment to deliberate release into the environment, a move that engaged new sources of expertise, such as ecologists, in risk assessment. Fears grew that agricultural biotechnology might accidentally produce new superweeds, alter ecosystems, trap the poor farmers of the developing world in dependency on imported seeds, and expose unsuspecting consumers to the risks of allergic reactions. Although the political culture of GMO regulation differed substantially internationally, in the United States, Germany, France, and the United Kingdom the dominant policy narratives defined the regulatory challenge in terms that allowed development of the technology to proceed, framing agricultural biotechnology as potentially risky but beneficial and indispensable given international competition, defining hazards as amenable to expert solutions, and developing experimental systems for measuring and monitoring risks (Cambrosio et al. 1992, Gottweis 1998, Jasanoff 1995). Whether, and under what conditions, these patterns of accommodation will prove durable, however, remains an open question—especially in some European Union countries, where public trust in GMO regulation to protect consumers and the environment has been lacking.

The global marketing of seeds and the rise of social movements opposed to GM foods in Asia, Latin America, and the United States, also suggest that the transnational dimensions of the politics of biotechnology are likely to remain important.

3.2 Bioethics

The policy narratives and practices of risk management offered one means for translating the unruly politics of biotechnology into governable forms; bioethics offered another—especially regarding human biotechnology and molecular medicine. The potential of the new biology to destabilize, redefine, or deliberately alter the identities of individuals, groups, or 'human nature' often generated apprehension or resistance (see *Human Sciences: History and Sociology*; *Biomedical Sciences and Technology: History and Sociology*). Thus, some observers worried that predictive genetic testing would threaten privacy and deprive people of uncertainty about fate; others feared that genetics would reinforce racial prejudices or produce new stigmatized groups; still others objected to the desacralization and commodification of human life. Such worries, which did not neatly fit into the technical and economistic discourse of risk management, were typically addressed through the interpretive frameworks and institutions of bioethics.

During the 1970s and 1980s, bioethics emerged as an institutionalized area of inquiry and technique for decision-making. The bioethics phenomenon, like the growth of risk management, was by no means confined to biotechnology. In medicine, health care, and clinical research, bioethics—performed in such diverse sites as academic literatures, national commissions, hospital ethics committees, and, most recently, biotechnology corporations—has grown into a prominent feature of public life (DeVries and Subedi 1998, Kleinman et al. 1999, Rothman 1991). The rise of biotechnology contributed to the rise of bioethics, fueling its growth with a cascade of controversies about genetic testing, gene therapy, and reproductive technology—matters that increasingly came to be seen as part of the professional jurisdiction of a new cadre of bioethics experts (see *Science and Technology Studies: Experts and Expertise*). Indeed, by the late 1980s, when the Human Genome Project was proposed, the notion that bioethical analysis could play a major role in addressing the societal dimensions of the new biology was sufficiently widespread that national governments flocked to build 'ethics' into their programs of genomics research (Cook-Deegan 1994).

The peculiar relationship between the domains of bioethics and biotechnology is nicely illustrated by the politics of governmental programs on the ethical, legal, and social implications (ELSI) of genomics. Here, a broad consensus supporting ELSI programs often coexisted with deep disagreement about what these programs should aim to accomplish. The US ELSI program, for example, was celebrated as an important innovation in science policy and presented as proof that social concerns would not be neglected, yet the program was also beset by criticism from many directions. Thus, the ELSI program was accused of being both hypercritical and unduly promotional of genetic technology; of taking an overly academic and long-term view and of narrowly focusing on the immediate; of being too small to address the pace of change and of being a waste of valuable research funds. But such debates about the shape of these programs missed the more pervasive, if subtle, ways that bioethics functions as a quasi-regulatory institution in contemporary states. Bioethics provided an idiom and institutional space for defining controversies about human genetics and genomics as ethical issues, better addressed through moral reflection than mobilization. More deeply, bioethics shored up the legitimacy of political institutions, suggesting that states could find rational and secular means for drawing moral boundaries to replace the apparently natural ones that the biotechnology revolution erased. In this way, bioethics—like other forms of expert advice (Jasanoff 1990, Hilgartner 2000)—has become an important tool not merely for making decisions but also for reordering societies challenged by rapid technological and social change.

Bipolar Disorder (Including Hypomania and Mania)

1. Introduction and Historical Background

Bipolar disorder, also known as manic-depressive illness, is a typically episodic, often severe, and sometimes disabling psychiatric illness characterized by marked changes in mood, thinking, and behavior (Goodwin and Jamison 1990, Sadock and Sadock 2000). Bipolar disorder is a major public health problem, although sometimes under-recognized. Characteristically, its symptomatic changes present in extremes of mania and depression, or with simultaneous excited and depressive features. Although mania and severe depression (melancholia) have been described as distinct conditions since antiquity, the unique aspect of bipolar disorder is their occurrence in the same person over time.

The concepts of mania and melancholia were well established by Hippocratic physicians (c. 400 BC). Aretaeus of Cappadocia (AD 150) is credited with having first proposed the association of mania and melancholia in the same person (Adams 1856). Elaborations of this concept did not appear in the European medical literature until the early 1800s, including descriptions of double or circular insanity by Jules Baillarger and Jean-Pierre Falret in 1854. Emil Kraepelin (1921) later proposed a more systematic, comprehensive, and influential description of manic-depressive insanity based on his observation of many patients with recurrent melancholic episodes and fewer cases with manias as well as depressions.

The contemporary distinction of bipolar (manic and depressive) and unipolar (depressive) forms of recurrent major mood disorders evolved in the writings of Karl Kleist and Karl Leonhard in the 1950s. In the 1970s David Dunner and Ronald Fieve proposed the further subdivision of bipolar disorder into types I and II, based on the presence of mania vs. hypomania, as well as recurrent depression. In the 1980s, Hagop Akiskal proposed an even broader bipolar spectrum disorder, ranging from minor to severe forms (Goodwin and Jamison 1990).

2. Mania and Bipolar Depression

Episodes of mania present with an increased rate of thinking and speaking, increased physical and sexual energy, decreased need for sleep, and changes in appetite. Thinking is typically rapid, pressured, overproductive, and semilogical, often with a grandiose flavor. As a result, attention and concentration are impaired. Manic persons are often distractible, with continuous shifting of topics that are only loosely connected or hard to follow. Attempts to interrupt pressured behavior often provoke irritable or angry responses. Overactivity includes incessant but disorg-

anized and aimless motion, often without clear or well-sustained aims. Dysfunctional behavior derives from grossly excessive self-confidence, and includes lack of inhibition, intrusiveness, impulsivity, recklessness, irritability, and sometimes aggressiveness. Risk taking is common, and may include unrealistic plans or implausible business schemes, impulsive overspending or gambling, disinhibited sexual activity, or reckless driving, with or without abuse of alcohol or illicit drugs.

Depending on the intensity of the mood elevation, two different types of manic episodes occur. Fully expressed mania usually involves disruptive or dangerous behavior requiring emergency treatment, white hypomania is a milder form of sustained, unnatural mood elevation that may not disrupt occupational and interpersonal relationships, and may require intervention or treatment, but rarely on an emergency basis. In hypomania, as well as in mania, judgment is often impaired.

Bipolar disorder also includes major depressive episodes in forms ranging from profound inertia to agitation. Characteristically, bipolar depression presents with generalized psychomotor retardation or slowing of thought and activity, with loss of interest in usual or pleasurable activities and impaired self-care. Along with a low level of energy, lassitude, loss of sexual libido, and abnormalities of sleep and appetite are usually found. Sluggish thinking, impaired concentration, and inability to make decisions are common, and feelings of guilt, worthlessness, and self-blame may be present. Self-assessments usually are severely distorted, unrealistically negative, and pessimistic. Sometimes, somatic complaints such as migraine-like headaches, aching muscles or joints, gastrointestinal, respiratory, cardiac, and other vegetative symptoms, may be more prominent than psychic symptoms. Despair and hopelessness are common, and there is a greatly increased risk of suicide during depressive or dysphoric-agitated phases of the illness, with much less risk during hypomania or mania.

3. *Other Psychopathological Features*

Bipolar disorder can present with mixed manic-depressive states that include both depressive and manic features at the same time or in rapid alternation. Indeed, many episodes of mania and most episodes of mixed states are characterized by striking lability of mood, with rapid shifts from one extreme to the other within minutes or hours.

In addition, psychotic symptoms can be found in perhaps three-quarters of bipolar disorder patients at some time. Bipolar disorder is, arguably, the most frequent form of idiopathic psychotic illness, exceeding even schizophrenia in frequency. Most commonly, the delusions of bipolar disorder are paranoid, with either grandiose or persecutory themes (often pertaining to religious or other fame- or power-based exaggerations), particularly in manic or mixed episodes. Nihilistic or guilty delusions and other pessimistic exaggerations are more common in depressive phases of the illness. Self-referential misinterpretations of random events, as well as auditory hallucinations, may occur in both types of episode. Psychotic features are often consistent with the current dominant polarity of mood, and so may be mood-congruent (olothymic). Alternatively, mood-incongruent delusions may involve impressions that thoughts are being externally controlled, inserted by, or broadcast to other persons. A small minority of patients are described as schizoaffective because they show an excess of psychotic over affective features. They often become chronically ill with severe disability, and such disorders are considered a type of schizophrenia in current nosological systems.

Persons diagnosed with bipolar disorder often show features of other psychiatric syndromes, such as major anxiety disorders, including panic disorder, obsessive-compulsive disorder, or lesser forms of generalized anxiety or particular phobias, and may meet diagnostic criteria for more than one disorder. In addition, abuse of alcohol or drugs occurs often in patients with bipolar disorder, and can severely complicate clinical management and worsen the overall prognosis. Whether substance abuse is a contributing cause of bipolar disorder, or the disorder favors addictive behavior remains unresolved.

Psychodynamic characterizations of patients with bipolar disorder recognize prominent narcissistic features, lack of empathy, instability of interpersonal relationships, use of denial and activity defenses in mania, and guilt-driven self-aggressiveness in depression. Mania has been considered an attempt to avoid or to compensate for depressive phases. Depression has been interpreted as a manifestation of self-aggressiveness in response to the loss of a loved object (psychoanalytic perspective), as a consequence of learned helplessness after repeated unavoidable experiences (developmental-behavioral model), and as an expression of negative self-evaluation activated by stress and learning (cognitive approach). Both polarities share common traits that may include emotional dependence, deficient awareness of internal emotional responses in oneself or others, and a lack of appreciation of differences between actual and idealized situations.

4. *Diagnosis*

The presence of at least one episode of mania is sufficient for a diagnosis of type I bipolar disorder, although most cases involve a series of manic and depressive recurrences over several years. Persons with recurrences of clinical depression and hypomanic episodes are considered to have type II bipolar

disorder. Both types are recognized in the World Health Organization's *International Classification of Diseases* (*ICD-10*, World Health Organization [WHO] 2000) and the American Psychiatric Association's *Diagnostic and Statistical Manual* (*DSM-IV-TR*, American Psychiatric Association [APA] 2000). The latter also recognizes rapid-cycling bipolar disorder, with at least four episodes of mania or depression within 12 months of clinical assessment (Dunner and Fieve 1974, APA 2000).

These standard diagnostic systems also recognize secondary forms of bipolar disorder that may arise in association with exposure to a variety of drugs or toxins, or emerge with various neurological or general medical disorders. Cyclothymia is also recognized as a less severe form of bipolar disorder whose diagnostic criteria are not as well established and overlap with those of type II bipolar disorder as well as certain personality disorders.

5. *Course of the Illness*

The onset of bipolar disorder is often unrecognized as such, and several years may precede diagnosis and appropriate treatment. Many cases start in adolescence, and sometimes before puberty, when their distinction from attention or conduct disorders of childhood is often difficult (Papolos and Papolos 1999). More than half of bipolar cases present initially with an episode of mania or hypomania, particularly in men, whereas initial depressions are more common in women. Women also tend to have more type II bipolar illness and prominent depressive episodes. In some cases, presenting with recurrent depression, mania or hypomania emerge later, sometimes during treatment with an antidepressant medicine, but late emergence of bipolarity is unlikely after three or more depressive episodes.

The natural duration of untreated episodes of mania or bipolar depression is about six to nine months, with approximately yearly recurrences, on average. With modern psychopharmacological treatments, acute episodes of mania last about one to two months, and depression, two to four months. Without treatment, episodes of mania are slightly more common than depressive episodes, but the total time in depressions exceeds that in manias over years of bipolar illness, regardless of treatment (Angst 1978, Tondo et al. 2001).

Single episodes of mania with or without depressions, as well as single episodes of depression with one or more hypomanic or manic episodes occur in small proportions of cases. Instead, episodic recurrences are the rule in adolescent and young adult bipolar disorder, and their course over years tends toward worsening. Initial intervals of more or less normal mood (euthymia) may average two to three years in young adults, but these intervals usually shorten with successive recurrences, leveling off at eight to nine months after six to eight recurrences (Angst 1978). About 15 percent of bipolar disorder patients eventually follow a more or less chronic course.

Pediatric-onset bipolar disorder often does not follow a clearly episodic course, but may instead involve highly unstable mood and behavior over periods of months or years. A pattern of discretely recurring episodes of mania and depression becomes established during adolescence and is usual in young adults (Faedda et al. 1995, Shulman et al. 1995, Papolos and Papolos 1999). Late-onset bipolar disorder also tends to recur with relatively high frequency from the start, and many geriatric cases become more or less continuous or chronic, and may respond unfavorably to treatment (Shulman et al. 1995).

The succession of manic and depressive episodes often follows fairly consistent or repetitive patterns in the same person over time, with manias preceding depressions or vice versa, or with a continuously circular course with no free intervals; fewer cases follow an erratic or unpredictable course (Angst 1978, Kukopulos et al. 1980). Rapid cycling occurs in about 15 percent of cases, but only a fraction of such persons sustain high rates of recurrence over many years. Rapid cycling is somewhat more common among women and persons with type II bipolar disorder. An uncertain proportion of cases of bipolar disorder follows a rather consistent hemicircannual or seasonal course, commonly but not always, with depressions in fall or winter and manias in spring or summer (Rosenthal and Wehr 1987). This recurrence pattern is more likely with greater distance from the Earth's equator, among women and in younger persons.

A majority of bipolar-disorder patients experience some degree of recovery between episodes of acute illness, and euthymic or stable periods often allow them to re-establish previous activities and relationships. Nevertheless, even with modern treatment, bipolar disorder can lead to sustained occupational and interpersonal dysfunction, particularly following youthful onset, psychotic symptoms, and early hospitalization. At least 5 percent of bipolar-disorder patients shift from a classic early course to a schizoaffective disorder marked by chronic psychotic symptoms and severe dysfunction. Poorer outcomes tend to associate with either very early or very late onset age, frequent presentation of mixed episodes and psychotic features, severe and sustained depression, and perhaps with a tendency toward sustained relatively rapid cycling and a relatively large number of untreated episodes (Goodwin and Jamison 1990). An important contribution to long-term outcome in bipolar disorder is the secondary psychological and social consequences of the illness, and its often profound impact on self-esteem, independent functioning, and interpersonal relations.

6. Increased Mortality

Premature mortality is a strikingly common outcome in bipolar disorder, in part owing to its strong association with suicide. More than one-third of bipolar disorder patients make at least one serious suicide attempt, and 15–20 percent of deaths in bipolar disorder patients are due to suicide (Goodwin and Jamison 1990. Suicide attempts have a particularly ominous implication in bipolar disorder (and in severe major depression), in that the ratio of attempts to fatalities is probably less than 5:1, whereas in the general population the ratio is approximately 20:1. The depressive phase of a bipolar disorder carries the highest suicide risk, and accounts for at least three-quarters of all attempts and fatalities. Mixed states with both agitated turmoil and dysphoria are also highly risky, but account for only a minority of suicides associated with bipolar disorder. Suicidal ideation arises from a desire to give up in the face of difficulties that seem otherwise inescapable, or intense anguish to which no end can be imagined other than in death. Risk of completed suicide in bipolar disorder is greater for men than women, and attempts are more frequent among women. Other risk factors include previous attempts, older age, abuse of alcohol or drugs, and probably a family history of psychiatric illness that includes suicide.

In addition to suicide, mortality rates are elevated in bipolar disorder owing to the effects of risk-taking behaviors and associated substance abuse leading to accidental deaths, medical complications of prolonged abuse of alcohol and other substances, and the impact of stress-sensitive cardiovascular and pulmonary disorders, in which mortality is at least three times higher than in otherwise comparable patients lacking bipolar disorder.

7. Epidemiology

Bipolar disorders have a lifetime prevalence ranging from 1.6 percent (for mania) to as much as 2–5 percent of the general population if type II and cyclothymic cases are included. These disorders represent a quarter to a third of all major mood disorders. The annual incidence of type I disorders is at least 0.05 percent. Women have a moderately excessive risk for bipolar disorder (sex ratio about 1.4:1) that is much less than in nonbipolar major depressive disorder. The median age at onset is about 20 years (Goodwin and Jamison 1990, APA 2000). There have also been secular trends for all major mood disorders to be recognized more commonly, and at younger onset ages over the past century. However, the contributions of improved case finding, broadening conceptualizations of the disorders, and the probable impact of substance abuse and other environmental factors to these trends are not clear. Cyclothymic and hyperthymic temperaments, as well as childhood attention deficit hyperactivity disorder may be predisposing factors for bipolar disorder.

8. Biology

The risk of depression, psychosis, or suicide in first-degree relatives of index cases of bipolar disorder is 20–25 percent. The same risk is found in fraternal twins, but it is about 70 percent in identical twins, leading to a monozygotic–dizygotic risk ratio of more than 3:1. Rare adoption studies carried out to evaluate the role of genetic versus environmental factors have found more affective illness and suicides among biological relatives of index cases of major affective disorders than in the adopting family. Despite this substantial epidemiological evidence of a familial contribution to the risk of affective illness, a specific mode of inheritance, let alone a discrete genetic marker or molecular defect specific to bipolar disorder has yet to be identified.

Other biological findings also are far from definitive (Nemeroff 1999, Baldessarini 2000b). Structural and functional brain-imaging techniques are receiving much attention, but the findings remain limited and inconclusive. Older findings of changes in biochemical measurements of stress-sensitive neurotransmitters and neurohormones have proved nonspecific by diagnosis, or incidental to altered general metabolic activity. There is also a tendency toward early appearance of the rapid-eye-movement phase of sleep in mania as well as in severe depression, with other alterations of ultradian or circadian biorhythms, but these and the biochemical markers are mainly state-dependent descriptors, and not necessarily clues to biological causes of the disorder (Nemeroff 1999). Relative cerebral deficiency of serotonin has been associated with aggression and suicide, but this is not specific to bipolar disorder. Cognitive and other neuropsychological deficits can also be identified in bipolar disorder, and some may be sustained between acute episodes of illness (Mayberg et al. 1997).

9. Clinical Management

Mania and severe episodes of bipolar depression require careful clinical management. Manic patients need protection if they show impulsive, hostile, or excessively uninhibited behavior, or if they refuse treatment. Patients need protection from exploitation by others who may take advantage of their hypersexuality and inappropriate generosity in manic or hypomanic states. In extreme cases, patients may need to be committed to specialized hospital units where they can be treated in structured, calm, secure settings. Depressed patients may require hospitalization because of a high risk of suicide or inability to care for themselves. In both cases, early transfer to partial

hospital, day treatment, or intensive outpatient treatment is often feasible.

Psychotherapeutic efforts are much less extensively evaluated in bipolar than in depressive disorders, in part reflecting traditional views that bipolar patients are often less able to accept their condition as a disorder requiring treatment. Nevertheless, psychotherapy methods that have been developed and scientifically evaluated for depressive disorders may also have utility in bipolar disorder when acute symptoms are adequately controlled medically. These include interpersonal psychotherapy, based on improving coping strategies for social and interpersonal relationships. Cognitive-behavioral approaches attempt to modify irrational or exaggerated concepts by encouraging development of more flexible schemas, and rehearsal of new cognitive and behavioral responses. Psychoeducational and group-based or individual supportive treatments are advisable, and usually feasible with medication (Huxley et al. 2000).

Patients and their families also benefit from education about the illness, its treatment, and expected course. Counseling is also useful to plan for the possible impact of the illness on career and financial and family planning. Genetic counseling regarding risks to offspring can be offered, and advice to women to avoid pregnancy during mood-stabilizing treatment (especially with potentially teratogenic anticonvulsants or lithium), as well as anticipation of a high risk of recurrences in the postpartum period, are also necessary.

10. Treatment

Treatment of single episodes of bipolar disorder primarily involves antidepressants for bipolar depression and antimanic antipsychotics or other central depressants (including some anticonvulsants and potent sedatives) for mania (Baldessarini and Tarazi 2001). Common overuse of antidepressants in bipolar depression can have a destabilizing effect in predisposed patients, manifest as an increased rate of mood cycling or sudden switching from depression to mixed, dysphoric states or potentially dangerous manic-psychotic excitement (Goodwin and Jamison 1990). Older (mainly tricyclic or monoamine oxidase inhibitor) antidepressants have a particularly high risk of inducing adverse mood shifts, but such reactions can occur with any mood-elevating drug. Modern antidepressants are more commonly employed now because of their far greater safety on acute overdose with suicidal intent. There is little evidence that antipsychotics or other central depressants used to treat mania can induce depression in bipolar disorder. Electroconvulsive therapy may be a temporary alternative in severe cases, and can be beneficial in both manic and depressive episodes.

Since the main feature of a bipolar disorder is recurrence of acute episodes, the principal aim of treatment is prevention of recurrences of both depression and mania. Lithium salts (carbonate or citrate) are the best established option for this purpose (Cade 1949, Baldessarini and Tarazi 2001). Lithium treatment has a slow onset of action (about ten days) and alone is usually insufficient for treating acute mania. Lithium has complex effects on interneuronal signal transduction and on other molecular regulatory events in nerve cells (Manji et al. 2000). This agent is effective in preventing, delaying, or lessening manic and depressive recurrences in about two-thirds of bipolar disorder patients over many years. Nevertheless, a minority of patients continue to experience some illness each year regardless of the treatment provided. Owing to its limited safety margin, serum concentrations of lithium are monitored regularly, and are safe and effective in the range of 0.6–1.0 mEq/L. Adverse effects include tremor, polyuria, diarrhea, nausea, weight gain, hypothyroidism, and occasional severe impairment of renal function with uremia. Increased tremor, fatigue, dizziness, hyperreflexia, confusion, lethargy, or convulsions indicate intoxication. A serious problem of long-term lithium treatment is that abrupt or rapid discontinuation is often followed by temporarily greatly increased risk for recurrences of mania, depression, or suicidality, even after years of effective treatment (Baldessarini et al. 1999b). Lithium treatment is a very rare psychiatric intervention with compelling evidence of reduction of suicidal behavior.

Potential alternatives and adjuncts to lithium include a growing number of anticonvulsants. A particularly potent and rapid antimanic effect has been found with valproic acid iand its salts. It is also employed empirically for maintenance treatment, although the long-term protective effects of this agent against bipolar depression and mania are not proved (Bowden et al. 2000). Virtually all antipsychotic drugs have short-term antimanic effects, and therefore are employed empirically to treat breakthrough episodes of mania or to manage patients with both affective and psychotic symptoms, but their ability to prevent recurrences of bipolar depression or mania for prolonged periods is not established. Testing of additional anticonvulsant, antipsychotic, antidepressant, and other experimental agents for the treatment of bipolar disorder is ongoing. However, none has yet proved superior to lithium for long-term management of depression and suicidal behavior as well as mania. Sometimes, combinations of two or more treatment options are employed when a monotherapy proves inadequate (Baldessarini and Tarazi 2001). Finally, cost-effective group, family, and individual psychosocial and rehabilitative interventions are increasingly employed, and have some research support (Huxley et al. 2000).

Birdsong and Vocal Learning during Development

Songbirds are one of the few groups of organisms other than humans that learn sounds for vocal communication during development, and the neural substrate that controls vocal learning and behavior is highly localized, making these circuits amenable to experimental manipulation and analysis. The song system is a model one for studying the neural and hormonal bases of vocal learning, and for examining plasticity of structure and function in neural systems generally. Similarities between vocal learning in birds and humans suggest that many aspects of the learning process have evolved to meet demands imposed by vocal communication (Marler 1976, Doupe and Kuhl 1999). Therefore, an understanding of the mechanisms underlying vocal learning in songbirds may have immediate application to problems in human vocal learning. In this review I concentrate on what is known about neural and hormonal mechanisms of vocal learning in zebra finches (*Taeniopygia guttata*), a well-studied species in which juvenile males gradually learn to produce a specific vocal pattern during a sensitive period of development, and by adulthood are normally incapable of altering that pattern or learning new ones.

1. A Brain–Behavior System

Zebra finches learn the sounds used for vocal communication during a sensitive period of development. Specific auditory experience is necessary for vocal

Figure 1
A time line of zebra finch vocal development showing approximate timing of some aspects of song learning. Birds fledge from the nest around 20 days of age and start singing soon thereafter. They are dependent on their parents to feed them up until 35–40 days of age. The exact timing of auditory learning from an external model (tutor song) and reliance on auditory feedback of self-produced sounds are not completely known. Juvenile birds use auditory feedback to refine subsong until it matches the template of the tutor song. Once song learning is complete, adult birds also require auditory feedback to maintain production of stable, stereotyped song. Large-scale growth and regression of brain regions involved with vocal learning and behavior occurs during the sensitive period (see text)

learning to proceed normally: juveniles must hear a 'tutor' song model (normally their father) from approximately 20 to 50 days of age in order to reproduce an accurate copy of that song later in development (e.g., Böhner 1990). Zebra finches begin to produce their first song-related vocalizations around 30–35 days, and gradually refine their utterances until they achieve a close match to the external tutor sounds they have heard earlier (Fig. 1). During this period of auditory–motor integration, birds must hear their own vocalizations: auditory feedback is necessary for juvenile males to learn to adjust the motor patterns giving rise to vocal output so that the latter gradually comes to match the tutor song (Price 1979). By 80–90 days, zebra finches are sexually mature and produce a stereotyped song pattern that is maintained without changes throughout adult life. Once a stereotyped song is produced, adults also rely on auditory feedback to maintain that stable song pattern (Nordeen and Nordeen 1992). Surprisingly, although it has been known for many years that there is a sensitive period for hearing external auditory sounds during early stages of vocal learning, it is not known whether there is also a sensitive period for hearing self-produced sounds (i.e., for experiencing auditory feedback).

Song behavior is highly sexually dimorphic: normal adult females never sing, even if treated with testosterone. However, females treated with sex hormones soon after hatching produce male-typical songs as adults (Pohl-Apel 1985, Simpson and Vicario 1991). The behavioral dimorphism reflects a profound neural sex difference: the sizes of cortical song-control regions are several times larger in males than in females (Nottebohm and Arnold 1976). The neural substrate for vocal learning and behavior is highly localized in males, comprising several interconnected brain regions (Fig. 2) that are highly amenable to investigation of structure–function relationships. For example, HVC and RA are part of a direct efferent system linking the cortex with descending motor circuitry that activates vocal musculature, and lesions of this pathway disrupt stereotyped song behavior in adult males (Nottebohm et al. 1976, Simpson and Vicario 1990, Wild 1997). The activity of HVC neurons in awake, singing birds correlates precisely with production of specific song syllables, indicating that the HVC → RA pathway is part of the on-line circuitry for producing learned vocal patterns in adult birds (McCasland and Konishi 1981). Furthermore, the activity of RA neurons in singing birds correlates with subsyllabic elements of vocal production, whereas HVC neurons apparently encode larger chunks of information, indicating a hierarchical organization in the neural control of vocal behavior (Yu and Margoliash 1996, Vu et al. 1994).

There is also a multirelay route from HVC to RA: a distinct population of neurons in HVC projects to Area X in the basal ganglia, which relays through the thalamic nucleus DLM to the cortical region lMAN, which projects onto the same RA neurons that receive inputs from HVC. RA-projecting neurons in lMAN send an axon collateral to Area X, which creates a forebrain loop connecting X, DLM, and lMAN (Vates and Nottebohm 1995). Lesions of the X → DLM → lMAN pathway have no effect on song production in adult birds, but profoundly disrupt song behavior in

Figure 2
A side view of adult male zebra finch brain showing a highly simplified schematic of the major circuits controlling vocal learning and behavior. HVC contains two separate populations of projection neurons, one sends axons to RA and the other to Area X. The HVC → RA pathway regulates production of already-learned songs in adult birds, and is assumed to be involved with later stages of song learning in juveniles. The HVC → X → DLM → lMAN → RA pathway is necessary for normal song production during early stages of vocal learning, but is clearly not on the main motor pathway for vocal behavior in older juveniles and adults (see text). RA projects to the motor neurons (nXIIts) that activate the vocal muscles.
Abbreviations: lMAN (lateral magnocellular nucleus of the anterior neostriatum), X (Area X of the avian basal ganglia), HVC (high vocal center), AUD, auditory cortex, RA (robust nucleus of the archistriatum), DLM (medial dorsolateral nucleus of the thalamus), nXIIts (tracheosyringeal portion of the hypoglossal nucleus)

juveniles during early stages of vocal learning (Bottjer et al. 1984, Sohrabji et al. 1990, Scharff and Notte bohm 1991). There is a dramatic decrease in the effectiveness of lMAN lesions in juvenile males around 55–60 days of age, which seems to correlate with the development of song as a motor pattern in the sense that the temporal sequence of notes becomes fairly regular at this point. These results suggest that lMAN circuitry is necessary for learning during early stages of vocal development, but may play no role in stereotyped vocal production. The decrease in the effectiveness of lesions within this pathway suggests a change in its function, whatever that may be. One possibility is that the function subserved by this circuit is either no longer important for vocal learning and production, or is taken over by other song-control circuits, such as the HVC → RA pathway. However, an alternative interpretation of the developmental decline in the ability of lMAN lesions to disrupt behavior is that the function of this pathway is conserved, but somehow masked or suppressed at later stages of vocal learning (see below). Either way, this pathway may be similar to mammalian basal ganglia pathways in terms of its involvement in motor aspects of learning, planning, and coordination of movement and motivation (cf. Alexander 1994, Graybiel et al. 1994, Bottjer and Johnson 1997).

2. *Steroid Hormones and Vocal Development*

Much evidence suggests that sex hormones are involved in regulating one or more aspects of behavior during the sensitive period for song learning (Bottjer and Johnson 1997). Blocking the action of androgens in juvenile zebra finches prevents the development of stereotyped vocal behavior (but has no effect in adults). That is, syllable order fails to become stereotyped in juvenile zebra finches that are castrated and treated with anti-androgens, such that the overall structure of song is unstable and abnormal. Interestingly, subsequent exposure to physiological levels of testosterone (T) in adulthood induces stereotyped song production over a period of weeks, suggesting that the final stages of auditory-motor learning can be carried out in delayed fashion upon exposure to high levels of T. The enhanced behavioral and neural plasticity associated with the sensitive period for vocal learning appears to depend, at least in part, on the relatively low levels of circulating hormones that normally occur during early stages of juvenile development. In accord with the idea that reduced levels of plasma testosterone are actually necessary for normal song development, chronic exposure to normal adult levels of T during juvenile development severely impairs vocal learning in zebra finches. Juvenile males receiving systemic T exposure at the onset of vocal learning (20–40 days) develop fewer song syllables than controls, suggesting that the ability to memorize tutor syllables is impaired by exposure to adult levels of T during this interval. These data indicate that the proper timing and amount of exposure to hormones are important factors in the normal development of vocal behavior. Because many song-control neurons contain hormone receptors (particularly in HVC and lMAN), it is likely that T may exert direct effects on song-control circuitry to alter functional properties of neurons during vocal learning.

One possible speculation suggested by this pattern of results is that blocking the action of androgens extends a sensitive period for vocal learning, whereas normal exposure to rising titers of androgens closes one or more windows of opportunity for learning. This pattern of results has strong parallels to studies of human language acquisition, which have shown that the capacity for language learning decreases sharply following puberty (e.g., Johnson and Newport 1989).

It is also known that the sensitive period for song learning can be extended by rearing zebra finches in isolation. Although birds that remain isolated produce highly abnormal vocalizations, birds that are provided with tutors in adulthood can learn some song syllables long after the normal sensitive period has ended (Eales 1987, Morrison and Nottebohm 1993). Interestingly, juvenile birds that have been socially and acoustically isolated have abnormally low levels of T, although hormonal titers recover by the time birds reach late stages of song learning (Livingston et al. 2000). Thus the extended capacity for learning produced by isolation may be due to a prolonged period of low hormonal titers, although lack of experience may also be a contributing factor. It is possible that any conditions that prevent learning tend to keep the sensitive period open. This idea suggests the hypothesis that the loss of plasticity associated with the closing of the sensitive period is due to learning; if vocal learning is prevented then the sensitive period remains open.

3. *Developmental Changes in Song-control Nuclei: Growth and Regression*

The neural substrate for song control undergoes large-scale morphological changes during the period of vocal learning in juvenile male zebra finches (Nordeen and Nordeen 1997, Bottjer and Arnold 1997). Substantial (e.g., threefold) changes in the overall size of song-control nuclei can include changes in neuron number and/or size and complexity of axon terminals and dendritic arbors. For example, HVC and RA grow substantially in males during song learning, more than doubling in volume, whereas lMAN shows substantial regression (Fig. 1). Regression of lMAN correlates with the loss in effectiveness of lMAN lesions, whereas the growth of HVC and RA are consistent with the idea that the HVC → RA pathway assumes greater control of vocal behavior as song learning progresses. The profound growth and regression of song-control brain regions suggest highly dynamic roles for vocal circuitry in one or more aspects of song learning, and must be accompanied by substantial remodeling of synaptic connectivity. An interesting feature of these changes is that their occurrence during development is delayed relative to circuits that are not related to song control. Thus, the major neural scaffold controlling song behavior is created as song is being learned.

The gross changes in volume of brain regions observed during song learning suggested the possibility that experiential factors might play a role in inducing such morphological changes in the substrate for song, such that these large-scale changes actually reflect vocal learning. However, the volume and neuronal number of telencephalic song-control nuclei is the same in hearing and deaf birds, showing that auditory experience has no influence on regulation of neuron number, and that normal patterns of growth and regression occur even in birds that do not engage in normal song learning (Burek et al. 1991). This result indicates that gross morphological changes in song-control circuits are in fact *not* a product of the learning process, but rather may be prerequisite to learned changes in behavior. In accord with this idea, Brenowitz et al. (1995) demonstrated that tutoring two groups of marsh wrens with either many syllables or few syllables led to the development of large versus small learned song repertoires, respectively, although the size (and neuronal number) of HVC and RA in the two groups did not vary. However, within the group tutored with many syllables, only birds with a relatively large HVC learned large repertoires. Thus, a large HVC may be permissive for a larger vocal repertoire, but is clearly not a consequence of such. It seems likely that the basic neural scaffold underlying vocal learning is dependent on innate factors such as endogenous levels of hormones and cytokines (Johnson et al. 1997, Rasika et al. 1999). However, the idea that large-scale changes in song-control nuclei are a necessary prerequisite for vocal learning has not been tested directly (i.e., the occurrence of these changes during the sensitive period for vocal learning is correlational; cf. Bottjer and Arnold 1997).

4. *Neural Signatures of Learning and Development*

If large-scale patterns of growth and regression in the neural substrate for vocal learning are not a reflection of learning, then what changes in the brain signify learning and the close of the sensitive period? Several studies have described normative developmental changes that occur during the sensitive period, and may underlie specific aspects of the learning process. For example, the axonal projections of the DLM → lMAN → RA pathway show exuberant growth during early stages of song learning followed by pruning (Nixdorf-Bergweiler et al. 1995, Iyengar et al. 1999). In addition, NMDA (*N*-methyl-D-aspartate) receptors decrease in density within lMAN during song learning, and the duration of NMDA-R-mediated synaptic currents in individual lMAN neurons becomes significantly shorter (Aamodt et al. 1995; Livingston and Mooney 1997). These changes indicate that NMDA-R carry a greater proportion of the synaptic current in juveniles than adults. NMDA-R figure prominently in activity-dependent adjustment of synaptic connections: because they require both a ligand (glutamate) and depolarization of the post-synaptic cell, they serve as molecular detectors of coincident pre- and post-synaptic activation and therefore provide a mechanism for Hebbian learning (e.g., Cline 1991). Thus, it is

possible that NMDA-R in lMAN neurons could detect correlated activity of auditory and motor aspects of song to reinforce synapses that correspond to the acoustic structure of tutor song. In general, highly precise patterns of synaptic connectivity as well as the behaviors they subserve are established during sensitive periods guided by activity-dependent mechanisms based on sensory experience (Knudsen 1999), so it therefore seems likely that experience-dependent synaptic rearrangements in song-control circuits, such as refinement of the DLM → lMAN → RA pathway, may underlie the emergence of specific vocal patterns.

If developmental changes in synaptic rearrangements and NMDA-R currents reflect learning, then one prediction is that they should be experience-dependent. This is at least partially true: isolation of juvenile birds to prolong the sensitive period (see above) does delay the shortening of NMDA-R currents, as well as loss of the modulatory subunit that gates the corresponding slow kinetics normally seen in juveniles (White et al. 1999, Singh et al. 2000). In addition, the number of dendritic spines on lMAN neurons decreases during song learning in normal birds, but remains high in age-matched birds that have been reared in isolation (Wallhaüser-Franke et al. 1995), and the exuberant growth of the lMAN → RA connection is prolonged in birds that have been deafened or raised in white noise (Iyengar et al. 1999). However, isolation does not prevent these normative changes permanently. For example, although NMDA-R currents are longer in isolate-reared birds compared to normals at early stages of song learning, they recover to normal levels at later stages (Livingston et al. 2000). Thus, although lMAN neurons of isolate-reared birds seem to remain in a more juvenile state initially, they eventually achieve normal levels despite continued isolation. Furthermore, because isolated birds can learn some new syllables as adults, this pattern indicates that the enhanced NMDA-R currents seen in normal juveniles during the sensitive period are not necessary for at least some types of learning to occur. However, it is possible that the greater contribution of NMDA-R to synaptic currents in young birds could subserve some early aspect of learning that is necessary for later song development. For example, longer NMDA-R currents might enable young birds to learn an association between specific articulatory gestures and the vocal sounds they produce.

One way to assess this latter idea would be to prevent the longer NMDA-R currents that normally occur at the onset of the sensitive period. Exposing juvenile males to adult levels of testosterone starting at 20 days severely disrupts vocal learning and causes premature shortening of NMDA-R currents as well as an accelerated loss of the slow modulatory subunit of the NMDA-R (White et al. 1999, Singh et al. 2000). This pattern is consistent with the idea that enhanced NMDA-R synaptic currents are necessary for some, perhaps unknown, aspects of vocal learning. The delay seen in several neural parameters caused by experiential and hormonal manipulations may provide neural correlates that contribute to the extended sensitive period for song learning in isolated zebra finches. Furthermore, the relative decrease in the contribution of NMDA-R currents could be responsible for closing one or more aspects of the sensitive period.

One particularly interesting neural signature of vocal learning is the development of auditory tuning in song control neurons (Doupe and Solis 1997, Margoliash 1997). For example, lMAN neurons in adult birds that project to RA are selectively responsive to playback of each bird's own song, and this selectivity emerges at about 60 days of age, around the time when birds are beginning to produce a relatively stable song pattern and lMAN lesions are losing the ability to disrupt vocal behavior (Solis and Doupe 1999, Rosen and Mooney 2000). This correlation suggests that the development of auditory tuning coincides with a decreased role for lMAN neurons in vocal development, and is consistent with an idea raised above—namely that learning itself acts to curtail the sensitive period. Perhaps auditory selectivity of lMAN neurons reflects the fact that the bird has achieved a match to the tutor song (or developed their own individual template), such that lMAN no longer contributes actively to regulating the song pattern. Indeed, Solis and Doupe (2000) found that birds that were prevented from developing a good match to the tutor song (via damage to the vocal motor nerve) showed lower auditory selectivity in Area X than did birds that were able to mimic the tutor song. Thus, it seems as if the development of selectivity to bird's own song is dependent on learning, and perhaps a reflection of it. As indicated above, refinements of axonal connectivity such as that seen in the DLM → lMAN → RA pathway may represent an important neural signature of learning: remodeling of synaptic connections in this pathway may be necessary for the increased auditory selectivity of lMAN neurons.

5. *Recent Findings*

As indicated above, adult male zebra finches normally are incapable of altering their previously learned, stereotyped vocal pattern. This behavioral pattern correlates well with neural data showing that lesions of the X → DLM → lMAN pathway are effective only during a restricted period of vocal learning, and not in adult birds. These results encouraged hypotheses of vocal learning that stressed the idea that 'age-limited learners' such as zebra finches develop a fixed central motor program, and that the basal ganglia-thalamo-cortical circuit from X to DLM to lMAN is no longer able to regulate behavioral and neural plasticity in

adult birds. However, traditional hypotheses have been challenged by recent data. (a) Exposing adult birds to delayed auditory feedback causes gradual deterioration of stable song, but original song patterns may be recovered when normal auditory feedback is restored (Leonardo and Konishi 1999). (b) Although lesions of Area X and lMAN do not impair adult song production, the act of producing 'undirected' song (i.e., not directed to a female) induces strong expression of the immediate early gene *zenk* in X and lMAN of adult males (Jarvis et al. 1998), and multiunit activity recorded in lMAN and X is consistently higher during production of undirected song (Hessler and Doupe 1999). (c) Although lesions of lMAN in normal adults do not cause behavioral disruption, lMAN lesions in adult birds that are not producing a normal stereotyped song pattern do produce changes in song behavior, and prevent delayed learning from a tutor in isolate-reared birds (Morrison and Nottebohm 1993). (d) Williams and Mehta (1999) demonstrated that vocal plasticity induced by injury to the vocal motor nerve (N XIIts) in adult birds is blocked by lesions of lMAN, and similarly Brainard and Doupe (2000) showed that lMAN lesions in adult deafened birds prevent gradual deterioration (i.e., the song remains stereotyped despite the absence of auditory feedback, suggesting that lMAN may monitor auditory feedback and respond if an error signal is detected; if lMAN is gone, the error signal produced by altered auditory feedback would not be detected in deafened birds).

In the aggregate, this pattern of findings suggests that the X → DLM → lMAN pathway is not irrevocably 'shut down' in adults after vocal learning is complete, despite the fact that lesions of this pathway are ineffective in normal adults. Furthermore, one or more functions of this circuit may be 're-invoked' by certain types of changes in learned song behavior. In addition, these results encourage the idea that adult zebra finches might be capable of new learning following the sensitive period, if appropriate conditions can be found (e.g., if the bird 'unlearns' his initial song pattern; Zevin et al. 2000). Loss of a stable vocal pattern may be a prerequisite to (re)inducing a greater degree of neural and behavioral plasticity in adulthood, perhaps by 'unmasking' an apparently latent function of lMAN circuitry that may be conserved in adult birds.

6. Conclusions and Questions

Vocal learning, like other developmentally acquired skills, is shaped by the interplay of innate factors and experiential influences during a sensitive period. The substantial growth and regression of song-control nuclei that occur during the period of vocal learning are not dependent on experience, and are likely regulated by innate factors that specify the amount of brain space allocated to vocal learning, thereby influencing how much can be learned (Nottebohm et al. 1981). Experience-independent specification of the basic neural scaffolding for vocal learning may also provide specific innate constraints on vocal learning, such as predispositions to hear or produce certain vocal sounds (Marler and Pickert 1984, Marler and Sherman 1985; cf. Seidenberg 1997). In addition, the fact that large-scale patterns of growth and regression occur as learned vocal behavior is being acquired may set temporal constraints on learning. Perhaps this is why humans, like songbirds, are much more adept at vocal learning as juveniles than as adults. If large-scale neural changes are necessary concomitants of vocal learning, then we must ask how experiential factors influence the fine scale of song-control circuitry during such changes. Is it possible that certain types of experience-dependent mechanisms, such as refinement of specific synaptic patterns, can operate only in the context of the overall growth and regression that occurs during song learning? Answers to such questions will begin to provide a better mechanistic understanding of sensitive periods in general.

Birth, Anthropology of

An anthropology of birth is based on the common human experiences of insemination, conception, pregnancy, and birth of an infant. Characteristic of the human species and central to the origins of culture are the immaturity of the newborn human and its long-term dependence on caretakers for survival. These experiences exist in every society, but details vary in different cultural environments.

1. *Cultural Anthropological Perspectives*

Anthropological perspectives on birth are concerned with the context, variety, and complexity of reproductive life, modes of caring for a newborn infant, and cultural factors including rules for behavior that are learned, shared, and transmitted within families and cultural groups. There is cross-cultural variation among societies during these universal human processes. Because birth and recruitment to society are important to all human groups, customs and rules surround fertility behavior in all societies.

The influence of culture appears in definitions, for example, of which individuals may become parents (maternal age or married status), or the beginning of life (the point of conception, pregnancy to a viable birthweight, or delivery of a live infant). Throughout history and across cultures, certain variations have occurred in the definition of when life begins—whether it is at birth, or from motion or other indication of consciousness of an infant, or at a formal tenth day ceremony. Naming an infant provides a universal identification of the beginning of social life. Membership in society is defined and protected by both rules and traditions of social behavior. For example, international differences in mate selection include monogamy, or single partners, in most of the Christian Western world, and polygamy, or multiple wives in religious groups such as Mormons in the United States, or in some Islamic countries.

Differences occur also in sexual behavior, timing of pregnancy, and reproduction of society over time. It is the basis of identity, including how many people will be members of each society. The concept of 'legitimacy' refers to the acceptability of infants born to married mothers in most societies. 'Illegitimacy' refers to birth to an unmarried mother. Despite the language of legality, this is not generally an issue of law, but of social or religious acceptability.

Additional international and intercultural differences are discussed in the following sections, including fertility and fertility regulation, prenatal care, a comparative view of birth rates in different countries (Table 1), infant and under 5 child mortality (Table 2), and finally, the impact of the modern international infectious disease of HIV (human immunodeficiency virus, Table 3).

2. *Fertility*

Fertility refers to the capability of reproduction in the human species from sexual relations of male and female to conception and pregnancy in the female. Sex and social continuity are of concern in all societies. This concern is a part of the ancient and universal desire to bring order to membership in society as well as the behavior of individual members. 'Infertility' of either partner indicates an incapacity to reproduce.

Pregnancy occurs as a result of the connection of male sperm to female ovum initiating cell division leading to conception and beginning development of an embryo, until around the third month of gestation when it begins to develop body structures recognizable as human, and enters the fetal stage. Cells differentiate and the fetus then grows and develops the human form of an infant.

Gestation is the period of intrauterine development. Human variation occurs in the length of gestation for live birth. The biologically expectable period of gestation is around nine months of pregnancy. However, there can be differences in the timing, location, and length of the birth process. In some societies infants are delivered by a midwife or nurse, or a birth specialist either at home, or in the institutional setting of a hospital or nursing home. In modern urban societies, delivery of an infant is usually conducted in a hospital by a nurse or a physician specializing in obstetrics. Even here, however, there are significant cultural differences. For example, in urban areas, the surgical procedure of caesarean section is used for an impeded delivery, or for selective timing of birth.

In developed countries medical care may include prenatal care with a medical specialist in obstetrics or a nurse practitioner in a professional medical en-

vironment. In many areas of the world, reproductive health and training for motherhood are carried out by a nurse midwife or an experienced female family member, although there is increasing professionalization of birth attendants internationally. Attention to the process of gestation is perceived as important to the quality of life of the potential human being in all societies.

3. Fertility Regulation

Fertility regulation refers to intentional methods of avoidance of pregnancy used by either male or female. There have been methods of fertility regulation at least as far back as the beginnings of recorded history, as families have sought to control the number and timing of births. Male methods of family planning can range from a barrier method such as the condom, or withdrawal, or the surgical procedure of vasectomy. Female methods include the oral contraceptive pill or the barrier method of the female condom. Extended breastfeeding of the previous infant has long been known to suppress ovulation and enable spacing between births.

Social concerns regarding birth and reproduction vary internationally, with age, ethnic identity, or religion. Cultural factors, such as assuring virginity of marriageable females in some societies, religious opposition to fertility regulation in others, or in a few societies, female genital surgery for removal of the clitoris to reduce female enjoyment of sexual relations, have an impact on quality of life as well as reproductive capacity.

Ending unwanted pregnancy is one of the most contentious issues of reproduction. It may be terminated by induced clinical abortion in those countries where it is legal and medically provided. The psychosocial effects of unwantedness of a newborn infant are difficult to measure, but outcomes appear consistently negative in terms of later parental disinterest, child abuse, or abandonment. However, while clinical abortion is legal in such countries as Sweden, Japan, or the United States, it is illegal in most Muslim and Catholic areas. In these countries, family planning is more likely to include abstinence during the expectable time of ovulation (sometimes difficult to determine), and birth rates may be comparatively higher.

4. Prenatal Care

Most developed societies have some form of preparation for birth. The importance of prenatal care is in testing for health of the fetus, and in teaching the pregnant woman how to maintain the best possible health for herself and her expected infant. This includes protective health care, measuring regular weight gain, providing training for the birth process, and social support.

An important component is also prevention of behaviors detrimental to infant development. For example, prenatal smoking, alcohol and drug use, or starvation to limit weight gain, can all have damaging effects on the developing fetus. These can range from decreased blood flow to the fetus from smoking to fetal alcohol syndrome (FAS), which can result in abnormal physical or mental development (Espy et al. 2000). As risks from these behaviors have become better known over the last several decades, preventing risks of learning impairment in the resulting child is an important component of effective prenatal care before birth (Newman 1996).

5. Premature Birth

Not all pregnancies continue to a viable birth. Loss can occur at any time. Abortion refers to expulsion of a malformed or incompletely developed embryo within the first three months of gestation. Later loss can result from fetal death. For example, if loss occurs in the first weeks of pregnancy, it is considered a 'miscarriage' of a non-viable fetus. Early delivery of a viable infant at a birth weight of 2500 g (about 5.5 16) can happen as early as seven months gestation, and is termed 'low birth weight.' 'Very low birth weight' refers to the infant born around 1500 g.

In developed and industrialized countries, extensive efforts are undertaken to ensure survival of the lowest birth weight infants. A viable low birth weight infant in developed countries is kept at a neonatal intensive care nursery in an incubator for clear observation, to maintain body heat, and to provide oxygen, if necessary to breathing, as well as to enable constant surveillance by special care staff. The purpose of enclosure in all countries is to keep the premature infant safe from infection. In developing countries without intensive care technology, such babies are seen as likely to suffer mental and physical limitations, and may not be given special care so that family and community resources can be focused on those infants perceived as more viable.

6. Birth Rate

Birth rates differ from country to country based on religion, cultural expectation, issues such as female participation in the workforce, or religious and political views of fertility limitation through birth control. It can also be influenced by political programs such as China's 'one child family' policy previously under-

Table 1
Total population and birth rate

Nation	Total population (millions)	Birth rate (per woman)
Australia	18.6	1.8
Brazil	165.9	2.3
China	1238.6	1.9
France	58.8	1.8
India	979.7	3.2
Indonesia	203.7	2.7

taken by the nation with the highest population in the world.

Table 1 indicates total population for 12 nations and the birth rate, or births per woman, for each country.

7. *Infant Mortality*

Infant mortality refers to death in the first year of life. While it has lessened worldwide in the twentieth century, the rates vary in different countries, ranging from 5 per 1000 live births in developed countries such as Australia and France, to as many as 76 per 1000 live births in Nigeria. Rates of Under 5 Child Mortality, while higher, are comparable nationally. Table 2 compares Infant and Under 5 Child Mortality in 12 countries.

Table 2
Infant and under 5 child mortality

Nation	Infant mortality (per 1000 live births)	Under 5 child mortality (per 1000)
Australia	5	6
Brazil	33	40
China	31	36
France	5	5

While infant mortality can occur from prenatal causes, or in the process of delivery, it can also occur through accident or by endemic infectious disease later within the first year of life.

In many areas of the world, fertility regulation and birth control methods have been used to increase the time between births and enable optimum developmental opportunity for each infant born. Exceptions occur in those countries where fertility regulation is forbidden by religious law. Birth spacing is accomplished in some countries by later marriage and in some by abstinence during the fertile period of ovulation.

8. *Sexually Transmitted Disease*

The most pervasive sexually transmitted diseases in the world have been syphilis, gonorrhea, and chlamydia. However, a powerful new influence on the culture of pregnancy and birth is the spread of the new infectious disease of the modern world, human immunodeficiency virus, or HIV infection, identified in 1980. While HIV can be transmitted by sharing needles among drug users, it can be transmitted sexually to both males and females. It is also transmitted from mother to infant prenatally, during delivery, or postnatally through breast feeding (WHO and UNAIDS 1998). This has had a devastating effect internationally on the number of infants born with HIV infection or being infected within the first year of life. While the prevalence of HIV differs geographically, and in many countries is less than 1 percent, the rate in some African countries is higher, ranging from 4 percent to 12 percent, as indicated in Table 3.

The fear of becoming HIV positive is beginning in some countries to change behavior toward careful

choice of sexual partners, and using barrier methods of protection. The failure to change in other areas has led to devastating epidemics of HIV.

9. *Conclusion*

Anthropological perspectives on birth enable cross-cultural comparison of healthy birth practices and effective family planning methods based on cultural acceptability. Effective fertility regulation and prenatal care enable continuing reproductive health. Cultural variation in reproductive rights, values, and education demonstrate differences in fertility, contraceptive use, and birth practices, as well as expected family size internationally.

Bleuler, Eugen (1857–1939)

Eugen Bleuler is a central figure in the history of European psychiatry. His importance is founded on the fact that he proposed *and* practiced a critically mediating link between two basic psychiatric positions which stood at two controversially opposite poles at the beginning of the twentieth century (and still do in part up to the present day); that is, the psychoanalytical depth psychological school on the one hand, which was situated predominantly outside the universities, and academic psychiatry on the other, which was principally oriented towards the descriptive somatic approach. In this respect Eugen Bleuler—to put it in layman's terms—stood, as far as his basic psychiatric conviction was concerned, as it were 'between' the two similarly aged exponents of the aforementioned competing approaches, namely Sigmund Freud (see *Freud, Sigmund (1856–1939)*) (1856–1939) and Emil Kraepelin (see *Kraepelin, Emil (1856–1926)*) (1856–1926).

Born in Zollikon, near Zurich, on April 30, 1857, Bleuler came from an old-established Swiss farming family on both his father's and his mother's side. After completing his medical studies between 1875 and 1881, he worked first as an intern at the psychiatric clinic Waldau, near Bern. Study visits took him to Paris (with Charcot and Magnan) and to Munich (with Von Gudden). In 1885 he went to work with Forel at the Zurich clinic named the 'Burghölzli' which had been founded in 1870, only to be appointed director of the Psychiatric Hospital Rheinau in the canton of Zurich the following year, a position which he held for 12 years, that is, until 1898. The professional position which followed also covered an unusually long period of time, and brought with it more far-reaching repercussions and to a large extent had a formative influence on the way Bleuler was to conceive the whole field of psychiatry. He took over the chair in psychiatry at the University of Zurich in 1898, succeeding August Forel (1848–1931), a position which was attached to the directorship of the 'Burghölzli.' Bleuler held this position for almost three decades until 1927.

At the end of his academic life—he was at that time also the Rector of the University of Zurich—he was said, in an account cited by the Swiss psychiatrist J. Klaesi, to have remarked, not without a hint of maliciousness, 'that the state forces one to be an old man at 72' (Klaesi 1970). Eugen Bleuler died in Zollikon in his 83rd year on July 15, 1939.

As far as content is concerned, Bleuler's work is characterized by its tireless attempt, influenced by a strong sense of tolerance, to approach the enigma of psychotic illnesses on as many levels as possible, while at the same time taking into consideration general or 'normal' psychological findings. On the one hand he wanted to avoid making any absolute one-sided dogmatic assertions, such as in the sense of Karl Jaspers' still derided, though at that time (and not only then!) highly popular 'brain mythologies' which, with no further reflection, identified the psychic with material mental processes along ingenuously materialistic lines. On the other hand Bleuler was concerned with regarding the psychotic person *not only* as ill, as

deviant, or as disturbed, but rather directed his attention to the fundamental comparability to healthy mental life, a standpoint which interested him above all because of the possibility for its therapeutic exploitation. This did not, however, mean that Bleuler in any way placed little value on the then-prevailing 'brain pathological'—in today's terminology, neurobiological—school of thought and the research approaches arising from it. On the contrary; like the vast majority of contemporary psychiatrists, he too was convinced that the brain function in the aetiology and pathogenesis of endogenously psychotic illnesses—predominantly, therefore, schizophrenic and (bipolar) affective disorders—played a decisive role. Unlike the many 'simplifiers,' however, Bleuler always insisted that it was of great importance for the handling of patients, for the diagnosis, and above all for the therapy to *understand* the clinical picture and each individual, concrete symptom, independent of the suspected aetiology.

Bleuler's handling of the basic concepts of association theory was not unified, and was hence liable to give rise to misunderstandings and controversial statements. On the one hand he repeatedly took up a clear position against the 'association psychology' in the narrow sense advocated earlier in the nineteenth century, in which (healthy as well as ill) human mental life was merely the sum total of individual intellectual associations prompted by sensory perception. Against this he set an affective psychology which aimed at comprehending the personality in its individual totality, but which was nonetheless coupled substantially with elements from association psychology in the field of the schizophrenias. Indeed, not only did Bleuler see no contradiction in this, he even saw it as objectively necessary. It was here that the (then as now) topical controversy surrounding the quantifying scientific *explanation* and the interpretative humanistic *understanding* of mental and, here in particular, psychotic manifestations arose. Bleuler also attempted in this context to overcome a rigid distinction between the two approaches, quite unlike Karl Jaspers, who strongly criticized him over this on several occasions (for instance in Jaspers 1923).

Unlike most of his university colleagues in his field, Bleuler saw in very general terms *no* fundamental contradiction between (explanatory) brain research in the broadest sense and the interpretative access to the psychotic of depth psychology which was at that time almost exclusively advocated by the still young Sigmund Freud. On the contrary, Freud's theory seemed to Bleuler to be virtually predestined for critical implementation into clinical psychiatry. For Freud himself, who fought a lifelong struggle to achieve 'academic' recognition for his theory, such a competent and influential researcher like Bleuler naturally took on a particularly great importance. Bleuler, however, emphasized the aspect of the *critical* adoption of psychoanalysis already mentioned so much over the years that it led to a rift. Much has been written about the escalating debate between Freud and his particularly creative and original disciples such as Carl Gustav Jung (see *Jung, Carl Gustav (1875–1961)*) or Alfred Adler. It is less well-known that Eugen Bleuler must also be mentioned in this connection. The psychiatry historians Alexander and Selesnick (1969) even went so far as to call him the 'first victim' of this controversy, as Bleuler resigned from the International Psychoanalytic Society in 1910 because of his discontent at its, in his view, authoritarian style of leadership. The fundamental importance of the depth psychology approach for psychiatry was for him in no way diminished because of this. Scherbaum (1992) points out the paradoxical situation that Bleuler was 'too psychoanalytical' for academic colleagues in his field, whereas the psychoanalysts for their part viewed him as being too critical, even 'disloyal,' and he poses the question of whether Bleuler's understanding of psychoanalysis might not also have been shaped by the same 'scientistic self-misconception,' which Habermas (1979) had observed in Freud himself.

One article was of decisive importance for the development of *clinical psychiatry*, an article which Bleuler had written for the *Handbuch der Psychiatrie* (*Handbook of Psychiatry*), edited by Gustav Aschaffenburg, entitled *Dementia praecox oder Gruppe der Schizophrenien* (1911; *Dementia praecox, or the Group of Schizophrenias*). The agenda was already set out in its title. Unlike Kraepelin, who was searching for 'natural illness units' and through whose influential textbook the concept of 'dementia praecox' had become both popular and influential in the German-speaking world (Hoff 1994), Bleuler did not speak of schizophrenia as a *single* unit, but of the *group* of schizophrenias. However, he was concerned with the question of which characteristics the otherwise very heterogeneous schizophrenic patients had in common. Bleuler was here describing first and foremost *psychopathological* phenomena, and was avoiding any all too narrow (and speculative) analogies to the brain function.

Two psychopathological distinctions which Bleuler introduced are important with regard to schizophrenic syndromes and are frequently confused: the basic and accessory symptoms on the one hand, and the primary and secondary symptoms on the other. *Basic symptoms* were, according to Bleuler, those things which were peculiar to every schizophrenic illness process, independent of its other clinical manifestation. Among these he counted schizophrenic autism (not to be confused with the syndrome of the same name in child and adolescent psychiatry), ambivalence (a volitional disorder), the disorder of formal thought (in particular the aforementioned disorder of associative thought processes), and affectivity. *Accessory*, that is, not necessarily existing and also frequently observed in non-schizophrenic and above all exogenous psychoses,

meant symptoms such as hallucinations, delusion, or catatonic states. While this differentiation is still of great heuristic value for psychopathological research today, the differentiation between the *primary symptoms*—which result directly from the organic illness process, as Bleuler also suspected—and the *secondary symptoms*—which constitute a subjective psychological reaction to the illness by the person affected—has lost considerable importance.

In contrast to the (as the term implies) prognostically very pessimistic concept of 'dementia praecox' such as in Kraepelin's work, Bleuler constantly stressed that there were also benign schizophrenic courses—and by no means only as an exception—which after one or more episodes turned into an extensive or complete recovery.

The *Lehrbuch der Psychiatrie* (*Textbook of Psychiatry*), which first appeared in 1916, achieved a virtually legendary reputation. In this work, Bleuler (1916) put forward his deeply personal view of this field in a systematically, vividly, and clinically oriented manner. He had worked five years on this book. It went through many editions, for which he himself took on the task of updating as necessary up to and including the sixth edition. After his death (1939) his son Manfred Bleuler took over the task.

Eugen Bleuler's writings on general psychology and philosophy have, on the other hand, all but been forgotten today. In his later work—such as in the work *Die Psychoide als Prinzip der organischen Entwicklung* (1925; *Psychoids as a Principle of Organic Development*)—he attempted to develop a comprehensive natural philosophical concept which was, however, not adopted on any great scale at the time. His basic idea of a memory which was independent of conscious processes and did not only refer to the individual person but—an evolutionary biological perspective—to the whole species ('Mneme') was, in its idiosyncratic embracing of biogenetic vitalistic ideas of the late nineteenth century, of virtually central importance for Bleuler's whole scientific understanding. Although Bleuler considered inappropriate the classification of his (later) work as 'vitalistic,' from the point of view of the history of psychiatry today the parallels are unmistakable. This is true in particular if one looks at Bleuler's objective of a comprehensive 'science of life' which did not separate the categories of physical, biological, mental, and even social phenomena from each other, but rather sought to understand them as scientifically equal forms to express a single integrative (life) principle. A weakening or even lifting of the aforementioned categorical dividing lines (though not *this* particular way) is, what is more, a highly topical subject in psychiatric research nowadays which, indeed, appears less and less able to maintain the classical differentiation of 'organic' and 'endogenous' as well as 'psychogenous' illnesses.

Despite the approaches in his later work which are irritating and speculative to today's reader, and the very clear fixing, especially in the context of questions of forensic psychiatry which are also in his work, in the dubious modes of discussion of his time such as in the 'degeneration theory,' Eugen Bleuler was without question one of the most original and consistent psychiatric clinicians and researchers of his time. His thought is also of interest to today's research into psychosis, and has been receiving increased attention in recent literature (Möller and Hell 1999, 2000, Stotz-Ingenlath 2000). What is particularly gratifying about this is the fact that research into the history of psychiatry has turned away extensively from the bad habit, which one often came across in the early years, of uncritically hagiographic and therefore unscientific excessiveness from eminent advocates in the field, and is now concerning itself discernibly with a comprehensive understanding of the history of our field supported by the original literature and other sources, and embedded in contexts from social history and the history of ideas.

Bloch, Marc Léopold Benjamin (1886–1944)

The French historian Marc Bloch is one of the authors most frequently cited by those working in contemporary historical disciplines around the world. This immense influence is founded on both scholarly and biographical grounds. As one of the founders of the field of the history of society and mentality, as a historical theoretician, and a critical intellectual who was executed by the Gestapo in 1944, Bloch has become an inspiration and model for generations of researchers working in a diverse range of scientific fields and from a variety of different political perspectives.

1. *Biographical Outline*

Marc Bloch was born in Lyon on 6 July, 1886 into a family of practicing Jews of Alsatian heritage. Bloch himself was an agnostic, and in his final will and testament he explicitly requested a secular funeral. Because his father was professor for Roman history at the Sorbonne, Bloch grew up in Paris, where he went to the elite secondary school Louis-le-Grand. From 1904 to 1908 he studied history and geography at the Ecole Normale Supérieure in Paris; following this period he spent two semesters in Berlin and Leipzig, where he attended lectures by scholars such as Gustav Schmoller, Karl Bücher, and Karl Lamprecht. From 1909 to 1912 he was the recipient of a Fondation Thiers scholarship, before becoming a teacher at secondary schools in Montpellier and Amiens.

Bloch fought on the front as an enlisted soldier in World War I, and in the course of being repeatedly wounded in action and decorated for his service he was promoted to the rank of captain. In 1919 he married and was appointed lecturer for medieval history at the newly founded French University of Strasbourg. In 1921 he was appointed associate professor, and in 1927 he received his full professorship. In 1929, together with his Strasbourg colleague Lucien Febvre (1878–1956), Bloch founded the journal *Annales d'histoire économique et sociale*, which rapidly grew to become a widely influential forum for innovative historiography. In 1936, after several unsuccessful attempts to apply for a position in Paris, Bloch was granted a Sorbonne professorship in economic history.

Immediately following the outbreak of World War II, he volunteered for military service to defend his homeland against Nazi Germany. As an officer sent to reinforce the 1st Army, he experienced both the anticipation of the *Sitzkrieg* and then the unexpectedness of the *Blitzkrieg* in the French coastal canal region. Like thousands of other French soldiers, Bloch was rescued from Dunkirk in June of 1940 in the emergency evacuation across the channel. From England, he returned immediately to France, where he was able to avoid imprisonment. Because Nazi law prohibited him from reassuming his teaching position at the Sorbonne, the Vichy government sent him to rejoin the faculty of the University of Strasbourg, which had been relocated to Clermont-Ferrand. At the same time, Bloch sought, and eventually attained, an appointment at the New School of Social Research in New York. Because of the complicated provisions for obtaining a visa, however, he would have been compelled to leave behind part of his family in France—a condition Bloch, the father of six children, was entirely unwilling to accept.

In December of 1940 Bloch was barred from government service by the 'Jewish Statute,' only to be exempted several weeks later along with a number of other prominent Jewish scholars, and allowed to resume his teaching duties. For the sake of his wife's health, Bloch applied a year later for a transfer to Montpellier, even though this meant that he would no longer be permitted to hold public lectures. It was at this point in time that Bloch's active involvement in the Resistance movement began. Following the occupation of the Vichy zone by the German army in November 1942, Bloch fled Montpellier with his family for his countryside home near Guéret in the Creuse district of France. From this time on he worked and lived for the resistance, operating under pseudonyms like 'Chevreuse,' Arpajon,' and 'Narbonne' he belonged to the masterminds of the *Franc-Tireur* movement. In 1943 he moved to Lyon, where he belonged to the regional leadership of the *Résistance*. On 8 March, 1944, Bloch was arrested by the Gestapo and brutally tortured before being thrown in prison. On 16 June, several days after the Allied troops landed at Normandy, Bloch and 29 other prisoners were taken to a field on the outskirts of Lyon and shot.

2. *Bloch's Work*

The thematic emphasis of Bloch's scholarly production lies in the social and economic history of the medieval period. Although Bloch was initially concerned primarily with the topic of serfdom, in the early 1920s he began to devote his attention to what

appeared to be a highly specific question in the field of political theology: namely, the issue of the widespread belief in feudal France and England in the healing power of the king; in particular, when he laid his 'holy hands' upon the sick who had gathered before the cathedral immediately following the coronation ceremony. This anthropological approach, however, so clearly inspired by Durkheim's sociology of religion, was one Bloch would only use intermittently in later years. Instead, he turned his focus to a comparative historiography of European agricultural structures and societal structures that spanned the period from late antiquity to early modern times.

As he wrote in his 1934 application for a teaching position at the Collége de France, Bloch no longer considered himself to be first and foremost a 'medievalist,' but rather a general historian of 'European societies.' His two-volume work *Feudal Society* (Bloch [1939–40] 1994) can be understood as an exemplary attempt at putting this perspective of an *histoire total* into practice. In what amounted to an intellectual testament, Bloch himself summed up his book as follows:

> 'I have given an example of something … that I chose to call "the dissection of a social structure." In the course of the development of Western society there was a phase, which we call feudal society, which had a certain social tone. It was this tone that I wanted to investigate. … Furthermore, I have attempted to bring into play in a European context the multifarious experiences which the comparative method allows us to grasp. If my work is truly original in one regard, then in my opinion its originality lies in both of these efforts: structural analysis and the incorporation of comparative experiences' (*Cahiers Marc Bloch*, No. 2, 1995, p. 16).

Bloch's originality lies indeed in this 'structural' and comparative approach, but also in the manner in which he conducts his scholarly interventions. Precisely because he took seriously the approach of Durkheim's disciples such as François Simiand, who in their work had critically engaged the traditional praxis of political history, Bloch had been confronted with the necessity of making a fundamental change in the theory and practice of historiography. In countless essays and reviews he called not only for a new, interdisciplinary and internationally oriented historiography that would address itself to new themes by means of new methods, but also new ways of educating historians and new forms of communication within the historian's guild. An important instrument, a sort of editorial 'lever,' in his efforts to this end was the journal *Annales*, which he published together with Lucien Febvre. It was in the course of this cooperative venture, and also as a result of the ensuing friendly competition between him and Febvre that Bloch developed his remarkable ability to quickly and succinctly formulate new scholarly perspectives. The fight between the two coeditors was thus all the more painful for Bloch, when, in the aftermath of the French defeat in 1940, they were forced to decide if and how the journal should continue to be published. Whereas Bloch argued in favor of discontinuing the publication of the *Annales* until the end of the war, Febvre was prepared to adapt—at least on the surface level—to the new conditions under occupation in order to continue to have a public voice. In the end, Bloch accepted this strategy and continued to publish in the *Annales* under the pseudonym 'Fougères' until the very end. At the same time, he continued to work on two booklength manuscripts, which were edited by Febvre after the war: an analysis of the French defeat (*Strange Defeat*) and a reflective work on the intellectual preconditions of historiography as science, craft, and art (*The Historian's Craft*, Bloch 1953).

3. *Reputation and Influence*

The beginning of Bloch's considerable reputation in French as well as international scholarly circles can be traced back to the 1930s. It was really after World War II, however, particularly in the closing decades of the twentieth century, that Bloch's ascendancy to the ranks of one of the world's most quoted historians took place. His books have been translated into all of the world's major languages: the number of printed copies of *The Historian's Craft* extends well into the six-figure range, one-third of which have appeared in Spanish translation. Bloch's heroic death has elevated him to the status of an icon, adored by intellectuals and academics representing a broad spectrum of disciplines and political convictions alike. Accordingly, one encounters a range of conflicting images of 'Marc Bloch': the Marxist or the conservative, the Jew or the nationalist, and recently even the 'postmodernist' Bloch, who supposedly drew on Nietzsche as a source of inspiration. Whereas such portrayals threaten to bury the author's historical work under ever-increasing layers of reception, recent years have seen an increased effort towards precise scholarly contextualization of this work in order to better reconstruct Bloch's contribution to the historical discipline of the twentieth century.

P. Schöttler

Blocking, Neural Basis of

Blocking is a conditioning paradigm, first described by Leon Kamin (1969), in which previous conditioning to a stimulus reduces the degree to which a second stimulus can be conditioned during compound conditioning.

A typical blocking experiment consists of two training phases and a testing phase. During the first training phase, animals in the experimental (blocking) group learn that a conditioned stimulus (CS; e.g., a tone) predicts the occurrence of the unconditioned stimulus (e.g., an electric shock), and as a result develop a conditioned response (e.g., blinking) to the tone. A different group of animals (the control group) experience no training during this phase. During the second phase, both groups are trained with a compound stimulus, which consists of the previously trained stimulus (e.g., the tone) and a new stimulus (e.g., a light) presented simultaneously (tone + light). Later, during the testing phase, both light and tone are individually tested in their capacity to elicit the conditioned response (CR). The typical results are that, whereas the animals in the control group learned about both stimuli (i.e., both the light and the tone elicit a conditioned response), those animals in the experimental group did not learn about the light. It appears that previous experience with the tone 'blocked' or attenuated subsequent learning about the light.

1. *Theoretical Interpretations*

Before blocking was described, a common assumption in learning theory was that temporal contiguity was sufficient for an association to be formed between stimuli. This assumption was challenged by blocking, since it implied that other factors, such as previous training experience with stimuli, influence the way an animal learns about those stimuli.

Kamin (1969) proposed a cognitive explanation for how such previous experience influences learning. According to him, animals form expectations about the world, compare current input to those expectations, and learn only when something previously unpredicted happens. Thus, he claimed that stimuli support learning only to the extent that the outcomes they signal are surprising.

In the case of the previously mentioned example of blocking, by the end of the first training phase, the unconditioned stimulus (US) is already fully predicted by the tone (CS1). Consequently, when the animal is presented with the light (CS2) during the compound phase (tone + light) the shock is not surprising anymore (the animal already knows, just by hearing the tone, that the shock is coming next) and therefore an association between the light and the tone does not occur.

This idea was formalized in a mathematical model proposed by Rescorla and Wagner (1972). Although it is beyond the scope of this article to present details of this model, the key idea is that the amount of learning that occurs on each trial is proportional to the difference between the animal's expectation of the US (based on all the CSs present on that trial), and the presence (or absence) of the US. The more surprising the US, the bigger this difference, and therefore the larger the amount of learning (or associative strength) that a stimulus can accrue. As training progresses, the CS becomes increasingly more predictive of the US. This makes the US less surprising at each trial, resulting in progressively smaller gains in associative strength to the CS.

2. *Neural Substrates*

Although blocking is observed in virtually all classical conditioning paradigms, it would be simplistic to assume that there is only one set of neural structures underlying blocking in all such paradigms. Rather, it is quite likely that different paradigms require the involvement of different neural systems mediating blocking.

One approach to studying the neural basis of blocking consists of identifying a biologically plausible mechanism that performs the kind of computations called for by a learning model such as Rescorla and Wagner's.

The formulation made by the Rescorla and Wagner model—that the associative strength acquired by a CS is progressively smaller as training progresses—implies the existence of a negative feedback mechanism regulating the amount of US information provided to the brain throughout training. Neural mechanisms that resemble such computations have been observed during some classical conditioning paradigms, notably fear conditioning and eye-blink conditioning.

During fear conditioning, a CS is paired with a painful electric shock. Once associated, the CS elicits

fear-related behaviors, one of which is a state of analgesia mediated by opioids (Fanselow 1984). Given that fear conditioning depends on the painfulness of the US, the analgesia mediated by the CS could progressively diminish the reinforcing efficacy of the US. During a blocking task, this would provide negative feedback on the acquisition of fear conditioning, automatically performing calculations that resemble those in the Rescorla and Wagner model. Initial evidence for this negative feedback mechanism was provided by the finding that administration of the opioid antagonist naloxone during phase two of blocking attenuates blocking (Fanselow and Bolles 1979).

Further exploration of a negative feedback mechanism for blocking occurred in the context of eyeblinking conditioning. During this task, a CS is paired with an airpuff US, which elicits an unconditioned response (UR) consisting of reflexive closure of the eyelid. Through conditioning, the CS comes to elicit a conditioned response (CR), which mimics the US and precedes it in onset time (for review see Gormezano et al. 1983). The basic circuitry for the formation of CS–US association is well characterized in this paradigm (Thompson 1986). The cerebellum receives information about the CS from the pontine nuclei, whereas the inferior olive (IO) provides it with US information (Mauk et al. 1986). Interestingly, neurons in the IO show evoked activity to the US early during eye blinking training but not later, once the animal starts performing CRs (e.g., Sears and Steinmetz 1991).

This reduction in US input as conditioning progresses resembles a negative feedback mechanism involved in the regulation of the US information from the inferior olive to the cerebellum. Such a mechanism is likely to be provided by the inhibitory projection from the interpositus nucleus in the cerebellum back to the inferior olive. The activation of this negative feedback mechanism seems to be regulated by the establishment of the conditioned response, so that once the animal has learned about the CS–US relationship, the information about the US starts to be suppressed. Kim et al. (1998) demonstrated that the CR-induced inhibition of the inferior olive activity is mediated by the inhibitory neurotransmitter Gamma-amino butyric acid (GABA), because when picrotoxin, a GABA antagonist, was directly infused in the inferior olive in well-trained rabbits, the Purkinje cells in the cerebellum responded to the unconditioned stimulus, even though the animals continued to perform CRs.

Such a negative feedback mechanism could account for blocking during eye-blinking conditioning. In order to test such a possibility, Kim et al. (1998) implanted rabbits with unilateral guide cannulae directed to the IO and trained the animals in a blocking procedure using a tone as CS1 and a light as CS2. During the compound phase (tone + light), some animals underwent infusions of picrotoxin into the IO, while the control animals received infusions of artificial cerebrospinal fluid. The results showed that whereas the control animals exhibited normal blocking, those animals receiving picrotoxin learned to respond to both the tone and the light, thus showing no evidence of blocking.

According to Kim et al. (1998), the infusion of picrotoxin in the IO during compound conditioning prevented the tone-induced neural activity in the Purkinje cells of the cerebellum from inhibiting the IO activity, allowing it to keep providing US information during the presentations of the compound, thus making it possible for an association to occur between the light and the US.

3. *Hippocampus and Blocking*

Since blocking has been considered an indication that animals actively select and process information from their environment according to its behavioral significance (Rickert et al. 1981), it is possible to infer that those brain regions that play a relevant role in the processing and selection of stimuli might also be involved in blocking.

One structure that has been proposed to play a critical role in stimulus processing is the hippocampus. Pyramidal cells in this brain region increase their firing rate in response to CS–US pairings in anticipation of the CR (Hoehler and Thompson 1980). This has been interpreted as evidence that the hippocampus might function to mark behaviorally significant stimuli. It has also been suggested that one function of the hippocampus in associative learning is the reduction of attention to stimuli that are irrelevant or for which the behavioral consequences are already known (Han et al. 1995).

There is indeed evidence for a hippocampal involvement in blocking. For example, blocking has been shown to be disrupted in eye-blink conditioning in rabbits when the dorsal region of the hippocampus was lesioned (Solomon 1977); in a conditioned suppression paradigm in rats with a lesion in the ventral hippocampus (Rickert et al. 1981), as well as in taste aversion learning in rats with dorsal hippocampal lesions (Gallo and Candido 1995).

4. *Summary and Conclusion*

Distinct neural regions might participate in blocking according to the particular paradigm in which it is being evaluated. However, the finding of a common mechanism that can support blocking would greatly improve our understanding of the kind of computations the brain performs during learning, which in turn give rise to phenomena such as blocking. Evidence for such a mechanism could also provide support for models of learning, if the neural mechanism resembles

the computations claimed by the model to occur during learning.

As of 2000, there is strong evidence for the existence of negative feedback mechanisms underlying blocking in two paradigms: fear conditioning and eye-blink conditioning. The biological plausibility of such mechanisms should motivate further research in this direction. Additionally, more efforts should be directed to elucidate the involvement of other brain regions known to be important for stimulus selection, such as the hippocampus. The experiments to date strongly suggest an important role for this structure in blocking, but the variability in the exact location and extension of the lesions across studies imposes some difficulty in the interpretation of the results. Future studies with more restricted lesions will be required in order to clarify the hippocampal involvement in blocking.

I. Orduña and M. Gluck

Bloomfield, Léonard (1887–1949)

Leonard Bloomfield, one of the key figures of American linguistics, was born in Chicago on April 1, 1887. He studied German philology and linguistics at the University of Wisconsin and Chicago, where he got his Ph.D. in 1909. In the same year, he got married to Alice Sayers. After serving as teaching assistant of German at the Universities of Cincinnati and Illinois, he went for graduate studies in 1913 and 1914 to the Universities of Leipzig and Göttingen. From 1913–21 he was Assistant Professor of Comparative Philology and German at the University of Illinois, and from 1921–27 Professor of German and Linguistics at Ohio State University. In 1925 Bloomfield was one of three linguists who founded the Linguistic Society of America, which soon grew into the most influential organization of the field. From 1927–40, Bloomfield was Professor of Germanic Philology at the University of Chicago.

During this period, the publication of his widely read book *Language* (1933), his growing influence on the field of general linguistics, and his international reputation made him one of the leading representatives of American linguistics. Although he was not a charismatic person, easily dominating an audience, but rather of reserved and unimposing personality, he still had an enormous impact on American linguistics. He had few students, but many linguists regarded themselves as members of a school bearing his name. His unique effect was completely due to sober argument and the strength and clarity of his writings. In 1940, he became Sterling Professor of Linguistics at Yale University. Applying his theoretical insights to practical concerns, Bloomfield participated actively in the Intensive Language Program of the American Council of Learned Societies, preparing textbooks and

courses of strategically important languages during World War II. In May 1946 he suffered a heavy stroke from which he never fully recovered. He died on April 18, 1949 in New Haven, Connecticut.

1. *Background of American Linguistics*

Although grounded in the great tradition of European historical and comparative linguistics, which had revealed the systematic relationship among the Indo-European languages, American linguistics developed its own, independent orientation during the first decades of the twentieth century. Two major factors were characteristic. First, the interest in the analysis of a wide variety of languages outside the Indo-European family, to which European linguistics was largely restricted. The primary motive for this extended perspective was the concern for the language and culture of American Indians, the systematic study of which was initiated by the anthropologist Franz Boas (1858–1942). Among the active followers of Boas were Edward Sapir (1884–1939) and Bloomfield, scholars who shaped the subsequent development. Growing interest in languages without written records raised methodological issues unfamiliar to European his torical linguistics. While Hermann Paul (1846–1921) in his influential book *Prinzipien der Sprachgeschichte* programmatically denied the possibility of a scientific approach to language other than the historical one, the American-Indian languages called for exactly such an approach, for an analysis that is independent of written historical sources. The systematic foundation of synchronic description as a scientific approach leads to the second characteristic of American linguistics, viz. the development of a specific descriptive methodology, whose most rigorous form became known as 'distributionalism.'

This interest in methodological clarification of descriptive linguistics corresponds to a large extent to similar developments in European linguistics at the turn of the twentieth century, initiated especially by Ferdinand de Saussure (1857–1913) with his *Cours de linguistique générale* (1916). American linguistics made, however, its specific contribution to the overall development called 'structural linguistics.' Many of the inspiring ideas stimulating this development were due to Edward Sapir. The classical formulation of the framework, however, that by its systematic character eventually shaped the development, was due to Leonard Bloomfield. In spite of their mutual respect and scientific appreciation, there is an interesting tension between the personality as well as the intellectual approach of these two important men. While Sapir was burning with brilliant ideas, Bloomfield shaped the field by careful and systematic argument. The tension is inherent, moreover, in Bloomfield's own contribution, where some friction between theoretical foundation and factual insights will be observed.

Trained in Indo-European philology with a special emphasis on Germanic languages, Bloomfield aimed from the very beginning at a systematic foundation of his field of interest, including the need of coming to grips with problems posed by languages outside the standard canon of traditional linguistics. In his first monograph, *An Introduction to the Study of Language* (1914), he still assumed that this task should be accomplished within the overall framework of European linguistics, with Wilhelm Wundt's notion of *Völkerpsychologie* as theoretical background for the study of language.

2. *Behaviorist Orientation of Linguistics*

A radical change in Bloomfield's attempt to turn linguistics into a science by general methodological standards is marked by the axiomatic approach he adopts in *A set of postulates for the science of language* (1926), where the psychological orientation of European linguistics is replaced by a strictly operationalist conception, with which he became familiar through the work of his colleague Albert Paul Weiss at the University of Chicago. This perspective, systematically elaborated in Bloomfield's most influential *chef d'œvre, Language*, has a characteristic ambivalence, or even paradoxy.

On the one hand, Bloomfield criticizes Hermann Paul and other European linguists not only for their exclusively historical orientation, but even more for their imprecise psychological theory on which their linguistic concepts are based, a perspective that Bloomfield himself had adopted in his *Introduction* in 1914. He now considered the scientific analysis of language as a strictly objective matter, without any commitment to psychological concepts. Under this perspective, he took it to be completely irrelevant for descriptive linguistics, which sort of psychology one adheres to. Linguistics should be established as an autonomous discipline, that need not rely on any concepts other than its own.

On the other hand, Bloomfield was strictly opposed against one particular type of psychology, insisting on a rigorous exclusion of all mentalistic concepts from scientific description and explanation. He considered any resort to internal states and mental accounts of linguistic (or other types of) behavior as unwarranted at the present state of knowledge, and presumably unnecessary and hence unpermissible for scientific accounts in principle. In fact, Bloomfield advocated what he called a mechanistic explanation of behavior, opting more specifically for Weiss' version of behaviorism. Both aspects of this ambivalent position—the behaviorist account of language as well as the principle of autonomous, formal analysis—are

worked out carefully and applied to all kinds of concrete problems in the 28 chapters of *Language*, supporting his unusual influence during the decades to come.

Bloomfield's proposal to extend the standard behavioristic stimulus-response schema to linguistic behavior is original, instructive—and misguided. Assuming that the conditioned response R caused by a stimulus S in the standard schema S → R can be mediated by a linguistic act, Bloomfield arrives at the following proposal: An external stimulus S causes a linguistic response r of the speaker, which acts as a linguistic stimulus s on the hearer causing the practical response R. This yields the complex schema S → r … s → R. Bloomfield illustrates this by a situation, where S is the condition of being hungry and seeing an apple on a tree, while R is the act of plucking and eating it. This connection can now be mediated by the act r of making some appropriate noise, transcribed as, e.g., 'I'm hungry,' and the perception s of that very noise. Thus, the dotted line between r and s represents the interindividual relation connecting the production and perception of a given phonetic form, while the arrow between S and r as well as s and R represents the intraindividual association of this form with the practical stimulus imposed on the speaker and reaction produced by the hearer, respectively. What is misleading in this proposal is in particular the fact that the features of S and R, which Bloomfield considers and defines as the meaning of the form produced by r and perceived as s, cannot have any systematic relation to the respective s and r, whose formal features must, of course, be identical in the relevant respects. Thus, the meaning of 'I'm hungry' would not be different, if there is no apple present, or if the hearer, being on a diet, doesn't want to eat. This observation is by no means restricted to Bloomfield's original example, but applies to the relation between language and the conditions of use in a rather principled way. In other words, the behavioristic attempt to account for linguistic meaning in terms of conditioned use of linguistic forms was doomed to fail, even though it was taken for granted by a whole generation of American linguists and psychologists, including Skinner (1957) in his programmatic *Verbal Behavior*.

One particular consequence of Bloomfield's approach was his strong conviction that a systematic theory of meaning could only be developed on the basis of a complete, explicit account of all possible aspects of speaker and hearer's environment and the physiological mechanisms determining the pertinent reactions. For this reason, he considered the scientific treatment of semantics out of reach, at least for the time being, and perhaps in principle, although he had no doubts about the central role of meaning for any satisfactory approach to language. For three decades, skepticism towards the possibility of a serious theory of meaning became a characteristic feature of American as opposed to European linguistics. There are residues of this skepticism even in Chomsky's *Syntactic Structures* (1957), initiating a radically different approach that paved the way of an explicitly mentalistic theory of language.

3. *Structural Analysis of Language*

Restricting the central task of linguistics to the descriptive analysis of (r … s), i.e., to the properties of linguistic form, Bloomfield developed a systematic and comprehensive account of the properties linguistic expressions might possibly exhibit. The central idea of the framework carefully laid out in *Language* is the assumption, that all relevant aspects of verbal utterances can be captured on the basis of strictly formal criteria, identifying their parts in terms of articulatory and perceptual distinctions and their subsequent classification according to their possible occurrences. More specifically, basic linguistic forms, called morphemes, are characterized as sequences of phonemes, where phonemes are classes of minimal segments identified by their articulatory properties (roughly corresponding, incidentally, to letters in alphabetic writing). Morphemes can then be grouped into form classes on the basis of their distribution, i.e., observable combination, giving rise to the properties of so called constructions, which are the invariant skeleton of increasingly complex utterances.

Methodologically, this framework was based on systematic segmentation and classification in terms of strictly acoustic and distributional criteria, applied to actual utterances in the sense of well-defined types of physical events. In this way, segments of the acoustic stimulus are classified as phonemes, sequences of phonemes are identified as morphemes, morphemes are grouped into several classes, particular sequences of which are classified as constructions. The details of this elegant framework—the relevant criteria for segmentation and classification, the properties of primitive and complex elements, and the specificity of the pertinent levels of structural analysis—have been discussed intensively and worked out carefully by a whole generation of linguists in the decades following the publication of Bloomfield's influential book.

A rigorous and comprehensive version of the overall approach was arrived at in Harris's (1951) *Methods in Structural Linguistics*, where the canon of distributionalism is formulated in the most systematic and radical form. Bloomfield's own exposition developed the major ideas with remarkable sensitivity and respect for traditional grammatical analyses, preserving their insights where possible and correcting them where necessary, identifying their appropriate place under the new, systematic perspective. This holds for traditional notions of descriptive grammar like parts of speech, morphological categories like gender, number, tense, etc., but particularly for the important discoveries establishing the historical relationship among

different Indo-European languages. In fact, more than one third of Bloomfield's seminal book deals with topics of comparative and historical linguistics, with different types of language change, and problems of dialect geography, i.e., issues that go beyond purely descriptive analysis. Bloomfield's intimate familiarity with the history of the field, combined with his capacity to fundamentally reconstruct its aims and methodology, explains to a large extent his unique impact.

In order to accommodate various grammatical phenomena treated in traditional linguistics, Bloomfield applies the behaviorist notion of habits controlling the speaker's behavior. A habit corresponds to a pattern of linguistic forms. Thus, speakers of English have a habit according to which finite verb forms agree with their subject, as in *the boy walks* vs. *the boys walk*. The paradigms of inflectional forms like *walk*, *walks*, *walked*, *walking* involved in these habits can be accounted for by systematic combinations of 'free' and 'bound' morphemes, such as *walk* and *–s*, *–ed*, or *–ing*. The patterns set up on this basis can then be extended to 'irregular' forms like *sing*, *sings*, *sang*, *sung*, *singing*, where the free form *sing* is combined with an alternation of the vowel instead of the affix *–ed*, yielding the form *sang*, and to even further irregularities like *go*, *goes*, *went*, *gone*, *going*, where went substitutes the combination *go-ed*. In a similar way, the systematic character of habits is supposed to control patterns of variation in the phonetic realization of linguistic forms. Thus, Bloomfield argues that the masculine and feminine form of French adjectives like *plat*vs. *platte*, phonetically [pla] vs. [plat] 'flat,' *gris* vs. *grise*, phonetically [gri] vs. [gri:z] 'gray,' *frais* vs. *fraîche*, phonetically [frɛ] vs. [frɛ:š] 'fresh,' and many others, are best be described by taking the feminine as the underlying form plus 'the simple statement that the masculine form is derived from the feminine by means of a minus feature, namely, loss of the final consonant' (Bloomfield 1933). A second operation must furthermore shorten the long vowel in the resulting forms [gri:] or [frɛ:], etc. in order to derive the actual masculine [gri], [frɛ], etc. In other words, an additional vowel shortening is necessary after the previous deletion of the final consonant.

4. *Beyond the Limits of Distributionalism*

These apparently minor details of descriptive technology are worth mentioning because of their far-reaching consequences. The assumption of an underlying form plus operations deriving its surface realization clearly stretches the notion of habit determining linguistic behavior, as the actual response must now be taken to depend on previous operations applying to underlying forms that control the articulatory patterns at best indirectly, if at all. Assuming underlying forms plus operations or rules of realization is obviously a step towards the recognition of internal, which means mental, representations, and operations, a notion that Bloomfield wanted to rigorously exclude from scientific methodology. But he goes even further in the prohibited direction. In his ingenious *Menomini morphophonemics* (1939), an analysis of an Algonquian dialect, he set up underlying forms and various operations of realization with by far more intricate conditions on their relative dependence than the simple case of French masculine adjectives. This dependence, which Bloomfield was very much concerned with, requires an ordering of the operations up to five steps. It is obvious that internal operations of this complexity cannot be accommodated to the notion of stimulus–response–habit in any serious sense. What is fascinating here, is first the depth of analytic insight of Bloomfield's analysis, and second his decision in case of a conflict between behaviorist methodology and descriptive adequacy. Although he was, of course, not aware of the conflict, clearly he discarded the orthodoxy in favour of the insight.

In the same spirit, Bloomfield (1933) argued implicitly for an ultimately mentalistic theory of sound change, summarizing the core of his opinion by the slogan 'Phonemes change.' This means in fact that the underlying pattern, rather than the acoustic realization, is relevant for the processes of linguistic change. In a far-sighted conclusion, based on his *Menomini morphophonemics*, he even envisaged the possibility that sound change may consist of the introduction of rules of alternation: 'our basic forms do bear some resemblance to those which would be set up for a description of Proto-Algonquian, some of our statements of alternation … approximate the historical development from Proto-Algonquian to present-day Menomini (1939). Chomsky and Halle (1968) have later developed this view systematically in generative phonology.

5. *Roots of a Mentalistic Conception of Language*

Thus, Bloomfield insisted on a strictly antimentalistic program of linguistic analysis, according to his opinion that 'Non-linguists … constantly forget that a speaker is making noise, and credit him, instead, with the possession of impalpable "ideas".' It remains for the linguist to show, in detail, that the speaker has no 'ideas' and that the noise is sufficient (1936). But while he defended this dogma by practically excluding semantics from the actual linguistic research agenda, he was, surprisingly, not able to exclude mentalistic concepts from the domain of his very central concern—the analysis of linguistic form: underlying forms, derivational rules, precedence order of operations, and even phonemes as parts of underlying forms are concepts that go beyond the mechanistic elements extracted from noise. This conflict between rigid methodological principles on the one side and

explanatory insights on the other mirrors one aspect of the above mentioned tension between Bloomfield and Sapir, in the following sense: although both scholars agreed on the general principles of linguistics as a scientific enterprise, including insights in relevant detail such as the description of Indian languages, or the nature of sound change, Sapir always insisted on the psychological nature of linguistic facts. This is clear from his *Sound patterns in language* (1925), and even more programmatically from *The psychological reality of phonemes* (1933). As a matter of fact, the orientation of Sapir's inspiring essays amounted to a mentalistic research strategy.

Thus, although Bloomfield in 1940 was Sapir's successor as Sterling Professor of Linguistics at Yale University, it was Sapir's notion of language as a psychological reality that dominated the subsequent period of post-Bloomfieldian linguistics, as shown, e.g., by the title and orientation of *The Sound Pattern of Russian* by Halle (1959) and *The Sound Pattern of English* by Chomsky and Halle (1968).

But the tension persists. While Sapir and Jakobson provided ideas and orientation of this development, it is still Bloomfield's radical clarification of the conceptual framework and descriptive technology that is the indispensable foundation of modern linguistics. And perhaps more importantly, his *Menomini morphophonemics* is the paradigm case not only of a complete descriptive analysis given in terms of an explicit, complex rule system, but also of an impressive victory of clear insight over methodological orthodoxy. Conceding the amount of mentalistic machinery implied in this analysis of sound structure, strong theories of syntax and even semantics have in the meanwhile been shown to be possible and productive—in spite of Bloomfield's antimentalistic bias.

Boas, Franz (1858–1942)

1. Biography

Franz Boas was born on 8 July, 1858, in Minden, in the German province of Westphalia. He was the son of freethinkers of Jewish origin who still cherished the ideals of the democratic revolution that had taken place in Germany in 1848. Coming from such an educated bourgeois background (*Bildungsbürgertum*), he had access to books on the natural sciences and geography, and this environment had a profound impact on his future aspirations. From 1877 onwards, he studied natural sciences and geography, first in Heidelberg and then in Bonn and Kiel. After completing his Ph.D. in physics (on the color of water) he went to Berlin, where he began to move in the academic and social circles characteristic of much of the German scientific community at that time. A major role model for him was Rudolf Virchow, the professor of medicine and anthropology.

The most decisive period for Boas was that from 1881 to 1887. In Berlin he frequented the meetings of a learned society, the *Berliner Gesellschaft für Anthropologie, Ethnologie, und Urgeschichte*, and sought to raise funds for research in North America while preparing intellectually for such a trip. In 1883–4, after a short period of service in the German army, he began to conduct field research among the Inuit of Baffin Island. This prompted him to shift his focus of interest from the landscape to its inhabitants. He found that the geographical determinism of his time did not hold up against his observations of the central Inuit, in that some of the behavior he observed was exhibited in spite and not because of the environment. After a stay in New York, he returned to Berlin to become assistant at the Museum of Ethnology in 1885. There he met a group of Bella Coola Indians who had been brought to Berlin as a living exhibit (*Völkerschau*). This encounter prompted his decision to study the American Indian peoples of the northwest coast. In 1886 he embarked on the first of his many research trips to this region, where he gained rich insights into the social organization and self-expression of the Kwakiutl. On his way back he stopped in New York, where he met the editor of *Science* magazine and was immediately appointed assistant editor. Thus, he now had the means to marry

Marie Krackowitzer, a woman from New York's liberal German-speaking community, to whom he had been introduced by his uncle. He decided to remain in America, despite the fact that in 1882 he had written that 'his dearest aim' was to become a German professor. Even then, he had known that if the USA offered him 'a better chance … I would go without hesitation.' A strong motivation for staying was that American science was, as he saw it, 'so far behind in comparison to Europe that a young man as I am, is able to accomplish much more' (Liss 1996). There was less teaching of anthropology or ethnology than in German universities, but the strong role of the natural sciences was to impact on the development of anthropology as an academic discipline. Boas' understanding of anthropology was that of an empirical science, part of a wider trend in the social sciences, oriented towards the works of Mach, Dewey, and James (Lowie 1956, p. 1015).

Boas' experiences in the field resulted in a rather rare intellectual approach, that of a commuter who kept travelling between different nations and their intellectual environments. He thus saw different milieus as an outsider and observer, sometimes integrated and engaged, sometimes detached. Over the course of his life he showed a strong sympathy for other such commuters. For example, he greatly encouraged George Hunt, brought up among the Kwakiutl by a Tlingit mother and a British father, to do his own fieldwork among the Kwakiutl, and also provided the funding for this work. Later, too, he was active in support of those moving between different environments, be they immigrants to the USA or people living on the fringes of their home community. Boas himself experienced the advantages of being an outside observer, maintaining that such a status sharpens one's perception of those features of a culture which are self-evident to those living within it. He was very conscious of diversity, variation, and individual differences.

Boas' basic research motivation was one for which no assumption of cultural heritage was needed: curiosity combined with ambition. For Boas, it was a particular thrill to find complex answers to simple-looking phenomena that others considered to be obvious. He stated that he was 'motivated by the effective appeal of a phenomenon that impresses us as a unit, although its elements may be irreducible to a common chance. In other words the problem that attracted me primarily was the intelligent understanding of a complex phenomenon (cf. Herskovits 1953, p. 10).

Boas assumed an entrepreneurial role in the organization of US anthropology when, in 1896, he became assistant curator of the American Museum of National History in New York (curator, 1901–5), and lecturer in physical anthropology at Columbia University (professor of anthropology, 1899–1936). Among other activities, he modernized the learned journal *The American Anthropologist* in 1898, and helped to found the American Anthropological Association in 1902. He was not only interested in founding institutions (indeed, others tried to do this as well), but in insuring their professionalization. It was this specific approach (which also brought him into conflict with those who had hoped for a broader amateur membership of the AAA), which resulted in the lasting success of his institutional activities. It should not be forgotten that the period between the Civil War and the 1920s was a great era for entrepreneurs in and around the sciences. Many institutions of higher learning, new disciplines, scientific journals, and learned societies were founded, and funding raised, but most of these efforts failed in the long run. Today, it is difficult to appreciate that Boas' efforts were unusually successful, as we only notice those institutions which have survived.

2. *Contributions to Anthropology*

Boas' major and lasting contribution lies in the methodological domain. He was always on the look out for differences and, as such, was less interested in the contemporary transformations of Kwakiutl Indian culture than in what he perceived to be its remembered past. His quest for difference also made him sensitive to variations within the ensemble of aspects which the informants or outsiders described as a culture. Any boundaries and standards were suspect to him. He raised certain issues 90 years before they were advocated by the postmodernists of the 1980s (Jacknis 1996). He was particularly skeptical about classification, and naive subjective classification aroused his anger (see for e.g., 'The principles of ethnographic classification'). A systematic discussion of the problem can be found in his linguistic paper on 'Alternating sounds'. Boas contended that people tend to classify according to familiar categories, but that anthropologists should be concerned with what was later called emic distinctions—the distinctions made by the people themselves.

Boas' empiricism shielded his work from the speculative thinking which dominated the discipline in the German-speaking countries. This methodological rigor contributed to the strong and lasting reputation acquired by American anthropology, particularly in comparison to other social and natural sciences. It was manifest in the way Boas and many of his pupils discussed and validated the results of their fieldwork. More than any other author of his time, he was conscious of two influences on anthropological sources: that of the method chosen and that of the observers' perspective, including artifacts created by the methods. He gave preference to texts emanating from the culture itself, and asked his interlocutors to produce and record texts of all kinds, not only ceremonial ones. Moreover, he carefully recorded the effects of his methods, e.g., how the phonograph was

used, and how different informants influenced the style and content of dictated or written texts. The aim of this never-ending endeavor was to achieve objectivity. For Boas, a command of the native languages was essential in order to 'understand directly, what the people … speak about, what they think, and what they do' (Boas 1906, pp. 183–8). His concept of objectivity introduced a clear frame of reference, distinguishing his approach from that of his German and American contemporaries—a frame of reference rooted within the culture itself.

The results of Boas' fieldwork may suggest to many readers that he spent prolonged periods within the cultures under investigation, participating intensively in their everyday activities. The reality was different. His most important results were yielded by repeated short stays in the field—up to three weeks in one place. As the letters to his family show, he profited from the contrasts he experienced, seeing the surprising and the colorful in what was self-evident to the local population. The value of his reports is rooted in his insistence that each phenomenon should be viewed from different perspectives, and evidence gathered from different informants. He also integrated the latest technological methods into his approach—photography as early as 1883, and sound recording in 1887.

One of Boas' research topics was largely disregarded by the subsequent generation, namely, the place of the individual within society. Boas' interest in this subject may be seen as a legacy of the liberal German milieu in which he grew up. It was in front of the German Society of New York that he stated in 1880: 'The invention is not difficult. Difficult is the retention and further development … . It is important to observe the fight of individuals against tribal customs. The same kind of struggle the genius has to undergo … in his battle against dominant ideas' (cf. Herskovitz 1953, p. 75). He continued to address this question later on, in his interpretation of esoteric cults, insisting that cults should be studied in connection with the broader base of belief in society as a whole. It would be an error, he argued, to see esoteric beliefs 'as the only true form of the inner life. They might as well be considered as a reaction … to the general cultural environment.'

The anthropological subject most intimately linked to Boas' name, and the one which prompted most references to his work in the second half of the twentieth century, was the *potlatch*. 'Potlatch' is a Chinook word for festivities, which Boas used to describe a group of redistributive ceremonies performed by the Kwakiutl. Redistribution was not the dominant feature in all cases, however. As he emphasized in his very first discussion of the subject in 1899, the creation of credit and obligation was also a central element. Moreover, the redistribution of wealth created prestige as well as obligation.

To judge from the attention he gave to the potlatch, Boas was clearly fascinated. His curiosity about otherness was captured by a phenomenon which, with historical distance, can be seen to be a travesty of one particular feature of (non-native) American civil life—too conspicuous consumption. (Both private universities and museums were dependent on such redistributions of wealth, and on the fact that benefactors were, in turn, endowed with prestige.) The Canadian administration did not recognize society's need to have ways of creating prestige. Nor did it understand that the indebtedness created by such ceremonies was, in fact, a creation of wealth and capital not entirely different from that of the modern banking system, in which the capital mobilized as credit by far outweighs the liquid capital deposited. Boas brought these arguments into the foreground in order to defend the Kwakiutl and neighboring groups against intrusion by the Canadian administration.

Later critics observed that the potlatch, as portrayed in Boas' works, was just one momentary impression in a rapidly changing situation (Mauzé 1986, pp. 21–63), and that Boas neglected other aspects of the economy, mainly land tenure and the livelihood of classes other than the nobility. However, these criticisms cannot diminish the importance of his discovery of a system of attributing merit which was, in itself, economically organized.

Boas was also skeptical about the evolutionism of his times, insofar as it implied a ranking of more or less progressive cultures. How was one to classify a culture which had a seemingly simple technology, but an extremely intricate social structure? For Boas, it was not acceptable to label these as 'early forms' of humanity. Assumptions about the coincidence of linguistic communities, biological inheritance, and culture were implicit in evolutionism and explicit in historical reconstructions of the 'genealogies of cultures.' Yet using material gathered from American Indians, Boas was able to show that linguistic communities, groups of descent, and culture do not necessarily coincide, and that they have in fact varied independently of each other in many cases. Thus the evolution of a given language or language group may run across different groups of descent which, over the course of time, may become members of different linguistic families.

In the first half of the twentieth century, Boas' contribution to science was most strongly identified with his work on physical anthropology. Here, he introduced the perspective of regarding differences in the human races as a phenomenon of domestication, rather than in analogy to differences in animal species. He maintained that nutrition, the instrumental and ornamental use of the body, crossing, and selection are the social facts shaping the variant physical appearance of humankind. Of his many empirical investigations, a study published in *The American Anthropologist* in 1912 is particularly notable. In this study, based upon a huge sample, he compared the head shapes of immigrants and their children. The shape of the head had, until then, been considered the best

indicator of hereditary lines. Yet Boas was able to show that these measurements changed considerably in the children's generation. This challenged the dogma that the physical type was determined by heredity alone.

Boas did as much as he could to collect texts, especially songs, tales, and myths, and to encourage others to do the same. He maintained that such materials have the merit of bringing out 'those points which are of interest to the people themselves' (Boas 1916, p. 393). He objected to other authors classifying genres according to their subjective standpoint or the standpoint prevalent in their own culture, and referred instead to the categories used by the people themselves (emic categories)—a procedure which, even today, is not always followed. He rejected explanations of symbolism which were not based on explicit data from the culture itself as pure speculation, whether they be such as those of the German *Kulturhistorische Schule*, or Freudian. In contrast, he placed particular weight on the recognition of myths and tales as artistic creations, arguing that these should not only be a source of anthropological research, but valued as a product of human creativity.

Boas' attitude to politics was interested but rather detached. The liberal German milieu in which he grew up advocated the separation of science from religion and politics. The sociologist Max Weber, who later matured in the same milieu, formulated the idea of value freedom in science. Having experienced the repression of such scientific freedom by the institutions of power and religion in the nineteenth century, the liberal scientific community saw this conception of science as an important basis for the growth of scientific endeavor and discourse—a neutral medium for the way society saw itself and for societal development. Detachment did not mean indifference, however. Boas had already described the goal of science to be 'the ice-cold flame of the passion for seeking the truth.' Moreover, observations of prejudice called for scientists to speak out. On several occasions, Boas spoke out against racial prejudice, defending the American 'Negro,' underlining the evidence of high cultural achievement in the African past, criticizing the US and Canadian policies which discriminated against Indian customs (namely the potlatch), censuring war and, last but not least, condemning anti-Semitism. His texts against anti-Semitism were printed in a widely read German newspaper (*Frankfurter Zeitung*) in 1926 and later distributed as leaflets by the German anti-Nazi resistance.

3. *Influences*

Boas' legacy cannot be identified with a particular theory. In contrast to other authors, after his investigation of the Inuit he produced few texts which attempted to provide a general ethnography. The organization of findings in his texts often obscures information rather than elucidating it. Central theoretical arguments are typically found neither in the introduction nor in the summary, but somewhere in the middle of the text, sometimes as footnotes. He did, however, introduce some important methodological approaches. It was Boas who cross-bred physical anthropology with ambitious statistical methods. He and his pupils were the first to take linguistic approaches, looking for the categories by which language was organized in the mind. This later lead to the study of phonemics with his pupil Edward Sapir, and later still, to the idea of the categorial grammar which takes Boas' perceptive of trying to find by induction categories immanent to the language itself, rather than transplanting the categories of Indo-German grammars.

In the decade after his death, more was written about Boas than about any American anthropologist before him. This may have created the impression of a Boas School. Indeed, his pupils included such anthropologists as Ruth Benedict, Melville Herskovits, Robert Lowey, Margaret Mead, Ashley Montague, and Edward Sapir. Later, however, harsh criticisms such as those of Lesley White exposed some limitations in Boas' work. His didactical methods apparently did not meet the standards of the North American universities. Moreover, considering that those who studied under him represented 'the greatest variety of interests, methods and theoretical orientation,' one cannot but agree with Herskovits' early statement (1953, p. 23) that 'the term "Boas' school" … is a misnomer.'

However, one cannot overlook the fact that functionalism and its later variations such as conflict theory owe their success to the methodological rigor introduced in Boas' aversion to speculative anthropology, and to the institutional foundations he laid. Evidently, Boas and Malinowski—the leading Anglo-Saxon anthropologist of the time—tended to ignore each other, although both were trained in the German approach to the natural sciences. In the few remarks he made on Malinowski and functionalism, Boas named the close observation of daily life as a merit, though underlining that fieldwork was already an established practice in US anthropology before the beginning of the twentieth century. He criticized the explanation of human behavior on the basis of the actual social environment alone, the approach taken in earlier British functionalism. Boas felt reference to historical data to be indispensable for an understanding of ongoing processes (cf. Boas 1938).

It was thanks to Boas that exotic presentations of unexplainable behavior and the reduction of unfamiliar cultural forms to an irreducible genetical heritage were gradually excluded as forms of scientific explanation. He brought the assumption of rationality to the foreground, making this the starting point of

anthropological explanation. This does not imply that all human behavior is rational, or that all social institutions are functional (in fact, Boas abhorred such generalizations). However, it does mean that explanations of individual behavior and culturally encoded behavior should relate to the goals, cultural strategies, and environmental conditions of the informants. Of course, behavior may still fail to achieve its goals or may even be erratic in view of all possible goals.

The 1980s and 1990s saw a return to the skepticism which distinguished Boas' approaches from those of most earlier theorists. His legacy is an antidote to reification (*Verdinglichung*), reminding us that any culture is multifaceted and continuously changing, and that individuals may row against its currents.

Body: Anthropological Aspects

The theoretical status of 'the body' in cultural anthropology has evolved in roughly four stages: (a) in earlier decades of the twentieth century it was an implicit, taken-for-granted background feature of social life; (b) beginning in the 1970s the body became an explicit topic of ethnographic concern; (c) from the 1980s the body began to become a problem to be accounted for with respect to its cultural and historical mutability; and (d) by the century's end the body offered a theoretical locus for rethinking various aspects of culture and self. This conception of the changing status of the body in anthropology guides the exposition that follows.

1. Early Reflections on the Body

Although the body was traditionally implicit in anthropological writing, a rereading of older sources is nevertheless likely to offer a surprising richness of insights on bodiliness. Paul Radin, for example, explicitly discusses indigenous philosophy of the body in a chapter on 'The Ego and Human Personality' (1927). In what we would today call an attempt to formulate an ethnopsychology of the person, he emphasized the Maori distinction between material (substance) and immaterial (form) aspects of the body as the resting place of various components of the person. In its anatomical aspect the Maori body was associated with psychical rather than physiological functions. After going on to discuss the person among the Oglala Dakota and the Batak, he concludes that these ethnotheories display an 'inability to express the psychical in terms of the body,' but must project it onto the external world (1927, pp. 273–4). Robert Lowie, in a chapter on 'Individual Variability' in religious experience, dealt with issues relevant to embodiment under the heading of 'sensory types' (1924, pp. 224–31). His data for this discussion were instances of visionary or revelatory imagery. Noting the absence of studies in this area by anthropologists, he was concerned with the manner in which imagination is concretely engaged with the various sensory modalities. Drawing primarily on Crow material supplemented by evidence from other North American tribes and from the African Bushmen, he suggested that the cross-cultural data conformed with then-current psychological findings that visual ima-

gery predominates in frequency over imagery in other sensory modalities, though certain individuals might show a propensity toward auditory or even motor, tactile, and kinesthetic imagery. Maurice Leenhardt (1947) reports a conversation between himself and an elderly New Caledonian philosopher about the impact of European civilization on the indigenous cosmocentric world. His interlocutor said that 'What you've brought us is the body.' For Leenhardt this pronouncement upends a stereotype that presumes the body lies on the side of nature (the primitive) and spirit on the side of culture (the civilized). Leenhardt vividly suggests that the very possibility of individuation has as its condition of possibility a particular mode of inhabiting the world as a bodily being.

Some of the earliest sustained treatments of the body in its cultural and social dimensions were Robert Hertz's (1909/1960) study of the symbolic pre-eminence of the right hand and Marcel Mauss' (1934/1950) justly famous article on techniques of the body. Mauss' work is almost universally cited as a precursor of the contemporary interest in the body. It anticipates the notions of practice and habitus later elaborated by Pierre Bourdieu (1977), though the notion of habitus had already passingly been used with a similar sense by Max Weber in his discussion on religions of ethical salvation. Important historically is the relation between this article on the body and Mauss' fragmentary but influential discussion of the person, appearing only four years later (1938/1950). In the latter article, he suggested that all humans have a sense of spiritual and corporal individuality, and saw the person as associated with the distinction between the world of thought and the material world as promulgated by Descartes and Spinoza.

2. *Anthropology of the Body*

In later decades, attention to the body largely took the form of studies of gesture, nonverbal communication, kinesics, and proxemics (Benthall and Polhemus 1975). In these studies, interest in the body in its own right was subordinated to interest in communication as a cultural process, with the body serving as the means or medium of communication. In other words, rather than beginning with a concern for bodiliness *per se*, these analyses took language as their model, using a linguistic analogy to study various types of languages of the body. Perhaps for this reason, they are rarely cited in the literature on the body and embodiment that has appeared in abundance since the late 1980s.

Two books by Mary Douglas define the threshold of a true anthropology of the body. In 'Purity and Danger' (1966), she made her famous argument that the dietary rules in the biblical book of Leviticus summarized the categories of Israelite culture, and made the general claim that social system controls induce consonance between social and physiological levels of experience. In 'Natural Symbols' (1973), Douglas made her equally famous argument that the bodily state of trance in different societies corresponds to the state of social organization characterized in terms of the 'grid' of cultural classifications and the 'group' control over the ego as an individual actor. Building on Mauss, she rejected both Edward Hall's work on nonverbal communication and Claude Levi-Strauss' work on mythical thought, on the grounds that they lacked hypotheses to account for variation across cultures. In presenting such a hypothesis, she committed herself to understanding the body as a 'medium of expression,' arguing that a drive to achieve consonance across levels of experience requires the use of the body to be 'coordinated with other media' so as to produce distinct bodily styles, and that 'The physical body can have universal meaning only as a system which responds to the social system, expressing it as a system' (1973, p. 112). Overall, Douglas' legacy to the anthropology of the body is encapsulated in her conception of 'two bodies,' the physical and the social, 'the self and society' (1973, p. 112).

Blacking's (1977) introduction to his edited volume on anthropology of the body offers a programmatic outline that is both more concerned with the body *per se* and its contribution to social processes than with the manner in which it reflects or expresses those processes, and which is more explicitly concerned with the relation between the biological and the cultural. Its 'chief concern is with the cultural processes and products that are externalizations and extensions of the body in varying contexts of social interaction,' and it rejects the distinction between biological and cultural anthropology on the grounds that culture has shaped the physical body, while features of culture such as language are biologically based (1977, p. 2). Blacking sketches four premises for the anthropology of the body: that society is a biological phenomenon, that all humans possess a common repertoire of somatic states, that nonverbal communication is fundamental, and that the mind cannot be separated from the body (1977, p. 18). Blacking emphasized the liberatory potential in anthropology of the body insofar as it could contribute to de-alienation and 'ownership of our senses.'

Once the body emerged from theoretical anonymity to become a recognized topic in its own right, its omnipresence in social life led to a multiplication of ways to organize its study. Following Douglas' inspiration to recognize 'two bodies,' Nancy Scheper-Hughes and Margaret Lock (1987) suggest we instead consider 'three bodies,' including the individual body, the social body, and the body politic. John O'Neill (1985) suggested thinking in terms of 'five bodies,' including the world's body (i.e., the anthropomorphized cosmos), the social body, the body politic, the consumer body, and the medical body.

3. The Body as a Theoretical Problem

It was not long between the emergence of the body as a topic and the transformation of the body into a problem. This aspect of the body's career in anthropology is deeply bound up with the career of anthropology in interdisciplinary studies. Scholars from virtually every branch of the human sciences have been influenced by reformulations of basic understandings of the body through the work of Michel Foucault on the discursive formations that have constituted the hospital (1973), the prison (1977), and sexuality (1978); the work of Pierre Bourdieu (1977) on practice and habitus; and the work of Maurice Merleau-Ponty (1962) on perception and embodiment. Equally, scholarly understandings of the body have been transformed by feminist works including Luce Irigaray's (1985) extended critique of psychoanalysis and Donna Haraway's (1991) studies of the encounter between gendered bodies and technology. Although it is a simplification to formularize the scope and nature of the theoretical sea change effected through such works, two aspects stand out. First, though work such as Blacking's called into question the distinction between mind and body, and between biological and cultural anthropology, subsequent work has gone even farther in calling into question the degree to which biological nature can be considered a stable substrate of human existence. Second, though Douglas encouraged us to think in terms of two bodies corresponding to self and society, subsequent work has gone beyond her tendency to treat the body-self as a passive lump of clay or tabula rasa upon which society imposes its codes, toward understanding it as a source of agency and intentionality, taking up and inhabiting the world through processes of intersubjective engagement. This radical shift has made the body a central problem, and one of some urgency, across a range of disciplines. Thus, Emily Martin, whose own work on gender, science, and technology (1987, 1994) has contributed significantly to the body's move to center stage in social theory, has posed the question of the 'end of the body' as we have known it.

In addition, there has been a chorus of statements about the historical malleability of the body. The radical 'situatedness' of the body extends even to the domain of biology itself, as is evident in recent feminist theory that eliminates 'passivity' as an intrinsic characteristic of the female body, and reworks the distinction between sex and gender (Haraway 1991, pp. 197–8), as well as the decoupling of female sexual pleasure with the act of conception. With biology no longer a monolithic objectivity, the body is transformed from object to agent (Haraway 1991, pp. 197–8).

The contemporary cultural transformation of the body can be conceived not only in terms of revising biological essentialism and collapsing conceptual dualities, but also in discerning an ambiguity in the boundaries of corporeality itself. Some have suggested that in contemporary civilization the human body can no longer be considered a bounded entity, due to the destabilizing impact of social processes of commodification, fragmentation, and the semiotic barrage of images of body parts. Others have explicitly problematized bodily boundaries between animal and human, between animal/human and machine, and between human and divine. Exploring these cultural boundaries can be incredibly rewarding and remarkably problematic given the circumstances of corporeal flux and bodily transformation sketched above.

4. Embodiment and Culture

This radical rethinking has also created an opportunity for a rethinking of culture and self from the standpoint of the body and embodiment. If the body was often a background feature in traditional ethnographies, so it has often remained implicit in anthropological theories of culture, which historically have been cast in terms such as symbols, meanings, knowledge, practices, customs, or traits. The problematizing of the body and its movement to center stage in social theory has also led to the emergence of studies that do not claim to be about the body *per se*, but instead suggest that culture and self can be understood from the standpoint of embodiment as an existential condition in which the body is the subjective source or intersubjective ground of experience.

This development can be seen taking place concretely over time in the work of a variety of anthropologists. For example, in the early 1970s, Strathern and Strathern produced a conventional monograph on body decoration in Mount Hagen, New Guinea. More recently, each author has developed their thought in light of a reformulated understanding of embodiment (A. Strathern 1996) and its gendered nature (M. Strathern 1992). Terence Turner (1980) published an influential essay on body decoration among the Brazilian Kayapo, and since then has moved from this conception of the 'social skin' to a more thorough development of the place of 'bodiliness' among the Kayapo and more generally in anthropological thinking (1995). James Fernandez, following his powerful treatment of metaphor and body symbolism in the Bwiti religion among the Fang in Gabon, later turned his attention to the place of the body in Bwiti explicitly with respect to developing theorizations of embodiment (Fernandez 1990). In work on ritual healing, ritual language, and the cultural constitution of self among Catholic Charismatics in contemporary North America, Thomas Csordas elaborated earlier arguments cast in terms of rhetoric with analyses made from the standpoint of embodiment (Csordas 1997). In her work on South Africa, Jean Comaroff (1985) refocused the traditional anthropological interest in body symbolism in the context of contemporary

approaches to the analysis of political economy and ritual healing, tracing these themes across the precolonial, colonial, and postcolonial periods. In two brief but compelling passages, Michelle Rosaldo (1984) did much to open the way for an understanding that collective symbols acquire 'power, tension, relevance, and sense' through embodiment (p. 141), and that emotions are 'embodied thoughts' (p. 143).

The theoretical crux of these new syntheses is a critique of tenacious conceptual dualities such as those between mind and body, subject and object, sex and gender, body and embodiment. These developments must be seen in the theoretical context of the prominence since the 1970s of notions such as the interpretive turn, the linguistic turn, the move to cultures defined as systems of symbols, and concepts such as textuality, discourse, representation, and semiotics broadly conceived. Understandings of the body itself in terms of the 'metaphor of the text' is evidenced in common scholarly phrases like 'the body as text,' 'the inscription of culture on the body,' or 'reading the body.' Recent work on embodiment offers the opportunity to balance what is thus, to some, an overemphasis on representation. When this tack is chosen, the key theoretical term that comes to take its place alongside representation is 'being-in-the-world.' The latter notion, drawn from phenomenology, does not supplant representation, but offers it a dialogical partner: in brief, semiotics offers the notion of textuality in order to understand representation, and phenomenology offers the notion of embodiment in order to understand being-in-the-world. 'The body' *per se*, can then be construed both as a source of representations and as a ground of being-in-the-world (Csordas 1994). Meanwhile, 'embodiment' becomes an avenue of approach to culture and self, just as textuality is an approach to the study of culture and self. Thus, to work in a 'paradigm of embodiment' is not to study anything new or different, but to address familiar topics—healing, emotion, gender, or power—from a different standpoint. There is not a special kind of data or a special method for eliciting such data, but a methodological attitude that demands attention to bodiliness even in purely verbal data such as written text or oral interview.

In summary, the body's career in anthropology has been on an upswing. From an early anonymity as a taken-for-granted background feature of social life, it has emerged in recent decades first as an explicit topic of anthropological research, then as a problem as its cultural and historical instability as a natural object became increasingly evident. More recently, embodiment has presented itself as an opportunity for reformulating earlier interpretations and rethinking fundamental concepts of culture and self. Through the 1990s the problem posed by the body of the relation between representation and being-in-the-world has been an increasingly prominent site at which anthropologists have become engaged in the wider interdisciplinary discourse of the human sciences. Relevant studies can be found under the rubrics not only of anthropology of the body, but also of medical anthropology and anthropologies of the senses, of space, of dance, of violence, and of science and technology (for a review see Lock 1993). On a wide variety of fronts, the body continues to advance.

Body, Evolution of

Major changes in body form have taken place during human evolution, related to the initial adoption and increasing commitment to bipedal locomotion, and continuing adaptations to climatic, dietary, and other environmental factors. Although all modern humans share a similar body plan, there is still substantial variability in body size and body shape within and between populations that is in part a reflection of environmental adaptation. This article reviews the evidence for both the evolution and modern distribution of body form in humans, and its behavioral and ecological significance.

1. *The Bipedal Transformation*

It is widely agreed that the transition from quadrupedal to bipedal locomotion was one of the most important innovations in human evolution; indeed, bipedality defines our lineage better than any other single characteristic (Clark 1964, Aiello and Dean 1990, Fleagle 1999). Efficient bipedal locomotion requires changes in a number of anatomical characteristics, including lengthening of the lower limb, restructuring of the pelvis, and other alterations. Some of these characteristics are apparent as early as 3–4 million years ago (McHenry 1991, Leakey et al. 1995). However, it is also becoming increasingly clear that the transition to fully terrestrial bipedality occurred in a number of stages, and that some anatomical adaptations to arboreality (tree climbing), especially in the forelimb, persisted for millions of years (McHenry 1991, White et al. 1994, Clarke and Tobias 1995, Leakey et al. 1995, Leakey et al. 1998, McHenry and Berger 1998, Asfaw et al. 1999). It is not until about 1.5 million years ago, with *Homo erectus* (or *ergaster*), that fully modern human body proportions, and by implication, fully modern bipedalism, are evident in the fossil record (Walker and Leakey 1993).

Thus, the adoption of terrestrial bipedality was gradual, and probably involved increasing reliance on this form of locomotion while still retaining the ability to use trees, e.g., for escape from predators. There are many theories on why and how human bipedalism evolved, including ecological and dietary shifts, and changes in social organization (for a recent review, see Fleagle 1999). While distinctively human proportions of the body, such as forelimb to hindlimb length, were established by 1.5 million years ago, within this basic body plan variations in other aspects of body size and shape are apparent throughout the more recent fossil record and among living humans.

2. *Environmental Adaptation*

2.1 *Ecogeographical 'Rules' and their Application to Modern Humans*

One aspect of the environment that has probably had a profound effect on human body size and shape is climate. Systematic relationships between climate and body form among homeothermic animals have been recognized for more than a century, and have been codified as Bergmann's and Allen's ecogeographical 'Rules' (Mayr 1963). Bergmann's Rule states that within a species or closely related group of species, populations living in colder climates will be larger in body mass than those in warmer climates, while Allen's Rule states that colder climates will be associated with shorter extremities and warmer climates with longer extremities. Both of these observations are actually consequences of a more general relationship between body mass and body surface area, in which both a larger body mass and relatively shorter extremities decrease the ratio of surface area to body mass, thus conserving heat, and vice versa. The same principle can also be applied to the overall shape of the human trunk: it can be shown that an absolutely wide trunk (and thus wide body) will lead to a decreased surface area/body mass ratio, regardless of body height, while an absolutely narrow trunk will lead to an increase in the ratio, again regardless of variation in height (Ruff 1991). This explains why both tall and short populations inhabit tropical Africa; both maintain an absolutely narrow body and thus a high surface area/body mass ratio.

Ecogeographical clines that conform to physiological (climatic) expectations have been demonstrated for many aspects of living human body form, including body mass, body breadth, relative limb length, and direct estimates of surface area to body mass (Roberts

Figure 1
Changes in estimated body mass (weight) during human evolution. Living humans are sex-sample-specific population means (Ruff 1994), other *Homo* data points are individual fossils (see text for explanation of two data points in parentheses), letters are non-*Homo* sample means: A: *Ardipithecus ramidus*, B: *Australopithecus anamensis*, C: *Australopithecus afarensis*, D: *Australopithecus africanus*, E: *Australopithecus* (*Paranthropus*) *robustus*, F: *Australopithecus* (*Paranthropus*) *boisei*. Estimates for *Homo* from Ruff et al. 1997 (plus two additional data points), for C-F from McHenry 1992, for B from Leakey et al. 1995, and for A from White et al. 1995 (my estimate based on similarity in humeral head size with middle of range for *A. afarensis*). Note changes in temporal scale (millions of years). (Modified from Ruff et al. 1997.)

1978, Ruff 1994). Other environmental factors, such as diet, obviously also can affect body form, but do not adequately account for these general trends (Ruff 1994). It is more difficult to evaluate such morphological variability in our fossil ancestors, but recent paleoanthropological discoveries combined with developments in methodology have provided some new insights.

2.2 Methods for Reconstructing Body Form from Skeletal Remains

Body mass (weight) for fossil specimens has been estimated using various parts of the skeleton, including craniodental dimensions, but it is clear that postcranial dimensions provide the least biased and potentially most accurate means for reconstructing body size, especially in an evolutionary lineage where changes in relative tooth and cranial size have been dramatic (Pilbeam and Gould 1974). Two basic types of methods have been employed: a mechanical approach, which uses features that are related to the mechanical load-bearing function of the skeleton, such as lower limb articular size, and a morphometric approach, in which features that actually reflect the size and shape of the postcranial skeleton are used. For the latter, it has been shown that stature, estimated from limb bone length, and body breadth, measured across the pelvis, together provide a good estimate of body mass (Ruff 1994). Aspects of body shape in fossil humans can be evaluated through intra and inter-limb bone length proportions (Trinkaus 1981), proportions of limb bone lengths to vertebral column (trunk) length (Holliday 1997), proportions of body breadth to body height, and reconstructed body mass to body height (Ruff 1994).

2.3 Temporal Changes in Body Size

Changes in body mass over 4.5 million years of human evolution are shown in Fig. 1. Because of large temporal differences in available data density, three different temporal scales are used. Also, because it is known that body mass varies ecogeographically in modern populations (see above), the data for the genus *Homo* are plotted separately for higher (30°) and lower latitudes (all non-*Homo* fossils are from lower latitudes). Body masses were estimated from both

lower limb articular size and using the stature/pelvic breadth 'morphometric' approach; references are given in the figure caption.

Several trends are apparent in Fig. 1. First, body size was relatively small in the earliest period of human evolution, and increased with the appearance of *Homo* at least two million years ago. This may have been associated with significant changes in ecology in *Homo*, i.e., increased diurnal travel through open country, possibly indicating an increased reliance on hunting (or at least increased foraging distance) (Wheeler 1992, McHenry 1994). The two low outlying *Homo* data points at about 1.77 million years ago are specimens belonging to a species (*Homo habilis sensu stricto*) that shows some distinctly non-*Homo*-like traits and may be better referred to another taxon (Wood 1999).

There was a further increase in average body size at about half a million years ago, coinciding with the first (postcranial) evidence for *Homo* from higher latitudes. As noted above, colder temperatures favor larger body size, so this may very well be an ecogeographical phenomenon. Finally, body size decreased beginning about 50,000 years ago, reaching modern values by 10,000 years ago in higher latitude samples, although lower latitude samples from that time period are still larger than living populations.

Overall, body mass in *Homo* prior to 10,000 years ago was about 10% larger than in living humans inhabiting the same areas today (Ruff et al. 1997). Larger body size may be related in part to the hunting of large game (Thieme 1997); a decline in body size over the last few tens of thousands of years may reflect increasing technological sophistication and decreasing reliance on brute strength for performing subsistence tasks (Klein 1989). There is evidence that body size continued to decline, at least in some regions, through the Mesolithic and Neolithic (Frayer 1984), perhaps because of decreased nutritional quality and/or increased disease transmission associated with the agricultural revolution (Cohen and Armelagos 1984). Body size has increased over the past century in many higher latitude populations, probably due to improvements in the environment (Eveleth and Tanner 1990), while the opposite trend has been observed in some lower latitude (Third World) populations (Tobias 1985).

2.4 Temporal Changes in Body Shape

As noted earlier, vestiges of arboreality, particularly a relatively longer and/or more robust forelimb, remained in the skeleton long after the first evidence for bipedality. In the few specimens where we can evaluate it, the trunk was relatively wide in these small-bodied early fossil taxa (Ruff 1991). About 1.5–1.7 million years ago, stature suddenly increased in *Homo* (along with body mass) and the trunk became relatively narrower as well. This coincided with a major ecological change in East Africa (the location of the first known *Homo* fossils) at this time, in which the climate became much more arid and the landscape more open (Potts 1998), favoring body linearity (Ruff 1991, Wheeler 1993). Alternatively or in conjunction, a dietary shift in *Homo* towards more meat eating may have required a less bulky abdomen and thus permitted a relatively narrower body (Aiello and Wheeler 1995).

Where they can be evaluated, the body proportions of later human ancestors appear to mirror the same ecogeographic clines found among living populations. So, for example, Western European Neandertals, who lived in a very cold climate for many millennia, were quite stocky and short-limbed, while their replacements, Upper Paleolithic-associated 'anatomically modern humans,' who very likely migrated in from farther south, were much more linearly built (Trinkaus 1981, Ruff 1994, Holliday 1997). Wide bodies and/or short limbs are not limited to Neandertals but rather are a general phenomenon of higher latitudes (colder climates), as evidenced by other recently described specimens from Great Britain, Spain, and northern China dating from 200,000–500,000 years ago (Arsuaga et al. 1999, Rosenberg et al. 1999, Trinkaus et al. 1999). In fact, it can be argued that pre-modern humans from higher and lower latitudes exhibit 'hyper-arctic' and 'hyper-tropical' body proportions, respectively, probably because of less efficient cultural buffering against the environment (Ruff 1994, Trinkaus et al. 1999).

3. Body Size as a Baseline for Other Comparisons

In addition to its ecological and behavioral significance, body size is important in human evolutionary studies because it is often used as a 'denominator' against which to evaluate other physical traits. One prime example is brain size, which is commonly expressed as a ratio against body mass, or encephalization quotient (EQ) (e.g., Pilbeam and Gould 1974). EQ increased in early *Homo* (1.5–2.0 million years ago) from previous estimated values, but then remained constant for at least a million years (to 0.5 million years ago), after which it increased again, exponentially, to modern values (McHenry 1994, Ruff et al. 1997). Skeletal robusticity has also been evaluated relative to body size, and shown to follow an inverse trend relative to brain size (Ruff et al. 1993).

Finally, the body size of earlier humans can be used as a baseline for interpreting the health of modern populations. Comparing present-day measures of stature and body mass with those of ancestral populations may give better estimates of potential body size limits and provide guidance in setting nutritional and other health standards (WHO 1995).

Body, History of

1. The Problem of Corporeality and the Two Approaches to the History of the Body

In a text fragment entitled 'Das Interesse am Körper', (the interest for the body), Max Horkheimer and Theodor W. Adorno argued that the 'love–hate relationship to the body' and the refusal of corporeality were the hidden references of the modern society after the Enlightenment. This oblivion of the body was related to the long-lived dichotomy between body and soul, i.e., with the Cartesian opposition of *res extensa* and *res cogitans*, which met with such success for many centuries (Danto 1999). The consequence was the naturalization of the body and its exclusion from social processes. This 'modern

body,' an idea which has been emerging since the eighteenth century and was supposed to be a 'stable experience' (Armstrong 1983), did not follow historical evolution: it could even be defined as the antithesis of cultural change. With the progress of secularization, mankind learned to consider society, its institutions and modes of representation as historical realities which man himself had called into existence. But the human body was not man made, and as such it could be of no interest as an object of historical interpretation. Even in the nineteenth and twentieth centuries, the body still remained a bastion of nature that opposed a limit to the general historicizing of thought. Since the middle of the nineteenth century, the history of the body had become the stronghold of evolutionary biology, while a number of other disciplines (anatomy, physiology, biomedicine, physical anthropology, occupational and nutritional science, hygiene, molecular biology, genetics, etc.) individually began to research into this seemingly immutable physical entity, using exact methods and laboratory experiments. Optimization of physical fitness, rationalization, normalization, healing, or maintaining in good health were the main objectives of their efforts. The fact that the body was thought to be independent of culture and that, at the same time, the modern age was literally obsessed by the impact of carnal corporeality on both individuals and society, explains the existence of a 'love–hate relationship' towards the body diagnosed by the Critical Theory of Adorno and Horkheimer.

Given this background, the history of the body proves to be a sensitive subject. However, it does not deal exclusively with the presence of the body in history. At this point, it is necessary to define two different conceptions:

(a) It must be stressed that the body was never absent from historiography. 'Either "the body" is not really a subject of its own, or it contains nearly all other subjects' (C.W. Bynum 1996). Historical works are full of phenomena which would be impossible to describe without frequent references to the human body. Demographers work with vital statistics to produce indicators on birth rate, morbidity, or mortality; some of these studies reduce the drama of life to quantitative relationships, other authors (such as A.E. Imhof (1992)) combined empirical findings on the extension of the average life expectance and the tendency towards a decline in the number of children with historico-cultural questions, from which was derived that the experience of the body and the meaning of life were omnipresent. Neither the history of political philosophy, nor the history of societies and mentalities as it was suggested by the School of the Annales in France from the 1920s onwards would make any sense without the presence of the body. As early as 1938, Lucien Febvre suggested writing a history of sensitivities and of the changing systems of emotions in order to understand human agency.

(b) It is clear that a continuous, conscious, explicit reflection on the role of the body only began in the last three decades of the twentieth century in social sciences and humanities. Once a static, biological, and naturalistic idea of the body started being criticized, body-related questions developed as a trend among historians and constituted a new field of research. As such, it is sometimes seen as an interdisciplinary meeting-point of several different approaches (discourse analysis, semiotics, gender studies, cultural studies, science, and technology studies, etc.); others consider it to be an independent sub-discipline of history.

These two conceptions of body history give rise to frequent misunderstandings. While one party insists on the innovative potential that body history has proved to offer since the 1970s, the other party dismisses it as a fashion trend that conceals the evidence that history, as a science focusing on the cultural interaction of human beings, has always been body history. From a historic–scientific perspective, however, there exist a number of arguments in favor of highlighting the shift of paradigms that took place in the 1970s, and asking how this new, theoretically-based examination of the body has influenced older fields of research like demography and social history.

2. *Continuities and Shift of Paradigms: Four Periods*

The historicizing of the body can be split up into *four phases* (which are not clearly distinct, but overlap frequently with one another).

In the first phase, which lasted until the early 1970s, a number of innovative studies looked at the human body, and the imagery that had crystallized around it, as objects of theoretically elaborated analyses. Later, they became 'classics' in the domain, although their initial intention had nothing to do with the new speciality named 'history of the body,' which began to emerge in the 1970s. The historical studies concentrated principally on the Middle Ages and the early modern era, whereas anthropology, philosophy, and psychoanalysis dared to delve into contemporary phenomena. Some of the most significant works of this period are Sigmund Freud's *Civilization and its Discontents* (1929/30), whose central theme is the extension of the body with the help of technical artifacts and the promotion of the human being to a god of prostheses, Mauss (1935), in which the body is analyzed as the first and most natural instrument at man's disposal; Paul Valéry's *problem of the three bodies* (1943), which looks into the various, parallel ways of speaking of the body; Maurice Merleau-Ponty (1945) and Samuel Todes (1963), which deals with the body as the condition of awareness, in compliance with a philosophy of finiteness; and Kantorowicz (1957), whose intention is to contribute to the political theology of the Middle Ages and looks at the mystical fiction of an immortal *political body* existing in parallel to the mortal *natural body* of the king.

A second phase began in the 1960s—accompanying the removal of the body's taboos in the

alternative culture of the time—giving rise to many publications and a new theoretical thinking in the 1970s. The principal references of this phase are the works of Michel Foucault (1977) (in particular *The Birth of the Clinic* and *Discipline and Punishment: The Birth of the Prison*), as well as Norbert Elias' (1969) *magnum opus*, *The Process of Civilization*, which was published in the late 1930s, but met with significant success only three decades later. Another important contribution was Mary Douglas' *The Two Bodies* (1973), in which the author examines the metaphorical relationships and cognitive interactions between the body as a social construction and the individual physical body. The new studies of the human body were based on the thesis of a constant interaction between knowledge and power. Foucault's concepts of a bio-power and of a political economy of the body were set against a liberal-Marxist scenario of disciplinary force which represses the body. Contrary to the assumption of a disciplinary society (in which the subject is oppressed by power), in Foucault's view the body is produced by knowledge-based power, which shapes everyday practices and generates regimes of visibility and discourses. In the concept of a 'normalizing society,' the body is the medium which binds together the macro-organization of power and the micro-practices through which social structures are stabilized. This perspective is directly connected to Norbert Elias' concept of the individual internalization of social constraints (force to force oneself?). The production of a modern human being can be defined in terms of an ever-growing self-control of the human being, mainly through the decoupling of emotion and bodily expression. The 1970s also saw the publication of interesting studies in various domains of social sciences notably by Helmuth Plessner (philosophical anthropology of the senses), Heinrich Schipperges (outlines for a philosophy of the body), Dietmar Kamper and Christoph Wulf (return of the body and fading of the senses), Rudolf zur Lipe (On the Own Body. About the Economy of Life) and Utz Jeggle (preliminary reflection on a popular knowledge of corporeality).

The third phase was strongly influenced by the feminist criticism of science, which admitted gender as a category for analysis and introduced new standards into body history. Thanks to Yvonne Verdier, Carolyn Bynum, Gianna Pomata, Ludmilla Jordanowa, Marie-Christine Pouchelle, and many others, new interpretations of the body appeared at the end of the 1970s, emphasizing its relation to gender history and clearing the ground for a far-reaching methodologically highly interesting discussion. In Germany, these endeavors are connected above all to the name of Barbara Duden, who published an innovative study, *The Woman Beneath the Skin: A Doctor's Patients in Eighteenth Century Germany* (Duden 1987). In this book about the interior, invisible corporealness of women in Eisenach (Germany) and their doctor Johann Storch, the historian and sociologist Barbara Duden examines the sociogenesis of the modern body in relation to a history of the lived body's receptivity to experiences. She analyses the loss of control over the body as a gate towards physical experience, and speaks in favor of a hermeneutic interpretation of the body's reality in the past. Although we cannot use our body, which we have possessed since the eighteenth century, as a bridge to interpret the experiences of people before the Enlightenment, the corporeality of every human existence gives us access to the context in which women and men experienced feelings in the past.

The fourth phase is characterized by a turn towards discursive, semiotic, and performative approaches and marks the beginning of a new era in the history of the body, which also lead to a post-structuralist reassessment of key authors of the 1960s, especially of Foucault. The 1990s saw the upcoming of new authors, in particular, Laqueur (1990) and Butler (1993) fulfilled the *linguistic turn* in body history and provoked the supporters of the traditional, experience-based study of corporeality. Laqueur examines the constitution of the body through discourse and action; from this point of view, sex is situational; it is explicable only within the context of battles over gender and power. In contrast, Butler—who, after her book was published, was wrongly considered to be an advocate of disembodiment—criticized the subject-centered constructionist approach by relating the materiality of the body to the performativity of gender: What I would propose in place of these conceptions of construction is a return to the notion of matter […] as a process of materialization that stabilizes over time to produce the effect of boundary, fixity, and surface we call matter?

In the meantime, several positions have been clarified. In the last few years, there has been a growing tendency to criticize the dissolving of the body into language (Bynum). However, this does not herald a return to an unreflected essentialism of corporeality. In contrast, analytical efforts converge in the concrete, mortal human body, without forgetting that the corporal existence of human beings will never be independent of the empire of signs, which is permanently created and transformed by cultural change.

3. *Fields of Research and Analysis*

For a long time, researchers in the field of body history were not sure whether they were looking into a completely new domain, or whether they had simply discovered a new and interesting perspective which offered the possibility of an innovative approach towards well-known social phenomena. The question becomes more complex: from the very beginning, body history was the fruit of interdisciplinary efforts. This can have two consequences: the loss of clarity due to friction between the disciplines, and the positive effects of synergy (cf. among others Feher et al. 1984). Authors who had already attempted a systematic approach to body history in the mid 80s presented an overview of the broad portion of

research based on social sciences. From a phenomenological point of view, Turner (1984) describes four tasks with which any social organization confronts bodies (and vice versa): (a) the reproduction of populations in time, (b) the regulation of bodies in space, (c) the constraints of the interior body through control and discipline, (d) the representation of the exterior body in the symbolic space of the society. O'Neill (1985) provides and alternative, more institution-based conceptualization, distinguishing (a) the world's body, (b) social bodies, (c) the political body, (d) consumer bodies, and (e) medical bodies.

In the narrower field of historiography, although there have been frequent variations in the main fields of interest, one can observe an obvious concentration of research on the Middle Ages and the Early Modern Era. Starvation and fasting, posture, body language, clothing habits, disciplining of the human body through the art of dancing, training of soldiers, seduction, sexuality, pregnancy, and childbearing: these and other themes were examined in the light of cultural anthropology and iconography and resulted in a new view of everyday life and bodily experience in past centuries. The 'education of the senses' (Peter Gay), the history of 'sensory awareness' (Rudolf zur Lippe), and an 'anthropology of the senses' (Lucien Febvre) turned out to be especially interesting fields of research. The conflict about the hierarchy of the senses, which began in antiquity, the theses of a mythopoetical constitution of the individual (Hartmut Böhme) and of a privilege of the eye at the end of the twentieth century (Paul Virilio) remain of symptomatic value. The history of sensory experience is closely linked with the history of wisdom and the remembering of the body, as a materialized matrix for inscriptions of cultural experience, the body is a part of the memory of a society. Step by step, performativity relates the signification process with the materiality of the body. It is the reiteration of practices and the regulation of discourses which generate the feeling of continuity and reliability of the real world.

Another area that offers many possibilities for research is the history of the perception of the body and of body-related imagery and esthetics (Elkin 1999). In the course of secularization, the image of the body as 'clockwork,' the perfect functioning of which was the proof of God's creation, was replaced by the idea of a machine working according to the laws of nature (with a male connotation: the man is considered to be the standard human being). Along with this evolution came the growing conviction that the body is a closed entity, as the medieval image of a 'grotesque', open body 'Michail Bakhtin' was gradually replaced by the modern, closed skin-self (Anzieu 1992). This evidence depended on new schemes of visibility: Barbara Stafford (1993) describes this historical shift toward visualization with the help of somatic metaphors and she points out the important role played by visual arts when it came to solving the representational problem of the embodiment or personification of knowledge. Crucial for this development was the eighteenth century, which saw the breakthrough of a *possessive individualism* in the perception of the body. This resulted in a degradation of the notion of a self extended into a unique and inviolable corporeal volume, to one in which the self only loosely possessed a body (Karl Figlio). The problem for the historical investigation into this body, which we possess and which is analyzed by science, is not how something that is obvious today had remained hidden for so long, but how the body had become so evident in the first place (Armstrong 1983). Thanks to the modern perceptions of the body, new ways of seeing collective bodies were also brought to the fore. Jacob Rogozinski showed that the incarnation of the individual in an all embracing global body is an old phenomenon, but in the nineteenth and twentieth centuries, the political hypostatization of this collective body became still stronger. While society depended more and more on technology, strengthening the thesis that social cohesion results from the linking-up of the elements of society by a powerful communicative, nervous system, nationalism encouraged the phantasm of a body of the people and of a blood community. The imagery of the body of the nation (Svenja Goltermann) e.g., proved to be mediated by the practice of male gymnastics, which aims at the appropriation of national order through individuals and social groups.

Medicine, dietetics inspired from humoral theory, and the modern conception of hygiene which emerged in the middle of the nineteenth century, also offer fertile ground for research in body history. Traditional, epidemiological approaches of research on disease are completed by analyses of illness, suffering, pain, and death of human beings that were increasingly considered as patients in the course of the nineteenth century, and thus were submitted to medical experts' power of definition. A similar process of professionalization and scientization took place in the areas of occupational and nutritional science. The interaction of physiology and the industrial society show, for instance, how epistemic regimes, technological artifacts, and social interests are intertwined in the production of knowledge, and how the thus-produced knowledge facilitates the appearance of individuals who consider their bodies as instruments of self-perfection (Sarasin 2001). In this context, the modification of individuals' self-images under the influence of scientific knowledge is studied in parallel with the unwillingness of the body faced with the exigencies of a working society, which is subject to the paradigms of efficiency and rationalization. In the leisure society of the post-war period, in which the body functions as a site of consumption, the questions arising from an invariably incomplete integration of the individual body into the social structure remain to be answered by further historical research.

4. *Controversies and Prospects*

Generally, in social sciences and humanities, experience-based concepts of the body implying a lived

corporeality are being challenged by poststructuralist–deconstructivist models that consider the body primarily as a discoursive effect or a product of the knowledge–power complex accumulated since the Enlightenment. Nonetheless, today, the consensus is that it must be essential to overcome this opposition of discourse and experience (Canning 1994). These debates frequently overlook the fact that the history of the body is in the midst of the fundamental discussion on the blurring of the boundaries between nature and culture. The ontological status of the traditional categories natural and social has become a critical question and this makes it obvious to consider the products of technology—and therefore the world we live in—as hybrid artifacts. From this point of view, the human body, too, would be a hybrid, i.e., a crossbreed in which social, technological, cultural and natural components cannot be held apart with certainty.

The materiality of the body plays a crucial role in this debate. This is obvious in disciplines such as biomedicine, cognitive sciences (CS), and artificial intelligence (AI), which lie in a paradoxical area of tension between hyperembodiment and disembodiment. Whilst scientists in the domain of AI start out from the assumption that intelligence can be modeled only on a material, body-bound base, which implies that machines that have emerging properties and therefore the ability of learning must by definition be techno-bodies (Lakoff and Johnson 1999), other authors (e.g., Flusser 1994) follow the principle from the subject to the project in order to develop visions according to which the conception of bodies has become a creative activity of mankind, escaping the blind contingencies of nature. It is essential to realize that the concept of information technology, genetic engineering, and xenotransplantation have made natural boundaries permeable and aims at putting mankind in a position to gain control over the evolutionary process of life which started billions of years ago.

It is precisely because of these perspectives, which are at once technocratic and playful, that the findings of body history have gained a major importance today. Although they are for various reasons not comparable, the concepts of the body suggested by biomedicine, information technology, and genetic engineering are in compliance with the more modern approaches of social sciences and humanities according to which the body is not an invariable, unchangeable entity, independent of time and history. When we are willing to reassess the body as a product of society, we have to think about how it is culturally constructed, or constituted. If historiography demonstrates that bodies were always modeled by culture, this means that the scientific and technological interventions in the physiology and (for the time to come) in the genome of the human being are nothing new in principle, they are simply an intensification of a traditional way in using bodies. In this sense, Donna Haraway pleads in favor of the curious and innovative application of the new possibilities offered by technology, and sees the creation of natural–cultural hybrids as a promising path towards the creative self-realization of mankind. This 'Cyborgs-optimism' is contradicted by another: distinguishing herself from technocratic feasibility fantasies, Barbara Duden supposes that although human beings are partially formed by culture, the somatic fundaments of life are an inescapable condition of their existence. Based on the paradigm of a 'historical somatology,' the examination of the time-bound forms of experiencing corporeality concentrates on the relation of human beings to their body, which changes in the course of history, as a *sine qua non* of experience. Such an approach considers the current colonization of the body by science and technology as an unprecedent process and an attack on the human condition itself. No doubt that Duden remains skeptic against the mythopoesis of a technology which models the desires of individuals in a way that they anticipate the possibilities of science and technology.

These divergent positions are the consequence of two conflicting evaluations of what must be the most fundamental challenges of mankind. In this context, body history becomes—whether it intends to or not—a moral authority and a source of criteria for the legitimacy of technological interventions on the human body. This clearly implies a heavy responsibility, but at the same time, it is a proof of the persistant relevance of the history of the body.

Body Image and Gender

Body image refers to perceptions, thoughts, and feelings about physical appearance. Although most people are relatively satisfied with their bodies, evaluative measures of body image indicate that many individuals, both men and women, from young to old, are dissatisfied and wish they could change some aspect of their bodies. On average, women are more dissatisfied with their bodies than men. This article reviews the measurement of body image, the factors that influence its development, and gender differences in which aspects of physical appearance are the strongest determinants of body image.

1. Assessment of Body Image

The assessment of body image is based either on perceptual estimation or on affective reactions to self-evaluation. Unfortunately, the two measures are poorly related to each other. Perceptual estimations refer to the accuracy of judgments about the relative size of various body components whereas subjective evaluations refer to how people feel about those judgments.

1.1 Perceptual Estimates Are Not Reliable

Perceptual techniques are used to assess the accuracy of judgments about physical size. For example, researchers distort physical images (e.g., photographs, silhouettes, or mirror images) and then have subjects select their actual image from among the distortions. The difference between perceived and actual body size is used as an indicator of body image. Unfortunately, perceptual distortions of body image are common and occur with equal frequency across many diverse populations. Moreover, the perceptual distortions are unrelated to body image satisfaction and do not indicate any pathological condition. Relatively little research has found these measures to have adequate reliability or validity, and therefore they cannot be recommended at this time (Polivy et al. 1990).

1.2 Subjective Evaluations Reflect Satisfaction With One's Body

Body image is also assessed through subjective evaluation, such as asking people to rate satisfaction or dissatisfaction with their bodies or parts of their bodies. Common techniques include the following: self-ratings of physical attractiveness; self-ratings of specific body part satisfaction (e.g., hips, thighs, nose, and chest); self-ratings of weight, size, or shape satisfaction; and self-reports of affective reactions (such as anxiety or dysphoria) to thoughts about the body. People's feelings about their bodies are often unrelated to objective reality—many young girls who are objectively underweight feel that they are fat and are actively trying to lose weight. Most people are also typically happy with some of their physical features while being unhappy with others. Although people who dislike many of their body parts tend to have

International Encyclopedia of the Social & Behavioral Sciences ISBN: 0-08-043076-7

more negative body image, how the various parts contribute to the whole has yet to be precisely determined.

1.3 Excessive Concerns About Body Image May Reflect Psychopathology

Some individuals are so preoccupied with trivial or imagined defects in their appearance that it interferes with normal psychological functioning. *Body dysmorphic disorder* is a pathological disturbance in body image in which individuals feel extreme distress about minor flaws in some part of the body, such as the size or shape of the ears, eyebrows, mouth, hands, feet, fingers, or buttocks. These thoughts can be so intrusive that individuals avoid work and public places, going out only at night when they cannot be seen. Those who have body dysmorphic disorder often undergo cosmetic surgery, but unfortunately for some, the surgery fails to alleviate body image dissatisfaction. Indeed, in some cases it increases their concerns as a doctors' willingness to provide surgery validates their views of abnormality, which may give rise to intensified or new preoccupations.

2. Development and Components of Body Image

Many different physical characteristics affect body image, including skin color, nose and ear size, hair loss, facial acne, pregnancy, wrinkles, varicose veins, straightness of teeth, and so on. Indeed, nearly every body part could influence overall body image, especially for those who perceive that body part to be unusual in some desirable or undesirable way. The features most closely associated with body image change over the course of lifespan development and differ as a function of gender.

2.1 Body Image Develops Early

Facially attractive infants receive more positive attention (e.g., increased smiling, eye contact, greater expectations of intelligence) than unattractive infants. For instance, mothers of attractive babies are more affectionate than are mothers of unattractive babies (Langlois et al. 1995). This differential treatment continues throughout childhood. School teachers, nurses, and parents rate attractive children as having better personalities, greater academic ability, and being more likely to be successful than unattractive children. These ratings are likely to have a strong impact on the self-esteem and body image of unattractive or overweight children. The children of parents whom themselves are preoccupied with body-weight issues or dieting or who have symptoms of disordered eating are at greater risk of developing body image dissatisfaction.

2.2 Adolescence is a Critical Period

Adolescence is a time of increased self-reflection and self-attention, and teenagers are especially concerned with how they are viewed by their peers (see *Adolescent Development, Theories of*). The physical changes that accompany adolescence, such as secondary sexual characteristics, oily complexion and acne, and tremendous individual variation in rate of growth lead most adolescents to be particularly conscious of physical appearance. Many girls become obsessed with body image issues, and by age 16 nearly all female adolescents report having at some point dieted in an attempt to lose weight. At the same time, boys are often concerned with being too short or not sufficiently muscular, especially when compared with popular male peers.

Negative comments from peers, particularly in the form of teasing, are important predictors of body image dissatisfaction (Grilo et al. 1994). Unattractive and obese adolescents are liked less, excluded from social events, and viewed by their peers as possessing more negative traits (e.g., lazy, sloppy) than their slimmer and more attractive peers. This social exclusion may promote a self-fulfilling prophecy, in that ostracized adolescents have fewer opportunities to acquire social skills (because of their limited social opportunities) and, in turn, their diminished social skills reinforce people's avoidance of them. In general, body image is at its most negative during adolescence.

2.3 Adulthood to Aging: Satisfaction to Dissatisfaction

As individuals mature into adulthood and focus on family and career issues, most individuals experience a reduction in body image concerns. However, individuals who gain large amounts of weight during adulthood experience increased body dissatisfaction, which may motivate efforts to improve a healthful lifestyle or lead to unhealthful dieting practices and weight cycling.

Changes in appearance and physical stamina that accompany old age may have a negative influence on body image. Older men may feel a decline in their body satisfaction because of their declining physical abilities, whereas women may be more concerned about excess weight as well as their wrinkling skin and hair loss. Both men and women may also be concerned about being too thin, since being frail may indicate poor or failing health.

3. Gender

Across the lifespan, women tend to have lower body image satisfaction than men. Women are more likely than men to evaluate specific body features negatively,

to attempt weight loss, to report anxiety about the evaluation of their physical appearance, and to have cosmetic surgery.

3.1 Women Are Especially Concerned With Body Weight

Body image dissatisfaction among women is usually related to self-perceptions of overweight. More than three-quarters of women would like to lose weight and almost none would like to gain weight. Believing oneself to be overweight, whether one is or not, is closely related to body image dissatisfaction. Beginning in early adolescence, women compare their body shape and weight with their beliefs about cultural ideals. A discrepancy from the cultural ideal often motivates people to undertake dieting in order to achieve a more attractive body size. Dieting is rarely successful, with fewer than 1 percent of individuals able to maintain weight loss over five years. Repeated dietary failures may exacerbate body image dissatisfaction and feelings of low self-esteem (Heatherton and Polivy 1992). Perfectionistic and low self-esteem women are particularly affected by body dissatisfaction, such that these personality traits in combination have been linked to increased bulimic symptoms (Vohs et al. 1999).

Black women are much less likely to consider themselves obese and are much more satisfied with their weight than are white women, despite the fact that black women are twice as likely to be obese. Black women also rate large black body shapes much more positively than do white women rating large white body shapes.

3.2 Men are Concerned with Size and Strength

Men are more likely than women to view their bodies as instruments of action (Franzoi 1995). Men who are physically large are viewed as more powerful than men who are physically slight, and many men try to increase their physical size. Very thin men are likely to experience body image dissatisfaction. Many men have a desire to be taller and tend to exaggerate their height. This is not surprising given the well-documented link between men's height and positive social outcomes. Many short men report dissatisfaction with their stature and some evidence suggests that they are more likely to experience decreased self-esteem and more negative body image relative to their taller male counterparts.

3.3 Physical Attractiveness Cues Vary by Gender

The specific attributes that are found attractive differ by gender. Facial features that indicate youthfulness (e.g., large eyes, small nose, big lips) and body features that are petite and thin (e.g., long legs, flat stomach) tend to be desirable for women. For men, facial features that imply maturity (e.g., square jaw, visible cheekbones) and body features that indicate mass and largeness (e.g., height, mesomorph build) tend to be desirable. There is only a modest association between objectively rated physical attractiveness and body image. However, subjective ratings of physical attractiveness (i.e., personal beliefs) are closely linked to body image satisfaction.

4. Culture

Throughout history, cultural influences have played significant roles in determining body image: the Greeks revered the male body, the Romans valued thinness, and people from the Middle Ages showed a preference for larger, rounder female body types. Thus, the determinants of body image change over time as a function of cultural and societal influences (Fallon 1990).

4.1 There is Variation Across Cultures

A limited number of physical attributes have defined attractiveness over time (e.g., fleshiness rather than flabbiness, cleanliness, and symmetry in one's body); the rest are defined within cultures. For instance, the stigma of obesity varies greatly across cultures: Fijians, Kenyans, Samoans, Mexicans and Israelis stigmatize obesity less than do Americans, Canadians, and the British. Individuals often conform their bodies to match local norms and standards. Extreme examples of this include the Burmese tradition of women affixing brass rings around their necks in order to stretch their necks to lengths of up to 40 cm, the East Indies tradition of filing teeth down to the gums, the South American (Abipone) tradition of inflicting deep wounds on the face, breasts, and arms, and the proliferation of Americans piercing and tattooing various body parts.

4.2 There is Variation within Cultures Over Time

Within a single culture, mandates for what is beautiful and desirable also undergo substantial variation across time, particularly for women. For instance, during the 1820s some women drank vinegar to lose weight and stayed up all night to look pale and fragile; in the mid-nineteenth century, a big, voluptuous figure was in vogue and women often worried about appearing too thin; in the early twentieth century a more slender but very sturdy physique was desirable. Although the preference for body size has fluctuated during the twentieth century, Western societies have been obsessed with thinness since at least 1970. Thus, body image is determined to a great extent by current societal norms and expectations.

T. F. Heatherton

Borderline Personality Disorder

The term borderline personality is used in two main ways:

(a) Borderline personality disorder, one of the personality disorders described in the classification system of DSM-IV (American Psychiatric Association 1994), that is, a circumscribed constellation of pathological personality traits that constitutes approximately 15 percent of all diagnosed personality disorders, and, at least in the USA, probably around 15 percent of all patients in psychiatric hospitals.

(b) Borderline personality organization, that is, the psychostructural features that together characterize all severe personality disorders, and that differentiate them from less severe personality disorders (that is, from patients presenting neurotic personality organization). Borderline personality organization includes the borderline personality disorder as one dominant constellation of pathological personality traits among others.

This terminological issue has practical implications: Borderline personality disorder, with its circumscribed symptomatology, has been subject to research regarding specific treatment approaches. The present trend is to treat these patients with a supportive psychotherapeutic approach, based either on psychoanalytic principles or on cognitive behavioral ones, plus a psychopharmacological approach to certain target symptoms. Dialectic behavior therapy (DBT) is one form of cognitive behavioral therapy that has proven effective in reducing suicidal and parasuicidal behavior in borderline patients (Linehan et al. 1991), and psychodynamic psychotherapy has proven effective in treating borderline patients in a day hospital setting (Bateman and Fonagy 1999). Low dose neuroleptics are effective in reducing severe anxiety and cognitive disorganization characteristic of borderline patients, and antidepressive medication, particularly the use of SSRI medication, has been effective in palliating their symptomatic depression (Soloff 1998).

1. The Characteristics of Borderline Personality Disorder

The DSM-IV description of borderline personality disorder defines it as a pervasive pattern of instability of interpersonal relationships, self-image, and affects, with marked impulsivity beginning by early adulthood and present in a variety of contexts. It is indicated by five (or more) of the following:

(a) Frantic efforts to avoid real or imagined abandonment.

(b) A pattern of unstable and intense interpersonal relationships alternating between extremes of idealization and devaluation.

(c) Identity disturbance: persistent and markedly disturbed, distorted, or unstable self-image and/or sense of self.

(d) Impulsivity in at least two areas that are potentially self-damaging, (e.g., spending, sex, substance use, reckless driving, binge eating).

(e) Recurrent suicidal threats, gestures, or behavior, or self-mutilating behavior.

(f) Affective instability due to a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety, usually lasting a few hours and only rarely more than a few days).

(g) Chronic feelings of emptiness.

(h) Inappropriate, intense anger or lack of control of anger (e.g., frequent displays of temper, constant anger, recurrent physical fights).

(i) Transient, stress-related paranoid ideation, or severe dissociative symptoms.

This personality disorder has substantial comorbidity or overlap with other severe personality disorders, particularly the histrionic, avoidant, dependent, paranoid, and narcissistic personality disorders.

Although there are no precise statistics, it is reasonable to assume that between 0.2 percent and 1.8 percent of the general population suffer from this personality disorder. Factor analytic studies have concluded that the dominant three factors underlying this symptomatic constellation are identity diffusion, affect dysregulation, and impaired impulse control (Clarkin et al. 1993). In the study of the changes in symptomatology that occur with treatment, there is a tendency for impulse control to improve first, affect dysregulation later, and identity disturbance, the most resistant aspect of this pathology, only after extended periods of treatment, if ever.

2. *Classification Problems: Categorical vs. Dimensional Models of Personality Disorders*

A currently dominant dimensional model, the five-factor model, has synthesized numerous factor analyses into the proposal that neuroticism, extroversion, openness, agreeableness, and conscientiousness constitute basic factors that may describe all 'officially' accepted personality disorders in DSM-IV (Costa and Widiger 1994, Widiger et al. 1994). The problem is whether these are really fundamental determinants of the organization of the normal personality or even of the personality disorders. An 'equalization' of these character traits seems strange when applied to the subtleties of the clinical features of specific personality constellations. To develop factorial profiles for each personality disorder on the basis of those five factors has an eerie quality of unreality for the experienced clinician.

Those researchers who are inclined to maintain a categorical approach to the classification of personality disorders, usually clinical psychiatrists motivated to find specific disease entities, tend to proceed differently. They study the clinically prevalent combinations of pathological personality traits, carry out empirical research regarding the validity and reliability of clinical diagnoses, attempt to achieve a clear differentiation between personality disorders, and, of course, keep in mind the clinical relevance of their approaches (Akhtar 1992, Stone 1993). This approach, pursued in DSM-III and DSM-IV, has helped to clarify—or at least to permit the clinical psychiatrist to become better acquainted with—some frequently seen personality disorders. The approach has been plagued, however, by the high degree of comorbidity of the severe types of personality disorders, and by the unfortunate politicalization of decision making, by committee, of what personality disorders to include and exclude in the official DSM system, and under what labels (Jonas and Pope 1992, Kernberg 1992, Oldham 1994).

Recent studies of alteration in neurotransmitter systems in severe personality disorders, particularly in the borderline personality disorder, although still tentative and open to varying interpretations, point to the possibility that neurotransmitters are related to specific distortions in affect activation (Stone 1993). Abnormalities in the adrenergic and cholinergic systems, e.g., may be related to general affective instability; deficits in the dopaminergic system may be related to a disposition toward transient psychotic symptoms in borderline patients; impulsive, aggressive, self-destructive behavior may be facilitated by a lowered function of the serotonergic system.

These aspects of inborn dispositions to the activation of aggression mediated by the activation of aggressive affect states are complementary to the now well-established findings that structured aggressive behavior in infants may derive from early, severe, chronic physical pain, and that habitual aggressive teasing interactions with mother are followed by similar behaviors of infants, as we know from the work of Galenson (1986) and Fraiberg (1983). The impressive findings of the prevalence of physical and sexual abuse in the history of borderline patients confirmed by investigators both here and abroad (Marziali 1992, Perry and Herman 1993; van der Kolk et al. 1994) provide additional evidence of the influence of trauma on the development of severe manifestations of aggression.

3. *A Psychostructural Nosology*

Borderline personality organization is characterized by lack of integration of the concept of self and significant others, that is, identity diffusion, a predominance of primitive defensive operations centering around splitting, and maintenance of reality testing. The defensive operations of splitting and its derivatives (projective identification, denial, primitive idealization, omnipotence, omnipotent control, devaluation) have as a basic function to maintain separately the idealized and persecutory internalized object relations derived from the early developmental phases predating object constancy: that is, when aggressively determined internalizations strongly dominate the internal world of object relations, in order to prevent the overwhelming control or destruction of ideal object relations by aggressively infiltrated ones. This primitive constellation of defensive operations centering around splitting thus attempts to protect the capacity to depend on good objects and escape from terrifying aggression.

Reality testing, as mentioned before, is present in borderline personality organization. It refers to the capacity to differentiate self from nonself, intrapsychic from external stimuli and to maintain empathy with ordinary social criteria of reality, all of which are typically lost in the psychoses, and manifested particularly in hallucinations and delusions (Kernberg 1984). All patients with psychotic personality organ-

Figure 1
Personality disorders: their mutual relationships

ization really represent atypical forms of psychosis. Therefore, strictly speaking, psychotic personality organization represents an exclusion criterion for the personality disorders in a clinical sense.

Borderline personality organization includes all the severe personality disorders in clinical practice. Typical personality disorders included here are the borderline personality disorder in the DSM IV sense, the schizoid and schizotypal personality disorders, the paranoid personality disorder, the hypomanic personality disorder, hypochondriasis (a syndrome which has many characteristics of a personality disorder proper), the narcissistic personality disorder (including the syndrome of malignant narcissism), and the antisocial personality disorder.

All these patients present identity diffusion, the manifestations of primitive defensive operations, and many evince varying degrees of superego deterioration (antisocial behavior). A particular group of patients typically suffer from significant disorganization of the superego, namely, the narcissistic personality disorder, the syndrome of malignant narcissism, and the antisocial personality disorder.

All the personality disorders within the borderline spectrum present, because of the identity diffusion, severe distortions in their interpersonal relations—particularly problems in intimate relations with others, lack of consistent goals in terms of commitment to work or profession, uncertainty and lack of direction in their lives in many areas, and varying degrees of pathology in their sexual life. They often present an incapacity to integrate tenderness and sexual feelings, and they may show a chaotic sexual life with multiple polymorphous perverse infantile tendencies. The most severe cases, however, may present with a generalized inhibition of all sexual responses. All these patients also evince nonspecific manifestations of ego weakness, that is, lack of anxiety tolerance, of impulse control, and of sublimatory functioning in terms of an incapacity for consistency, persistence, and creativity in work.

An additional group of personality disorders also presents the characteristics of borderline personality organization, but these patients are able to maintain more satisfactory social adaptation, and are usually more effective in obtaining some degree of intimacy in

object relations and in integrating sexual and tender impulses. Thus, in spite of presenting identity diffusion, they also evince sufficient nonconflictual development of some ego functions, superego integration, and a benign cycle of intimate involvements, capacity for dependency gratification, and a better adaptation to work that make for significant quantitative significant differences. They constitute what might be called a 'higher level' of borderline personality organization or an intermediate level of personality disorder. This group includes the cyclothymic personality, the sadomasochistic personality, the infantile or histrionic personality, and the dependent personalities, as well as some better functioning narcissistic personality disorders.

The next level of personality disorder, namely, neurotic personality organization, is characterized by normal ego identity and the related capacity for object relations in depth, ego strength reflected in anxiety tolerance, impulse control, sublimatory functioning, effectiveness and creativity in work, and a capacity for sexual love and emotional intimacy disrupted only by unconscious guilt feelings reflected in specific pathological patterns of interaction in relation to sexual intimacy. This group includes the hysterical personality, the depressive-masochistic personality, the obsessive personality, and many so-called 'avoidant personality disorders,' in other words, the 'phobic character' of psychoanalytic literature (which remains a problematic entity).

Figure 1 summarizes the relationship among all the personality disorders mentioned, and represents their overall classification into neurotic and borderline personality organization.

What follows is a summary of the psychoanalytically based psychotherapy for borderline personality organization as developed and manualized by a team of psychoanalysts, psychoanalytic psychotherapists, and researchers at the Department of Psychiatry of the Cornell University Medical College (Clarkin et al. 1999).

4. *Therapeutic Strategy*

From a therapeutic perspective, the main objective of the psychodynamic psychotherapy to be described is to focus upon the syndrome of identity diffusion, its expression in the form of the activation of primitive object relations in the transference, and the exploration of these primitive tranferences as they reflect early internalized object relations of an idealized and persecutory kind. The goal of this strategy is to identify such primitive transference paradigms and then to facilitate their gradual integration, so that splitting and other primitive defensive operations are replaced by more mature defensive operations, and identity diffusion is eventually resolved (Kernberg 1984).

The essential strategy takes place in three consecutive steps: First, the dominant primitive object relation is identified in the transference, and is described in an appropriate metaphorical statement that includes a hypothesized relation between two people linked by a dominant peak affective state. Second, within this dominant relationship, the patients' representation of self relating to the representation of a significant other ('object representation') is described, and patients are shown how that self-representation, linked to its corresponding object representation by a specific affect, is activated with frequent role reversals in the transference. These role reversals show themselves in the patients' alternatively enacting their representation of self or of the corresponding object, while projecting the other member of the internalized object relationship into the therapist. In this second phase patients learn not only to understand the different ways in which the same transference disposition may show in completely contradictory behaviors, but also to gradually tolerate their identification with both self and object representations in this interaction. Thirdly, the idealized internalized object relations are interpretively integrated with their corresponding, opposite, split-off persecutory ones, so that the patients, who already have learned to accept their identification with contradictory internalized representations of self and object at different points of their treatment experience, now learn to integrate them, to accept that they harbor both loving and hateful feelings toward the same object, that their self concept is both 'good' and 'bad,' and that their objects are neither as exclusively good or bad as they originally perceived them.

This gradual integration of the internal world of object relations leads towards the tolerance of ambivalence, a toning down and maturing of all affective experiences and emotional relations with significant others, a decrease in impulsive behaviors, and a growing capacity for self-reflection and empathy with significant others as the patients' self-concept consolidates in an integrated view of themself, and they experience relationships with significant others in a new, integrated way (see *Transference in Psychoanalysis*).

5. *Therapeutic Techniques*

The essential techniques taken from psychoanalysis that, in their respective modification, characterize the technique of this psychodynamic psychotherapy, are: interpretation, transference analysis, and technical neutrality.

The technique of interpretation includes the clarification of the patient's subjective experience, the tactful confrontation of those aspects of the patient's nonverbal behavior that are dissociated or split off from his or her subjective experience, the interpret-

ation in the 'here and now' of hypothesized unconscious meanings of the patient's total behavior and their implicit conflictual nature, and the interpretation of a hypothesized origin in the patient's past of that unconscious meaning in the here and now.

Transference analysis refers to the clarification, confrontation, and interpretation of unconscious, pathogenic internalized object relations from the past that are typically activated very early in the relationship with the therapist. In simplest terms, the transference reflects the distortion of the initial therapist–patient relationship by the emergence of an unconscious, fantasized relationship from the past that the patient unwittingly or unwillingly enacts in the present treatment situation.

Technical neutrality refers to the therapist's not taking sides regarding the patient's unconscious conflicts, and helping the patient to understand these conflicts by maintaining a neutral position. Therapists, in their total emotional reaction to the patient, that is, their countertransference reaction, may experience powerful feelings and the temptation to react in specific ways in response to the patient's transference challenges. Utilizing their countertransference response to better understand the transference without reacting to it, therapists interpret the meanings of the transference from a position of concerned objectivity, which is the most important application of the therapist's position of technical neutrality.

The therapist's emotional response to patients at times reflects empathy with the patients' central subjective experience (concordant identification in the countertransference), and reflects at other times the therapist's identification with what the patients cannot tolerate in themselves, and are projecting onto the therapist (complementary identification in the countertransference). Both reactions, when the therapist is able to identify and observe them, serve as valuable sources of information.

Countertransference analysis is in fact an essential aspect of this psychotherapy. The countertransference, defined as the total emotional reaction of the therapist to the patient at any particular point in time, needs to be explored fully by the therapist's self-reflective function, controlled in the therapist's firmly staying in role, and utilized as material to be integrated into the therapist's interpretive interventions. Thus, the therapist's 'metabolism' of the countertransference as part of the total material of each hour, rather than its communication to the patient, characterizes this psychotherapeutic approach.

The tendency to severe acting out of the transference characteristic of borderline patients has been mentioned already; in addition to its management by the modification of technical neutrality and limit setting in the hours mentioned before, the treatment begins with the setting up of a treatment contract, which includes not only the treatment setting and frame, but also specific, highly individualized conditions for the treatment that derive from life-threatening and potentially treatment-threatening aspects of the patient's psychopathology. Particularly, the establishment of realistic controls and limit setting that protect the patient from suicidal behavior and other destructive or self destructive patterns of behavior are typical objectives of contract setting.

In the course of the treatment, it will become unavoidable to face very primitive traumatic experiences from the past reactivated as traumatic transference episodes in which, unconsciously, the patient may express traumautophilic tendencies in an effort to repeat past traumas in order to overcome them. Primitive fears and fantasies regarding murderous and sexual attacks, primitive hatred, efforts to deny all psychological reality in order to escape from psychic pain are the order of the day in the psychodynamic psychotherapy of these patients.

This internalized object relation, that has transformed the primitive affect of rage into a characterologically anchored, chronic disposition of hatred is activated in the transference with alternating role distribution: the patients' identification, for periods of time, with their victim self while projecting the sadistic persecutor onto the therapist, will be followed, rapidly, in equally extended periods of time, by the projection of their victimized self onto the therapist while the patients identify themselves, unconsciously, with the sadistic perpetrator. Only a systematic interpretation of the patient's unconscious identification with both victim and perpetrator may resolve this pathological constellation and lead to a gradual integration of dissociated or split-off self representation into the patient's normal self. The effects of the traumatic past reside in the patient's internalized object relations; the key to its therapeutic resolution is coming to terms with this double identification.

O. F. Kernberg

Borders, Anthropology of

1. Introduction

The anthropology of borders is characterized by three perspectives which, though they sometimes overlap, can be distinguished by their relative emphasis on the cultural, territorial, and social dimensions of borders, respectively. These three dimensions may distinguish different types of border, or they may be aspects of a single border. Indeed, anthropologists are rarely interested in only one type of border or the other, and in many cases the borders they analyze have all three dimensions.

Anthropologists have a long-standing interest in borders. In the past, this was reflected in a concern with bounding their field of study. Cultural variation was considered a function of geographic and social isolation and early ethnographers advocated analyzing this diversity by treating each social unit as a discrete organic whole. But as the mobility of people dramatically increased (with urbanization, industrialization, etc.), culture contact rather than cultural isolation became the focus of the day. Diffusionists and acculturationists had always been interested in culture contact, but their work was overshadowed and ultimately displaced by the rapid rise and supremacy of functionalism. The belated 'rediscovery' of the value of their insights for contemporary theoretical questions about global cultural interconnectedness indicates a major shift within the discipline: from a concern with what borders encompass to an interest in the borders themselves.

Some anthropologists have been primarily interested in cultural borders which separate and connect different worlds of meaning and identity, others in borders which mark out geopolitical space, and yet others in borders which order social relations and indicate membership of 'community.' All three have been integral elements in the emergence of an anthropology of borders.

2. Cultural Borderlands

Borders have become a metaphor for the cultural flux and indeterminacy of much contemporary life. In anthropology the border metaphor was introduced by critics of the classic anthropological view of culture as shared, consensual, and discrete. Often with personal experience of cultural contradictions—as members of sexual, ethnic, or other minorities—these critics sought ways to study the differences within and the spaces between cultures, ways that could incorporate the changes, inconsistencies, and incommensurabilities of everyday life. These inter-cultural spaces are often referred to as 'borderlands,' a usage that evokes the geopolitical and the metaphorical, the literal and the conceptual. In this view, borders and borderlands exist not just at the edges of the nation-state, but anywhere cultures meet (Rosaldo 1989).

Borderlands are zones of cultural overlap characterized by a mixing of cultural styles. They are liminal spaces, simultaneously dangerous and sites of creative cultural production open to cultural play and experimentation as well as domination and control. The fusion of registers in borderlands may be ultimately empowering for those who inhabit these zones, but it

need not always be so, as testified by the lives of many Mexican migrants in the American Southwest.

Not everyone agrees that it is helpful to extend the use of 'border' and 'borderland' in this way. When cultural encounters share some of the specific socio-political processes characteristic of borders between states, such as unequal access to official forms of power, the borderland metaphor may be appropriate. But where there is no strong analytical connection to state border processes, understanding of the border can become reductive and delocalized (Heyman 1994).

Cultural differences and the juxtaposition of different worlds of meaning come to be emphasized at the expense of stressing inequalities of power. Heyman and others feel uneasy about this differential emphasis, reflecting wider tensions within the discipline over the relative prominence to be given to culture and power. The force of the image, they feel, takes over from the analysis.

In a sense, of course, borders are always metaphors, since they are arbitrary constructions based on cultural convention. Metaphors, moreover, are part of the 'discursive materiality of power relations' and in this respect no less concrete in their consequences than state borders (Brah 1996, p. 198). Metaphorical and state borders are not, therefore, as far apart as some studies imply. In fact, the anthropology of borders has benefited from the productive interaction of approaches that emphasize one or the other. The following sections outline other anthropological analyses of borders from which the border-as-metaphor draws its force and resonance.

3. *Territorial and Political Borders*

State borders entail a mapping out in geographic space and recognition in international law. They mark the limits of sovereignty and of state control over citizens and subjects, limits that may be upheld by force or by the threat of force. They are often highly visible physically, which has led some scholars to refer to them as 'real' borders in contrast to borders without territorial counterparts. This can be misleading, and the materiality of state borders should not blind us to their cultural and symbolic dimensions (just as we should not assume that cultural and symbolic borders automatically have no materiality).

Apart from the Mexican–US border, state borders have not until recently been subject to systematic comparative scrutiny by anthropologists. Where they did appear in ethnographic accounts, they often figured only as a backdrop to some other line of inquiry. Prior to the 1970s even studies of the Mexican–US border rarely included the border as a variable in the analysis. As a result, the anthropology of state borders was slow to develop.

A fledgling 'school' of anthropological border studies briefly emerged at the University of Manchester, UK, in the 1960s, but subsequently fizzled out. During this period, several books appeared specifically with borders in their titles; each influenced by Max Gluckman who was Departmental Chair at the time (e.g., Cohen 1965, Harris 1972). Taken together, they began something that took another 20 years to bear fruit. But though these books did not problematize the state borders near which their authors did research, and though they did not cross-refer to one another, they nevertheless identified some common themes in the political anthropology of borders which laid a solid foundation for contemporary anthropological analyses of nations and states. They pointed out, for instance, how proximity to a state border can intensify local conflicts, which can easily escalate into conflicts over nationality, a threat which only cross-cutting linkages (of kinship, common residence, and shared social and economic interests) help to keep in check. Understanding these borders thus requires local ethnographic knowledge, and not just knowledge of state level institutions and international relations.

The value of localized studies for understanding how cultural landscapes are superimposed across social and political divides was developed by Cole and Wolf (1974) whose field site in the Italian Tyrol was specifically chosen because its successive historical partitioning allowed them to explore the transformation of local political loyalties in relation to nation-building. What particularly interested Cole and Wolf about the South Tyrol was the durability of a cultural frontier long after the political borders of state and empire had shifted. National boundaries had clearly survived the demise of state borders, and remained important in everyday life. Despite their similarities, the two villages studied had followed a different political and cultural course since World WarI. Villagers minimized these ideological and cultural differences in public encounters, but in private quickly resorted to ethnic stereotypes to explain the actions of the others. Cole and Wolf thus reiterate Barth's (1969) observation that ethnic boundaries may be maintained despite relations across them. Their major contribution, however, was in demonstrating the need to combine the study of local and extra local influences to understand and explain this process.

Here, then, is an example of where ethnic boundaries result from, and evolve with, the rise and demise of state borders. Each can only be understood by reference to the other. In this respect Cole and Wolf combined symbolic border studies (see section 4) with a political economy perspective that situates ethnographic knowledge of local boundaries within wider historical and political processes, a novel combination that marked an important transition in the anthropology of borders and heralded the beginning of a new form of inquiry. Subsequent anthropological research on national and international borders was to draw explicitly or implicitly upon this groundbreaking work

(see Donnan and Wilson 1999 for examples). Anthropologists began to use their field research at state borders as a means of widening perspectives in political anthropology to encompass the formal and informal ties between local communities and the larger polities of which they are a part. Some studied border areas as a way of examining how proximity to an international border could influence local culture or could create the conditions that shape new rural and urban communities. Others focused on the voluntary and involuntary movement of people across borders as traders, migrants, and refugees. Yet others concentrated on the symbols and meanings which encode border life. The Mexican–US border, where the issues of underdevelopment, transnationalism, and the globalization of power and capital, among other aspects of culture, increasingly concern the growing number of historically informed and wide-ranging ethnographic accounts, offers excellent examples of all of these trends (see Alvarez 1995, Stoddard 1975 for overviews).

Regardless of theoretical orientation or locale, however, most of these border studies have focused on how social relations, defined in part by the state, transcend the territorial limits of the state and, in so doing, transform the structure of the state at home and in its relations with its neighbors.

This new anthropological interest in how local border developments can have an impact on national centers of power and hegemony was partly stimulated by historical analyses of localities and the construction of national identities (e.g., Sahlins 1989). Cole and Wolf's insistence on the need to view the anthropology of borders as historical anthropology is recalled. As the South Tyrol case so clearly shows, borders are spatial and temporal records of relationships between local communities and between states. Ethnographic explorations of the intersection of symbolic and state borders have salience beyond anthropology because of what they may reveal about the history of cultural practices and about the role of border cultures and communities in policy-making and diplomacy. This kind of research highlights the growing importance of a border perspective in political anthropology, a perspective in which the dialectical relations between border areas and their nations and states take precedence over local culture viewed with the state as a backdrop.

The next section outlines the work of some of the scholars whose innovative theorizing of the symbolic dimensions of social boundary making has provided a cornerstone to the anthropology of state borders worldwide.

4. *Social and Symbolic Borders*

One of the most influential theorists in the anthropology of borders has been Fredrik Barth (1969), who argues that people may traverse group boundaries and maintain regular relations across them without affecting the durability and stability of the boundaries themselves. Barth's focus is on ethnic groups, which he argues are social constructions, the result of individuals strategically manipulating their cultural identity according to context, rather than the pre-determined outcome of some objective list of culture traits. Membership of ethnic groups should thus be understood as based on self-ascription and ascription by others: individuals claim membership in a particular group and others confirm or question that claim. Attention is thereby drawn to the boundary between groups: to how and why people distinguish themselves from others, and to the rules of behavior that sustain such boundaries in the face of relations that transcend them. Barth's boundaries are above all 'social' boundaries: they may or may not have a territorial dimension, and cultural differences become significant only in so far as they are useful for organizing social relations.

Barth's work both revolutionized the study of ethnic groups and stimulated further research on borders. Some of this research demonstrates that borders mark affective and identificatory as well as structural and organizational disjunctures: those on the inside not only inhabit a separate social system from those on the outside but they identify themselves differently. Any social border is thus a consequence of the various possible relationships between these two dimensions on each side of the border as well as across it (Wallman 1978). This highlights the relational nature of social boundaries, drawing attention to what they mean to people and to how they are marked. These are issues developed by Anthony Cohen (1985). Echoing Barth, Cohen suggests that borders are constructed by people in their interactions with others, from whom they wish symbolically to distinguish themselves. However, we cannot predict what the distinguishing features of these symbolic borders will be, or exactly where the lines will be drawn. Moreover, they may mean different things to different individuals, both to those within a border as well as those outside it. In fact, borders recognized by some may be invisible to others. The anthropologist's task is to uncover these borders and their meanings in order to grasp what it involves to belong or be excluded.

Cohen has been criticized for devoting more attention to one side of the border than the other. For him, the significance of symbolic borders is that they allow people to retain a sense of distinctiveness in a world where the diversity of local communities is increasingly threatened by cultural and structural incorporation into the nation-state. This inevitably leads him to emphasize what goes on within a border, since this is how he can identify the symbolic beliefs and practices that people deploy to mark and celebrate their sense of difference. When he does consider what lies beyond the border, it is often only to show how

external events can be manipulated to symbolic advantage at the local level.

Similar criticisms have been leveled at Barth. As we have seen, Barth also emphasizes that boundary making involves both self-ascription and ascription by others. But he too tends to focus on only one side of the border, emphasizing internal identification rather than external categorization and the shaping influence of wider structures. This minimizes the relative power relations upon which the external ascriptive process depends, and underplays the fact that some people can impose their categorizations on other people. Relationships of domination and subordination can only be restored to theoretical centrality in border studies by recognizing that those on one side of a border may be better able than those on the other side to determine where and how the line is drawn (cf. Jenkins 1997). Indeed, we saw earlier that some anthropologists who focus on state borders have attempted to build this dimension into their analyses.

5. *Conclusion*

Three reasonably distinct but mutually enriching streams in the anthropology of borders have been identified. All three show that anthropologists have brought to the study of borders sensitivity to what borders mean to those whose lives they enframe. It is in this emphasis on how borders are constructed, negotiated, and viewed from 'below' that the value and distinctiveness of an anthropology of borders arguably resides

H. Donnan

Boserup, Ester (1910–99)

Ester Boserup (1910–99) summed up her research as focusing '… on the interplay of economic and non-economic factors in the process of social change, both today and in the past, viewing human societies as dynamic relationships between natural, economic, cultural, and political structures, instead of trying to explain them within the framework of one or a few disciplines' (1999). Boserup's book, *Woman's Role in Economic Development* (1970) generally is acknowledged as initiating the formal field of study: Women in Development (WID) frequently referred to as Gender and Development (GAD) since the 1980s. While the WID/GAD field is multidisciplinary and built on the research and practice of numerous women and men, Boserup's contribution is substantial. By demonstrating that women are often marginalized in the course of development rather than gaining from the process, her work helped shift the focus of development research from growth of income toward people's wellbeing.

Boserup was born in Copenhagen, Denmark, May 18, 1910. She studied economics at the University of Copenhagen during the Great Depression (1929–35) which influenced her search for theoretical explanations of economic processes that went beyond the equilibrium approach. Her major field of study stressed theoretical economics but also allowed her to take courses in sociology and agricultural policy. After graduating, she worked for 12 years for the Danish government writing on regulations and agricultural policy in Europe. From 1947 to 1957, Boserup worked in Geneva for the United Nations' Economic Commission for Europe and began collaborative work with the FAO (UN Food and Agriculture Organization). During this period, her research focus expanded to developing countries.

In 1957, Boserup and her husband (Mogens Boserup) left the UN and went to India for the *Asian*

Drama research project with Gunnar Myrdal. Ester Boserup drafted chapters on agriculture, Gandhism, and development planning. Her travels in South and Southeast Asia exposed her to different types of farming and land tenure systems. She began to formulate her own concepts of the process of development that countered much of the received wisdom of the time; for example, she observed that labor was still a constraint in traditional agricultural systems so that the marginal product of labor could not be zero (or close to it) as commonly assumed and that rural-urban migration was often caused more by pull factors, such as attractive money incomes, than by push factors. In 1960, Boserup and her husband resigned from the *Asian Drama* project because their ideas about the development process had grown too far from Myrdal's.

For the rest of her life, Boserup worked as a consultant for organizations such as the FAO Trade Division in Rome and the Center for Industrial Development (later called UNIDO). This was the period when she published her most influential works: *The Conditions of Agricultural Growth* (1965/1993) and *Woman's Role in Economic Development* (1970). She played a central role in the UN World Population Conference in Bucharest in 1974 and the first UN World Conference on Women in Mexico City in 1975. In the 1990s, she stopped participating in conferences because of her health, but she continued to be active in research and writing, stressing dynamic, multidisciplinary approaches to development issues, until her death September 24, 1999 in Ascona, Switzerland.

1. *Boserup's Theoretical Contributions*

Boserup's work reflects her background in classical and neoclassical economics. In 1936, she began building her analysis with a comparison of Marx's theory of underconsumption and Keynes's theory of propensity to consume (1999). Boserup established her reputation as a researcher with *The Conditions of Agricultural Growth* in the mid-1960s. Her main thesis in this work is that technological change and property rights are endogenous. The book was published at a time when growth theory was dominated by neoclassical models that treated technology as exogenous. Boserup hypothesized that increasing population density led to transformation of the environment and introduction of new technology, in particular in a change of agricultural systems from shifting (slash and burn) techniques to use of the plow and irrigation. This view countered the Malthusian and neo-Malthusian positions on population growth that took the carrying capacity of the earth and technology as given and predicted that continued population growth would lead to soaring prices for grain, wars, disease, and at best a return to subsistence survival for most people.

While Boserup's analysis was a bold break with much of the received wisdom of the time, it still contained elements of the linearity present in the works of writers like Marx and Rostow and implicitly posited a view of development as progress from family production to modernity characterized by labor specialization and monetization of the economy. Statements that Boserup made at times in her writing demonstrate that her views were more complex; she noted, for example, that reversals can occur such as the fall of the Roman Empire (1999). The complexity, however, showed up more consistently in her multidisciplinary, dynamic approach rather than in addressing issues of non-linearity and variety in development processes. Although there are differences in current views about what motivates technological change, the conceptualization of technology as endogenous has been a significant contribution to development theory. It is the basis of much of the new growth theory of the 1980s and 1990s, but new growth theorists are more likely to explain the technological adaptation in terms of human capital and positive externalities rather than population pressure.

Her book on agricultural growth gave Boserup the credentials in the academic community necessary to stir interest in her next major work, *Woman's Role in Economic Development* (1970). The timing was also good since activism among women was growing and interest in changing public policy was increasing among men and women. Boserup brought gender into development analysis as an integral factor that has remained central to much subsequent development work. She pointed out that both colonialism and modern development programs had frequently marginalized women from rights that they previously had.

She brought in her ideas from the agricultural growth book to identify shifting agriculture with low population density, tools such as the hoe, common property, and women taking an active role in subsistence farming. This system, common in Africa, she identified as a female farming system. She contrasted this with the system often found in more densely-populated Asia of plowed fields, irrigated crops, and private property, which she termed a male farming system. She noted that the gender roles in economic activity were distinct in all the societies she studied and although considered 'natural' by members of each group, they varied across cultures—illustrating that the gender roles were constructed socially rather than biological. Despite her awareness of these variations in occupation and time use by gender, Boserup focused on constructing a general view and downplayed the variation among agricultural systems. She stated that the agricultural system would tend to progress from the female farming, shifting system to the male farming, plowed system as population density increased. Continuing growth of population would lead to more intensive farming of irrigated land by both women and men (a mixed system) (1970). Much of the

research that had focused on women and gender at that time had been done by anthropologists who frequently use in-depth case studies as a methodological approach. As a trained economist, Boserup used the approach of collecting large amounts of data on the roles of women and men from many countries (mainly in sub-Saharan Africa and South/Southeast Asia) and making inferences—thus, the 268 tables in her book.

2. *Continuing Influence of Boserup's Pioneering Effort*

Woman's Role in Economic Development has been cited often and has generated debate and controversy that has deepened our understanding of human development. The publication of the book in 1970 marks the beginning of the multidisciplinary WID field that brought together researchers, practitioners, and policy-makers/advocates initially to work to integrate women into the development planning process (see Tinker 1990). Boserup's work clearly demonstrated that she recognized that women had long been actively participating in the actual development process (Jaquette 2001).

The WID/GAD field has evolved gradually to focus extensively on relative gender analysis of how women and men fare in the costs and opportunities associated with economic transformation policies and the process of globalization and how differences in age, class, religion, and location influence the results. Significant critiques of *Woman's Role* were published by Huntington (1975) and Beneria and Sen (1981). Huntington challenged Boserup's classification of female and male farming systems and suggested that women in Africa had been in subordinate relations with men, more like peasants and aristocrats, long before the colonial period. Beneria and Sen acknowledged Boserup's contributions but critique the lack of clear theoretical framework, the dominance of the capitalist model of development in her work, and the lack of feminist analysis of women's subordination and their reproductive roles (1981). Boserup's publications also motivated the *Persistent Inequalities* volume (Tinker 1990) that remains a leading contribution to the WID/GAD field. Debate continues both over the rhetoric of what to call this evolving field and appropriate theories and policies that recognize diversity and give voice to the people affected throughout the world.

Boserup's pioneering publications have contributed significantly to our understanding of how economic policies and processes affect people's well-being and agency—all people, not just the men of the society. While best known for her work on gender and agricultural systems, Boserup also wrote about the 'bazaar and service occupations' (1970) now called the informal sector that has gained much attention with economic restructuring policies since the 1980s. In addition, she wrote on rural–urban migration, polygamy, property rights, and urban employment. Her work is global and multidisciplinary in perspective, addressing the links between culture, environment, technology, population, employment, and family. She framed the argument for women's rights in terms of development that was more acceptable to the mainstream at the time (1999). She brought efficiency as well as equity into the argument for women's rights and a just society, but she did not depict women as victims (Jaquette 1990). Boserup used her publications to make women's work visible.

Boundaries and New Organization Forms

Organizational boundaries, the demarcation between an organizational entity and its external environment, underwent considerable remaking in the last decades of the twentieth century. Long thought to be relatively stable, boundaries were once only redrawn either to increase efficiency or gain more leverage over external factors. But organizational boundaries have become much more fluid and permeable as organizations experiment with a variety of new organizational forms to access critical knowledge, skills, and resources.

New systems of organizing do not arrive on the scene ready made and announce their availability. The historian David Hounshell (1984) illustrated how the mass production model emerged piecemeal in the USA in the latter half of the nineteenth century, beginning with the use of interchangeable parts in rifles made at the armories. Subsequently, the manufacture of sewing machines and then bicycles, and later meatpacking and beer brewing all played a critical role in the eventual development of the assembly line by Henry Ford. Similarly, new forms of organizing have recently emerged incrementally, in fits and starts, and are now visible in a variety of guises. Several notable lines of research have stressed that the boundaries of organizations are shaped largely by considerations of efficiency and power. For much of the second half of the twentieth century, arguments drawn from economics and sociology stressed that organizational boundaries sharply demarcated an organization from its external environment. Indeed, many organizations operated like medieval castles, walled off and protected from external influences. When boundaries were redrawn, considerations of scale and scope loomed large as decisions to shift boundaries were based on weighing the costs of internalizing a transaction vs. conducting it in the market (Coase 1937, Williamson 1985, Chandler 1990). In another line of work, emphasizing the ability of an organization to maintain autonomy and control over its environment, boundaries were recast to reduce uncertainty, to reduce dependency on external parties (Pfeffer and Salancik 1978), and to reshape the production chain in order to enhance strategic position within an industry (Porter 1980). These lines of research have been challenged in recent years by a wide proliferation of alternative governance arrangements and new types of organizational forms.

Organizations now seem to worry more about their adaptability to a changing landscape than their adaptive fit to a specific environment (see Powell and Smith-Doerr 1994, Stark 1999). These new forms enhance absorptive capacity (Cohen and Levinthal 1990), the capability to access skills and knowledge located outside the organization, and the ability to reconfigure organizational practices and structures to respond to a rapidly changing environment in which internal activities are more and more interdependent with external parties. Considerable effort is underway to explain both the causes and consequences of this transformation.

The unraveling of the old system of bureaucratic employment in the large firm is now widely recognized, but developing a set of metrics to assess the spread of new forms of work and organization is a challenge. The developments underway in various capitalist economies are multilevel in nature, involving a transformation in the ordering of work at the point of production, a profound change in the boundaries of many organizations, and a remaking of relations with competitors. These developments are discontinuous because there is no clear stopping point in the process and no road back to the previous system (Helper et al. 2000). Performance is replacing seniority as the condition of employment. Learning and speed are replacing quantity as the criteria for evaluating organizations. These shifts bring new actors and identities and new business models to the fore, and push aside incumbents.

1. *New Forms of Workplace Organization*

Jobs emerged in the late nineteenth and early twentieth centuries as a way to package work in settings where the same task was done repeatedly. But work today is changing into short-term projects often performed by teams. Consequently, the future organization of work is likely to be much less frequently honeycombed into a pattern of highly specified jobs. Work is now more commonly organized around a team or work group charged with responsibility for a project. Sabel (1994) terms this process of joint exploration 'learning by monitoring.' The activities of work teams are coordinated by a process of iterated goal setting. General projects, such as the design of a new car, are initially determined by study of best practices and prospects for competing alternatives. Then broad plans are in turn decomposed into tasks for work groups. The goals are subsequently modified as work teams gain experience in executing the required tasks. Through these revisions, changes in the parts lead to modifications in the conception of the whole, and vice versa. The same procedure of monitoring decentralized learning, moreover, allows each party to observe the performance of the other collaborators closely enough to determine whether continued reliance on them, and dedication of resources to the joint projects, are warranted (Sabel 1994).

This form of production integrates conception and execution, with design and production running on parallel tracks. With concurrent design and development, participants constantly evaluate one another's work. If project groups decide who supplies their inputs, they need not choose the traditional

internal unit but instead may turn to outside suppliers if they provide better value. This reconceptualization of work is designed to reduce and expose fixed costs, to make the expenses of all units dependent on their contribution, and to fuse the knowledge housed in different parts of the organization.

These new arrangements are deeply corrosive of the old system of sequential steps, linear design, and vertical integration that provided worker and manager alike with security. A key consequence of the remaking of the division of labor is that important tasks no longer need be performed inside the organization. This change remakes not only the organization of work, but also the boundaries of organizations.

2. *Flattening of Hierarchies. Spread of Networks*

Just as the changed conception of work as organized around project teams transforms firms internally, the growing involvement of organizations in an intricate latticework of collaborations with 'outsiders' blurs the boundaries of the firm, making it difficult to know where the firm ends and where the market or another firm begins. The former step redraws internal lines of authority, while the latter spreads the core activities of the firm across a much wider array of participants, with an attendant loss of centralized control. Astute observers of these developments, such as Rosenbloom and Spencer (1996), suggest that industrial competition today resembles less a horse race and more a rugby match in which players frequently change uniforms.

Various forms of interorganizational collaboration have grown rapidly in recent years (Gomes-Casseres 1996, Doz and Hamel 1998, Mowery and Nelson 1999). So intensive are these partnering efforts that the interorganizational network is increasingly the relevant unit of production. This form of collaboration does not dampen rivalry, but instead shifts the playing field to sharp competition among rival networks with fluid membership. The growth of alliances and partnerships entails novel forms of complex collaboration with suppliers, end-users, distributors, and even former competitors.

3. *Research and Development*

Recent empirical research shows significant change in the boundaries of organizations, most notably in the area of research and development (R&D). A recent US National Research Council analysis of trends in industrial R&D reports that the innovation process has undergone a significant transformation in the past decade, a change that is both 'substantial' in magnitude and consequential to economic performance (Merrill and Cooper 1999). There are four components of this reorienting of R&D: (a) a shift in the industries and sectors that dominate R&D toward new emerging technologies and nonmanufacturing industries; (b) a change in the time horizons of R&D, with industry focusing more on shorter-term development and relying more on universities for basic research; (c) a change in the organizational structure of R&D, with greater decentralization of research activities and increased reliance on both outsourcing and collaboration among firms, universities, and government laboratories; and (d) changes in the location of R&D, with successful research increasingly dependent on geographic proximity to clusters of innovative organizations. A companion National Research Council survey of 11 industries, purposefully diverse in character and technology but all resurgent in the 1990s, notes that common to each industry are: (a) increased reliance on such external sources of R&D as universities, consortia, and government laboratories; and (b) greater collaboration with domestic and foreign competitors, as well as customers, in the development of new products and processes.

The motives for the upsurge in collaborations are varied. In one form, they are an effort to reshape the contours of production by relying more on subcontractors, substituting outside procurement for in-house production. The subcontractors work under short timeframes, provide considerable variety of designs, spend more on R&D, and deliver higher quality, while the 'lead' firm affords reciprocal access through data-sharing and security through longer-term relationships (Dyer 1996). There is no natural stopping point, however, in this chain of decisions to devolve centralized control. Thus, fixing the boundaries of an organization becomes a nearly impossible task, as relationships with suppliers, subcontractors, and even competitors evolve in unexpected ways. As these network ties proliferate and deepen, it becomes more sensible to exercise voice rather than exit. A mutual orientation between parties may be established, based on knowledge that the parties assume each has about the other and upon which they draw in communication and problem solving. Fixed contracts are thus ineffectual, as expectations, rather than being frozen, change as circumstances dictate. At the core, then, of this form of relational contracting are the entangling strings of reputation, friendship, and interdependence.

Much sophisticated technical knowledge is tacit in character—an indissoluble mix of design, process, and expertise. Such information is not easily transferred by license or purchase. Moreover, passive recipients of new knowledge are less likely to appreciate fully its value or be able to respond rapidly. In research on the commercial field of biotechnology, an industry rife with all manner of interorganizational collaborations, we have argued that learning is closely linked to the conditions under which knowledge is gained (Powell 1996, Powell et al. 1996). Thus, regardless of whether collaboration is driven by calculative motives, such as

filling in missing pieces of the value chain, or by strategic considerations to gain access to new knowledge, network ties become admission tickets to high-velocity races. Connectivity to an interorganizational network and competence at managing collaborations have become key drivers of the new logic of organizing.

The growth of new organizational forms is driven by divergent factors and pursued in a different manner by a wide array of organizations. Larger organizations are making their boundaries more permeable in order to procure key components or critical R&D. Subcontracting and outsourcing are steps taken to reduce fixed overheads. Organizations cooperate with ostensible competitors in order to take on projects too risky or challenging for one entity to pursue alone. Clusters of small organizations collaborate, cohering into a production network to create what no single small entity could on its own. In sum, organizations are coming to resemble a network of treaties because these multistranded relationships encourage learning from a broad array of collaborators and promote experimentation with new methods, while at the same time reducing the cost of expensive commitments. These developments do not mean that competition is rendered moot, instead the success of organizations is linked to the nature and depth of their ties to organizations in diverse fields.

Bounded and Costly Rationality

Some kind of model of rational decision making is at the base of most current economic analysis, especially in microeconomics and the economics of organization. Such models typically assume that economic decision makers have sufficient cognitive capacities to solve the problems they face, and have preferences and beliefs that are consistent in a rather strong sense. In particular, it is typically assumed that decision makers (a) do not make logical errors, and can solve any relevant mathematical problems; (b) can process all available information in the time required (including computation, storage, and retrieval); and (c) have an adequate understanding of the decision problems they face, which includes having precise beliefs about the relevant uncertainties and precise preferences among the various consequences of their actions. However, this model has been criticized as inadequate from both normative and descriptive viewpoints. The various strands of this critical movement form the topic known as 'bounded rationality.' This article sketches the

historical roots and some current developments of this movement, distinguishing between attempts to extend the standard models and the need for more radical departures.

Unease with mainstream models of *homo economicus* had already been voiced by J. M. Clark at the beginning of the twentieth century, but the work of Jacob Marschak and Herbert Simon provided the stimuli for a more intense level of activity. The term 'bounded rationality' was coined by Simon: 'Theories that incorporate constraints on the information-processing capabilities of the actor may be called *theories of bounded rationality*' (Simon 1972, p. 162). (For a review of empirical evidence of bounded rationality, see Conlisk 1996.)

The current mainstream theory of rational individual decision making in the face of uncertainty was elaborated by Savage (1954). This will here be called the 'Savage Paradigm,' and will be the main starting point of this article. Extensions of this theory to describe rational strategic behavior in multiperson situations are the subject of the theory of games (see below). The notion of optimizing is central to all these models of rationality.

The general concept of bounded rationality covers the two rather different approaches of Marschak and Simon. Marschak emphasized that the Savage Paradigm could be extended to take account of costs and constraints associated with information acquisition and processing in organizations, without abandoning the notion of optimizing behavior. This approach will here be called 'costly rationality,' and is elaborated in Sect. 4.

Simon was more concerned with behavior that could not so readily be interpreted, if at all, as optimizing. However, in some of his publications he apparently considered bounded rationality to be a broader concept, subsuming costly rationality as a particular case. The narrower concept will here be called 'truly bounded rationality' (Sect. 5).

1. *Uncertainty*

Discussions of rational decision making—unbounded and otherwise—have been closely tied to uncertainty. The very beginnings of formal probability theory were in part stimulated by questions of how to act rationally in playing games of chance with cards and dice. During the first half of the twentieth century a number of alternative views were developed concerning the nature of uncertainty, the possibly of different kinds of uncertainty, and whether, or in what circumstances, it could be measured (Arrow 1951, Savage 1954, Chap. 4). One could be uncertain about natural events, the consequences of action, the laws of nature, or the truth of mathematical propositions. There was general (but not universal) agreement that, if uncertainty could be measured (quantified), then that quantification should obey the mathematical laws of probability. However, the 'frequentist school' reserved the legitimacy of probabilistic reasoning for 'experiments' (planned or naturally occurring) that were repeated indefinitely under identical conditions. The 'personalist school,' which included a diverse set of methodologies, argued that the concept of probability was applicable to events outside the frequentist realm. Some personalists went so far as to deny that the frequentist view could be applied meaningfully to any events at all, i.e., all probability judgments were 'personal.' (See the accounts of Arrow 1951 and Savage 1954 of the work of Ramsey, Keynes, Jeffries, Carnap, and De Finetti. In some sense, the personalist view might also be ascribed to earlier authors, such as Bayes and Laplace.) The personalist view was given a solid foundation by Savage (1954).

Central to the development of thinking about uncertainty was the simple idea that uncertainty about the consequences of an action could (or should) be traced to uncertainty about the 'state of the world' in which the action would be taken. An essential feature of the concept of the 'state of the world' is that it is beyond the control of the decision maker in question. A further clarification was provided by the theory of games (put forward by J. von Neumann and O. Morgenstern in 1944, and further elaborated by J. Nash, J. Harsanyi, R. Selten, and others). In multiperson decision-making situations in which the participants have conflicting goals, this theory distinguishes between two aspects of the state of the world from the point of view of any single decision maker, namely (a) the 'state of Nature,' which is beyond the control of any of the persons involved; and (b) the actions of the other persons, the latter being called 'strategic uncertainty.' (For material on the theory of games, especially noncooperative games, see *Game Theory*; *Game Theory: Noncooperative Games*; *Game Theory and its Relation to Bayesian Theory*)

The remainder of this article concentrates on a critique of the theory of rational behavior as it is applied to single-person decision making, or to multiperson situations in which the persons do not have conflicting goals. (For discussions of bounded rationality in a game-theory context, see Rubinstein 1998 and Radner 1997.)

2. *The Savage Paradigm*

A sketch of the Savage Paradigm is needed here in order to understand the notions of costly and bounded rationality. (For a systematic treatment, see *Utility and Subjective Probability: Contemporary Theories*; *Utility and Subjective Probability: Empirical Studies*.) The essential building blocks of the model are (a) a set of alternative states of the world, or simply states, which are beyond the decision-maker's control; (b) a set of alternative actions available to the decision maker, or as Savage calls them, 'acts'; and (c) a set of alternative consequences. An act determines which

consequence will be realized in each state (of the world). Hence a parsimonious way to think about an act is that it is a function from states to consequences.

The decision maker (DM) is assumed to have preferences among acts. These preferences reflect both the DM's beliefs about the relative likelihood of the different states, and the DM's tastes with regard to consequences. A few axioms about the independence of beliefs from consequences enable one to impute to the DM two scales: (a) a probability measure on the set of states, reflecting the DM's beliefs; and (b) a utility scale on the set of consequences, reflecting the DM's tastes. Using these two scales, one can calculate an expected utility for each act, in the usual way, since an act associates a consequence with each state. Thus, for each state, one calculates the product of its probability times the utility of the associated consequence, and then adds all of the products to obtain the expected utility of the act. One proves that expected utility represents the DM's preferences among acts in the following sense: *the DM prefers one act to another if and only if the first act has a higher expected utility*. (This theorem is sometimes called the expected utility hypothesis.) The rational DM is assumed (or advised) to choose an act that is most preferred among the available ones, i.e., has the highest expected utility; this is the assumption of optimization.

The simplicity of this formulation hides a wealth of possible interpretations and potential complexities. First, the axioms of the theory enable the DM to infer preferences among complicated acts from those among simpler ones. Nevertheless, the required computations may be quite onerous, even with the aid of a computer.

Second, if the decision problem has any dynamic aspects, then states can be quite complex. In fact, a full description of any particular state will typically require a full description of the entire history of those features of the DM's environment that are relevant to the decision problem at hand.

Third, the description of the set of available acts reveals—if only implicitly—the opportunities for the DM to acquire information about the state of the world and react to it. The laws of conditional probability then determine how the DM should learn from observation and experience. In fact, this is what gives the Savage Paradigm its real 'bite.' An act that describes how the DM acquires information and reacts to it dynamically is sometimes called a strategy (plan, policy). In a model of a sequential decision problem, the space of available strategies can, of course, be enormous and complex. This observation will be a dominant motif in what follows.

(The formula for learning from observation is sometimes called 'Bayes's theorem,' after the eighteenth-century author Reverend Thomas Bayes. Hence, the method of inference prescribed by the Savage Paradigm is called 'Bayesian learning.')

3. *The Simon Critique*

As Herbert Simon emphasized in his work, the cognitive activities required by the Savage Paradigm (and its related precursors) are far beyond the capabilities of human decision makers, or even modern human/computer systems, except with regard to the simplest decision problems. This led Simon and his colleagues (especially at Carnegie-Mellon University) to investigate models of human decision making that are more realistic from the point of view of cognitive demands, and yet do not entirely abandon the notion of rationality. This research also had an impact on the emerging field of artificial intelligence (see Simon 1972, 1981, and references therein). Savage himself was aware of the problem of bounded rationality, but he nevertheless felt that his model was a useful one for thinking about rational decision making (Savage 1954, pp. 16, 17).

4. *Costly Rationality and the Extended Savage Paradigm*

As just sketched in the previous section, the Savage Paradigm does not appear to take account explicitly of the costs of decision making. However, nothing prevents the DM from incorporating into the description of the consequences of an act the costs—in terms of resources used—of implementing the corresponding actions. The costly activities involved in decision making include:

observation and experimentation;
information processing, i.e., computation;
memory; and
communication.

The last category may be important when the decision-making process is undertaken by a team of individuals.

If the resources used by these decision-making activities are limited, then those limits may impose binding constraints on the activities themselves—constraints that must be taken into account in the DM's optimization problem. If the constraints are on the rate of resource use per unit time, then more extensive decision-making activities may cause delays in the implementation of the eventual decisions. To the extent that a delay lowers the effectiveness of a decision (e.g., by making it more obsolete), one may think of delay as an 'indirect cost.' Extending the Savage Paradigm to incorporate the costs of decision making may in some cases be natural, and in other cases problematic. The first class of cases is here called 'costly rationality.'

The notion that observation is costly was implicit in the Neyman–Pearson theory of hypothesis testing, and was made explicit by Abraham Wald in his pioneering studies of sequential statistical procedures (see Wald 1950 for an influential codification of his general approach). The cost of observation also figures in

more classical (nonsequential) statistical problems such as the design of sample surveys and agricultural experiments. Given some model of the costs of observation, the DM chooses the kind and amount of observation, optimally balancing the expected benefits of additional observations against their costs. Such decision problems fit naturally into the Savage Paradigm, although taking account of these costs typically complicates the analysis. For example, in the case of clinical trials and similar problems, the calculation of optimal policies quickly becomes computationally intractable for many problems of realistic size.

Even after the information has been collected, it still must be further processed to produce the required decisions. This information-processing task may be quite demanding. Examples include (a) computing a weekly payroll; (b) scheduling many jobs on many machines; (c) managing multiproduct inventories at many locations; and (d) project selection and capital budgeting in a large firm. Such tasks are typically too complex to be handled by a single person, even with the aid of modern computers. In such circumstances the required processing of the information is decentralized among many persons in the organization. The theoretical study of decentralized decision making in an organization whose members have identical goals was introduced by J. Marschak in the theory of teams (Marschak and Radner 1972).

Computer science has provided a number of useful models of information processing by both computers and humans, and the decentralization of information processing in human organizations finds its counterpart in the theories of parallel and distributed processing in computer systems. T. A. Marschak and C. B. McGuire, in 1971, were probably the first to suggest the use of a particular model of a computer (the finite automaton) to represent the limited information-processing capabilities of humans in economic organizations. S. Reiter and K. R. Mount were early contributors to this line of research, and went further in analyzing economic organizations as networks of computers. (For more recent developments, see Radner 1997, Van Zandt 1999, and references therein.) One conclusion from this literature is the iron law of delay for networks of processors of bounded individual capacity. This 'law' can be paraphrased in the following way: as the size of the information-processing task increases, the minimum delay must also increase unboundedly, even for efficient networks, and even if the number of available processors is unlimited (Radner 1997, and references therein).

Memory storage and communication among humans and computers are also resource-using activities, and cause further delays in decision making. Both the storage and transmission of information and the results of information processing seem to be relatively 'cheap' compared with observation and processing, at least if we consider computer-supported activities. The proliferation of large data banks, and the flood of junk mail, telephone calls, and e-mail, lend support to this impression. It appears that today it is much cheaper, in some sense, to send, receive, and store memos and papers than it is to process them. (For game-theoretic models of players with limited memory, see Rubinstein 1998. For models of costly communication in organizations, and some implications for organizational structure, see Marschak and Reichelstein 1998.)

5. *Truly Bounded Rationality*

Many real decision problems present difficulties that prevent the DM from usefully treating them as optimization problems. Among these difficulties are:

inconsistency;
ambiguity;
vagueness;
unawareness; and
failure of logical omniscience.

As will be seen, these difficulties are somewhat related and overlapping. In particular, it is difficult to distinguish in practice between 'ambiguity' and 'vagueness.'

Regarding inconsistency, Savage (1954, p. 57) wrote:

> According to the personalistic view, the role of the mathematical theory of probability is to enable the person using it to detect inconsistencies in his own real or envisaged behavior. It is also understood that, having detected an inconsistency, he will remove it. An inconsistency is typically removable in many different ways, and the theory gives no guidance for choosing.

Some 'inconsistencies' have been observed so frequently, and have been so 'appealing,' that they have been used to criticize the Savage axioms, and to form a basis for a somewhat different set of axioms (e.g., the so-called 'Allais paradox' and 'Ellsberg paradox' (see *Utility and Subjective Probability: Contemporary Theories*; *Measurement Theory: Conjoint*). In other cases, it has been argued that inconsistent preferences arise because the DM is forced to articulate preferences about which they are not 'sure.' (This explanation is related to 'vagueness'; see below.) In particular, this unsureness may be related to uncertainty about what are the states of the world, a circumstance that can lead to a preference for 'flexibility' (see below). Finally, it has been observed in experiments that inconsistencies are more frequent the closer the alternatives are in terms of preference. This observation led J. Marschak and others to the elaboration of models of 'stochastic choice' (see *Decision and Choice: Random Utility Models of Choice and Response Time*).

Allusion has already been made to the DM's possible vagueness about his/her preferences. However, he/she could also be vague about any aspect of his/her

model of the decision problem, and is likely to be so if the problem is at all complex. Vagueness can be about the *interpretation* of a feature of the model, or about its *scope*, or both. Unfortunately, there has been little if any formal theorizing about problems of vagueness.

At a moment of time, the DM may be *unaware* of some aspect of the problem: for example, he/she may be unaware of some future contingencies that could arise, or of some actions that are available to him/her. This phenomenon is particularly interesting if the DM is aware of the possibility that he/she may be unaware of something. For example, if the DM anticipates that in the future he/she will become aware of new acts of which he/she is currently unaware, then he/she may prefer present actions that allow for 'flexibility' of choice in the future. (This idea was formalized by T. C. Koopmans, D. Kreps, and others: Kreps 1992. For other theoretical treatments of unforeseen contingencies, see Dekel et al. 1998.)

As a consequence of the preceding considerations, decision theorists recognize that it is impossible for a DM to construct a complete model of his/her 'grand decision problem,' i.e., for their whole life! A common research strategy is to suppose that the DM can break up the grand decision problem into subproblems that can be solved independently without (much) loss of utility. Savage called this the device of constructing 'small worlds,' but showed that the conditions for this to be done without loss are unrealistically stringent (Savage 1954, pp. 82–91).

Finally, I come to what is perhaps the most difficult aspect of truly bounded rationality. Up to this point it has been assumed—if only implicitly—that the DM has no difficulty performing mathematical calculations or other logical operations. In particular, having formulated a decision model, he/she will be able to infer what it implies for their optimal strategy. As has already been pointed out, this assumption is absurd, even for small-world models, except for 'Mickey Mouse' problems that are constructed for textbooks and academic articles. The crux of the matter is that, in any even semirealistic decision problem, *the DM does not know all of the relevant logical implications of what he or she knows*. This phenomenon is sometimes called 'the failure of logical omniscience.' Examples of the failure of logical omniscience are:

(a) A DM who knows the axioms of arithmetic is uncertain about whether they imply that 'the 123rd digit in the decimal expansion of pi is 3,' unless he/she have a long time to do the calculation and/or has a powerful computer with the appropriate software.

(b) Twenty years ago, a DM who knew the axioms of arithmetic was still uncertain about whether they imply Fermat's last theorem.

The following examples are closer to practical life, and possibly more intimidating:

(a) Given all that a DM knows about the old and new drugs for treating a particular disease, what is the optimal policy for conducting clinical trials on the new ones?

(b) Given all that is known, theoretically and empirically, about business organizations in general, and about telecommunications and AT&T in particular, should AT&T reorganize itself internally, and if so, how?

Savage (1954, p. 7fn) commented on this class of problems:

> The assumption that a person's behavior is logical is, of course, far from vacuous. In particular, such a person cannot be uncertain about decidable mathematical propositions. This suggests, at least to me, that the tempting program sketched by Polya of establishing a theory of the probability of mathematical conjectures cannot be fully successful in that it cannot lead to a truly formal theory …

(For further discussion and references, see Savage 1972.)

In spite of some interesting efforts (see, for example, Lipman 1995), it does not appear that there has been significant progress on what it means to be rational in the face of this kind of uncertainty.

6. *Satisficing, Heuristics, and Non-Bayesian Learning*

In view of the difficulties posed by the various manifestations of 'truly bounded rationality,' a number of authors have proposed and studied behavior that departs more or less radically from the Savage Paradigm. These will be discussed under three headings: satisficing, heuristics, and non-Bayesian learning.

The term 'satisficing' refers to behavior in which the DM searches for an act that yields a 'satisfactory,' as distinct from an optimal, level of expected utility. The target, or 'satisfactory,' level of expected utility is usually called the DM's 'aspiration level.' In the simplest model, the aspiration level is exogenous, i.e., a given parameter of the model. More ambitious models describe some process whereby the aspiration level is determined within the model, and may change with experience (Simon 1972, Radner 1975). Such aspiration levels are called 'endogenous.' In some problems even optimal behavior bears a resemblance to satisficing. One category is the 'secretary problem' (Radner 2000).

The term 'heuristics' refers generally to behavior that follows certain rules that appear to produce 'good' or 'satisfactory' results most of the time in some class of problems (Simon 1972, see *Heuristics for Decision and Choice*). For example, the calculation of an optimal schedule for assigning jobs to machines is typically intractable if the numbers of jobs and machines are even moderately large. Nevertheless, human schedulers routinely construct 'satisfactory' schedules with such numbers, using various rules of

thumb that have been developed with experience. Heuristics are central to many artificial intelligence applications. Satisficing plays an important role in many heuristic methods, and also in the processes of their modification.

The discussion of heuristics leads naturally to the consideration of non-Bayesian learning (NBL). Bayesian learning (i.e., the application of the calculus of conditional probability) is of course part of the Savage Paradigm in any decision problem in which the DM conditions his/her action on information about the state of the world. Many standard statistical methods use NBL. For example, the use of the sample mean to estimate a population mean is typically inconsistent with the Savage Paradigm (although in some cases the latter can be shown to be a limit of Bayesian estimates, as some parameter of the problem goes to infinity). Most psychological theories of learning postulate some form of NBL. A central question in the theory of NBL is: under what conditions, if any, does a particular NBL procedure converge asymptotically to a procedure that is Savage-Paradigm optimal as the DM's experience increases? (Rustichini 1999).

Again, one must ask: is there any satisfactory meaning to the term 'rationality' when used in the phrase 'bounded rationality'? The convergence of NBL to optimal actions could provide one (weak) meaning. Nevertheless, the problems raised by the various phenomena grouped under 'truly bounded rationality' may eventually lead students of decision making to answer this last question in the negative.

Bibliographic Notes

Many important works on bounded rationality have been omitted from the bibliography because of space limitations. The references cited in the body of the entry have historical interest, provide an overview of a topic discussed, and/or provide a key to other literature. The following provide additional references and information on the application of notions of bounded rationality in economics and management: Arrow 1974, Radner 2000, Shapira 1997, Van Zandt 1999.

Bounded Rationality

1. Introduction

The central ideas of bounded rationality (BR) are straightforward. First, humans are cognitively constrained in various ways, e.g., we can consciously attend to only one choice problem at a time. Second, these

mental properties have behavioral consequences: they significantly affect decision-making. Third, the harder the problem the more likely it is that a decision-maker's information-processing constraints will matter (Simon 1981).

The first claim is uncontroversial. Cognitive psychologists have demonstrated, for example, that our short-term or 'working' memory holds only a few (between about five and nine) chunks of information (Miller 1956). The second claim follows close on the heels of the first. Since our working memory is small, our conscious attention must be selective. Hence, e.g., an agency head can work on only one problem at a time, no matter how many his subordinates present to him.

The third claim is important for demarcating domains in which BR theories have empirical 'bite', i.e., their predictions differ from those of other theories—especially those of BR's main competitor, rational choice (RC) theories. Consider Simon's formulation: 'the capacity of the human mind for formulating and solving complex problems is very small compared with the size of the problems whose solution is required for objectively rational behavior in the real world—or even for a reasonable approximation to such objective rationality' (1957, p. 198). Thus, bounded rationality describes a relation between a person's mental abilities and the complexity of the problem he or she faces. It is not a claim about the brilliance or stupidity of human beings, independent of their task environments. It is easy to miss this central point and to reify the idea of bounded rationality into an assertion about our absolute capacities (e.g.,'people are dumb'). The fundamental notion is of cognitive limits, and as is true of any constraint, if cognitive constraints do not bind in a particular situation, then they do not matter: they will not affect the outcome. And whether they bind depends partly on the demands placed on decision-makers by the problem at hand. Simon has called the joint effects of 'the structure of task environments and the computational capabilities of the actor … a scissors [with] two blades' (1990, p. 7). Theories of bounded rationality have cutting power—especially relative to RC theories—only when both blades operate.

Since this is the program's foundation, it is worthwhile exploring its implications via an example. Consider a group of normal adults, randomly paired up to play either chess or tic-tac-toe. A pair can either play their assigned game or they can stipulate a particular outcome, take their money for participating in the experiment and leave. The intuitive prediction is that more people assigned to tic-tac-toe would stipulate an outcome (a draw): after all, that game is trivial.

However, so—in a sense—is chess: Zermelo proved long ago that there exists an optimal way to play chess, and if played optimally then, as in tic-tac-toe, the same outcome always occurs: either white wins or black does or they draw. Indeed, for classical game theory, which ignores cognitive constraints, chess and tic-tac-toe belong to the same class: they are zero-sum, finite games of perfect information. Hence they are game theoretically equivalent. In the real world, of course, these games are not equivalent. Normal adults do not play tic-tac-toe; it is pointless. But they do play chess; indeed, for some it is a career. The point is simple but vital: our mental abilities are a binding constraint in chess but not in tic-tac-toe. Accordingly, BR and RC theories make observationally equivalent predictions about the latter but not the former. Hence BR theories have cutting power in chess—knowing the players' cognitive capacities gives us predictive leverage—but not in tic-tac-toe.

The example provides a more subtle point. Chess simplifies towards a game's end, but the players' cognitive capacities remain the same. Since the task's demands are falling while mental resources stay fixed, at some point *those resources may no longer be a binding constraint*. If that happens, the players will play optimally, and so a standard RC theory will accurately predict their behavior from that point on: a chess master burdened by a big disadvantage in the endgame will resign, for he knows it is hopeless. Once the players can identify the optimal strategies, the game becomes completely predictable, hence continuing is as pointless as playing tic-tac-toe.

This example reveals the subtlety of the contest between BR and RC theories. Theories from these two research programs predict different behaviors in chess only when the game is sufficiently complex so as to make players' mental capacities binding constraints. For expert players, this condition holds early in the game but not at the end. Thus, the two types of theories make observationally equivalent predictions about the endgame behavior of experts.

The lesson is that the theoretical significance of bounded rationality turns on the *difference* between cognitive resources and task demands, not on the former's absolute level.

2. *The Main Branches in Political Science of BR*

Bounded rationality should not be confused with a theory (e.g., of satisficing), much less with a specific formal model (e.g., Simon 1957). It is best considered a research program: a sequence of theories with overlapping sets of assumptions, aimed at solving similar problems. Political scientists have often conflated BR with the specific theory of satisficing, but that conflation produces a serious underestimation of the program's substantive content. In principle, the program's empirical domain is vast—it is as imperialistic as the rational choice program—and so its set of possible theories is also very large.

Many research programs contain multiple branches. So it is for BR: political science alone exhibits two main orientations toward bounded rationality. The first orientation sees the glass as half full, emphasizing how people manage to do 'reasonably well' *despite* cognitive limitations, *even in complex tasks*. Here belong Simon's line of work and also Lindblom's theory of incrementalism (Lindblom 1959, Braybrooke and Lindblom 1963, Bendor 1995). In the second branch, the glass is half empty: it emphasizes how people make mistakes *even in simple tasks*. Here is the Tversky–Kahneman (T–K) research tradition on heuristics and biases. (For a superb overview see Dawes 1998.)

2.1 The Glass Is Half Full

As noted above, one of Simon's key premises is that a decision maker's 'inner environment' (Simon 1981) of information processing will become manifest only when the task is sufficiently difficult. This implies that in order to discover the important types of mental limits, one should study people facing hard problems, such as chess.

But analyzing chess revealed more than mental limits: it generated new questions for the Simonian line, especially about performance. People's performance in chess varies tremendously, and this variation demanded an explanation. Thus, a new research focus emerged: how do some decision-makers *do so well*, given that they face similar cognitive constraints? Thus, scholars in this branch came to see the glass as half full: on some hard problems some humans perform very well, relative to an empirically sensible aspiration level. Given that objectively optimal play in chess-like problems is clearly impossible, what is interesting is not whether people behave fully rationally—we know they don't—but how do relatively competent agents work around their cognitive limits. (See, e.g., Simon 1990, and the associated references.)

2.2 The Glass Is Half Empty

In sharp contrast to the Simonian program's focus on 'good' performance in difficult domains, the prototypical experiment of the T-K tradition shows that even highly trained subjects answering simple questions can perform suboptimally. Kahneman and Tversky's goal—clearly stated in their seminal paper (Tversky and Kahneman 1974, p. 1124)—was to map subtle mental processes that can cause cognitive illusions, similar to the study of perceptual illusions. This project's results are more striking if they are shown to occur even in simple tasks, just as perceptual illusions are more striking if demonstrated with simple stimuli. The results are still more striking if one shows that even experts are vulnerable to illusions.

Subsequently, however, the field has tended to emphasize more the errors themselves, rather than the underlying cognitive mechanisms: 'The … approach triggered an explosion of research on inferential error, and the list of illusions, foibles, flops, and bloopers to which ordinary people were apparently prone became rather long … soon, if there was a mistake to be made, someone was making it in the presence of a social psychologist' (Gilbert 1998). (After reading many of these studies, the glass probably does look half empty—or worse.) This focus on mistakes triggered a scholarly backlash which has tried to show that humans are better decision makers than the T–K program apparently claims (e.g., Gigerenzer 1991; for a reply see Kahneman and Tversky 1996). Unfortunately, this debate has clouded Tversky and Kahneman's original intention, which was not to show that *Homo sapiens* are dolts but rather to uncover fundamental cognitive mechanisms that leave their imprint nearly everywhere. Given the primary objective of demonstrating that certain mental processes are ubiquitous, T–K's approach made sense. But it had the unfortunate side effect of making the program largely inattentive to variations in performance. With a few exceptions (e.g., the study of how people calibrate subjective probabilities), specialists in the T–K branch have shown little interest in performance variation; in particular, genuinely expert performance, at the level of chess masters, has been neglected. Instead, performance evaluations in this branch mostly use dichotomous theoretical standards: do people make choices in accordance with the axioms of expected utility theory? Do they revise beliefs in a Bayesian manner? The answers—generally no, they don't—are less informative than would be answers based on a quantitative scale measuring degrees of sophistication, even if the empirical best was far short of the theoretical ideal.

However, these differences in how the branches' study performance reveal that in one respect the T–K research agenda is more ambitious: it is harder demonstrating that cognitive limits show through on simple problems than on hard ones. Thus, the T–K program has worked on *pushing out the boundaries of BR* by showing that even quite subtle problem representations ('framing') can induce suboptimal performance. (Establishing which problem-representations are transparent—i.e., cognitively obvious—and which are opaque has been important throughout the T–K program (Kahneman and Tversky 1996).) One needn't go all the way to chess to uncover our mental limitations: humans are sufficiently sensitive (hence vulnerable) to framing so that judgmental or decisional imperfections appear even when a task exhibits no combinatorial explosion. Thus, a main finding of the T–K program is that BR has predictive bite in a larger domain than once thought.

3. Essential Properties of Humans as Information-processors

What are our essential properties as information-processors? Synthesizing Hogarth (1987) and Simon (1990) gives us the following list.

(a) Selective perception of information: our objective environments always contain far more information than we can perceive or attend to. Thus, perceptions must be guided by anticipations and other forms of top-down processing (e.g., schemas).

(b) High order information-processing, especially conscious thinking and attention, is largely serial. This has significant implications for the real-time behavior of busy officials.

(c) Compared with modern computers, humans process many kinds of information slowly, partly due to physiological limits (neurons are much slower than electronic circuits).

(d) Compared with computers, people are poor at calculation.

(e) Memory is actively reconstructive, not photographic. It therefore lacks photographic fidelity.

(f) Although there is no known limit to long-term memory, working memory is very small (Miller 1956). Thus, because everything that enters the former goes through the latter, short-term memory is a key bottleneck in information-processing.

The other crucial type of cognitive property are ways in which humans work around the above constraints. Simon calls these mechanisms for procedural rationality (1981, 1990). Three are especially worth noting.

(a) Recognition processes. After long experience, experts have stored a great many patterns about their tasks in long-term memory, both about situations ('this is situation type x') and actions ('in situation x, do y'). For familiar problems a fundamental trick is to *substitute recognition for search*.

(b) Heuristic search. When recognition fails, experienced decision-makers fall back on search. For reasonably complex problems search is heuristic: optimality is not guaranteed. Instead, heuristics make complicated problems manageable: they cut them down to (human) size and, in the hands of experts, often yield 'good' solutions. There are two types of heuristics. If the task is highly and recognizably structured, experts will use powerful task-specific heuristics. When these are unavailable they use general (but weak) heuristics such as satisficing (stop searching for alternatives when you find one that satisfices—exceeds your aspiration level—rather than requiring an optimal solution). Note the place of satisficing here. Far from being the heart of BR, it is merely one of several general-but-weak heuristics.

(c) Heuristic search occurs in *problem spaces*: mental representations of the task at hand. Experts learn to use economical and sometimes powerful problem representations.

4. Applications: Theories of Politics

4.1 Budgeting

Building on Lindblom, Wildavsky and his colleagues constructed an incremental model of budgeting (Davis et al. 1966) which received substantial empirical support. Crecine (1969) argued that the general heuristic of decomposition—when faced with a hard problem, decompose it into smaller, easier subproblems (Simon 1981)—is central to budgeting, and developed a model of city budgeting based on that idea. Padgett (1980) created a model of federal budgeting that continued to use the BR notion of heuristic search but which implied that allocations will sometimes be nonincremental.

4.2 Organizational Reliability

Landau (1969) has shown that certain types of structural redundancy can make organizations more reliable than any of their subunits. (Consider several R&D teams working in parallel.) Relatedly, Ladha (1992) and others have shown how using Condorcet's jury theorem can reduce both type 1 errors (e.g., the Food and Drug Administration's approving bad drugs) and type 2 errors (rejecting good drugs). Significantly, these results hold even if individual decision-makers face quite severe cognitive constraints.

4.3 The Evolution of Cooperation

Axelrod (1981) and Bendor and Swistak (1997) have used evolutionary game theory to analyze how cooperation might emerge and stabilize when central authority cannot solve Hobbes' problem. (Evolutionary game theory assumes that people learn to use strategies that work and to discard those that fail; agents need not optimize.)

4.4 Subgovernments

Bendor and Moe (1985) constructed a model of subgovernments with myopic actors (legislators, an agency and interest groups). The simulation outcomes were typically 'pluralist equilibria,' characterized by a balance of power between the interest groups.

4.5 Electoral Competition

In Kollman et al. (1992), adaptively rational political parties compete for the support of voters in two-party elections. In unidimensional policy spaces the parties converge to the median voter (Pages, personal com-

munication, September 1999); this result appears to hold for a wide variety of search heuristics. Hence Downs' famous result can be derived with weak cognitive assumptions. In a multidimensional policy space, the parties behave 'sensibly' but can get hung up on local optima. This suboptimization depends crucially on nonobvious aspects of voters' preferences.

4.6 Prospect Theory

The key premise of prospect theory, Tversky and Kahneman's most important theoretical contribution, is that choices are evaluated relative to a reference point, e.g., the status quo. The second assumption is that people are risk-averse about gains (relative to the reference point) but risk-seeking about losses. The third premise is loss-aversion: losing x hurts more than gaining x helps. This simple and elegant structure has yielded suprisingly powerful predictions in the study of bargaining (Neale and Bazerman 1991), international politics (Levy 1997), and voting (Quattrone and Tversky 1988).

For an excellent and accessible review of the BR program in economics see Conlisk (1996). Rubinstein (1998) is very instructive but much more technical.

Bourgeoisie/Middle Classes, History of

1. Introduction

The history of the bourgeoisie and the middle classes concerns the development and the transformation of social formations that are made up of those occupying intermediary social positions. These social formations and their members take on mediating or leading functions in society, economics, politics, and culture. The historiography of the bourgeoisie and middle classes takes as its point of departure the development of the modern bourgeoisie out of the older urban

bourgeoisie (burghers) of Europe. It concentrates on Western and Central Europe and on the USA, the history of which has, from the eighteenth through the twentieth centuries, been shaped to a large degree by the bourgeoisie and the middle classes (Kocka 1995a, 1995b, Zunz et al. 2001). It asks how the functions and meaning of the 'bourgeoisie' and the 'middle classes' have changed in these core areas, how, since the late nineteenth century, the conception has diffused to the periphery of Europe and worldwide, and how, in the process, it has transformed and run up against certain limits. Finally, it analyzes the attempts to eliminate or transform the bourgeoisie in socialist countries and the reconstruction of modern middle classes in post-socialist societies (Hoepken and Sundhaussen 1998).

Historical research on the middle classes investigates symbolic and social structures of long duration, historical continuities and ruptures, and regional and national similarities and differences. Of special interest are the particular characteristics of different formations and actors in various historical contexts. Research topics include the social, economic, professional, political, cultural, and legal characteristics and structures of the middle strata, whether in hierarchically differentiated societies, under conditions of social and cultural inequality, or in processes of class formation. Historians are also concerned with symbolically mediated practices and processes, in which individuals and groups come together in historically identifiable middle classes such as the traditional 'middle estates,' the exclusive 'modern bourgeoisie,' the economic and political 'bourgeoisie,' and the 'broad and inclusive middle classes.' Common to both historical and systematic concepts of the bourgeoisie and the middle classes, however diverse they are otherwise, is the preoccupation with the central region of the society in question, that is with that which takes shape between the extremities. The fundamental assumption is that society is formed and integrated not 'from above' (aristocracy, upper class, oligarchy), or 'from below' (working class, the propertyless, the uneducated), or 'from outside' (foreign domination).

2. *Definitions*

The concepts 'bourgeoisie,' 'middle class,' 'middle classes,' and many similar terms applying to particular eras and cultures, have more or less in common, depending on the historical period, the society in question, and the historical situation. A typical characteristic of the historical scholarship on these topics is the tension between exclusive and inclusive concepts of the bourgeoisie and the middle classes.

Definitions vary with regard to the composition of the bourgeoisie, the criteria for inclusion and exclusion, the social and symbolic processes of integration and delimitation, and with regard to the functions and aspirations of the middle classes in society and history. In the fields of social and economic history, scholars may employ classifications that are descriptive, historically and culturally specific, and statistical; or they may, for heuristic purposes, adopt abstract definitions, which are derived from particular theories of the bourgeoisie or from general theories of society. In either case, the focus is on the correspondence between social position and interests. In contrast, cultural historians and culturally oriented social historians understand the bourgeoisie and the middle classes primarily in terms of images of self and other, strategies, performances, discourses, rituals, institutions, sociocultural practices, habitus, and mentalities. In the history of ideas and of philosophy, as well as in theories of the state, law, and constitutions, scholars usually rely on normative and systematized conceptions of the bourgeoisie and middle classes. Social historians also draw on *Begriffsgeschichte*, the history of ideas, and the history of mentalities in order to show how, under what conditions, and why the concepts 'middle class,' 'bourgeoisie,' and 'middle classes' have been employed for the self-definition of individuals and groups, or for the purposes of establishing boundaries between self and other (Kocka 1995a, p. 12, Koselleck et al. 1991). Of special interest, in this regard, is how such classificatory activity affects consciousness and social action. A central element in all definitions and research agendas is the question of exclusion and inclusion.

2.1 *Exclusive Formations: Middle Class and Bourgeoisie*

Exclusive formations of the middle classes include wealthy property owners, entrepreneurs, those with high salaries, the highly educated and highly qualified, as well as administrative, political, and cultural elites. These groups are characterized by similar economic and political situations. They are also linked through social networks and have similar cultural orientations and life-styles. Historical research has been directed toward eliciting the meaning of the concepts and categories just cited in concrete historical situations, and discovering the historically and regionally specific terms that allow them to be grouped together in a single formation. In England and the USA, this social phenomenon has, since the eighteenth and nineteenth centuries, been referred to as the 'upper middle class' or 'middle class' (singular). In francophone Europe, the relevant terms are *notables*, *bourgeoisie*, or *classe moyenne* (singular). The German-speaking peoples of Europe have employed the terms *Bürgerstand*, *Mitt*elstand, or Bürgertum. The corresponding labels in Italy are *borghesia* or *ceti medi*, and in Spain *burguesía* (Kocka 1995a, Zunz et al. 2001). In the nineteenth century, the bourgeoisie in this narrow sense made up approximately 5 percent of the population, although this percentage was somewhat higher in cities.

In contemporary scholarship, these formations are understood in terms of Max Weber's sociology of classes and status groups, and are referred to using the historical-systematic concept of the 'modern bourgeoisie' or 'middle class' (Kocka 1995a, 1995c, Zunz et al. 2001). Understood in this way, the bourgeoisie is a heterogeneous formation, which includes economically independent and dependent classes (both entrepreneurs and civil servants, both professionals and employees), the members of which have similar values and styles of life. The concept of the 'modern bourgeoisie' differs from the Marxian concept of the 'economic bourgeoisie.' The latter is defined in terms of the ownership of capital, access to the means of production, kinds of revenue, and strategies of capital deployment and commercialization. The economic bourgeoisie, which is the counterpart of the working class, is the central category of political-economic development theory. Historical scholarship that has been influenced by Karl Marx and Marxian theory distinguishes among the precapitalist bourgeoisie (speculative capital, merchant capital, usury) those land owners and agriculturalists who have a dynamic relationship to property and capital, the petite bourgeoisie of artisans, the bureaucratic bourgeoisie, the modern commercial and industrial bourgeoisie, and the monopolist bourgeoisie (Radandt et al. 1981). Since the late nineteenth century, the Marxian conception of the bourgeoisie has, in many variations, become established in scholarship and in public discussion. From the late nineteenth century and up until the 1980s, Marxian theory was also very influential in non-Marxian sociology and social theory as well.

More recently, the sociological and economic conceptions of the middle classes and the bourgeoisie have been challenged by cultural historians, who insist upon the central importance of phenomena which, in classical Marxian theory, are part of the superstructure. From a cultural historical perspective, membership in the middle classes depends primarily on particular ideas, values, attitudes, and sociocultural practices. Emphasis falls on the symbolic mediation of that which is bourgeois or middle class through discourses, images, institutions, and places of socialization and sociability such as the family, the school, the public sphere, the theater, literature, voluntary associations, coffee houses, festivals, architecture, and monuments. Research of this type leads to further important insights into the bourgeoisie. If, however, bourgeois culture is not linked back to the social groups that foster it, this kind of approach may become merely a socially diffuse cultural history of modernity.

2.2 Inclusive Middle Classes

The history of the exclusive middle class has been shaped by the need to establish distinct boundaries with reference to traditional elites, the working class, and the 'inclusive' or 'broad' middle classes. The 'inclusive middle classes' may seem to be less homogeneous than the exclusive bourgeoisie in terms of profession, status, education, income, style of life, attitudes, and values. Nevertheless, from the viewpoint of both historical actors and historians, they have often been thought to belong together. Their unity is often characterized with qualifying expressions such as 'finely graduated' or 'leveled.'

The factors that unite the inclusive middle classes vary from one land, historical period, and social situation to another. These common factors may include professional and economic interests, similar legal claims, traditions and mentalities, political viewpoints and voting behavior, similar hopes and fears with regard to upward or downward mobility, or attitudes with regard to style of life, which may in turn be oriented toward those of the exclusive bourgeoisie. The social spectrum of the inclusive middle classes extends from mid-level entrepreneurs to independent professionals, mid-level and low-level civil servants and employees, mid-level farmers and tenants, and even to workers with higher salaries and qualifications. When social, professional, and economic criteria are used to assess the size of this group in the Western and Central European countries of the nineteenth century, it may be estimated to have made up 15–30 percent of the total population. When other criteria are employed, this percentage may rise or sink.

In the USA and in France, the inclusive middle class is referred to as 'middle classes' or *classes moyennes* (plural), respectively. The corresponding term in Germany is *Mittelstand*, and in Switzerland *Mittelstand* or *Bürgertum* in the broadest sense of the term. In the German-speaking countries, the term *Volk* was also used in this sense, especially in the socially and politically most inclusive societies of the early twentieth century (Kocka 1995a, Tanner 1995, Savage 2001, Charle 2001). In the second half of the twentieth century, the concept of the inclusive middle classes has been extended even further. As it gains in influence and in integrative potential, the older concept of the exclusive middle class seems to be falling increasingly into disuse.

It is common for both historical actors and historians to distinguish between historically older and newer groups of the broad middle classes. Master artisans and small businessmen are referred to as the *alter Mittelstand* (old middle estate) or the 'old middle class' (Haupt and Crossick 1998). From the early nineteenth century and up to the 1970s, they have often been viewed as a historical relict and as potential victims of modernization. Employees i.e., members of the strata of white-collar workers, which has been expanding since the late nineteenth century and which continues to become increasingly differentiated, are referred to as the 'new middle class.' They are often thought to have developed a distinctive class con-

sciousness at a relatively late date, due especially to their intermediate position between the bourgeoisie and the working class. In different societies and in different historical periods, employees may be understood either as agents or as victims of modernization (Mills 1956, Kocka 1977).

3. *History of the Bourgeoisie and the Middle Classes*

Recent scholarship on the eighteenth and nineteenth centuries has concentrated on the conditions and forms of the genesis of the modern exclusive bourgeoisie. The historiographical literature on the twentieth century focuses especially on the transformation, the crisis, and the declining significance of the exclusive bourgeoisie. With reference to the development of the modern bourgeoisie in Central and Northwestern Europe, Jürgen Kocka distinguishes between three phases, including an ascendant phase from the eighteenth to the early nineteenth century, a culminating phase from the middle of the nineteenth century to World War I, and a period of differentiation, dissolution, and even renaissance, which lasts into the late twentieth century (Kocka 1995a, 1995c). Attempts to assign the history of the broadly inclusive middle classes to historical periods usually posit a period of decline in the nineteenth century and a new period of ascendance in the twentieth century, which culminates in the inclusive middle-class society. In the following summary of the history of the bourgeoisie and the middle classes, reference is made to periods of 'genesis,' 'expansion,' and 'contraction.'

3.1 *The Genesis of the Modern Bourgeoisie and Middle Classes* (*Eighteenth to Nineteenth Centuries*)

The modern bourgeoisie took shape in the eighteenth and nineteenth centuries, though the precise time varied by region and by nation (Kocka 1995b, Schrader 1996, Gall 1993, Charle 2001). It included the following social groups: (a) the more dynamic part of the older urban bourgeoisie of the cities and communes; (b) those civil servants of the modern territorial state who were not part of the feudal hierarchy; (c) merchants, bankers, industrial entrepreneurs, and those members of the independent artisanry who were able to remove themselves from the order of the corporative estates; (d) professionals, literati, and artists; (e) enlightened or economically innovative portions of the landholding nobility, as well as non-noble estate owners and agriculturalists (in Southern and Western Europe the landowners often lived in cities, which is why they were counted among the bourgeoisie); (f) participants in emancipatory movements that were cultural or confessional, liberal or democratic, or regional or national in character.

Communication, symbolic representation, and social integration among the ranks of the bourgeoisie were promoted through institutional changes, which were implemented partly by the bourgeoisie itself, and partly by the monarchs and the state in the context of reforms and revolutions (freedom of trade, religious freedom, freedom of association, freedom of speech and of the press, political participation and accountability). The bourgeoisie developed its self-understanding and its language in the fields of the economy, culture, politics, and law. Bourgeois praxis developed in the representative organs of the estates, in free associations, in scientific academies, in literary circles and salons, in the print media, and in the reformed institutions of higher education, administration, law, legislation, and government. In these contexts, 'bourgeois' notions of collective and individual autonomy, representation, and the free play of public opinion were formed. In both the workplace and in public debates, new understandings of property and interest, ability and performance, self-cultivation and virtue, individual and society, contract and constitutions, and tradition and progress took shape. New experiences and discourses allowed the emerging middle class to criticize existing conditions, conceive of new social and symbolic orders, and lay claim to leading or mediating positions as well as to central functions and competences in society.

The bourgeoisie improved its chances for gaining favorable positions in a system of material, social, political, and cultural inequality by generalizing its own understandings of law and removing traditional privileges. It distanced itself from the traditional 'upper estates' of the court, the landed nobility, and the urban patriciate by adopting the role of a modern, dynamic, and achievement-oriented cultural and functional elite. It constituted itself in opposition to the nobility and the clergy as a 'third estate,' which represented the general public and was, in principle, open to everyone. The 'bourgeoisie' and the 'middle class' are concepts that imply a program and that serve to mobilize and justify certain forms of social action in the transition from estate society to class society. In principle, they ignore traditional differences of status, profession, and confession.

Typically, however, new forms of differentiation and new tensions arise fairly rapidly within the bourgeoisie, for example between the economic bourgeoisie (*Wirtschaftsbürgertum*) and the educated bourgeoisie (*Bildungsbürgertum*), between professional groups and status groups, between rural and urban groups, along local, regional, and national lines, among different confessions, or between political traditionalists and progressives or liberals and democrats. The integration of the bourgeoisie is a complicated and lengthy process, which usually succeeds only partially. The unity of the bourgeoisie is more a

postulate than a reality (Banti 1996, Siegrist 1996). It is most evident in critical historical situations or in conflicts with others, to whom the bourgeoisie feels itself to be superior, whether morally, economically, politically, or in terms of performance (nobility, manual laborers, the propertyless, the uneducated, the disenfranchised, and strangers or foreigners).

3.2 Contraction and Expansion: Bourgeosie and Middle Classes in the Nineteenth and Twentieth Centuries

In the process of the formation of the modern bourgeoisie, some groups of artisans and merchants, who previously belonged to the inclusive urban bourgeoisie, were economically marginalized and socially downgraded. In contrast, the educated bourgeoisie, merchants, and entrepreneurs belonging to ethnic and confessional minorities, and rural industrialists acquired new rights and gained in status. In England, the concept of the 'middle class' served to mobilize business people, industrialists, and mine owners from the provinces in the context of the electoral reform movement of 1832. It helped to integrate in a single group all of those who had not had the right to vote for the Lower House and who had felt themselves to be neglected by the upper middle class (London wholesalers and financiers, aristocratic landowners). Since the 1830s, in England as on the European continent, the interconnection among political, social, and legal rights possessed by the bourgeoisie had begun to emerge (Koselleck et al. 1991). This bundle of rights was viewed by bourgeois philosophers and social theorists as the very basis of political virtue in a well-ordered society. In the course of the nineteenth century, in Europe and in the USA, perceptions of the 'bourgeois' or 'middle-class' male person became closely linked with the concept of the politically enfranchised 'citizen' (*citoyen*, *Staatsbürger*). In those parts of Central and Eastern Europe in which the political rights of citizens remained limited, property owners and the educated often shared political power at the local level. The towns and cities, in which various property-based or tax-based voting laws remained in effect until World War I, were, in many parts of Europe, the domain of the bourgeoisie. In Central Europe, the concept of the bourgeoisie lost much of its political content after the failure of the 'bourgeois revolutions' of 1848/9. Under these conditions, emphasis shifted to the cultural and aesthetic connotations of the concept. Throughout Europe, the bourgeoisie experienced significant gains in processes of 'inner' nation-building and cultural nationalization in the old nation-states, and through nationalist movements and the formation of new nation-states in Northern, Southern, and Eastern Europe.

Since the late nineteenth century, the bourgeoisie has continually renewed itself by incorporating members of new and expanded professional, functional, or status groups such as managers, engineers, planning and transportation experts, journalists, and high-level employees. These groups proliferated under conditions of intensified industrialization, commercialization, and urbanization or with the concentration of capital, the expansion of the role of science in society, increasing bureaucratization, and the rise of new communication media. The exclusive bourgeoisie allied itself increasingly, though not unreservedly, with social groups whose middle-class status was dubious, but who offered themselves as supporters of the established order. Tenants, agriculturalists with medium-sized holdings, and independent artisans and merchants were offered greater protection and drawn into the bourgeois alliance. Employees gained social and legal privileges over workers and were, thus, prevented from cooperating more closely with the socialist and trade-union organizations of the working class (Kocka 1977).

At no time has the bourgeoisie been unchallenged. In the nineteenth century, the critique of the bourgeoisie was formulated from aristocratic, corporativist, Catholic, anti-Semitic, and socialist points of view. Since the late nineteenth century, the traditional, exclusive conception of the bourgeoisie has come increasingly under attack from members of social movements that arose within the bourgeoisie and the middle classes themselves. The leading concepts of the bourgeois progressives, social reformers, life-style reformers, and democrats are science, achievement, rationality, political equality, and social justice. Progressive and democratic critiques of the bourgeoisie contrast, however, with those of the authoritarian and conservative-elitist movements for renewal of the early twentieth century. The latter often attracted members of the bourgeoisie and petite bourgeoisie, even though they cultivated a specifically 'antibourgeois' discourse, in which the established and increasingly pragmatic bourgeoisie was accused of decadence and the inability to lead. In the twentieth century, antibourgeois sentiment formed a broad spectrum that ranged between conservative-corporativist and fascist programs, on the one hand, and communist ideology, on the other.

The concept of the exclusive bourgeoisie and antibourgeois discourses were supplemented in the twentieth century by conceptions of a broad and leveled-off middle class, which is typical of advanced industrial society. In the history of Europe and the USA, this perspective drew upon older ideas, such as those of social democratic, social-liberal, Christian-social, egalitarian, and communitarian traditions. After World War II, the USA made the concept of the inclusive middle class into a guiding principle for the reconstruction of the defeated states of Europe and Japan (Zunz et al. 2001). This concept unites socially, culturally, politically, and economically heterogeneous groups in a common vision of political and social citizenship in a democratic system and a market

economy. During the era of the conflict between the East and the West, this vision was also motivated by a broadly based anticommunism i.e., by a rejection of a model of society, economy, and government that explicitly excludes the middle and claims to constitute society from below, under the leadership of the party of the working class.

In the noncommunist countries of Europe, in the first decades after 1945, those who wanted to conserve or renew the exclusive bourgeoisie of the past mounted an attack against the concept of the leveled and encompassing middle-class society. The exclusive bourgeoisie had lost prestige because of the Great Depression and due to the role that it had played in the fascist states. Now, however, its representatives mourned the waning and the demise of the bourgeoisie. Up until 1970 they warned of the decline of the bourgeoisie and the resulting threat posed to the nation and to Europe by 'mass culture,' 'consumer society,' 'Americanization,' 'materialism,' the 'welfare state,' the 'excesses' of democracy, the 'weakening of bourgeois values,' the 'loss of individuality,' and the 'leveled middle-class society' (Siegrist 1994, Savage 2001). The debate over the bourgeoisie experienced a new surge around 1968, which had, however, other causes, as the 'establishment,' on one hand, and students, intellectuals, socialists, and communists, on the others, battled one another in the language of anti-Marxism and Marxism. Since the 1970s, the discussion about the bourgeoisie has been superseded by debates over 'elites' and over traditional cultural, ethnic, and gender-based differences and discriminations within and outside the middle classes.

4. *Middle Classes, Functional Equivalents, and the Limits of the Concept*

The development of the middle classes in Eastern and Southeastern Europe, Latin America, Japan, and in the colonies and postcolonial societies of Africa and Asia differs considerably, both temporally and qualitatively, from that of core regions in the history of the middles classes. The concepts have their limits.

In many parts of the world in the nineteenth century, the bourgeoisie was hardly present. The social groups and the corresponding discourses, mentalities, and institutions were largely lacking. When concepts are imported and extended to phenomena that are more or less similar to the bourgeoisie, their meaning changes significantly (Kocka 1995a, 1995c). Marxian or economic and social historical studies, which, on the basis of theoretical premises and European concepts, identify bourgeois and middle-class groups in these areas, rarely do justice to their materials.

Recent approaches in the cross-national and cross-cultural comparative history of the middle classes focus on cultural and historical differences, and also on the specific meaning of similarities. Comparisons may show, for example, that institutional, economic, and technical innovations, which in Western and Central European history are associated with the bourgeoisie, are planned and carried out by other actors and groups in those areas without a bourgeoisie. In such cases, it is not very helpful to apply the concept of the bourgeoisie to such groups. Modernizing landowners in estate societies, civil servants in authoritarian states without a bourgeoisie, and rural and urban oligarchies and military leaders in preindustrial societies may be understood, at best, as 'functional equivalents' of the bourgeoisie. Latin American estate owners and the mercantile elite of large cities and ports may, in the course of the nineteenth century, have come to approximate the economic bourgeoisie. In societies that are sharply differentiated by status group and ethnicity, however, they form a political-social 'oligarchy,' rather than a 'modern bourgeoisie.' With the growth in the twentieth century of new agrarian, mercantile, bureaucratic, and industrial middle strata, the middle classes in such societies have expanded, and the traditional oligarchies have been forced to include them, at least to a degree, into the political elite (Florescano 1985). Even then, however, the situation differs significantly from that in Europe.

In Eastern Europe in the nineteenth century, progressive groups of nobles, members of ethnic and confessional minorities, and Western-educated intellectuals and civil servants assimilated to the pattern of the bourgeoisie of Western and Central Europe. The formation of the bourgeoisie did not, however, proceed beyond the initial stages. In Southeastern Europe, modern middle classes began to emerge in the late nineteenth century, when, following the demise of the Ottoman empire, the segmented and not extremely hierarchical society changed into a national, centralized, and bureaucratic one. The national functional and cultural elites made the state into a resource and became a specific type of bourgeoisie (Höpken and Sundhaussen 1998). In the communist societies of Eastern Europe, both genuinely and ostensibly bourgeois and middle-class groups were marginalized in the context of the communist program of the classless society under the leadership of the working class. Those who remained were, along with the new functionaries, redefined as members of the functional middle strata. The leading middle stratum was termed 'nomenclatura,' whereas the others were known as the 'service class' and the 'socialist intelligentsia.' Given this historical background, the problems involved in forming postsocialist middle classes are quite significant.

In twentieth-century Japan, where, previously, a historical bourgeoisie had hardly existed, there was a dramatic development of the inclusive middle classes. In the early twentieth century, the word *sarariiman* (salary-man), which at first meant scribe, office employee, and civil servant, became a catch-all term for

members of the qualified, salaried middle classes (Gordon 2001). Since the 1960s, the concept of *churyu* has become popular. This means 'mainstream' and includes all those who consider themselves to be modern, average, and normal with regard to attitudes toward work, family, consumption, and life-style. They make up the statistical and social 'middle mass' (Kelly 2001), with which, in public opinion polls, 90 percent of the population aligns itself. The broad conception of the middle classes in Japan has its roots both in national ideas of community and in the inclusive view of the middle class that has been imported from the USA in the postwar period.

5. *Historiography and Emphasis in Current Research*

The exclusive bourgeoisie and (to a lesser degree) the broad middle classes have, from the very beginning, employed historical writing as a means of self-presentation, legitimation, community building, and self-reflection. History serves the bourgeoisie as a means of locating itself in space and time, and orienting itself in a modern, dynamic society, which it seeks constantly to transform and to stabilize. The historiography of the middle classes is characterized, first, by teleological notions of progress and modernization; second, by a narrative of crisis and decadence and of danger and dissolution, which draws upon older religious and aristocratic motifs but is subsequently transformed and takes on a life of its own; and, third, through the motifs of conservation and stabilization. Central elements of this history are elevated by the bourgeoisie and middle classes to the status of norms and, thereby, dehistoricized. They then take on the form of myths or theories of law, society, and development, which are insensitive to variations in era and context. The bourgeoisie displays a tendency toward idealizing, sacralizing, and naturalizing its own past. For this reason, its historiography has often been the target of historians of various ideological or social provenance, who are critical of or opposed to the bourgeoisie.

Until the 1970s, the history of the bourgeoisie and the middle classes was, by and large, written from the perspective of either proponents or opponents. Since the 1980s, historical research on the bourgeoisie has, in some important senses, become more impartial, more independent, more scientific, and more innovative. Traditional versions of history at local and national levels have been relativized and revised with reference to interdisciplinary, international, and comparative approaches in historical research (Kocka 1995b, 1995c, Siegrist 1996). As a result of a stronger focus on the dimensions of 'gender' and 'religion' (Hall and Davidoff 1987) as well as 'ethnicity,' new perspectives have been achieved with regard to the periodization and evaluation of historical materials. In Europe and, to a somewhat lesser degree, the USA, the bourgeoisie and the middle classes rank among the best researched topics in historical scholarship.

H. Siegrist

Bowlby, John (1907–90)

Edward John Mostyn Bowlby was born in London on 26 February, 1907, to Mary Bridget Mostyn and Anthony Alfred Bowlby. They had six children, who were usually referred to in groups of two: 'the girls' (Winnie and Marion), 'the boys' (Tony and John), and 'the babies' (Jim and Evelyn). Only 13 months apart, 'the boys' had a close relationship, including intense rivalry. But in addition to keeping his end up with a slightly older brother, John was caring towards a younger brother with chronic problems due to a thyroid deficiency, discovered too late to be cured. John was born at a time when it was customary for an upper-class mother to hand over her children to a nanny and nursemaids. The nanny in charge practiced a firm, regular, and disciplined routine. A particular nursemaid took care of John on a daily basis. He loved her, and years later she said that she was always fondest of John. However, she left the family when John was about four. The effect of this on John is unknown, as he never discussed it (van Dijken 1998). The Bowlby children saw their mother for a short time each day, and their father on Sundays. Their father, who was knighted in 1911 as a result of being a surgeon to royalty, was absent even more during World War I. However, there were long family holidays in the country to the New Forest in July and to Scotland in late summer. This remained a family tradition with John, his wife Ursula, their four children, and later their grandchildren retreating to the Isle of Skye each summer. John did much of his writing there, as well as walking and enjoying the 'season,' including the Skye Ball with its Scottish reels. Skye is where John died on September 2, 1990, and where he is buried, on a remote hillside overlooking the cliffs and sea.

When John was 11, he and Tony were sent off to boarding school. From there, John went to the Royal Naval College, Dartmouth. But at 17, he decided that the Navy was not for him, writing to his mother that he wanted a job which would 'improve the community as a whole' (van Dijken 1998, p. 46). At Trinity College, Cambridge, John followed his father by studying medicine, with a departure into psychology in his final year, graduating in 1928. Rather than going straight into clinical school, John spent a year teaching in two boarding schools, including one for disturbed children. Their early disrupted childhoods impressed Bowlby, and he decided to combine his medical training with psychoanalytic training. After becoming medically qualified at University College Hospital in 1933, Bowlby went to the Maudsley to train in Adult Psychiatry, and then to the London Child Guidance Clinic in 1936. He became an Army psychiatrist in 1940, and after the war he went to the Tavistock Clinic, where he remained (Holmes 1993).

At the Institute of Psycho-Analysis, where he had been accepted when only 22, Bowlby was assigned to Joan Riviere and then to Melanie Klein, who supervised him after his analytical qualification in 1937. Differences grew concerning the importance of real-life experiences over unconscious fantasies. For example, when treating a hyperactive and anxious three-year-old boy, Bowlby noted that the boy's mother had been admitted to a mental hospital and was having a another breakdown. Klein, however, did not allow Bowlby to treat the mother, devaluing what was actually happening in the child's life. Yet Bowlby was keenly interested in what happened, thanks to his love of nature, his scientific training, and his clinical observations.

1. *The Theme of Separation*

Bowlby was particularly interested in what happened around separation. This interest may have sprung from his own childhood experiences, as well as later when working with maladjusted children. 'I was struck by the high incidence of severely disrupted relationships with mother-figures in the early histories of children and adolescents who had been referred to the clinic on account of repeated and apparently incorrigible stealing.' He continued, 'First-hand observations of young children admitted to residential nursery or hospital and not visited by parents revealed the intense and prolonged distress they suffer. Moreover, visits home showed that the child's relationship with the mother is seriously disturbed for weeks or longer after reunion. These observations lent considerable support to the hypothesis that the experience of separation and loss of mother-figure in the early years could have adverse effects on development, at least in some cases. That raised a question: if the disruption of a child's relationship with mother-figure in the early years creates much distress and anxiety, what is so special about the relationship that has been disrupted?'

(1991b, pp. 302–3). The prevailing answer was that bond formation stemmed from the association of mother with the provision of food, thereby satisfying a primary need. But in Bowlby's view, this 'cupboard love theory' (p. 303) was insufficient.

2. *An Ethological Perspective*

During the 1950s Bowlby ran a weekly workshop in a dingy room in the old Tavi, in Beaumont Street. The group was entirely heterogeneous: a Freudian and a Kleinian analyst, a Hullian and a Skinnerian learning theorist, a Piagetian, an ethologist, sometimes an antipsychiatrist, psychiatric social workers, having in common only an interest in parent–child relations. John Bowlby's intellectual dynamism and judicious enthusiasm held the group together. During that period Bowlby formulated his ideas on 'the child's tie to his mother' and 'separation anxiety' with inputs from ethology and systems theory' (Hinde 1991, p. 216).

With an ethological perspective, the occurrence of species-characteristic behavior suggests that such behavior may have been selected for during the course of evolution. Bowlby applied this thinking to attachment behavior defined as any form of behavior which attains or maintains proximity to a caregiver in times of need or stress. He argued that individuals who exhibited attachment behavior would have been more apt to survive and leave offspring who in turn would reproduce, compared with those who did not. Obviously selection for attachment behavior could not have happened without a similar pressure on its complement, caregiving behavior. 'During the course of time, the biologically given strategy of attachment in the young has evolved in parallel with the complementary parental strategy of responsive caregiving, the one presumes the other' (Bowlby 1991c, p. 293).

Bowlby further suggested that attachment behavior reflects a distinct motivational system in its own right, not dependent on prior association with any other motivational system such as hunger, and usually subserving a particular biological function. Bowlby postulated a function of protection from harm, by keeping a child in touch with one or more caregivers. With this approach, activation of a fear behavior system would lead to activation of the attachment behavior system. Attachment behavior would lead to proximity to the caregiver, which would in turn deactivate the fear system, enabling activation of an exploratory or social system (e.g., Bowlby 1969/1982).

Bowlby realized that an evolutionary argument could provide insight into behavior which otherwise appeared abnormal. 'It is against this picture of man's environment of evolutionary adaptedness that the environmentally stable behavioural equipment of man is considered. …not a single feature of a species' morphology, physiology, or behaviour can be understood or even discussed intelligently except in relation to that species' environment of evolutionary adaptedness' (Bowlby 1969/1982, p. 64). Bowlby used this reasoning to understand as 'natural' the occurrence of 'irrational fears' as well as the occurrence of attachment behavior throughout the life span. In considering the fears of childhood such as fear of strangeness, separation, or darkness, Bowlby disagreed with influential analysts such as Klein or Freud who had labeled them as irrational. Instead he argued that our tendency to fear what had been dangers in the environments in which we evolved is 'to be regarded as a natural disposition of man…that stays with him in some degree from infancy to old age…Thus it is not the presence of this tendency in childhood or later life that is pathological, pathology is indicated either when the tendency is apparently absent or when fear is aroused with unusual readiness and intensity' (Bowlby 1973, p. 84).

Similarly, attachment behavior in times of stress should not be viewed as a sign of weakness, even beyond childhood. Long before research began on the role of attachment in adulthood, Bowlby wrote 'such tendencies…are present not only during childhood but throughout the whole span of life. Approached in this way, fear of being separated unwillingly from an attachment figure at any phase of the life-cycle ceases to be a puzzle, and instead, becomes classifiable as an instinctive response to one of the naturally occurring clues to an increased risk of danger' (Bowlby 1973, p. 86).

In one of his final contributions, Bowlby summed up thus, 'Once we postulate the presence within the organism of an attachment behavioural system regarded as the product of evolution and having protection as its biological function, many of the puzzles that have perplexed students of human relationships are found to be soluble. …an urge to keep proximity or accessibility to someone seen as stronger or wiser, and who if responsive is deeply loved, comes to be recognised as an integral part of human nature and as having a vital role to play in life. Not only does its effective operation bring with it a strong feeling of security and contentment, but its temporary or long-term frustration causes acute or chronic anxiety and discontent. When seen in this light, the urge to keep proximity is to be respected, valued, and nurtured as making for potential strength, instead of being looked down upon, as so often hitherto, as a sign of inherent weakness' (Bowlby 1991c, p. 293).

3. *Development of an Attachment Bond*

Thus, an attachment behavior system, organized as a distinct motivational system, gives rise to attachment behavior when activated by stress, particularly threats

or perceived threats of separation. An infant is born with 'a marked bias to respond in special ways to several kinds of stimuli that commonly emanate from a human being' (Bowlby 1969/1982, p. 265). As attachment behavior develops, it forms the basis for an inferred attachment bond. Bowlby described particular phases in its development: pre-attachment (from birth to about 2 months), involving signaling without discriminating one person from another; attachment-in-the-making (2–6 months) where signals become directed to particular persons; clear-cut attachment (0.5–4 years) with locomotion and goal-corrected behavior; and finally a goal-corrected partnership (4 years onwards) with perspective taking, communication skills, and sharing mutual plans. Although additional attachments may develop throughout life, these early attachments endure.

What is not common to all individuals is the quality of attachment, which tends to be consistent throughout life, and is reflected in the three basic patterns: avoidant, secure, and ambivalent. Although Bowlby has been mistakenly quoted as stating that such patterns are indelibly 'fixed' over the first year, he in fact stressed that any continuity must depend on a continuous flow of interactions. 'It is evident that the particular pattern taken by any one child's attachment behaviour turns partly on the initial biases that infant and mother each bring to their partnership and partly on the way that each affects the other during the course of it' (Bowlby 1969/1982, p. 340). Bowlby continues, 'By the time the first birthday is reached both mother and infant have commonly made so many adjustments in response to one another that the resulting pattern of interaction has already become highly characteristic' (Bowlby 1969/1982, p. 348). In addition to the immediate characteristics of the infant, the behavior of the caregiver is determined by 'the particular sequence of environments, from infancy onwards, within which development takes place' (Bowlby 1969/1982, p. 378). Thus, while a consistent cycle of interactions tends to maintain a given quality of attachment, if the cycle were to change, then so would the pattern of attachment.

As to which pattern of attachment is desirable, Bowlby was concerned with what might be called 'psychological desiderata.' However, other perspectives may prevail, such as 'biological desiderata' for increasing inclusive fitness, or 'cultural desiderata.' Although influencing each other, the three desiderata, biological, psychological, and cultural, may differ, especially in modern industrialized societies (Hinde and Stevenson-Hinde 1991). Nevertheless, it was 'psychological well-being' which Bowlby as a practicing psychiatrist regarded as basic. Making an analogy with 'physical well-being,' Bowlby argued that 'psychological well-being' had an absolute meaning, with security of attachment an essential ingredient. Security in turn depends on antecedent interactions with a 'sensitively responsive' mother, as found in Mary Ainsworth's pioneering Baltimore study (Ainsworth et al. 1978) and subsequently in many others (DeWolff and van IJzendoorn 1997).

4. *Assessing the Quality of Attachment*

Bowlby's collaboration with Mary Ainsworth (1913–99) remains a model for creativity in science. Their friendship spanned 40 years, from 1950 when Ainsworth joined Bowlby at the Tavistock. After her longitudinal study of mother–infant behavior in Uganda, Ainsworth joined the faculty at the Johns Hopkins University in 1955. Appreciating that assessments of attachment must involve how a child uses mother as a 'secure base' when the attachment behavior system is activated, Ainsworth developed a Strange Situation procedure for infants (12–18 months old: Ainsworth et al. 1978). This was modified for older children, with her guidance (2.5–4.5 years: the Cassidy and Marvin system; 6 years: the Main and Cassidy system; reviewed by Solomon and George, in Cassidy and Shaver 1999). Ainsworth's procedure paved the way for empirical studies to explore the framework provided by Bowlby.

The Strange Situation procedure involves a series of episodes in an unfamiliar laboratory setting, including two separations and two reunions from an attachment figure. The coding emphasis is on the reunion episodes, which show how the child organizes behavior to mother following the stress of separation. A Secure pattern involves the child greeting mother with full gaze and positive affect. Interactions are calm, while also intimate and indicative of a special relationship. The two main insecure patterns may be contrasted with this, and indeed with each other. Whereas the Avoidantly attached child shows minimal responses and maintains neutrality, the Ambivalently attached child emphasizes dependence on mother, with angry/whiny resistance and/or immature behavior. A Disorganized pattern reflects confusion and apprehension. Beyond infancy, one may see a transition from Disorganization to a Controlling pattern, reflecting an effort to reduce uncertainty by taking charge.

The move beyond behavioral observations to the level of representation was largely inspired by one of Mary Ainsworth's former Ph.D. students, Mary Main. Once children reach Bowlby's 'goal-corrected partnership' stage, their verbal behavior may be used to index representations of attachment (reviewed by Solomon and George, in Cassidy and Shaver 1999). Mary Main and colleagues developed the Adult Attachment Interview (AAI), based around 18 questions designed to access one's current state of mind with respect to attachment. Correspondence between parents' AAI classifications and their infants' Strange Situation classifications has now been reported in over 18 studies (reviewed by Hesse, in Cassidy and Shaver 1999).

5. *Emotional Communication*

In Bowlby's own words, 'Thus what is happening during these early years is that the pattern of communication that a child adopts towards his mother comes to match the pattern of communication that she has been adopting towards him. Furthermore, from the findings stemming from the Adult Attachment Interview, it seems clear that the pattern of communication a mother adopts towards her infant and young child is modeled on the pattern characteristic of her own intrapsychic communications. Open and coherent intrapsychic communication in a mother is associated with open and coherent two-way communication with her child, and vice versa' (1991c, pp. 295–6). To Bowlby, 'the concern of a psychoanalyst is not only with the extent to which a patient feels free to express his emotions openly, but with the prior questions of whether he knows what his feelings are and what has aroused them' (1991c, p. 294).

One reason for the success of attachment theory is that it lies at the heart of our emotional life. 'Many of the most intense emotions arise during the formation, the maintenance, the disruption and the renewal of attachment relationships. The formation of a bond is described as falling in love, maintaining a bond as loving someone, and losing a partner as grieving over someone. Similarly, threat of loss arouses anxiety and actual loss gives rise to sorrow; while each of these situations is likely to arouse anger. The unchallenged maintenance of a bond is experienced as a source of security and the renewal of a bond as a source of joy' (1991b, p. 306).

6. *Implications*

6.1 *Normative Development and Parenting*

The implications of attachment theory for the development and expression of emotions within close relationships, including how patterns may be transmitted across generations, is clear from the above. Furthermore, the sense of security which must underlie any appreciation of emotions within one's self and their expression to others depends upon having attachment figures who are sensitively responsive to emotional needs. A number of studies have revealed what types of parental interactions promote security, thereby paving the way for methods of parental guidance and childcare policies in general.

6.2 *Psychopathology*

With children who have already developed disorders, particular patterns of insecure attachment shed light on aspects of parenting that might be modified to promote security. For example, the Disorganized pattern, often seen in clinical samples, appears to be associated with fearfulness in either parent or child or both, thereby suggesting a window for intervention (Lyons-Ruth, in Cassidy and Shaver 1999). Additionally, attachment theory has direct implications for disorders related to separation or loss, such as abnormal grief, neurotic depression, or agoraphobia (see Holmes 1993).

6.3 *Social Policy Issues*

When a child goes to hospital, we now take it for granted that parents may visit or even live in. However, before Bowlby's influence, hospital practice involved leaving caregiving to the experts and keeping relatives away. Obstetric practice followed similar lines, and Bowlby (1953) did not hesitate to challenge this: 'reflect for a moment on the astonishing practice which has been followed in obstetric wards of separating mothers and babies immediately after birth and ask ... whether this is the way to promote a close mother–child relationship. It is hoped that this madness of western society will never be copied by so-called less developed societies.' His concern over separation from attachment figures remains relevant to our present provision of care for adults, such as the elderly and mentally ill.

Regarding daycare, Bowlby was keen to put right the misinterpretation of what he wrote. In stressing the importance of early caregiving, he did not mean that a parent must be with the child all the time. From the above it will be clear that attachment theory is about the quality of a relationship rather than amount of time spent together. Similarly with adoption, attachment theory does not say that early adverse experience cannot be overcome. Indeed the implication is that adoptive parents, if sensitively responsive to the child's needs, may do a great deal to set interactions in a cycle that will promote security.

Finally, attachment theory has been applied to the level of society. As a professor of social planning has urged, 'We need also to institute a style of governing our relationships with each other which takes as its first principles reciprocity of commitment, predictability, and respect for the unique structure of meaning and attachment which makes life worthwhile for each of us.' Such an argument implies the 'need to create a world in which we dare become attached' (Marris 1991, p. 89).

7. *Conclusion*

Thus, Bowlby produced a framework for understanding a core aspect of behavior, as set out in his trilogy, *Attachment and Loss* (1969/1982, 1973, 1980). The fruits of his theory are gathered together in the *Handbook of Attachment* (Cassidy and Shaver 1999), dedicated to John Bowlby and Mary Ainsworth. With 36 chapters and an inspired Epilogue by Mary Main, the Handbook is organized into six sections: Overview, Biological perspectives, Attachment in infancy and

childhood, Attachment in adolescence and adulthood, Clinical applications, and Emerging topics and perspectives. The last major publication of Bowlby himself was a biography of Charles Darwin (Bowlby 1991). With a convincing application of attachment thinking, Bowlby explained Darwin's lifelong psychosomatic symptoms in terms of unmourned loss of mother at age eight. Additionally, a keen reader may find parallels between the two men. Like Darwin, Bowlby had a distant father who was a doctor, both were younger sons, both were open to evidence, and both lacked rancor towards their detractors. Finally, it might be said of their theories that they have the quality of immediacy and 'obviousness.' In retrospect it seems obvious that species have evolved by natural selection, that people are attached to one another and suffer when they separate 'but it took child-like simplicity of vision combined with mature determination and attention to detail to root out the obvious and to create for it a secure theoretical base' (Holmes 1993, pp. 34–5; see also van Dijken 1998).

Brain Aging (Normal): Behavioral, Cognitive, and Personality Consequences

1. Introduction

Many of the effects of aging on behavior depend on changes that occur in the brain. But because the effects of normal aging on behavior, cognition, and personality are not completely determined by neurobiological factors, it is important to consider not only the age-related limitations imposed by inevitable biologically based losses, but also the extent to which there is plasticity of brain function during the later years. To understand fully the consequences of brain aging for behavior, it is important to keep in mind that human aging occurs along multiple dimensions simultaneously, and that there is dynamic interplay between brain aging, physical health and various behavioral and socioenvironmental influences. This entry draws on a developmental framework for summarizing and organizing current research findings and conceptual issues in the study of brain aging and its consequences for human behavior. From this perspective (see Baltes 1997), it is recognized or presumed that there are simultaneous gains and losses in function along various dimensions of human aging, and that there are potentials as well as limits in function throughout the adult life span.

2. Normal and Pathological Brain Aging

The substantial increases in the relative and absolute numbers of older individuals throughout the world pose serious challenges for medicine as well as for the behavioral and social sciences (e.g., Fries 1997). In trying to understand the relationships between brain aging and behavior, it is important to distinguish between the effects of brain aging on behavior that occur for all individuals, referred to as normal brain aging, and the effects of disease on behavior that are more prevalent in older populations. Even the study of normal brain aging reveals an enormous range of differences both among species and within populations in the course of biological senescence. All neurophysiological systems gradually decline in efficiency throughout the adult years. Although senescence

affects all individuals and all biological systems, different rates of senescence can be observed for different systems within individuals. For particular individuals, for example, long-lived macromolecules can become damaged through racemization of amino acids or glycation of proteins. Alternatively, individual differences might be observed in terms of the amount of shrinkage of large neurons and the buildup of amyloid deposits developed in extracellular spaces of neurons in the cortex and hippocampus.

Unsurprisingly, there are qualitative as well as quantitative differences between the effects of normal aging and dementing illness. The hippocampus is, or appears to be, only mildly affected by normal aging, yet there is substantial atrophy of hippocampal structures and in the entorhinal in patients in the early stages of Alzheimer's disease. At different levels of organization within individuals, it is useful to consider differences in the rates of degenerative changes for different structures and functions. However, it is also important to consider that a threshold model may be more useful than a continuous decrement model for describing some of the functional relationships between decline of cognitive functions and age-related changes in brain function; that is, significant cognitive deficits may appear somewhat abruptly only after a critical amount of structural deterioration has occurred.

3. *What is Brain Aging the Aging of?*

Until recently, it was generally accepted that progressive loss of numbers of neurons was an inevitable consequence of normal aging, and that age-related declines in cognitive function could be attributed to neuronal death. Early studies reported that age-related neural loss was 25–50 percent in most neocortical areas and in some areas of the hippocampus, but new studies have revealed that neuronal viability and not neuronal death is significantly involved in normal brain aging. Shrinkage of dendritic branching, and other changes in neuronal viability and in the neural architecture with aging are central to the understanding of age-related changes in cognitive function (e.g., Morrison and Hof 1997, Raz 2000).

As already mentioned, brain aging is both global and specific or selective. Various aspects of biological aging, together or separately, conspire to produce age-related losses in behavioral and cognitive function. Current theories of biological aging emphasize genetically programmed deficits, the cumulative negative consequences of mutation, and the cumulative negative effects of wear and tear on function (for reviews, see Finch 1996). Among the brain areas most affected by aging are the frontal-striatal circuits of the caudate. Other areas that are known to be substantially affected by normal aging are the prefrontal cortex and the dense network of projections connecting the prefrontal cortex and subcortical monoaminergic nuclei. The extent of age-related deterioration is also substantial for the posterior association areas and the neostriatum. The primary sensory areas of the brain are largely unaffected by aging. In light of findings of preserved brain function in the sensory areas, reliable declines in sensory efficiency with aging are attributed to receptor function and peripheral neural function.

The most prominent behavioral deficits associated with aging have to do with a general slowing in the speed of performance. Age-related slowing in information processing speed accounts for a substantial part of the variance associated with age differences in performance across a wide range of cognitive tasks (e.g., for comprehensive reviews, see Cerella 1991, Salthouse 1996). The performance of older adults can be precisely described in terms of a ratio of about 1.4–1.7 of the performance of young adults. To quote Cerella:

> The effects in some 288 experimental conditions are primarily determined by a single aspect of the information processing requirement, namely, task duration. The evidence is near-to-overwhelming that age is experienced, at least to a first approximation, as some sort of generalized slowing … success over such a diversity of data suggests that aging effects stem from some elementary aspect of the biology of the nervous system. (Cerella 1991, pp. 220–1)

Age-related slowing in cognitive performance across tasks may be associated with a number of brain-aging phenomena such as changes in neurotransmitter substances at the synapse, neural demyelination, disruptions in neural circuitry related vascular lesions, and increases in the extent or amount of recruitment and activation of brain volume. With regard to possible age differences in the amount of recruitment of brain areas, the results of several recent fMRI studies suggest that more cognitive resources are required for older adults than for younger adults to carry out cognitive tasks. In these studies, younger persons showed a relatively well-defined pattern of activation involving the inferior prefrontal-orbitofrontal cortex during the encoding of episodic information, and involving the right prefrontal cortex during the retrieval of episodic information. In contrast, older adults showed more widespread activation patterns at encoding and retrieval.

Much of the work in the cognitive neuroscience of aging has focused on age-related memory loss. Some aspects of memory function show large deficits associated with normal aging, whereas other aspects of remembering appear to be relatively unimpaired in healthy older adults (e.g., semantic priming, implicit memory). Relatively substantial age-related declines in cognitive function can be observed in tasks that entail the active and simultaneous processing and storing of information. This kind of processing, referred to as working memory, is a key component of cognitive tasks that require juggling lots of infor-

mation at once. Research bearing on the neural substrates underlying age-related deficits in working memory suggests that working memory requires cooperation among scattered areas of the brain. Which specific areas are activated depends on whether the task requires spatial or semantic memory. Working memory has been associated with the prefrontal cortex. Structural imaging studies indicate shrinkage of the prefrontal cortex with aging. However, functional imaging studies indicate increased activation in the prefrontal areas for older adults than for younger adults. These findings can be interpreted as suggesting that older adults use more cognitive resources to carry out demanding cognitive tasks.

New developments in behavioral genetics bear on the understanding of cognitive changes associated with aging. For example, in a recent study of 5,888 older adults (65 years old and above), the presence of apolipoprotein E epsilon 4 allele (APOE-ε4) was associated with cognitive decline over a seven-year period (Haan et al. 1999). APOE-ε4 is a plasma protein involved in cholesterol transportation. The gene coding for APOE is located on chromosome 19. Relatively little cognitive decline was found for healthy individuals, but systolic blood pressure, atherosclerosis, diabetes mellitus, and subclinical cardiovascular disease were predictive of cognitive decline.

In describing the consequences of brain aging for behavior, cognition, and personality, it is important to consider the consequences of age-related changes in immune function and in hormonal function (e.g., Uchino et al. 1996). Recent research indicates changes in estrogen levels in women is an important factor in both normal brain-cognitive aging and in neurodegenerative disease. Clinical studies show that estrogen has a protective effect in regard to the onset of Alzheimer's disease and perhaps in regard to the course of normal age-related neurodegeneration. It seems that estrogen can protect neurons against amyloid induced toxicity and other toxic effects. The relationship between loss of estrogen and risk of degenerative disease is of obvious relevance to postmenopausal women. Examination of the links among N-methyl-D-aspartate (NMDA) receptors, estrogen levels, hippocampal circuitry, and memory function is a significant area for future research.

The role of the cerebellum in cognition and behavior also deserves mention in this review. The cerebellum serves to coordinate voluntary movement, and may also play a role in the progression of dementia, schizophrenia, and other psychiatric disorders (see Rapoport et al. 2000).

Recent descriptions of the evolution of the human brain might also bear on the understanding of brain aging and its consequences for behavior. For example, Rapoport (1999) suggested that the evolution of primates is characterized by the emergence of neural networks in the neocortex that are activated by mental activity *per se*, absent of sensory and motor stimulation. Thus, even though the heritability of longevity is small, less than 35 percent, it is possible that repeated selection of genotypes has enabled development of brain organizations responsive to higher-order cognitive functions.

4. *Brain Plasticity and Brain Reserve Capacity*

Considering the inevitable aspects of brain aging and the increased prevalence of dementing diseases in later life, how and to what extent is it possible to improve, sustain, or restore effective behavioral and cognitive function in later life? The term, 'brain plasticity' refers to an individual's potential for change, especially the potential for growth or maintenance or restoration of function in response to loss or disease. Recent conceptions of brain plasticity are based on a number of findings showing that some aspects of neural circuitry and synaptic connectivity are capable of growth and repair throughout life. Brain plasticity and effective cognitive function may be interdependent in that continued active involvement in cognitive activities might serve to facilitate brain plasticity, or at least lead to the use of alternative strategies for effective cognitive and behavioral functioning. That is, brain plasticity is probably an outcome of deliberate cognitive efforts to restore, protect, or promote function plasticity more so than a normally occurring or spontaneous phenomenon in later life.

There is abundant evidence demonstrating that associative learning, especially deliberate or explicit learning, produces changes in cortical sensory and motor function. Among the many important questions still to be answered is how intraneuron and interneuron function is altered in response to stimulation. Along these lines, recent work examining long-term potentiation shows how changes in the sensitivity of neural transmission are affected by repeated stimulation and how such changes in sensitivity are maintained across time. Repeated stimulation produces alterations of presynaptic and postsynaptic neurons. Studies of changes in neurochemical function as a result of stimulation promise to contribute to the understanding of the potentials and limits of brain function in later life.

Early approaches to neuropsychological rehabilitation by Luria and others emphasized recovery of function by reorganization of surviving neural circuits. Various forms of rehabilitation achieve moderate degrees of success in restoring or improving behavioral function after acute brain injuries, through methods designed to produce reorganization or adaptation of brain circuitry (Robertson and Murre 1999). Traditionally, the focus of rehabilitation has been on teaching brain-injured individuals to regain function by performing actions in ways that use different neural apparatus. However, new methods and approaches in rehabilitation medicine are emerging that are based on

neural network theory and take into account the possibility of restoration of damaged networks (e.g., Plaut 1996).

Some researchers have suggested that there are links between brain plasticity and vulnerability to and protection from cognitive/functional impairment due to strokes and neurodegenerative diseases such as Alzheimer's disease (e.g., Satz 1993). The extent to which there is brain plasticity or brain reserve capacity could determine the threshold levels at which particular neurological diseases produce observable symptoms, and recent research has focused on the development of measures that index protection from the deleterious effects of normal brain aging and neurological disorders such as Alzheimer's disease. For example, the neural correlates of processing speed, working memory, learning rates, and sensory function are likely to be differential predictors of cognitive and personality function for different aged adults. Brain plasticity or brain reserve capacity may be called upon when an individual faces high levels of cognitive demand, or when the individual faces challenges associated with normal brain aging or with rehabilitation in response to neurological damage or disease.

5. *Conclusions*

Age-related changes in behavior, cognition, and personality during adult years and in later life depend on the interplay of brain aging and behavioral factors (i.e., learning, regularly occurring adaptive organism–environment transactions). Age-related losses occur for many aspects of brain aging, but there is also growth and stability for some aspects of brain function throughout life. Concepts of brain plasticity and brain reserve capacity give emphasis to the potential of individuals to continue to improve, maintain, or optimize behavioral function in response to insidious losses associated with normal aging, and to relatively abrupt losses associated with disease.

Brain Asymmetry

Brain asymmetry or cerebral asymmetry refers to anatomical, physiological, or behavioral differences between the two cerebral hemispheres. The hemisphere that is larger, more active, or superior in performance is dominant. The scientific study of cerebral dominance is recent and dates back to Paul Broca's discovery in 1865, based on observing acquired language deficit (aphasia) following left hemisphere (LH) stroke, that the left cerebral hemisphere of right-handed people is dominant for language. Until the mid-1940s, the general neurological consensus was that the LH of right-handers is dominant for all higher

functions and that the RH is dominant in left-handers. European neurologists and neuropsychologists, such as Hecaen, Piercy, McFie, and Zangwill, then noted that the LH is dominant for language and planned movements (praxis), whereas the RH is dominant for visuospatial functions. This led to replacing the dogma of exclusive LH specialization by the theory of complementary hemispheric specialization (Denes and Pizzamiglio 1999, Heilman and Valenstein 1993).

Beginning in the 1960s, research on Vogel and Bogen's split brain patients in Sperry's lab at Caltech confirmed dramatically the model of complementary hemispheric specialization by comparing the positive competencies of the two hemispheres instead of inferring them from deficit. More importantly, split brain research showed that each disconnected cerebral hemisphere constituted a complete cognitive system with its own sensations, perceptions, memory, even language, personality, and consciousness (Zaidel et al. in press). The two hemispheres can process information simultaneously and independently. This is the thesis of hemispheric independence (Zaidel et al. 1990).

Split brain research, in turn, gave an impetus to research on asymmetric functions in the normal brain, notably by Kimura and Bryden at McGill. Earlier studies by Shephard Ivory Franz in 1933 on complementary normal hemispheric specialization for reading and nonsense shape recognition were ignored because of his untimely death and due to his own antilocalizationist stance on mind/brain relations. Curiously, both Franz's work and subsequent work in Hebb's lab at McGill in the early 1950s were motivated by issues of transfer of training (across the retina or across the hands) and were confounded by issues of attentional scanning from left to right.

Today, cerebral asymmetry remains a cornerstone of human neuropsychology and serves as a model system for a fundamental question in cognitive neuroscience: how do separate subsystems of the mind/brain maintain their independence, on the one hand, and interact, on the other?

In this article, the focus is on asymmetries in the brains of normal right-handers. Asymmetries observed after unilateral brain-damage or in the split brain are discussed elsewhere in this book. Also omitted are discussions of individual differences in cerebral asymmetry associated with left-handedness and with sex. Finally, the coverage excludes abnormal asymmetries associated with congenital disorders, such as dyslexia, and with psychopathology, such as schizophrenia.

1. *Anatomical Asymmetries*

In a seminal paper published in 1969, Geschwind and Levitsky described a dramatic anatomical asymmetry: the left planum temporale, underlying the sylvian fissure near Wernicke's area, was larger than the right in 70 percent (really 80 percent) of right-handers. Correspondingly, the sylvian fissure is larger on the left in 70 percent of right-handers and this is said to be associated with LH specialization for language. The association is imprecise: lesion studies suggest that about 98 percent of right-handers have language specialized in the LH. A similar anatomical asymmetry is already present in the fetus by 31 weeks of gestation. These asymmetries occur whether the area is defined by anatomical landmarks or cytoarchitectonically. They appear to be reduced in left-handers. Lesion, PET and fMRI studies suggest that planum temporale asymmetry is related to phonological decoding and auditory comprehension.

Geschwind and Galaburda also found that pars opercularis (Broca's area) is larger on the left. More grossly, the frontal region is wider and larger in the RH whereas the occipital region is wider and larger in the LH.

Scheibel described an asymmetry in dendritic organization in the left and right operculum: Higher order dendritic branching was greater on the left, whereas lower order dendritic branches were longer on the right. This was attributed to quicker early RH development but greater LH development after the first year of life. This dynamic epigenetic pattern of changing histological asymmetries contrasts with the stable gross asymmetries described above.

2. *Neurochemical Asymmetries*

The neurotransmitter dopamine is involved with control of motor behavior and higher integrative functions, and is lateralized to the LH. By contrast, noradrenergic innervation and the neurotransmitters norepinephrine, as well as serotonin, are associated with up regulation and down regulation of autonomic and psychological arousal, respectively, and are lateralized to the RH. This is said to confer LH dominance to the 'activation' regulatory system, but RH dominance to the 'arousal' regulatory system. Activation refers to 'readiness for action,' and leads to motor functions. Arousal refers to 'orientation to input stimuli' and leads to attentional control. These, in turn, are conjectured to determine hemispheric specialization for perception, action, emotion, and cognition.

There are also asymmetries in neuroendocrine activity. Thus, there is asymmetry in cerebral control of cortisol secretion during emotional situations (Wittling in Davidson and Hugdahl 1995). There is also asymmetry in neuroimmunologic activity. LH activation seems to be immunoenhancing, whereas RH activation is immunosuppressive.

Fluctuating levels of steroid hormones, such as changes of estrogen during the menstrual cycle, may

affect LH function by modulating regional dopamine and other catecholamines. The corpus callosum is further believed to mediate dopaminergic asymmetry. Thus, increased callosal function may be associated with reduced dopaminergic, and consequently functional, asymmetry. It is, therefore, postulated that stable steroid hormones, notably testosterone, affect the organization of hemispheric asymmetry prenatally, whereas fluctuating hormones, notably estrogen, affect the activation of neurotransmitter tracts and selectively change callosal function.

Asymmetries in brain receptors, such as nicotinic acetylcholinergic receptors, may underlie asymmetric hemispheric activation, predominantly on the right, during uptake of recreational drugs, including alcohol, caffeine, and especially nicotine. Asymmetric hemispheric effects have also been shown for pharmacological agents, such as lithium bicarbonate, methylphenidate, and chlorpromazine. This is important for biological psychiatry. For example, changes in behavioral hemispheric asymmetry following floxetine treatment successfully predicts therapeutic response in depression.

3. *Physiological Asymmetries*

3.1 *PET and fMRI*

These techniques measure hemodynamic response and have a good spatial resolution (~ 4 mm) but poor temporal resolution (several seconds). Cabeza and Nyberg (2000) provide a valuable review of imaging during cognition. In general, these studies display bilateral activations that contrast with the asymmetric effect of lateralized lesions.

3.1.1 Attention. Sustained attention (vigilance) tasks yield prefrontal and parietal activation, preferentially in the RH. *Spatial compatibility* (Stroop) tasks selectively engage the anterior cingulate and left prefrontal cortex. *Orienting of visuospatial attention* selectively engages right posterior parietal cortex. *Divided attention* tasks selectively activate left prefrontal cortex. Thus, attention involves a bilaterally distributed network whose components are lateralized to one or the other hemisphere.

3.1.2 Motor. Unimanual choice reaction time selectively activates left prefrontal-intraparietal areas compared to simple reaction time, consistent with LH specialization for action. Spatial compatibility tasks activate dorsal premotor and superior parietal areas, predominantly on the left. Imitation of hand movements and of object manipulation activate bilateral inferior frontal areas, more on the left, and bilateral parietal areas, more on the right (mirror neurons).

3.1.3 Perception. Perception of *objects* and *faces* activates the same ventral pathway but there is greater right lateralization for faces than for objects. Perception of *smell* activates olfactory orbitofrontal cortex, especially on the right. Right occipitotemporal (fusiform) cortex is selectively involved in processing specifitj c visual form information (same view of same object), whereas the left is more involved in processing categorical information (different exemplars). *Music* perception engages right superior temporal cortex for melodies, but left Broca's area/insula for rhythms. Recognition of pictures of self selectively activates right prefrontal cortex.

3.1.4 Imagery. Generation of images from words activates left inferior posterior temporal lobe, although more complex visual imagery selectively engages right temporal cortex. Imagery of maps engages right superior occipital cortex, whereas mental navigation engages the left middle occipital gyrus.

3.1.5 Language. Spoken word comprehension activates bilateral medial and superior temporal gyrus but activation during written word recognition is left lateralized. Surprisingly, left prefrontal cortex is activated equally during written word recognition with or without spoken responses. Written words also selectively activate left posterior temporal cortex. There is a progression of hemispheric specialization: feature conjunction in letters occurs in medial extrastriate cortex contralateral to the stimulus visual field (VF). Letter shapes activate posterior fusiform gyrus opposite the processing hemisphere, whereas letter names activate anterior and posterior fusiform gyrus bilaterally. Letter strings activate left posterior fusiform area, whereas legal words (visual word forms) activate left anterior fusiform area with stimuli in either VF. Lexical access via the visual word form activates the posterior temporal lobe bilaterally, whereas phonological recoding activates a left-lateralized network of posterior (fusiform gyrus, presumably involved in sub-lexical graphemic processing) and anterior (inferior frontal gyrus, presumably involved in phonological recoding) structures. This supports the 'hemispheric dual route model': both hemispheres have lexical routes ('sight reading'), but only the LH has a nonlexical ('phonetic') route.

Deaf native users of American Sign Language show normal LH activation during language processing. In addition, they show recruitment of RH fronto-

temporal-parietal regions presumably for processing location and motion information present in ASL. This RH recruitment may be subject to a critical period.

Listening for the moral of a fable selectively activated frontal and temporal regions of the RH.

3.1.6 Memory. The *phonological loop* component of working memory distinguishes between a phonological store, associated with left parietal activation, and a rehearsal buffer, associated with activation in Broca's area. *Working memory* engages prefrontal and parietal regions. These are lateralized by type of material: Broca's area and left parietal areas are activated for verbal/numerical tasks; activations for nonverbal material tend to be bilateral.

Tulving's hemispheric encoding/retrieval asymmetry (HERA) model posits that (a) the left prefrontal cortex is selectively involved in semantic memory retrieval, (b) the left prefrontal cortex is selectively involved with episodic memory encoding (personally experienced past events), and (c) the right prefrontal cortex is selectively involved in episodic memory retrieval. However, recent data show material-specific laterality: LH activation during both encoding and retrieval of words, and RH activation during both encoding and retrieval for patterns, faces, scenes, or nonverbal sounds.

Different semantic domains engage different cortical regions. For example, retrieval of animal information engages left occipital regions, perhaps reflecting processing of physical features, whereas retrieval of tool information engages left prefrontal regions, perhaps reflecting processing of linguistic or motor information. Similarly, generating action words engages left temporo-occipital regions, close to motion perception regions. In other words, knowledge about object attributes appears to be stored close to the regions involved in perceiving those attributes.

There may be a dissociation in right prefrontal cortex between dorsal cortex, associated with free recall, and ventrolateral cortex, associated with cued recall. Finally, autobiographical retrieval is associated with activation in a right fronto-temporal network.

3.1.7 Emotions. Activation during perception of different *emotions* converges in the left prefrontal cortex. Dolan (in Gazzaniga 2000) reports lateralized right amygdala activation during masked (unconscious) presentation of conditioned fearful faces, but left lateralized amygdala activation during unmasked (conscious) presentation.

3.2 The Electroencephalogram (EEG)

The EEG has a good temporal resolution but poor spatial resolution and, therefore, it provides a relatively crude measure of hemispheric asymmetry. It is now beginning to be used together with imaging techniques like fMRI, that have a good spatial resolution but poor temporal resolution. EEG measures tend to focus on ongoing changes in the frequency domain whereas event-related potential (ERP) measures focus on stimulus-yoked changes in the voltage wave pattern over a second or so. Different frequency ranges of the EEG have different functional significance. Early work by Galin and Ornstein in the 1970s focused on the α band (8–12 cycles per second or Hz), whose power is inversely related to cognitive engagement. They found a larger right-to-left power ratio during verbal (LH) tasks and a smaller ratio during spatial (RH) tasks. They also found differential stable asymmetries in different professionals: lawyers with larger R/L ratios (more LH activity), and artists with larger L/R ratios (more RH activity).

More recently, focus has shifted to asymmetries in higher frequency bands of the EEG. For example, the gamma band (25–35 Hz) showed a dissociation between word and nonword reading or listening in the LH but not in the RH. Also promising, are measures of intrahemispheric and interhemispheric connectivity and coherence from large (128) electrode arrays that permit better spatial localization and provide indices of network dynamics during cognition.

Davidson (in Davidson and Hugdahl 1995) used EEG measures of α suppression to characterize anterior hemispheric emotional asymmetries and individual differences in emotional reactivity, mood, and temperament. Approach-related positive affect was associated with left anterior activation, whereas withdrawal-related negative affect was associated with right anterior activation.

3.3 Et-related Potentials (ERP)

Separate components of the ERP are associated with semantic and syntactic components of postlexical integration in language comprehension (Brown et al. in Gazzaniga 2000). The left perisylvian area is critical for syntactic processing, as well as for aspects of higher-order semantic processing. Within 200 msec after stimulation, processes related to lexical meaning and integration emerge in the ERP waveform:

(a) A transient negativity over left anterior electrode sites (left anterior negativity, LAN) emerges 200–500 msec after word onset. The LAN is associated with initial parsing and processing of syntactic word category information.

(b) A transient bilateral negativity (N400) develops between 200 and 600 msec after word onset. The N400 is associated with contextual effects of semantic processing (e.g., semantic unexpectedness of a noun in a sentence or discourse).

(c) A transient bilateral positivity develops between 500 and 700 msec, called the syntactic positive shift (SPS) or the P600, and is associated with syntactic

correction operations, such as arise from syntactic violations.

(d) A slow positive shift over the front of the brain develops across the sentence, and is associated with its overall meaning. The slow shift has separate left and right lateralized components.

Anterior LH specialization for grammar but not for semantics normally develops at age 36–42 months and is absent in later language acquisition.

3.4 Psychophysiological Asymmetries

Consistent with the thesis of hemispheric independence, brain asymmetry applies to cognition, emotion, and regulation of autonomic physiological processes.

Neurotransmitter, neuroendocrine, immunomodulatory, cardiovascular, and electrodermal activity, skin temperature, and vasomotor activity are all asymmetric.

Neural control of cardiovascular function is lateralized. Peripheral autonomic chronotopic control of cardiac activity (heart rate) is controlled by right-lateralized sympathetic and parasympathetic pathways. By contrast, AV conduction and cardiac contractivity are left-lateralized. Emotional stimuli in the LVF yield larger heart rate and blood pulse volume changes than stimuli in the RVF. These peripheral asymmetries are not associated with corresponding cognitive asymmetries. Finally, there may be an asymmetry in pain sensitivity, greater in the RH.

In sum, the LH appears to specialize for motor functions and in the regulation of the body's defense against invading agents, whereas the RH appears specialized for control of vital functions supporting survival and coping with stress.

4. Behavioral Asymmetries

4.1 Models of Behavioral Asymmetry

Behavioral asymmetries, or laterality effects, in the normal brain are measured by restricting input stimuli or behavioral responses or both to one sensory or motor side. By far the most common experimental paradigm is hemifield tachistoscopy with unimanual responses. Stimuli are flashed for less than 180 msec to one visual hemifield (projecting to the opposite hemisphere) to prevent involuntary saccades towards the stimulus, and response choices are signaled by different fingers of one hand, again controlled by the opposite hemisphere. For the sake of simplicity, the following methodological discussion refers to a hemifield experiment, but similar comments apply to experiments in other modalities.

Split brain research motivates two limited case models of behavioral laterality effects in the normal brain. The first is the exclusive specialization model, where only one hemisphere, say the LH, can process the stimuli, so that stimuli in the left visual field (LVF) must be relayed from the RH to the LH through the corpus callosum prior to stimulus processing. This model is called the callosal relay (CR) model. The second is the relative specialization, or hemispheric independence (of representation and strategy) model, where each hemisphere can process the stimuli, though usually not equally well, and the input VF determines the processing hemisphere. This is called the direct access (DA) model. Consider the example of a lateralized lexical decision task with orthographically legal nonwords and unimanual word/nonword responses. A callosal relay model predicts a main effect of input VF (RVF advantage or RFVA) as well as a main effect of an independent stimulus variable (say, wordness) but no significant interaction between the two (assuming that words and nonwords are equally complex and equally susceptible to delay or degradation in callosal relay). By contrast, a main effect of VF (RVFA) and a significant interaction of VF and an independent variable, say wordness, implies that the DA model holds.

Some behavioral laterality tasks, like phonetic perception in dichotic listening to nonsense consonant-vowel (CV) syllables, are CR, exclusively specialized in the LH. Surprisingly many, like lateralized lexical decision, are DA. For reasons still unclear, it appears that the VF of the target, rather than the response hand, determines the hemisphere in control of processing. Even when DA obtains, there may be implicit interhemispheric priming effects and resource borrowing, leading to the concept of 'degrees of hemispheric independence.' Many tasks probably engage both DA and CR components.

4.2 Methodology

4.2.1 Signal detection. For reasons still unclear, behavioral laterality effects are more likely to occur with accuracy than with latency as the dependent variable. The signal detection measure of bias, β, often shows a more negative bias in the LVF than in the RVF. A speed-accuracy tradeoff analysis of some DA tasks suggests that the two hemispheres have similar speed-sensitivity functions, suggesting similar decision strategies, but different speed-bias functions, implying hemispheric differences at the response choice stage. This highlights the need to apply signal detection measures to behavioral laterality experiments. That is rarely done.

4.2.2 Previous trial effects. Common laterality tests show previous trial effects involving the correctness,

the VF, and the target identity of the previous trial. They exhibit a selective implicit RH error monitoring, and same-VF or same-target priming effects across trials, indicating the importance of context effects and the ubiquitousness of hemispheric momentum effects in time.

4.2.3 Bilaterality effect. Bilateral displays, with targets in one VF and distractors in the other, increase hemispheric independence and the behavioral asymmetry.

4.2.4 Reliability and validity. This is a sorely neglected topic. A standard measure of the laterality index is $(L-R)/(L+R)$, where L = accuracy in the LVF, etc. Voyer (1998) carried out a meta-analysis of 88 experiments and found an average test-retest or split-half reliability of the laterality index of 0.68. Dichotic listening had greater reliabilities than VF studies, and auditory verbal tests had greater reliabilities than nonverbal tests. Verbal dichotic tests had an average reliability of 0.70. Dichotic listening to stop consonant-vowel (CV) syllable pairs showed the highest reliability, 0.80. Accuracy yielded higher reliabilities than latency. Number of items affected split-half but not test–retest reliability. Split-half reliabilities were higher than test-retest reliabilities. Extensive testing with dichotic CVs yielded reliabilities around 0.83 and testing with lateralized lexical decision including lateralized distractors yielded reliabilities around 0.81.

The reliability of the difference between the two VF scores is maximized when they are negatively correlated with each other, but when each is based on a large number of trials that are positively intercorrelated. Indeed, the correlation between the two ear scores in dichotic listening varies from 0.1 to -0.72 and the use of bilateral stimuli in VF studies reduces the correlation between the two VFs.

Voyer's estimate of criterion validity from cross-correlations of laterality measures between tests yielded a low validity of 0.26. However, the procedure assumed a true global measure of hemispheric specialization. This is unlikely. Different functions even within the same domain, such as language, are lateralized to different degrees. Thus, phonetic perception appears to be exclusively lateralized whereas visual and especially auditory word recognition are more bilaterally represented. Instead, one can use the split brain as establishing construct validity. By administering the same behavioral laterality tests to split and normal brains, it is possible to establish the underlying degree of lateralization of the relevant functions (Zaidel et al. 1990). This procedure reveals that lateralized lexical decision measures relative hemispheric specialization, but dichotic listening to nonsense CV syllables is exclusively specialized in the LH. Consequently, individual differences in the right ear advantage reveal individual differences in LH competence or in callosal relay (from RH to LH), or both.

4.2.5 Laterality and ability. There is another sorely neglected aspect of the validity of behavioral laterality tests: the degree to which lateralized performance predicts the underlying or associated ability in free vision. It is possible that a RVFA reflects better LH performance overall and thus better scores on any test predominantly controlled by the LH. This concept is captured by Levy's individual differences in stable hemispheric arousal asymmetry. Such characteristic asymmetry is said to account for half of the variance in asymmetry scores across tasks, and it contributes more to asymmetry in tasks with bilateral stimuli. However, no relationship was found between characteristic arousal asymmetry and performance on various tests of cognitive ability.

The question remains whether performance in a lateralized version of a task predicts free vision performance on the same task? It does, but surprisingly weakly. For example, there was an unexpected RVFA in a test for recognizing facial emotions and a moderate correlation ($r = 0.433$) between the RVFA and performance on a free vision version of the test. In a lateralized lexical decision task, there was the expected RVFA but free vision measures of vocabulary correlated positively with accuracy in either VF (LVF: $r = 0.524$, RVF: $r = 0.59$), and reading comprehension correlated only with LVF accuracy ($r = 0.385$). Voyer also observed a positive correlation between the RVFA in a lateralized mental rotation test and free vision performance on a test of spatial ability. Since the correlations are relatively small, it is misleading to infer hemispheric specialization of a cognitive test from the VFA in a lateralized version of the same or a similar test.

4.3 Domains of Specialization

Consistent with the theory of hemispheric independence, hemispheric differences can occur at any level of information processing.

4.3.1 Attention. Hemispheric engagement by lateralized stimuli creates an activational bias to the opposite half of space and enhances processing of material in that location. Task demands, such as processing facial emotions, may selectively activate the specialized hemisphere. Clinical and imaging studies suggest that the RH is specialized for alerting, arousal, and vigilance. Indeed, testing of covert orienting of spatial attention using the Posner paradigm discloses a greater cost for detecting LVF targets with invalid cues in the RVF than for detecting RVF targets with invalid cues in the LVF. There is some suggestion that the RVF shows selective sensitivity to

object-based cueing, whereas the LVF is selectively sensitive to location-based cueing.

4.3.2 Perception. Older views held that hemispheric specialization is divided by modality, material, or stage of processing, with the LH specialized for auditory, verbal, or output processing; the RH for visual, nonverbal, or input processing. A more recent view is in terms of information-processing styles: the LH is analytic and the RH is synthetic, and a related current view holds that the LH is local and the RH is global, for example, in processing hierarchic patterns. A more precise statement of the latter view is that the LH is specialized for processing relatively high spatial and temporal frequencies whereas the RH is specialized for relatively low frequencies, given the context (Ivry and Robertson 1998). The evidence for hemispheric specialization in the normal brain, in terms of relative frequencies, is still controversial, and the evidence from normals for hemispheric specialization in global/local processing is weak. The global/local hemispheric dissociation has better support from neuroimaging studies in normals and from behavioral studies in hemisphere-damaged patients.

The RH is said to be specialized for processing facial emotions and emotional prosody. In space localization, the LH is said to be specialized for processing categorical relations, such as on-off, inside/outside, above/below, or near/far; the RH is said to be specialized for coordinate, metric relations. The claim appeals to selective RH involvement in magnocellular vision, still a controversial view. The claim received mixed empirical support (Hellige 1993).

4.3.3 Imagery. The componential theory of visual imagery distinguishes image generation, maintenance, scanning, and transformation. There is controversial evidence for LH specialization for image generation and for RH specialization in image rotation. Kosslyn believes that categorical image generation (by description of parts) is specialized in the LH, whereas image generation by stored metric memories is specialized in the RH.

4.3.4 Emotions. There is a LVFA (RH specialization) for recognizing and, perhaps, expressing facial emotions, as well as emotional intonation and emotional gestures. The RH may have a selective role in expressing negative emotions and the LH in expressing positive ones. Heller (in Banich and Heller 1998) distinguishes emotional valence (pleasant, unpleasant), controlled by anterior cortical regions, (pleasant more on the left, unpleasant more on the right), from emotional arousal (high, low) controlled by right posterior regions. Heller also distinguishes two groups of individuals with high trait anxiety: those with anxious apprehension (worry), and increased LH EEG activation (α suppression), and those with anxious arousal (panic), and increased RH activation. Pettigrew believes that bipolar disorder is the result of a slow interhemispheric switching mechanism that becomes stuck on the left (mania) or on the right (depression).

4.3.5 Language. Findings from neurological patients guide the design and interpretation of behavioral laterality experiments in normal subjects: the anterior LH is specialized for phonology and syntax, more posterior (temporal) language areas in the LH control semantics, and the RH is specialized for pragmatics.

Dichotic listening studies suggest that phonetic perception (e.g., distinguishing stop consonant-vowel syllables by place of articulation and voicing) is specialized in the LH. Ivry finds that the perception of voice onset time is specialized in the RH, whereas the perception of place of articulation is specialized in the LH, because voicing is carried by low speech frequencies and place is carried by high frequencies.

Word repetition priming is case- and font-sensitive in the LVF but not in the RVF and the word superiority effect (detecting a letter is faster in a word than in a nonsense string) is greater in the RVF, suggesting that word recognition in the LH is quicker and deeper. However, format distortion, for example, a LtErNaTiNg case or vertical presentations, selectively impairs word recognition in the RVF, more for words than for nonwords, suggesting a selective contribution of pattern recognition to word recognition in the LH. Word length can affect word recognition in both hemispheres, more in the RH than in the LH. Both hemispheres show comparable word frequency effects, but the LH shows a selective word regularity effect (better recognition of words with regular than with exceptional spelling-to-sound correspondence). The preceding observations are consistent with the view that both hemispheres can recognize words via a lexical route ('sight vocabulary') but that the LH has selective access to a nonlexical route (spelling-to-sound, 'phonics'). However, when taxed, the RH does show regularity effects, suggesting that it has latent competence for spelling-to-sound conversion.

When we fixate during reading, we look ahead, thus selectively attending to the RVF in English (read left-to-right), but to the LVF in Arabic (read right-to-left). Indeed, hemifield tachistoscopic studies show that while both types of languages are specialized in the LH, early visual stages of word recognition engage the RH more in Farsi than in English.

Semantic priming experiments suggest that the RH activates automatically more distant semantic relationships and multiple meanings of ambiguous words.

The LH may be more specialized for function words (closed class items) than for content (open class items). Sentences are more effective primes for the LH than for the RH, showing that the LH is selectively specialized for syntax. Still, both hemispheres show sensitivity to grammatical agreement, suggesting that the RH does have some grammatical competence. Finally, RH activation of multiple distant meanings may help it make predictive inferences in discourse, especially when breaks in coherence occur.

Based on lateralized priming experiments, Chiarello concluded that lexical orthographic relationships are more available to the RH, phonological relationships are more available to the LH, and semantic relationships are available to both. Automatic lexical semantics is more available to the RH, whereas controlled, strategic, lexical semantics is more available to the LH.

4.3.6 Olfaction. Unlike vision, hearing, and somesthesis, the olfactory system is mainly uncrossed: left nostril → LH, right nostril → RH. Studies of normal subjects suggest that the olfactory thresholds of the two hemispheres are the same. Odor discrimination and intensity judgments show an advantage in the right nostril (RH), but odor naming shows a left nostril superiority. However, results are inconsistent and behavioral imaging and lesion studies reach conflicting conclusions. Nonetheless, there is agreement that interhemispheric interaction is critical for olfaction: birhinal presentation (both nostrils) increases perceived odor intensity and facilitates odor naming, although it does not affect detection thresholds.

5. Convergence

There are systematic discrepancies between profiles of hemispheric specialization observed in the normal brain (Bradshaw and Nettleton 1983, Bryden 1982), in the split brain (e.g., Zaidel et al. in press), and in hemisphere-damaged patients (Denes and Pizzamiglio 1999, Heilman and Valenstein 1993). Laterality effects are typically smallest in the former and largest in the latter. Thus, unilateral lesions can lead to devastating cognitive deficits not mirrored in the disconnected, let alone the normal, hemispheres (Benson and Zaidel 1985). For example, large perisylvian LH lesions can lead to global aphasia and yet the disconnected RH is neither word deaf nor word blind. Similarly, right posterior lesions can lead to neglect of the left half of space and denial of illness (anosognosia) and yet the disconnected LH does not exhibit neglect or denial. In general, it seems that unilateral lesions incorporate loss of function in diseased tissue, diaschisis, and pathological inhibition of residual competence in the healthy hemisphere. Those effects are minimized in the split brain and absent in the normal brain. Consequently, the disconnected hemispheres exhibit greater functional competence than inferred from lesion studies. The normal hemispheres, in turn, evince even greater competence than the disconnected hemispheres, presumably because they can borrow resources from each other even when they process information independently.

Hemispheric representation for language is illustrative. Phonological and syntactic deficit follow exclusively LH lesions, semantic deficits follow predominantly LH lesions and pragmatic deficits follow predominantly RH lesions. But the disconnected RH has substantial auditory language comprehension, including some grammar, a modicum of lexical (but not sublexical) reading, and on occasion even some speech (Zaidel et al. in press). Consequently, appeal is often made to RH language in trying to account for perplexing symptoms in aphasic syndromes, including covert reading in pure alexia, semantic errors in deep dyslexia, or good miming in the presence of misnaming written words in optic aphasia. The normal brain suggests that RH language competence is even richer, including grapheme-phoneme correspondence. The challenge for future research is to release latent RH language capacities for clinical recovery in aphasia, and to modulate degree of hemispheric specialization in the normal brain for cognitive optimization.

Brain Damage: Neuropsychological Rehabilitation

Rehabilitation in its broadest sense means 'the restoration of patients to the highest level of physical, psychological and social adaptation attainable' (WHO 1986). This includes measures to reduce handicap caused by social disadvantage, improve social integration, designing disability-favorable environments and many others. For the purposes of this article, however, attention will be concentrated on the subset of rehabilitation activities whose aim is to augment cognitive functions, and use the following definition of specifical neuropsychological rehabilitation: 'the systematic use of instruction and structured experience to manipulate the functioning of cognitive systems such as to improve the quality and/or quantity of cognitive processing in a particular domain of mental activity' (Robertson 1999, p. 703).

Neuropsychological rehabilitation is, therefore, a specialized component of more general rehabilitation, whose aim is the maximization of the functional independence and adjustment of the brain damaged individual. Rehabilitation in general may include a wide range of goals, the following of which are a tiny subset of examples: achieve standing balance; diminish family tension by reducing incidence of temper outbursts; achieve independent use of the lavatory; allow verbal communication via keyboard-operated voice synthesizer; reduce depression by increasing level and range of day-to-day activities; achieve supported participation in a workplace.

While neuropsychological rehabilitation may have a part to play in achieving some of the above goals, its domain is that of cognition—namely attention, memory, perception, gnosis, praxis, reasoning, and executive control. Setting goals for cognitive rehabilitation is therefore a superficially more straightforward task than in the wider realm of rehabilitation. Of course, some more general rehabilitation interventions (e.g., reducing depression or increasing level of participation in everyday activities) may have effects on cognition; these, however are not neuropsychological rehabilitation *per se*, because the result is a by-product of a more general goal, and the intervention was not specifically and directly planned to alter cognition.

1. History

While the attempt to foster recovery in brain function has a long history, it only properly took scientific root in conjunction with the great breakthroughs in the understanding of brain function made by the great European neurologists in the late nineteenth and early twentieth centuries. Paul Broca, for instance, described attempting to teach an aphasic patient to read again, stating: ' … I am convinced that, without returning to aphemics (aphasics) the part of their brain, one could, with enough perseverance, treating them with the infatigable consistency of the mother that teaches her infant to speak, one could, I say, obtain considerable results' (cited in Ryalls and Lecours 1996, p. 240).

The deadly technological advances of the twentieth century took a hand, however, in forcing a more active interest in neuropsychological rehabilitation. During World War I, Kurt Goldstein in Frankfurt and Walter Poppelreuter in Cologne were pressed into service trying to rehabilitate the bullet- and shrapnel-blasted brains of the German infantry. As early as autumn 1914, Poppelreuter founded an institution, a military hospital devoted to rehabilitation. Goldstein developed a theoretical model for neuropsychological rehabilitation, arguing that *restitution* of cognitive function may be possible through repetitive stimulation of the impaired brain regions, but only if some of the substrate of the cognitive functions in question were spared. Where the damage was more severe and widespread, *compensation* should be the aim of rehabilitation. As early as 1917, electrically powered memory devices were in use, providing repeated stimulation of stimuli that patients were required to learn by heart (for review, see Poser et al. 1996).

It was during the carnage of World War II, however, that another great neuropsychologist A. R. Luria turned his attention to the rehabilitation of brain damaged Russian servicemen and women. He developed four main principles of rehabilitation: (a) respect for the unique and variable nature of the brain's functional systems across individuals; (b) making use of the intact brain system to replace the damaged one; (c) allowing for previously internalized acts to be externalized, through speech or other external aids, until the behavior can again be performed automatically; and (d) using feedback constantly to provide patients with information about their strengths and weaknesses (Luria 1963). Luria emphasized the interaction between assessment of the nature of the cognitive impairment and the development of individually tailored methods to foster recovery.

2. Effectiveness of Neuropsychological Rehabilitation

The pioneering work of the first half of the twentieth century was carried out without controlled clinical

trials of the effectiveness of the therapeutic procedures being carried out. This was not surprising, because the notion of controlled clinical trials of behavioral or psychotherapeutic methods was at that time relatively unknown, and it was really only in the late 1960s and early 1970s that the effectiveness of various types of neuropsychological rehabilitation began to be formally assessed.

Even after the instigation of controlled trials in the 1970s, however, the evidence about the effectiveness of neuropsychological rehabilitation for a range of neuropsychological disorders is still not unequivocal. This is probably because (a) the number of trials is still very small and (b) the statistical power and methodological adequacy of most trials is not optimal. Furthermore, with only a few exceptions, rehabilitation methods have not been tied closely to underlying theoretical models of cognitive function. Nevertheless, there are some grounds for optimism in the clinical trial literature. Robey (1994), for instance, carried out a meta-analysis of 21 studies of aphasia rehabilitation and concluded that there was an effect of therapy, particularly when it was started relatively early following brain damage. More recently, one study has found changes in cerebral metabolism that may have been associated with training-induced improvements in language comprehension (Musso et al. 1999).

Another pioneering series of studies took place in New York in the 1970s, where a purely behavioral approach to rehabilitation of unilateral left neglect—a loss of attention and/or responding to the left side of space—was attempted (Weinberg et al. 1979). This strategy involved training patients to engage in habitual scanning towards the left side of space. Promising results in the New York studies were supported in subsequent studies of a more extensive and adapted form of training carried out in Rome. Pizzamiglio and colleagues subsequently showed that in three patients with unilateral neglect following primarily subcortical lesions, recovery was mainly associated with cerebral activation in right hemisphere cortical regions known to subserve the relevant visuoperceptual functioning in normal subjects.

3. Compensatory vs. Restitutive Approaches to Goal-setting in Cognitive Rehabilitation

In the 1990s, advances in our understanding about the plasticity of the adult central nervous system (Nudo et al. 1996) required that a new attempt be made to formulate a theory of recovery of function which allows not only for compensation as a mechanism of recovery but also for partial restitution of the impaired neuropsychological processes themselves. This was particularly true given the evidence that cell genesis was found to be possible in the adult human (Eriksson et al. 1998) and that in mice the extent of such new cell proliferation in the dentate gyrus was influenced by hippocampal-dependent associative learning (Gould et al. 1999).

It is, however, still acknowledged that behavior changes can occur following lesions that are determined by compensatory changes in the way the behavior is subserved by the brain. For instance, it was shown that while unilateral neglect following right hemisphere damage apparently recovers on measures such as line bisection, patients still showed very marked distortion in their representation of contralateral space as measured by a closely similar task requiring no motor response but only perceptual judgment (Harvey and Milner 1999). It is probable that the basic problem originally causing the neglect remains, but that patients have learned to compensate for this by adjusting their motor responses to the external world.

Compensatory approaches that target specific functional behaviors, without attempting to foster restitution in the underlying damaged brain circuits, have been argued for (Wilson and Watson 1996), and in the case of memory rehabilitation, there is as yet no evidence for direct and lasting improvement of memory through restitution-oriented therapies. Hence compensatory approaches to memory problems appear to be—for the time being at least—the treatment of choice.

The theoretical underpinnings for restitution-oriented rehabilitation were discussed in a review paper (Robertson and Murre 1999) arguing that such approaches are feasible in the case of lesions that spare a proportion of connections in a lesioned circuit. In such cases, targeted input that respects the facilitatory and inhibitory architecture of the cognitive systems may potentially 'rescue' circuits that would otherwise disintegrate. Such 'rescue' had indeed been demonstrated in monkeys (Nudo et al. 1996).

The question of how to choose between a restitutive and a compensatory approach to rehabilitation is crucial and not a question of purely academic interest. Faced, for instance, with someone who cannot move her arm, does one devote limited rehabilitation resources to trying to get her to move that arm, or to developing compensatory strategies to allow as normal a life as possible while avoiding the use of that arm? Faced with someone showing severe expressive dysphasia, do we try to train him to produce spoken words or do we teach him alternative means of communication? Confronted with 'dysexecutive' problems, do we focus our efforts on structuring the environment to support more organized behavior, or do we struggle to retrain at least some internally mediated executive control skills?

Quantitative theoretical models have been proposed that suggest ways of choosing between restitutive and compensatory approaches (Robertson and Murre 1999), but until we can routinely image the living human brain in such a way to assess the residual

connectivity in a lesioned circuit, rehabilitationists must rely on other methods. The presence of residual behavioral function apparent under certain circumstances may represent a reasonable proxy basis for assessing which individuals may potentially be amenable to restitution via guided recovery of primary lesioned circuits. Such an approach has already been adopted in the successful Constraint Induced Movement Therapy for hemiplegia (Taub and Wolf 1997, Miltner et al. 1999). Specifically, patients with a minimal degree of hemiparetic limb function could have that function partially restituted through a combination of restraint of the nonimpaired limb and graded movements of the partially hemiparetic limb.

4. *Theory–Practice Links in Neuropsychological Rehabilitation*

The last two decades of the twentieth century saw increasingly strong links between cognitive neuroscience theory on the one hand and the development of rehabilitation methods on the other. One good example of this comes from studies of the interaction of the brain's perceptual and motor systems. The theoretical basis of this arose from findings that certain types of visual information may have privileged access to the control of motor responses, yet not be available to awareness. The notion that the so-called dorsal stream (Ungerleider and Mishkin 1982) may provide visual information for the motor system that is not available to awareness has received strong evidence from a series of experiments by Goodale and Milner (Milner and Goodale 1995). They have shown how cortically damaged patients who are incapable of consciously discriminating perceptual features (e.g., orientation) may nevertheless be able to make appropriate motoric responses that are sensitive to these features.

In the light of these results, we predicted that the manifestation of unilateral neglect may be alterable by changing the purpose of otherwise very similar responses to spatially extended objects. Spatial-neglect-based deviation to the right of center was, for instance, significantly less when subjects reached towards metal rods as if to pick them up in the center compared to when they pointed to their centers. This, and other experiments, suggested that prehensive movements towards objects allow 'leakage' of information about their spatial extent via an unaffected stream of information available for motor-manipulative responses. This finding was compatible with data showing that while a conscious, 'ventral' representation of a stimulus can contaminate or over-ride the short-lived motor representation, no such reciprocal influence seems to occur (Rossetti 1998). In other words, this latter finding is compatible with data showing that activation of the dorsal stream appears to have effects on the ventral stream. In a rehabilitation outcrop of this study, people suffering from unilateral left neglect were actually encouraged repeatedly to pick up rods. In so doing, not only would one be repeatedly facilitating the putative 'crosstalk' between the dorsal and ventral systems, but one would also induce perceptual conflict in neglect patients: even though reaching to grip reduced neglect, their grip was still biased to the right of center. Hence when they picked up the rod at the point which visually seemed to them to be the center, they would experience contradictory feedback from both the proprioceptive and visual modalities to show that this was not in fact the case. The authors predicted short-term improvements in neglect as a result of a brief number of such exposures. Indeed, significant short-term improvements in neglect were found on neglect tasks after subjects experienced proprioceptive and other feedback discrepant from the judgments they made based on visual information alone (Robertson et al. 1997). The ventral/dorsal concept in cognitive neuroscience is not however the only one that has generated rehabilitation methods. Other examples include theories of frontal lobe/executive function leading to rehabilitation methods (Levine et al. 2000).

In the field of learning and memory, another theory–practice link was shown in work by Baddeley and Wilson (1994) and Wilson et al. (1994). They demonstrated that people with severe memory disorders learn better when trial and error methods are avoided during learning. Errorless learning is a teaching technique whereby people are prevented as far as possible from making mistakes while they are learning a new skill or new information. Instead of teaching by demonstration which may involve trial and error, the correct information or procedure is presented in ways that minimize the possibility of erroneous responses. Errors are likely to be reinforced by people with poor episodic memory because of their reliance on implicit memory which is inefficient at error elimination. Errorless learning has proved effective over a range of tasks, including learning names, new information, identification of line drawings, and programming an electronic aid. It is also effective for a range of diagnostic groups including head injury, stroke, encephalitis, and Korsakoff's syndrome, and a range of times post-insult from post-traumatic amnesia to 12 years post-infection.

In short, rehabilitation made significant progress during the twentieth century, but the progress in the next century will likely depend on much closer links being forged with the basic cognitive neuroscience of the brain as well as with combining behavioral and pharmacological methods for accelerating brain repair. The possibility of gene therapy also beckons, but it is entirely likely, as in the case of neural transplants, that the requisite improvement in behavior only occurs when such methods are combined with the best behavioral stimulation.

Brain Development, Ontogenetic Neurobiology of

Human infants have the longest period of dependence upon caregivers of any mammal, and changes in behavior during their development are obvious to all of us. Over time, the largely reflexive movements of the newborn infant are replaced by the highly purposive activity of the adult. The long period of human postnatal development allows the developing nervous system to reflect variability in the environment experienced by the infant as well as variability in genetic endowment. Much of the structural development of the nervous system has taken place before birth. Studies of primates have led to important advances in our understanding of how brains develop, including information on the prenatal development of the cerebral cortex (Rakic 2000).

Within common postnatal development there is variability among infants and children. One infant is fearful when presented with new people or objects; another does everything possible to seek out new levels of stimulation. Questions of cognitive and emotional development and individual differences have had a long history within psychology and education. There has also been considerable progress in exploring cognitive, social, and emotional behavior and in

specifying the knowledge and processing mechanisms involved in behavior at varying ages (Ruff and Rothbart 1996).

However, despite some impressive starts (e.g., Johnson and Morton 1991), links between psychological and biological development remain largely unexplored. One reason for the current high level of interest in human brain development is to establish connections between the psychological development of children and the study of the genetics and neurobiology of how brains become organized before and after birth. During the 1990s, the adult human brain has become increasingly available for analysis with new methods of neuroimaging. The effort to apply functional imaging methods to infants and children has barely begun and important obstacles to overcome in making these adaptations remain (Thomas and Casey 1999). In this essay we briefly summarize progress in developmental biology and psychology, concentrating on efforts to adapt current methods to achieve linkages between their separate findings.

1. Neurobiology

1.1 Cortical Structure

The human brain develops before birth largely under the instructions contained in the genetic message of 48 chromosomes containing tens of thousands of genes. For all humans, the gross organization of the brain is very similar. For example, the cerebral cortex, containing the primary sensory and motor systems, is a six-layered structure. Although differing in detail between brain regions, the cerebral cortex shows remarkable similarity in cellular structure across the entire brain, suggesting the strong influence of genetics on the brain's gross organization (Rakic 2000).

From the study of non-human animals, neurobiologists have shown that nerve cells follow a pathway from their place of origin to their eventual location within the cortex. This process of cell migration continues during the early years of life. From birth through childhood, there is evidence from infant autopsies on how the structure of the human cortex develops in each sub-region (Conel 1939). Although brain areas develop at different rates, in all areas cell migration proceeds from the deep layers to the more superficial layers of the cortex (Rakic 2000).

Despite the uniformity in the overall structure of the brain, there is evidence of the importance of experience even in the size and shape of sub-regions. Identical twins, for example, who share the same genetic endowment, have similar brain structure as revealed by imaging studies, but there are often striking differences in the shape of structures, particularly within the right cerebral hemisphere (Posner and Raichle 1994).

1.2 Connections

As brain cells establish layers of the cortex, they also form connections (synapses) with other neurons, forming the sensory and motor systems of the brain. The density of synapses rises rapidly during the first few years of life to reach a peak at about age two to three years. Synapse density then stays roughly constant until declining following puberty. Brain regions appear to differ in the detailed time course of these events (Huttenlocher and Dabholkar 1997).

Connections between neurons are thought to be central to the networks underlying thought and emotion, and findings of rapid changes in synaptic density over the first few years of life can thus be of great importance in shaping how we think about human development. To date, however, few methods have been available to relate synaptic density directly to child behavior, nor are methods available for connecting the details of brain changes with the obvious behavioral changes. For these reasons, few empirical data have been available to constrain theoretical swings in the relative emphasis placed on experience and genes as the basis for changes observed both in the brain and in behavior. Some theorists have thought experience was of primary importance in acquired behavior and others have stressed genetic constraints on what can be learned. New methods for imaging the human brain should eventually provide data to consider the roles of both genetics and experience in shaping the brain and behavior.

The formation and loss of connections between nerve cells continue throughout life, and are widely thought to form the major basis for changes in behavior during life. The early plasticity of the human brain is revealed in cases of brain injury. Even the removal of an entire hemisphere in early infancy may result in very little, if any, deficit, while a much smaller lesion in an adult may cause paralysis of one side of the body and, depending upon the hemisphere, specific deficits of cognition. As we shall see, in some systems there appear to be sensitive periods during which input is extremely important in shaping brain connections. However, in general, the ability to form new connections and learn new facts and procedures continues throughout life.

2. Neuroimaging

2.1 Adult Studies

Neuroimaging studies have used changes in blood flow or chemistry to examine parts of the brain active while normal adults perform tasks. These studies have provided a general picture of where cognitive and emotional processing is carried out by the brain (Posner and Raichle 1994). They give hope of helping us understand how genetics and experience work to-

gether to produce the behavior patterns of the adult. Neuroimaging studies have examined in the brains of normal adults such processes as perception, working memory, language, spatial attention, attentional selection, arousal, and happy and sad emotional states. The nearly universal picture that emerges is that tasks within each domain activate a specific network of neural areas that often include both posterior and anterior areas of the cortex as well as subcortical structures. As the complexity of tasks increases, more areas are recruited. Most tasks involve both bottom-up activity driven by sensory input and top down activity driven by the motivations, expectations, and attention of the person. Because measures based on changes in blood flow lag neural activity by hundreds of milliseconds, however, it is not possible to measure their time course directly by vascular changes (Posner and Raichle 1994).

Time dependent imaging methods can be obtained by recording electrical or magnetic fields from outside the skull, providing a measure of the time course of mental processing in the millisecond range. These studies have shown that the top down processing is usually delayed for a time following an unexpected target, although if a cue indicates the aspect of the stimulus the subject is to select, top down processing may be rapid.

2.2 Pediatric Studies

Measures of changes in blood flow have just begun to be used in child studies. Methods that require exposure to some amount of radiation cannot be used with children unless there is a medical condition that justifies it. However, structural and functional magnetic resonance imaging (fMRI) techniques have opened the field of imaging to developmental research.

Nevertheless, many special issues arise in the application of the fMRI technique to the study of normal children. Data from fMRI are very sensitive to motion artifacts. When dealing with children, this problem is especially acute, since for most, lying still for long periods of time is extremely difficult. Some fMRI studies have involved infants who are sedated for medical reasons. This prevents motion artifacts, but prevents the use of any functional task. In addition, sedation makes interpretation of results more difficult, especially when they are compared with those of non-sedated adults. Finally, children may experience anxiety and distress upon being in an unknown, hospital-like environment and especially seeing and entering the scanner magnet (Thomas and Casey 1999).

Electrical signals have long been recorded from infants and young children. They provide evidence of the time course of information processing and some evidence on anatomy. There is also hope that optical methods might be particularly useful with infants because of the low density of the skull at this age.

2.3 Marker Tasks

Another method that has been useful for studying development during early childhood is the use of marker tasks. Marker tasks are behavioral tasks that have been shown in adults to involve particular brain systems and even specific portions of these systems. By studying infants' ability to perform different marker tasks with increasing age, it is possible to make inferences about the developmental course of these systems and networks. There must be some caution here because the location of cognitive processes may itself change with development.

A clear example is the use of reaching during the first year of life to study children's ability to inhibit proponent actions elicited by the situation (Diamond 1990). Usually, infants reach where they are looking. A toy is placed under a transparent box. The opening of the box is on the side so that the subject can reach it only if the tendency to reach directly through the transparent top of the box is inhibited. At six months, infants appear to be constrained to reach along the line of sight, but by 12 months they are able to reach through the opening even while looking through the top. A comparison of infants with the performance of monkeys and adult humans with specific brain lesions on similar tasks suggests this task is sensitive to the development of the dorsolateral prefrontal cortex. Maturation of this brain area seems to be critical for the development of this form of inhibition.

3. Perception and Attention

During the first year of life, the visual system undergoes remarkable development supporting increases in visual acuity, the ability to control foveation and attention voluntarily, and recognition of faces and other visual objects. Infant visual acuity has been traced month by month during the first year of life by recording looking preferences (Ruff and Rothbart 1996).

Visual experience is critically important for the normal maturation of the visual system. For example, if one eye of a cat is closed, the representation of that eye in the cortex and its ability to drive visual cells is greatly reduced. Human infants who undergo unilateral removal of cataracts show clear effects of the time of this deprivation period on the development of the visual field (Maurer et al. 1999). Thus, the genetic plan for visual system development includes a critical role for exposure to the visual world.

There are also many indications from animal and human studies that sensory systems maintain the

ability to change with experience well into adulthood. In one set of studies, monkeys were trained to make discriminations with one of their fingers. The representation of that finger in their cortex was altered by the experience, with more cortex devoted to the trained digit than to the others (Merzenich and Jenkins 1995). Patients who have lost a limb due to amputation often develop feelings of the missing limb at other body locations that are represented in parts of the somatosensory cortex adjacent to those of the missing limb (Ramachandran and Blakelee 1998). These changes appear to occur as the result of the loss of input from the missing limb, allowing innervation from adjacent parts of the cortex.

Infants as young as four months can learn to anticipate the location of an event by moving their eyes to a location at which the target will occur. Thus, caregivers can teach important aspects of where to attend and use orienting to counteract distress well before the infant begins to speak. Infants also show preferences for novel objects in the first few months of life. Later in childhood more complex forms of attentional control (effortful control) begin to emerge. Infants first show the ability to reach away from the line of sight (described above), and later the toddler begins to develop the ability to choose among conflicting stimuli and courses of action (Ruff and Rothbart 1996).

4. *Learning and Cognition*

There has been an explosion of information about cognitive processes in infancy and childhood. The infant brain seems to have primitive capabilities for face and object recognition, number processing, language, and imitation from early infancy (Spelke 1998). The nature of these innate achievements is under active debate. Some views stress the infant as having a primitive ability to represent aspects of visual objects, including their solidity (Spelke 1998). Others feel infants have only low level specific tendencies based on aspects of the stimulus, so that more detailed representation emerges only with experience (Johnson 2000). In the case of numbers, while a primitive notion of the quantity of very small numbers seems to be present in animals and infants, a lengthy process including connections to language is needed to allow precise computation (Dehaene 1997).

4.1 *Language*

Experience begins to shape the direction of language even before the child is able to babble. Newborns enter the world with the ability to discriminate phonemes of all the world's languages. However, exposure to their own language leads to development of structures that emphasize the phonemes of their native language and reduces the ability to discriminate phonemes not present in that language (Kuhl et al. 1992). Nonetheless, the ability for relearning phonemes remains present even as an adult. There is no single sensitive period for language, but in some domains there is reason to believe that the degree of plasticity in learning new skills can be reduced or lost as the organism develops. For example, immigrants to the US from China show grammatical skills that reflect the age of their first exposure to English, but a different language skill, word knowledge, is independent of the age of first exposure (Weber-Fox and Neville 1996). These findings suggest that only careful empirical studies can help us understand the skills for which exposure at a particular time in brain development might be of special importance.

In the 1960s, the so-called Whorfian hypothesis held that the nature of thought was constrained by a person's language. Eleanor Rosch (1973) tested this idea in the domain of color names by working with a New Guinea tribe that used only two names for colors (dark and light). She nevertheless found they were better able to learn nonsense names for prototypical hues determined by locating the hue at the center of the set of colors spanned by English category name (for another view see Roberson et al. 2000). The Rosch result was interpreted as meaning that the color names used in English were not arbitrary; they surrounded particular hues that were highly memorable. Subsequently, anthropologists at Berkeley showed that there was a very nice relationship between names used for colors in the world's languages. Although languages differed in the number of color names, the particular spectral frequencies given names tended to emerge in the same order and were clearly related to the brain's systems for color analysis. Far from language specifying what could be best perceived, names seemed to depend upon the structure of the human visual system. The words we use influence the communication of our percepts and even the ability to remember them, but our perception seems to have laws related to the structure of the brain.

4.2 *Categories and Skills*

The development of the human brain is closely related to the acquisition of the many skills that children learn. Of particular importance in all cultures is the learning of categories. Work by Rosch and others extended the prototype analysis described in Sect. 4.1 to many other categories besides color (Smith and Medin 1981). Priming experiments showed that when people thought about a category like animals, they could easily retrieve information about prototypical animals like dogs and cats, but the category name actually slowed them down in thinking about salmon or fly, since fish and insects do not come close to the usual prototypical animals. Most people are familiar with basic categories, which, like dog,

couch or chess, describe a class of things that have physical similarity and common use. They do less well with abstract categories like game, which are harder to think about in terms of a central tendency. Expertise allows people to make finer distinctions than are present in the basic category, so they might think of dogs in terms of separate breeds, each with its own prototypical structure.

Priming experiments give us a good way of seeing what items are automatically activated when we think of one member of a category. Of course, we can also use our attention to overcome or restrict the boundary of activated items. In one experiment, people were taught to think body part when they saw the category name animal. When they did so, targets like arm and finger were responded to quite rapidly. However, if the target was introduced very shortly after the prime, the person would still be fast to COW, indicating that the animal category was automatically activated by the prime, but its access was reduced in efficiency as attention was directed to the learned associations (Neely 1977).

A basic tenet of the cognitive study of expertise has been the idea that experts differ from novices based on the information they have stored in memory about their domain of expertise. Early work in this area involved the memory of chess masters compared to more ordinary players. The chess master could retain the position of many more pieces, provided they were in the orderly position expected from an actual master's level game. If the pieces were randomly placed, the master was little better than the ordinary player (Chi et al. 1988).

Of course, few people become chess masters, but the study of expertise illuminates the learning of many skills acquired in school. Skills such as reading, processing number, or science are based upon relatively automatic access to a rich domain of information in semantic memory. These skills are often closely related to language.

We now have a basis for understanding something about the neural systems that lie behind this acquisition of skill. This work may begin to provide hints about how complex information of the type acquired by school subjects might be organized within the brain. It has been possible to show that the amount of cortical tissue given over to an area of processing can reflect experience with that kind of processing. This was mentioned in our discussion of cortical changes in the representation of a finger used by monkeys in learning tactile discriminations (see Sect. 3). The same finding has also been shown to apply to pianists and violinists who appear to have sensory and motor representations for the fine movements of their instruments that are far beyond those found in nonmusicians. In some laboratory tests, a few hours of training with a particular sequence of movement was sufficient to increase the amount of the cortex activated by the sequence (Karni et al. 1998).

One reason these results with monkeys and humans are so important is that there is now evidence of mapping related words and pictures within semantic areas of the left hemisphere. When subjects were shown pictures of tools, animals, etc., in an fMRI experiment, different brain regions were active within both frontal and posterior cortex for the different categories (Martin et al. 1995). Actual storage of this information may involve brain areas that process attributes such as motion and color. Observations also suggest that brain lesions of the left temporal lobe can disrupt the ability to recognize specific categories of items while leaving other categories completely intact, and reports from animal studies show that experiences stored at a common time may activate common cells (Erickson et al. 2000).

The priming, lesion, and neuroimaging data all suggest that concepts with common semantic and perceptual features may be stored together. It would be expected, based on the monkey results, that the size of these areas would change with recent experience. This experience might influence how easy it is to learn new material or how likely information in that domain will come to mind. We know that maps of important features are very common in the visual, auditory, and motor systems, so it should not be too surprising that related items are stored in adjacent areas within semantic networks.

We are a long way from understanding the details of how the storage of concepts takes place. We know that at least some aspects of dealing with such concepts as object and number categories are present at birth. However, even a primitive understanding of the structural brain changes that occur during the acquisition of concepts should provide teachers and others who work with children new perspectives on methods to use for teaching skills.

4.3 Reading

Reading is a high-level skill that is common in modern society, but not characteristic of all human communities. Neuroimaging studies have shown that the processing of English words involves posterior and anterior areas of the left cerebral cortex related to English orthography, phonology, and meaning (Posner and Raichle 1994). These imaging studies fit well with models in which letters are automatically integrated into a single visual unit (visual word form). The visual word form is probably a series of neural areas in the occipital and temporal cortex that becomes organized around the presentation of visual words. It represents an important adaptation of the visual cortex to performance of a high level skill not learned until childhood.

In acquiring reading, visual words are transformed into a speech-based code. Imaging studies suggest that problems with this speech-based code form the basis

of many forms of dyslexia (difficulty in learning to read). Speech-based codes play an important role in adult reading as well, although there is some dispute as to whether some words look up their meaning more directly from the visual word form system. Whatever the fact of the adult state, it seems likely that the skill of reading English depends both upon learning the alphabetic principles that relate visual letters to sound and development of the visual word form system (Posner and McCandliss 1999). Nevertheless, complete language systems, e.g., American Sign Language, can be constructed without the use of a speech-based code. Neuroimaging studies of sign suggest that many similar left hemisphere areas are recruited in interpreting sign language, but there is much more right hemisphere activity than in reading English (Neville et al. 1998).

5. *Temperament and Emotion*

Human brains differ from one another in gross anatomy. As noted in Sect 1.1, even identical twins whose brains are generally similar may show quite striking differences in the size and shape of particular areas. Moreover, we know that infants come into the world with prepared reactions to their environment and that even siblings can be very different in their reaction to events. On infant, for example, is easily frustrated, has only a brief attention span and cries with even moderate levels of stimulating play. Another may tolerate even very rough play, frequently seek out exciting events, and maintain attention over extended periods. Differences in this reactivity to the environment, together with the mechanisms that regulate them, constitute temperament. As experience accumulates with socialization, temperament becomes the basis for the adult personality (Rothbart et al. 2000).

Much of early temperament relates to positive and negative emotions such as fear or smiling and laughter. The brain's fear system has been widely studied in animals and by neuroimaging in adults. It involves a very specific anatomy including subcortical brain areas such as the amygdala as well as orbital frontal cortex. Differences in temperament and personality depend upon genetic endowment as expressed in brain structure and function and as influenced by experience. These dimensions are not fixed but develop over the life course.

For example, the full fear reaction is not present at birth, but requires some months to develop. Fearful infants have difficulty in exhibiting approach both to strange objects and people. Thus, fear serves a regulatory function. Fear as measured by responses to novel toys in infancy predicts fearfulness at age seven years. In addition, shyness or fear in social situations also appears to be an enduring temperamental variable. Later in childhood, maturation of the frontal lobe produces more reliance on effortful control systems, allowing increased scope for methods of socialization. The strength and effectiveness of this later developing effortful control system are also an important temperamental difference. Fear and effortful control are both major regulatory systems in later childhood and play an important role in the development of high level systems of morality and conscience (see *Temperament and Human Development*).

6. *Summary*

Human brain development seeks to relate basic perspectives from developmental neurobiology and psychology. Studies involving methods of brain imaging now provide opportunity for examining how the development of brain areas influences the expression of cognitive and emotional behavior, and how the brain itself is modified by experience. The study of brain development should help illuminate both general principles of brain plasticity and the basis for human variability.

Brain, Evolution of

When did the human brain evolve, and how did it happen? Obviously, to answer this question will require a time machine, and thousands of generations of observations to ascertain both the variability and direction of selection pressures in the past. We can, however, flesh out an initial understanding of how we got to be the animal *par excellence* that utilizes its brain for intelligent rationalizations based largely on the use of arbitrary symbol systems. The evidence consists of two components: (a) the 'direct' evidence from the fossil record; and (b) the 'indirect' evidence of the comparative neuroscientific record of extant living animals, particularly those most closely related to us, such as the chimpanzee. There is a third possibility: since the human genome project has sequenced almost all of the genetic code, the future study of evolutionary neurogenetics might provide more data about the actual genetic history of our Genus through time, as well as that of the great apes mentioned above. As this latter possibility is simply a mote in our eye at present, this article must concentrate on the evidence provided by the first two components.

1. Lines of Evidence

1.1 Direct Evidence

The term *paleoneurology* is used to describe evidence appraising the size and morphology of the casts made from the inside of actual fossil cranial remains. Occasionally, the casts are 'natural,' i.e., where fine sediments have filled the inside of the cranial cavity, and became compacted through time. These casts often retain whatever morphological details were imprinted on the internal table of bone of the cranium. The famous australopithecine Taung child's skull, described by Dart (1925), is one of the best-known examples. Curiously, these 'natural' endocasts are only found in the S. African australopithecines, of which several exist, and date from about 2.5 MY to about 1.5 MY. Most often, the paleoneurologist makes a cast of the inside of the fossil skull using rubber latex, or silicone rubber, and extracts this from the cranium. The partial cast is reconstructed by adding plasticine (modeling clay) to the missing regions. The whole is then measured by immersion into water, and the amount of water displaced is regarded as the volume

of the once-living brain. Other measurements and observations are made on the original cast.

During life the brain is surrounded by three dural sheaths (dura mater, arachnoid tissue and its cerebrospinal fluid, and pia mater) that interface between the actual brain tissue (cerebral cortex, mostly) and the internal table of bone of the skull. The gyri and sulci (convolutions) of the once-pulsating cerebral cortex are rarely imprinted on the interior of the skull, and the degree of replication often varies in different regions, i.e., sometimes the frontal lobe imprints more details than the parietal lobe. The degree of replication also varies in different animals. Two extremely important considerations emerge from this: (a) the resulting imprints are never complete and thus 'data poor,' and never include subcortical structures; and (b) controversial interpretations of what the underlying brain once looked like are guaranteed. Nevertheless, these endocranial brain casts do provide extremely important information regarding the size, shape, rough estimates of the lobar dimensions of the brain, and cortical asymmetries that have relationships to hemispheric specializations, including handedness. In addition, if the imprints of the underlying gyri and sulci are available, these can provide important information regarding the organization of the cerebral cortex, and whether the patterns of these are the same or different as in known extant primate brains. The infamous 'lunate sulcus' is a good example, as it is a demarcation boundary between purely sensory primary visual striate cortex (PVC) and multi-modal association cortex. When the lunate sulcus appears in an anterior position, it is most similar to the condition known in modern apes. When it is found in a posterior position, it is more in a human-like condition. Ascertaining its correct position is essential in deciding whether or not such a fossil hominid had a brain organized along human or ape lines. Finally, meningeal arteries and veins that nourished the dura mater also imprint on the internal table of bone and these sometimes show patterns that are useful for deciding taxonomic issues; these have no known relationship to behavioral functions of the brain.

1.2 Indirect Evidence

This line of evidence is 'data rich,' providing comparative neurological information on living species, such as brain size (both absolute and relative, i.e., related to body size), the actual makeup of the brain from the gross to microscopic levels, including neural nuclei, fiber systems and interconnections, and distribution of neurotransmitters and neuroreceptors. Additionally, the brain can be studied ontogenetically, and neuroscientists can actually study the relationships between how the brain varies neurologically and how these variations relate to the behavioral variation. This richness is simply lost to the paleoneurologist as it is not available as direct evidence. However, it is necessary to realize that the extant living species, e.g., chimpanzee, macaque, are end points of their own evolutionary lines of development and are not our ancestors, however closely related. It is the blending and complementation of these two approaches which provide the best set of evidence for when and how our brains evolved.

2. Characteristics of the Human Brain

2.1 Brain Size, Absolute and Relative

The human animal is obviously obsessed with size, and those who study the brain comparatively, perhaps more so. With an average brain weight of 1,330 grams (Tobias 1971), the human species has the largest absolute brain size within the primate order, but is actually dwarfed by elephants and some of the Cetacea, where brain weight can exceed 7,500 grams. Of course, the body weights are very much higher in elephants and whales. But even for its body weight, *Homo sapiens* does not have the largest relative brain weight, being outdone by several monkeys, some rodents, and even some fish. Normal modern human brain size varies between roughly 900 and 2,000 grams, although some very small number of exceptions does occur, with sizes ranging from about 750 to 900 and 2,000 to 2,200 grams. There exist both human population variation as well as differences between the sexes. In general, Arctic peoples have larger brains than those living in the tropics, and the smallest brains appear to be found among Ituri forest pygmies, also displaying small stature. Males in all populations for which good autopsy data have been gathered show brain sizes on the average of 100–150 grams greater than females, an amount roughly the same as the range of modern human racial variation. It should be pointed out that these differences, and their possible relationship to cognitive skills, are highly controversial and simple correlations are deceptive (Holloway 1996). Table 1 provides a listing of the major fossil hominid taxa and their respective brain sizes. Notice that the range of values from the earliest australopithecine to modern *Homo* is roughly 1,000 ml, or about the same amount as the normal range of variation within our species.

2.2 Encephalization (Encephalization Coefficient, E.Q.)

Nevertheless, the human animal does come out on top of the evolutionary heap when its absolute brain and body weights are considered together. When the log (base 10) of brain weight is plotted against the log 10 of body weight for a group of relevant taxa, the result is a linear line, where (log 10) brain weight = a + b (log 10) body weight. For a large array of primate data (Stephan et al. 1981), the slope of the line (b in the

Human	1,330	65,000	100	6.91 (100)	2.87 (100)	28.8 (100)

Source: Holloway 1997.
Formulae:
a EQ Homo = Brain wt/1.0 Body $wt^{0.64906}$, b EQ Jerison = Brain wt/0.12 Body $wt^{0.66}$, c EQ Primates = Brain wt/0.0991 Body $wt^{0.76237}$, d EQ Stephan = Brain wt/0.0429 Body $wt^{0.63}$
Note: Each formula is based on a different set of data. The EQ Homo equation simply uses the average brain and body weight for *Homo sapiens*, and assumes an intercept where both brain and body weights are zero. The value of whichever animal is calculated is then given as a direct % of modern *Homo sapiens*. EQ Jerison is based on data for almost 200 mammals, while the EQ Primates is based on Martin's (1983) data set for primates only. The EQ Stephan equation is based on insectivores only. The numbers in the parentheses are the % of the *Homo sapiens* value.

equation above) is about 0.76, and the correlation coefficient is 0.98, indicating that the relationship is almost perfect. This relationship will naturally vary depending on the databases and the transformations used. This is known as an allometric equation, and these are used frequently in biology to assess the underlying relationships between the size of parts of the body and the whole. The slope sometimes has an interpretation suggesting functional relationships between the brain and other variables. For example, in the above example, the slope is 0.76, extremely close to 0.75 or 3/4, which often describes a metabolic relationship (Martin 1983). The slope of 0.666, or 2/3, has been championed by some (e.g., Jerison 1973) as indicating an important geometric relationship between volume and surface area. It is important to realize that these slopes vary depending on the taxa examined. In general, as the taxa become more similar, the slope decreases. Species within a genus generally have a slope around 0.3; within a species the slope is smaller yet, being about 0.2, and the correlation coefficient is also reduced.

Just as the human animal is curious, it is also vainglorious, always trying to find a measure that places it at the top. Thus we can fabricate a device, the *Encephalization Coefficient*, or E.Q., which shows that relative to any database, the human animal is the most encephalized animal living. The point for *Homo sapien*s shows a clear positive residual above the expected regression line, and in fact the human value is about three times that expected for a primate with its body weight. Table 2 provides a number of different equations based on differing databases, which happily give *Homo sapiens* the highest value. (Actually, young

immature dolphins will provide a higher number, but when compared to an immature human, the value is higher in the latter.) Two additional points should be made: (a) E.Q.s are relative to the databases used, and thus there is an inherent 'relativity' to relative brain sizes; and (b) E.Q.s do not evolve, only brain weight/body weight relationships do, and E.Q.s are simply a heuristic device enabling comparisons between taxa; they have no reality outside of the database chosen, or species within a taxa, and are not designed to discuss within-species variation. For example, female humans are 'more' encephalised than males, given their smaller body sizes and smaller brains but the relationship is simply a statistical artifact with no known behavioral manifestation given their equal overall intelligence.

We will discuss somewhat later how the processes of hypertrophy and hyperplasia have been positively selected for in the course of the last 2 MY of hominid evolution. (Hypertrophy refers to increases in size of the neural components, e.g., neurons, dendritic branching, nuclei, fiber tracts; hyperplasia refers to increased production of cells through mitotic division.) It is most probably the case that these processes are controlled by regulatory genes, and one of the major differences between ourselves and our closest nonhuman primate relative, the chimpanzee (brain size = ca. 385 grams), relates to the schedules by which hyperplasia and hypertrophy are turned on and off during ontogenetic development (Holloway 1995).

2.3 Brain Organization and Reorganization

It is well known that the brains of most animals are extremely similar to each other in terms of their overall organization, by which are meant neural nuclei and fiber systems. The human animal does not appear to show any different structures when compared to Old World monkeys such as the macaque, or the Great Apes, including chimpanzee, gorilla, and orangutan. Even the neural fiber tracts that are involved in human language appear in these primates (Deacon 1997). One might ask, then, given the obvious species-specific repertoires that exist in all animals, how can these behaviors differ without differences in the underlying nervous systems? This is one of the major challenges of studying brain evolution, and in particular understanding what neural organizations account for the specificity of, say, human behavior, the ability to use language composed of arbitrary symbols. In other words, all mammals have a cerebral cortex, a thalamus, cerebellum, hypothalamus, etc., and basically these structures possess almost identical divisions of nuclei and do the same neural tasks. Clearly, brain size alone will never explain species-specific behavior, and the relationships between neural nuclei and fiber tracts will only go so far in explaining behavioral differences.

Allometric equations showing the relationship between one bodily component and the whole are instructive here. If we were to plot the logs (base 10) of primary visual cortex (PVC) against brain volume, we would find that the human PVC is 121 percent less than predicted, and similarly, the lateral geniculate nucleus of the thalamus is about 144 percent less than expected for a primate of our brain size. In contrast, if one were to plot the amount of cerebral cortex against brain weight the result is a straight line, and the human point lies almost exactly on the line. In short, the human cerebral cortex is as large as would be expected for a primate of its brain size. But do portions of the cerebral cortex vary in size between different primates? In humans, the residuals mentioned above suggest that compared to chimpanzees, the amount of PVC is significantly smaller in humans, or alternatively put, the posterior association cortex of the parietal and temporal lobes is relatively larger in humans. Since there are no essential differences between chimpanzees and humans in their visual abilities and competencies, these differences reflect selection for expanded functioning of the association cortex in humans. This is precisely what is meant by 'reorganization.'

When used in a comparative or evolutionary context reorganization means changes in the sizes and proportions thereof of neural nuclei and their fiber tracts. Given that chimpanzees and hominids last had a common ancestor some 5–7 MY, and that chimpanzees appear to have large PVC cortices, we infer that one aspect of human brain evolution has been some reorganization of the cerebral cortex, namely an increase in posterior association cortex (or, equally, a reduction in PVC) involved in polymodal cognitive tasks, where visual, auditory, and motor information are brought together in a synthetic whole. The trick, of course, is to demonstrate objectively when, where, and why these changes took place. This example of PVC has been purposefully chosen because one of the sulcal landmarks of the cortex that defines the anterior border of PVC is the 'lunate' sulcus, named for its crescentic shape, and there is some hope of identifying its position on some of the early hominid brain endocasts.

Neuroanatomists have been trying for many decades to demonstrate the major differences between us and other primates, and aside from gross brain size, very little has been shown. The frontal lobe, and particularly its prefrontal portion, has been a favorite target and indeed, Brodmann (1909) claimed it was proportionally larger in humans, a view most recently championed by Deacon (1997). Unfortunately, other works have shown that the human brain has just as much frontal lobe as would be expected for a primate of its brain weight (Semendeferi et al. 1997, Uylings and van Eden 1990), although the picture regarding prefrontal cortex has yet to be determined objectively using cytoarchitectonic criteria, which is how prefrontal cortex is differentiated from the pure motor cortex behind it. Hominid brain endocasts do not, alas, provide any sulcal landmarks with enough

reliability to determine the boundaries of prefrontal cortex, which is so important to impulse control, and higher cognitive functions such as planning and abstraction. Thus these regions cannot be measured in a phylogenetic sequence. The Neandertals, living from about 200,000 to about 28,000 years ago have frequently been described as having smaller frontal lobes; this is not based on objective measurements, but rather a perception that the large brow ridges on these humans were constraining frontal lobe development. Studying the Neandertal brain endocasts and comparing them to modern humans, I have failed to see any significant difference between these two groups.

Similarly, regions such as 'Broca's and Wernicke's areas,' anterior and posterior association cortical regions involved in motor (Broca's) and receptive (Wernicke's) aspects of speech, are not determinable on most fossil brain endocasts, although we can determine, for example, that Broca's region is more human-like on the brain cast of early *Homo*, some 1.8 MY. This is the famous KNM-ER 1470 endocast of *Homo rudolphensis* from Kenya, which had a brain volume of 752 ml, but which may not be a direct ancestor to our own line of *Homo*.

While the concept of reorganization has a heuristic value in directing our attention to changing quantitative relationships between different neural nuclei and fiber tracts, we cannot yet describe behavioral differences between closely related animals such as chimpanzee, gorilla, and orangutans, or different species of the genus Macaca, or indeed different breeds of dogs with their different temperaments, aptitudes, and sociality. We simply do not know what magic level of neural description is necessary to describe species-specific behavior. More recent research on prairie and mountain voles suggests that the difference in the females' ability to retrieve pups back to the nest depends on the distribution and number of neuroreceptors for the hormone oxytocin found in several nuclei of the brain, particularly the thalamus. Otherwise, their brains appear identical (Insel and Shapiro 1992). In addition, it is necessary to remember that the brain possesses aspects of plasticity that we did not appreciate except within the past decade, and that as the brain's organization unfolds ontogenetically, interactions with environmental stimuli are always occurring, and the brain builds its organization partly through its plasticity. It is difficult enough to study and understand such patterns in laboratory animals, let alone in our fossil ancestors! While the above suggests a somewhat pessimistic tone, we should remember that advances in noninvasive technology such as MRI, fMRI, and PET scanning have enormously increased our understanding of how the brain works, and how neural systems integrate and dissect data from the environment, always providing us with newer paradigms for further exploration about our brains and behavior, and in time, those of our closest relatives, the apes, in particular the chimpanzee.

2.4 Human Brain Asymmetry

The cerebral cortices of the human brain are usually asymmetrical, and tend to grow in a torque manner, reflecting minor differences in maturation rates. The hemispheres are seldom, if ever, equipotential in terms of functioning. Our left hemisphere is often characterized as 'analytic' and involved with language tasks, while our right hemisphere appears most competent in visuospatial integration, and is often thought of as the 'intuitive' or 'gestalt' hemisphere. These characterizations, while crude, hold up fairly accurately for right-handers and many ambidextrals. From radiographic studies, it was possible for LeMay (1976) to ascertain different petalia patterns for right- and left-handed humans with a high degree of precision. These petalias are small extensions of cerebral cortex that extend farther in one part of a hemisphere than on the other side. For example, we speak of a left-occipital right-frontal torque pattern of petalias as occurring with high frequency in right-handed individuals. This means that the left occipital lobe bulges somewhat more posteriorly on the left hemisphere while the right hemisphere is somewhat broader in width in the frontal lobe. In true left-handers, who are represented in human populations by about 8–10%, the pattern is reversed, meaning they exhibit a right-occipital left-frontal pattern. Petalia patterns for a large collection of apes indicated that while chimpanzees, gorillas, and orangutans sometimes demonstrated asymmetries, they did not show the particular torque pattern described above for humans. The gorilla, incidentally, was the most asymmetrical of the apes (Holloway and de LaCoste-Lareymondie 1982). On the other hand, brain asymmetries, particularly in the *planum temporale* (temporal cortex) of the chimpanzee, show a strong left-hemispheric size difference compared to the right (Gannon et al. 1998). This is simply puzzling as we do not have any evidence that chimpanzees use this structure in communication as do humans, and the fact that we share this difference with chimpanzees suggests that brain organizational features relating to complex cognitive functioning has been around for at least 5–7 MY. As our non-invasive scanning techniques become more sophisticated, we can expect to learn how these asymmetries function is animals other than ourselves.

Hominid brain endocasts, when complete for both sides (unfortunately, this is very rare) allow the paleoneurologist to assess the cerebral asymmetries, and indeed, even australopithecines appear to show beginnings of the right-handed torque pattern found in humans, and, as one progresses through time, the petalia patterns become more accentuated in the modern human direction. If we add to these observations those of Toth's (1985) studies on the early stone tools of about 2 MY, which strongly suggest right-handedness, this underlines the fact that our early ancestors, brains, despite their small size (sometimes

within the extant apes' range), were reorganized, and that they probably had some modes of cognition very similar to our own.

3. *Synthesis: Putting Together Size, Organization, and Asymmetry During Human Evolution*

As mentioned earlier, human brain evolution has clearly been a process of integrating neurogenetic processes that led to increased size of the brain (hyperplasia and hypertrophy) and these neurogenetic changes also played roles in the reorganization (quantitative shifts) of neural nuclei, fiber tracts, and cortical cytoarchitectonics. In addition, it is probable that other changes occurred at the neurochemical level, involving neurotransmitters and receptor sites, but these are not well known from the comparative record, let alone the fossil one. This integration was sometimes gradual, sometimes 'punctuated,' at least based on the fossil hominid record currently available. The only reliable evidence from paleoneurology suggests that Brodmann's area 17 (PVC) was reduced early in hominid evolution, signs of the reduction being clear in *Australopithecus afarensis* some 3 to 3.5 MY. While this would have meant a relative increase in posterior parietal cortex (area 39) and peri- and parastriate cortex (areas 18 and 19 respectively), the faithfulness of sulcal impressions does not allow for unambiguous definition of these areas. Similarly, it is not possible at this time to measure and delineate remaining areas of the temporal cortex and superior parietal lobule unambiguously. What is suggested, however, is that visuospatial abilities were most probably cognitively enhanced early in hominid evolution. It is not until we come to *Homo rudolphensis* at ca. 1.8 MY that a case can be made for some frontal lobe reorganization in the third inferior frontal convolution, Broca's area. Thus it would appear there was a gradient of cerebral reorganizational changes starting posteriorly, and progressing anteriorly. Table 3 outlines these changes.

Table 4 outlines the major size changes in the human brain during its evolutionary odyssey. Paleoneurological data simply are not detailed enough to integrate the two tables of size and reorganizational changes into one holistic sequence of events. Basically, the paleontological record supports an early reorganizational change resulting in an increase in posterior cortex associated with visuospatial processing, perhaps accompanied by a relative small allometric increase in brain size from *A. afarensis* to *A. africanus*. This would correlate well with geological and paleontological evidence that shows that early hominids were expanding their ecological niches and becoming more diverse in their subsistence patterns in mixed habitats. We know this based on the fact that stone tool types are becoming standardized in form, tool inventories grow larger, and right-handedness is highly probable. With the advent of *Homo*, we find strong evidence for a major increase in brain size, both allometric (related to body size) and non-allometric, and a reorganized frontal lobe, broader, and showing a more modern human-like Broca's area. This suggests that indeed there had been some strong and dramatic selection pressures for a somewhat different style of sociality, one most probably based on a primitive proto-language that had some arbitrary symboling elements as the standardization of stone tools (e.g., Acheulean handaxes) increases, suggesting social cohesion and control mediated through symbolically-based communication. Needless to say, this is but one speculative account of the evidence. But from about 1.8 to roughly 0.5 MY, we think there were minor allometric brain size increases to the earliest *Homo erectus* hominids of Indonesia and China, where brain sizes ranged from 750 to 1250 ml in volume. We have very little evidence for body sizes, but we believe, on the basis of the KNM-WT 17,000 Nariokotome youth from Kenya at ca. 1.6 MY, that these did not differ significantly from our own.

This is also a time during which cerebral asymmetries are becoming more strongly pronounced. With the advent of Archaic *Homo sapiens*, about 0.15–0.2 MY, we find brain sizes well within modern human values, and no evidence for further allometric increases, except possibly for the Neanderthal humans in which it can be argued that their larger brain and body sizes (lean body mass: bone and muscle) were adaptations to colder conditions. If further changes took place in cerebral and/or subcortical organization, they are simply not apparent from a paleoneurological perspective. Yet, the Upper Paleolithic is the time when cave art makes its appearance, and one cannot help but wonder whether the explicit use of art involving symbolization might not also have been the time for the emergence of language. In fact, however, there is nothing in the direct fossil evidence, and in particular paleoneurology, which provides any evidence for such views. Claims for a single mutation are ridiculously speculative. Finally, it would appear that there has actually been a small reduction in brain size, probably allometric in nature, from about 0.015 MY to the present.

The totality of evidence shows that the brain has always been evolving during our evolutionary journey, with myriad changes taking place at different tempos during different times. As suggested recently (Holloway 1997, p. 200):

> In sum, the major underlying selectional pressures for the evolution of the human brain were mostly social. It was an extraordinary evolutionary 'decision' to go with an animal that would take longer to mature, reach sexual maturity later, and be dependent for its food and safety upon its caretakers (parents?) for a longer period of time. The benefits for the animal were many, including a longer learning period, a more advanced, larger, and longer-growing brain, and an increasing dependence on social cohesion and tool making and tool

Table 3
Summary of reorganizational changes in the evolution of the human brain

Brain Changes	Taxon
(1) Reduction of primary visual striate cortex, area 17, and a relative increase in posterior parietal cortex	*Australopithecus africanus* *Australopithecus afarensis*
(2) Reorganization of frontal lobe (3rd inferior frontal convolution, Broca's area)	*Homo rudolphensis*
(3) Cerebral asymmetries, left-occipital right frontal petalias	Australopithecines and early *Homo*
(4) Refinements in cortical organization to a modern *Homo sapiens* pattern	*Homo erectus* to present

Source: Holloway 1997.
Note: (4) is inferred, as brain endocasts cannot provide that level of detail necessary to demonstrate the refinements in cortical organization from surface features alone.

Table 4
Brain size changes in hominid evolution

Brain changes	Taxon	Time (MY)	Evidence
1. Small increase, allometric[a]	*A. afarensis* to *A. africanus*	3.5–2.5	Brain endocast increase from 400 to 450 ml.
2. Major increase, rapid, both allometric and non-allometric	*A. africanus* to *H. habilis*	2.5–1.8	KNM–1470, 752 ml (300 ml increase)
3. Modest allometric increase in brain size to 800–1000 ml	*H. habilis* to *H. erectus*	1.8–0.5	*H. erectus* brain endocasts and postcranial bones
4. Gradual and modest size increase to archaic non-allometric	*H. erectus* to *H. sapiens neanderthalensis*	0.5–0.075	Archaic *Homo H. sapiens*, Neandertal endocasts 1200–1700 + ml.
5. Small reduction in brain size among modern allometric	*H. sapiens H. sapiens sapiens*	0.015–present	Modern endocranial volumes

a Related to increase in body size only.

using to cope with the environments that they encountered. Needless to say, language abilities using arbitrary symbol systems were an important ingredient in this evolution.
The fossil record shows us that there was a feedback between the complexity of stone tools (which must be seen as a part of social behavior) and increasing brain size and the expansion of ecological niches. The 'initial kick,' however, the process that got the ball rolling, was a neuroendocrinological change affecting regulatory genes and target tissue-hormonal interactions that caused delayed maturation of the brain and a longer growing period, during which learning became one of our most important adaptations.

These ideas have been detailed elsewhere (Holloway 1996), where more details may be found.

4. *And to the Future?*

There appear to be two common presumptions about our future brain evolution. One is that our biological evolution has stopped. The second is that our brains will continue to grow in size, with bulging frontal lobes (sort of a cross between E.T. and X-Files …), to handle our growing dependence on technology. What we have witnessed from the past fossil record is that our brains and bodies work largely in allometric fashion, and given the high metabolic cost of operating bigger brains (about 20–25% of our metabolic resources go to supporting our brains, which constitute only 2% of our total body weight), the second scenario seems highly unlikely. The first scenario is simply untrue, but it would require vast amounts of information from each generation of many living populations, something feasible perhaps, but not currently being collected. Furthermore, it is quite controversial whether brain size has any close relationship to intelligence, however intelligence is actually measured. Recent research based on MRI determinations of brain volume and selected batteries of cognitive tests have shown correlations between test scores and brain volume ranging from 0.4 to 0.6. (Andreasen et al. 1993). This is a figure significantly larger that previously reported (e.g., Van Valen 1974), and will need more replication studies. But if protein resources were to nosedive throughout the world for a significant period of time, selection would probably favor smaller body sizes in our species, and that would result in smaller brains, given an allometric relationship of

roughly 0.3 between stature and brain size. While genetic engineering may well provide some respite between the ever-increasing mass of humanity, ecological and nutritive degradement, this too is likely to be nothing more than short-term fending off of the unstoppable future. These degradations are part and parcel of the human brain's capacity to ignore warnings that should curtail greed and stupidity. The paleontological record for most mammals suggests that at the taxonomic level of the genus (such as *Pan*, *Homo*, *Canis*, *Notocherus*, etc.), one finds a recognizable record of that genus spanning approximately 5 to 10 million years. Our genus has a duration of about 2 MY. We, as a genus, despite our largish highly encephalized brains, have another 3 MY to go if we wish to be as successful in the paleontological longevity game.

Brain Implants and Transplants

The concept of brain repair with cells or tissue transplants is immensely attractive. After all, tissue and organ transplantation has progressed significantly over the past 30 years, and allowed extended life to patients with deadly, and previously incurable, diseases of the heart, lungs, liver, kidneys, and other organs. Transplantation to the brain, however, presents an altogether different, complex series of problems. Even with our rapidly evolving knowledge about the brain, its intricate neural networks, sensitivity to injury, and delicate chemical balance, make this most complex organ so much more difficult to treat.

These problems notwithstanding, our understanding of the brain is advancing. It is no longer considered a stable, unchanging organ in the adult and the long-held dogma that repair and regeneration of the brain cannot take place is wrong. Trophic factors, neural transplants, and stem cell grafts are just a few of the many ways by which the central nervous system can be modified.

1. How do Transplants Work?

There are several ways in which implants or transplants can work in the central nervous system: (a) provide replacements for lost cells, with integration

into the brain circuitry and reconstruction of the damaged brain; (b) function as a biological mini-pump—a way to deliver desired substances locally, avoiding the blood–brain barrier (BBB) and side effects; or (c) supply trophic signals and metabolic support for existing neurons, thus providing stimuli for neuronal survival and regeneration. While the first mechanism of action requires a neural transplant, the other two do not.

Thus, direct transplants of neurons into the brain are only one possible therapeutic strategy. Other types of implants are possible, which may avoid some of the problems associated with fetal cell transplantation for neurodegenerative diseases, or offer new therapeutic strategies for other conditions.

2. *Parkinson's Disease*

Successful grafting of brain tissue has been reported since the late nineteenth century. The modern era of neural transplantation, however, can be traced to the work of several pioneers who started their work before 1970. Parkinson's disease (PD) was the first clinical target for which transplantation to the central nervous system was tried. This is a common chronic degenerative disorder, affecting about one million people in the USA alone. A relatively small group of cells in the area of the brain called the *substantia nigra*—'the dark substance'—undergoes a gradual degeneration, until the vast majority of the neurons in that area is lost. These cell bodies produce the neurotransmitter dopamine, which is secreted at the terminals of these neurons located in a brain region called the striatum. Once the levels of dopamine in the striatum decreases by 80 percent, Parkinsonian symptoms occur. The patients suffer from a chronic deterioration, with characteristic tremor and slow movements progressing to rigidity, inability to initiate movements, and eventually complete disability and premature death. Medical treatment is available, but is far from perfect. L-DOPA in various forms increases the availability of dopamine and can dramatically ameliorate the symptoms for five to seven years. However, this drug does not forestall the disease process or protect the neurons of the *substantia nigra*. PD became the first target for trials of neural transplantation because in this disease major symptomatology can be traced to the loss of a single neurotransmitter, and this neurochemical system has a well-defined target. Also, excellent animal models of PD exist.

2.1 *Rodent Models*

Critical to the development of the field is the demonstration that transplantation into the brain is not only technically feasible, but also has functional effects. For the neural grafting field to develop, good animal models were required. Ungerstedt (1968) developed a unilateral 6-hydroxydopamine (6-OHDA) model of PD in which rats received lesions of the nigrostriatal system on one side. This resulted in the animals spontaneously rotating to the side of the lesion. The number of these rotations would increase in the presence of amphetamine that increases dopamine secretion from presynaptic terminals. Further, rotations occur in the opposite direction if the animals receive the dopaminergic receptor agonist apomorphine.

One of the most influential early papers demonstrating the potential of neural grafting was co-authored by Stenevi and Bjorklund (1979) who grafted into the rat brain dopaminergic cells obtained from various peripheral nervous system and central nervous system sources. Adrenal tissue, cervical ganglia, ventromedial mesencephalon, dorsolateral pons, median pontine raphe, from fetal, newborn, and adult rats, were transplanted into different CNS locations. These experiments served to elucidate the specific parameters critical for predicting graft viability. In 1979, using the rotational model, Bjorklund and Stenevi (1979) from Lund University in Sweden, as well as Freed (1980), Hoffer (1983), and their co-workers from the National Institute of Health in the USA, demonstrated that the experimental disease could be ameliorated by transplantation of fetal cells taken from a specific area of the brain—the ventral mesencephalon (see also Perlow 1979). The rotational imbalance induced by the unilateral 6-OHDA lesion was completely reversed by the graft, and recurred when the graft was destroyed.

Following these initial landmark demonstrations, a series of logical experiments in rodent models was pursued to elucidate the parameters required for optimal transplantation. These included the appropriate quantity of transplanted tissue, number of transplants, the age of the donor fetus, and the preferred target area. Issues of graft survival were critical—both keeping the donor tissue alive until the implantation, and survival within the host, where the graft has to obtain blood supply and avoid rejection by the host immune system. For ventral mesencephalic neurons, the optimal donor age in the rat is constrained to a specific time window of two to three days. The grafts appeared to survive especially well when transplanted directly into the striatum, their usual target area, where they integrated with the host brain and secreted dopamine. In the earliest experiments, a cavity was created in the recipient's cortex, and a solid graft of embryonic rat ventral mesencephalon was placed on the dorsal surface of the striatum. This method provided limited recovery of function because the solid graft was able to only integrate with the dorsal part of the target. To circumvent this problem, Dunnett et al. (1981) developed a cell suspension grafting technique, in which trypsin was used to dissociate a solid graft into a single cell or aggregate

suspension. This allowed stereotactic placement of the cells into several locations deep within the striatum. This resulted in a more robust behavioral recovery. The time between tissue dissection and graft is a crucial factor. Graft viability *in vitro* prior to implantation depends on several factors, including the handling of the suspension following trypsin treatment. Studies were undertaken to establish the minimal number of surviving grafted neurons required in order to produce a functional effect in the rat model. Brundin et al. (1985) established that 120 grafted dopamine neurons, or about 2 percent of the normal number of dopamine neurons in the rat nigrostriatal system, are needed to mediate a functional response. The grafted cells consistently reinnervated the host brain, but the fiber outgrowths radiated only 1–2 mm from the site of the transplant. Multiple grafts were therefore needed to achieve good coverage of the striatum. The grafts were innervated by host neurons. The tonic secretion of dopamine was established, and the electrophysiological and metabolic properties of the grafted cells were equal to those of normal dopaminergic cells in the *nigra*.

Rejection by the host immune system was not a severe obstacle. Allografts (grafts between individuals of the same species) and even xenografts (cross-species transplants) survive much better in the brain compared to other organs. In many respects, the brain is a relatively 'immunologically privileged site.' This is because neural cells lack MHC antigens. Further, the brain has no lymphatic drainage system and is protected in part by the blood–brain barrier. The blood–brain barrier tends to keep cells of the immune system out of the brain, and some of the astrocytes (an important supporting cell type in the brain) actually secrete substances that suppress the immune response. Nonetheless, trauma can activate the immune system and abolish the relative tolerance.

Although the studies in the rodent model established the feasibility and basic parameters of neural grafting, it is very difficult to translate results from rodent experiments directly into human patients. Our brains are vastly larger, there are differences in anatomy and embryology, and it is difficult to model complex behaviors in rodents. Some stepping stones were needed to cross this wide gap.

2.2 Primate Models

In California, several cases of rapid onset Parkinsonism were seen among intravenous narcotic addicts. Their doses of an illicit synthetic drug contained n-methyl 4 phenyl, 1,2,3,6 tetrahydropyridine (MPTP), which was later determined to be a potent toxin that destroys the dopaminergic neurons of the *substantia nigra*. The patients developed a syndrome that resembled advanced Parkinson's disease. The discovery of MPTP provided a means by which an animal model of the disease could be established. Interestingly, there are species differences in the sensitivity of an organism to the toxic effects of MPTP. Monkeys are perhaps the most sensitive. When MPTP is given to monkeys, they display many of the cardinal clinical features of Parkinson's disease and pathologically display lesions of the nigrostriatal system. Transplantation in the monkey model confirmed many of the findings in the rat model. The importance of appropriate cell source and target area was confirmed. Furthermore, recovery of symptoms such as rigidity, bradykinesia, and tremor was demonstrated. Functional recovery was long-term (see Sladek et al. 1988, Bankiewicz et al. 1990). In most studies, integration of the graft with the host brain was observed. Sladek and others concluded that less than optimal graft placement and creation of a cavity for the graft predisposed to glial scar formation and can inhibit fiber outgrowth. Nonhuman primate models employing focal and systemic administration of MPTP had a high predictive value as to what will work in humans. Monkeys have a relatively large brain, which closely resembles the human brain anatomically. Moreover, more complex behaviors could be demonstrated in monkeys compared with rodents (see Bakay et al. 1987).

2.3 Clinical Studies

Even though scientific data clearly favored fetal tissue as the best donor source for transplantation, adrenal medullary autografts were the first donor tissue tried clinically in patients with PD. In animals, adrenal medullary tissue had been shown to poorly survive in rats and monkeys and only elicit modest functional effects. However, use of this cell type did not induce the same social and ethical debate that fetal tissues did. Patients initially received adrenal medullary autografts, (tissue from the same organism). In these studies, solid grafts of adrenal medulla were transplanted into a cavity in the brain of the recipient. After the 1987 report of success in the study from Mexico, further clinical trials were disappointing, because the grafts survived very poorly if at all. A more gradual approach was needed, making use of the advances made in animal studies.

The next clinical trials were based on the success of the fetal cell suspension transplantation paradigm. Several groups, from Sweden, the UK, the USA, and France conducted carefully monitored studies of human fetal mid-brain cell transplantation into patients with Parkinson's disease. The reports from the different teams were mixed. Whereas some investigators reported marked improvement, others could not demonstrate a significant positive effect. For example, the Yale team reported no change in the condition of the patients after transplantation. They transplanted cryopreserved cells from a single fetus to each patient. An autopsy case from their series failed to demonstrate

surviving cells. The Lund University program in Sweden started clinical transplantation in 1984. They used cells from three to seven fetuses (six to nine weeks gestational age) per patient. From three to seven passes of the stereotactic needle for each treated side were required. Results showed marked variability between patients. The researchers used a positron emission tomography (PET) scan to demonstrate high metabolism of dopamine precursors in the area of the graft. Importantly, all cases demonstrated PET scan evidence of graft survival, and some of the patients were followed up for more than 10 years with continuing benefit from the transplantation. Similar outcomes were seen in patients from the University of South Florida in Tampa study (see Freeman et al. 1998). Clinical improvement was documented in all of the first six patients. These patients were transplanted with cells from six to eight fetuses per patient; the cells had been kept in cool hibernation medium for up to two days. While the patients still needed their medication (L-DOPA), all of them were more active, with fewer signs of Parkinson's disease. PET scans suggested high dopamine metabolism in the grafts. This activity persisted and even increased with time. After one of these patients died from an unrelated problem 18 months after the transplant procedure, his brain was studied. The graft indeed survived, was integrated into the brain, and was producing dopamine. There were no signs of rejection, even though immunosuppressant medications were stopped six months after the transplantation, a year before the patient died.

These results of preliminary clinical trials established that neural transplantation could be a valid therapeutic option for a human neurodegenerative disease. Also, the predictive value of animal models, particularly the monkey MPTP model, was confirmed. The methodology of clinical neural transplantation was refined. Nevertheless, even when good graft survival was demonstrated, none of the patients was completely cured. The variability between the studies and between patients in the same study was significant. Several controlled randomized studies are going on to determine the efficacy of transplantation to treat Parkinson's disease. More research is also required in order to further improve functional outcomes.

3. *Huntington's Disease*

Based on the experience gained with PD, another devastating brain disease was approached—Huntington's disease (HD)—a severe genetic disorder of the brain. It is inherited in an autosomal dominant fashion, meaning that the children have a 50: 50 chance of inheriting the disease from an affected parent. Most patients are normal until the fourth decade of life, when a relentless cognitive, psychiatric, and motor deterioration starts. The disease primarily affects the striatum—part of the basal ganglia. The largest neuron population in the striatum—GABA-ergic inhibitory neurons—degenerate first. The most prominent feature is a severe chorea, manifesting as involuntary jerking of the body and extremities, which after several years is replaced by rigidity and total disability. Death comes after an average of 15–17 years. There is no treatment.

The first step to human transplantation for HD was to develop an animal model. Although no perfect model has yet been found, there are several methods to produce relatively selective damage to the cell population that is typically affected in HD. Importantly, there are differences between PD and HD. In PD, only the tonic secretion of dopamine needs to be reestablished; the transplanted cells function as little more than biologic minipumps. In HD, however, the transplants have to reconstitute the host circuitry in order to achieve their full effect.

A logical series of investigations, in rodent and then primate models of HD, has proven that grafts of fetal striatum (the affected part of the basal ganglia) survive, reinnervate the host, and restore function. The first reports of successful fetal striatal grafts in a rat model of HD were by Deckel et al. (1983) and by Isacson et al. (1986). In these studies, rats received injections of fetal striatal cells bilaterally into previously lesioned striata. The grafts survived well and partially corrected the behavioral impairments seen in this model, such as nocturnal hyperactivity, cognitive impairments on a T-maze test, and abnormal responses to amphetamine and apomorphine. Further studies delineated the parameters for successful transplantation, including the optimal timing of the transplantation, the appropriate age of the donor fetus, and the precise source of the transplanted fetal tissue.

Studies in nonhuman primate models revealed many similarities between fetal allografts and normal neonatal striatal development. Primate models also allowed the study of the behavioral outcomes and the use of computerized axial tomography (CAT) scans, positron emission tomography (PET) and magnetic resonance imaging (MRI) to obtain information for comparison with the human disease (Helm et al. 1992, Peschanski et al. 1995). Several studies of fetal cell transplantation for HD are now underway. Initial reports have been encouraging (Philpott et al. 1997).

4. *Challenges on the Road to Large-scale Clinical Application*

There are reasons for cautious optimism regarding the potential to successfully treat PD and HD with fetal cell transplants. However, in the present form, this treatment in not ready for large-scale human application. Currently, transplants are only performed in several centers around the world, by highly specialized teams as part of clinical studies. The experience gained

so far provides 'proof of concept,' but the reproducibility and the therapeutic value will need to be better established before the methodology can spread beyond a few academic centers.

There are several challenges that are facing the field of neural transplantation in the twenty-first century. The methods of transplantation are still developing. Research is continuing to establish the optimal anatomic location of the implant for each condition, the correct amount of cells to transplant, and the appropriate timing of transplant therapy for optimal effect in the human patient. Easily reproducible methods are needed to ensure correct identification of the grafted cells.

Another challenge is assuring maximal graft survival and integration into the host brain. The transplanted tissue is subject to stresses such as lack of nutrients, oxidative stress, and lack of trophic supportive signals. Although neural grafts tend to be rejected less than do grafts of other tissues, this 'immunological privilege' is only partial. Thus, allografts and particularly xenografts can be rejected.

The greatest obstacle to large-scale clinical implementation of neural transplantation is probably the source of the cells: six to eight spontaneously aborted fetuses are needed for each successful treatment with fetal brain cells. In many countries, any use of aborted fetuses and abortion itself are highly controversial. Therefore, in the future alternative strategies must evolve. The ideal source of cells for transplantation should be available, reliable, survive well after grafting, and demonstrate functional effects.

5. *Sources of Cells*

5.1 *Embryonal Stem (ES) Cells*

There are a number of potential sources of cells for transplantation. Rapid advances in our ability to grow and manipulate stem cells in culture makes this technology a highly promising source of cells. Stem cells can provide a limitless source of neural cells for grafting. However, with human ES cells some ethical and religious issues may arise. Research on human ES cells is gradually gaining acceptance and legal support. A law was passed in the UK which allows the use of human ES cells for research, and Pope John Paul II, when addressing the 18th International Society for Transplantation meeting in Rome, expressed the approval of the Roman Catholic Church for ES research.

5.2 *Immortalized Cells*

The use of adult-derived, immortalized cell lines may circumvent the use of embryonal cells. These cell lines can be derived from rodent neuroepithelial stem or progenitor cell population, or even from human neuroepithelial tumor cell lines. When implanted into the rodent brain, these cells differentiate into both mature neurons and glia. Moreover, the implants take on the characteristics of the surrounding brain tissue—resembling cortex, cerebellum, or hippocampus when transplanted into each of these areas, respectively (Borlongan et al. 1998).

5.3 *Xenografts*

The use of xenografts may obviate the need to use any human tissue, and may be readily and cheaply available. A number of preclinical studies have demonstrated successful xenografts from rat to mouse, rat to monkey, human to rat, and monkey to human. Because the brain tends to reject grafts less than do other organs, transplantation of porcine fetal neurons into the human brain may be possible, with adequate immunosuppression. Still, lifelong immunosuppression carries significant risks. Another challenge is the risk of transmission of retroviruses from other species to the human population. Pigs have relatively few retroviruses in their genome compared with primates, yet the porcine retrovirus PERV is common enough to cause concern. Despite this controversy, a clinical study with fetal porcine neural transplants was initiated in 12 patients with PD. Initial results showed a very limited clinical response, with no evidence of infection with PERV. An autopsy case from this trial revealed very few surviving cells. A similar study in 12 patients with HD showed a favorable safety profile, but no clinical improvement after one year (Fink et al. 2000). Major challenges remain to the routine use of xenotransplantation for neurodegenerative diseases.

5.4 *Polymer-encapsulated Grafts*

Xenografts can be placed into polymer capsules which immunoisolate the cells and prevent them from being rejected. The membrane is made of a polymer (PAN-PVC or others) and engineered to have a specific morphology. It allows nutrients and active substances to pass freely, but blocks cells and large molecules such as immune globulins. Encapsulating the transplanted cells allows expansion to the sources of cells for transplantation-xenografts, which may be performed without immunosuppression. This type of graft may be utilized when continuous local delivery of active substances such as dopamine is desired. The implant can be retrieved if side effects occur (Emerich 1997). Encapsulated grafts producing dopamine resulted in behavioral recovery in the rat model of PD. Since the gene for HD is known and can be tested for, there is an opportunity to try a preventive strategy. The onset of the disease may be delayed by delivery of trophic factors, which support the cell population at risk. Experiments with encapsulated grafts in a monkey model of HD demonstrated neuroprotection by the graft. The neuroprotection strategy may be

applied to other degenerative diseases. The principle of this intervention is delivery of a trophic factor known to support the brain structure or cell population most at risk in that disease. Nerve growth factor (NGF) was used in models of Alzheimer's disease (AD), and ciliary neurotropic factor (CNTF) was utilized in preclinical and clinical studies in the treatment of amyotrophic lateral sclerosis (ALS).

5.5 Other Sources

Research of sources of cells and tissue for transplantation into the brain is very active. New directions are sought and old ideas are revisited in the search for treatments for the most devastating diseases of the brain. We can only mention some of the promising developments:

(a) Stem cells derived from adult rat bone marrow appeared to differentiate into macroglia and to improve outcomes in a rat model of stroke.

(b) Autologous dopaminergic cells may still be used to treat Parkinsonism if their function and survival can be improved. The carotid body is a source of dopaminergic cells, and some graft survival was reported after transplantation of these cells into rhesus monkeys.

(c) Neural progenitor cells are further along their development into mature neurons and glia than stem cells. Intensive research is going on to improve our ability to manipulate these cells and use them in transplantation.

(d) More than one type of cell can be transplanted together. Co-grafting of neural cells with various types of supporting cells may increase graft survival. Co-transplantation of neurons with Schwann cells from peripheral nerve in rodent models of spinal cord injury may enhance graft survival. Sertoli cells from the testis are known to secrete substances ranging from growth factors to immunomodulatory factors and may provide nutrients to the neighboring neurons. Co-grafting with Sertoli cells enhanced survival of dopaminergic neurons. Similar beneficial effects were seen when fetal kidney cells were used (Granholm et al. 1998, Hoffer and Olson 1997).

Interestingly, even grafts of supporting cells alone can be beneficial. Local delivery of a variety of trophic factors may account for this effect. Thus, whether we transplant neurons or not will depend on what we want to achieve with the graft, or on our treatment goal.

6. Other Implant Strategies

6.1 Gene Therapy and Brain Implants

Neuroprotection and other treatment goals may be achieved by cell implants combined with gene therapy. Direct implants of viral and other vectors are possible, in order to stimulate the host cells to improve or restore lost function. In a recent study, implants of a modified lentivirus (a human retrovirus modified so that it cannot replicate *in vivo*), engineered to carry a gene for human glial-derived neurotrophic factor (GDNF) were injected into the striatum of rhesus monkeys. Robust transduction of striatal cells with the gene was seen. The majority of the cells incorporating the gene were neurons. GDNF production and increased activity of dopaminergic neurons were seen both in aged monkeys with naturally low function of the dopaminergic system and in monkeys which received MPTP (Kordower et al. 2000).

Gene transfer may be combined with cell transplantation or used to enhance the success of other types of transplants. Adrenal medullary tissue is a source of dopaminergic cells, but the grafts displayed very poor survival and no significant therapeutic benefit was derived. Transfection of these cells with genes for trophic factors may enhance their survival.

All types of gene therapy are still experimental. Concerns include long-term safety and stability of the constructs. Expression of transgenes tends to diminish over time. In order to be useful for chronic human illness, extended expression and therapeutic effect have to be demonstrated.

7. Other Diseases and Conditions

So far, we have concentrated on two degenerative diseases of the brain. These were the first conditions in which experience was gained with cell transplantation in humans. In Parkinson's disease a clear benefit and success of neural transplantation was demonstrated. However, as the sources of cells and tissue for transplantation expand, and as new methods develop, transplantation research is expanding to include various conditions in the central nervous system (CNS). Among these are degenerative diseases such as AD and ALS, but also brain injury and stroke, and spinal cord injury. These are common conditions, and the leading causes of disability in the developed world.

7.1 Transplantation for Stroke

Nishino et al. (1993), and Grabowski et al. (1993) demonstrated successful transplantation of fetal cells in a rat model of stroke, with improvement in function both with a striatal and a cortical graft. More recent studies (Borlongan et al. 1998) show similar functional improvement with transplantation of a human immortalized neural cell line in a rat model of striatal infarction. The rationale for these studies was based on the success of transplantation for striatal damage in animal models of PD and HD. Local secretion of trophic factors and neurotransmitters probably played a role in the rapid functional gains. Further extensive

experimentation in rodent and nonhuman primate models is needed in order to understand the neurophysiology of transplantation for stroke and learn the parameters for successful transplantation.

7.2 Transplantation for Chronic Pain

The most common goal of neural transplantation is restoration of function in conditions where irreversible loss of neurons has occurred. However, if we consider that transplanted cells can deliver multiple beneficial substances locally, other medical problems become amenable to treatment with cell transplantation. Chronic pain syndromes are very common. Back pain alone permanently disables eight million Americans. Adrenal medullary transplants produce a variety of neurotrophic factors in addition to dopamine and opioid peptides. In the human spinal cord, endogenous opioids (endorphins) block pain sensation and dopamine potentiates opioid action. Experiments in animals and in a small number of human subjects demonstrated moderate to good improvement in pain after adrenal medullary allografts into the spinal canal (Sagen 1998). Encapsulated chromaffin cell grafts were also tried and may provide a similar effect without inducing an immune response (Aebischer et al. 1994).

8. The Future of Transplantation in the Brain

Cell transplantation and related implant strategies into the brain are constantly developing, expanding both the potential sources of cells for transplantation and the range of conditions that may be treated by these methods. This growth parallels our understanding of neuropathophysiology and human genetics, and our ability to manipulate mammalian cells in culture. Cell transplantation and other therapeutic biological implants have the potential to treat some of the most common and devastating diseases. However, even for Parkinson's disease, the technology has not yet advanced beyond experimental use.

Treatment of all types of brain injury with transplantation will require a better understanding of the conditions required for regeneration in the brain as well as further advances in our understanding of the pathophysiology of these diseases. It is likely that future transplantation efforts will make use of a combination of strategies under development at the beginning of the twenty-first century. For example, stem cells may be transplanted with peripheral cells (co-transplantation), and with a vector of gene therapy to improve the local conditions for survival and connectivity.

The long-term outlook for transplantation in the CNS primarily depends on our ability to improve the convenience, reliability, and availability of cells for transplantation, and on the efficacy of transplantation to correct functional deficits. Ultimately, the development of this field parallels advances in our knowledge of the basic mechanisms of cell development and differentiation.

Brain: Response to Enrichment

Can experience produce measurable changes in the brain? The hypothesis that changes occur in brain morphology as a result of experience is an old one. In 1815 Spurzheim asked whether organ size could be increased by exercise. He reported that the brain as well as muscles could increase with exercise 'because the blood is carried in greater abundance to the parts which are excited and nutrition is performed by the blood.' In 1874 Charles Darwin mentioned that the brains of domestic rabbits were considerably reduced in bulk in comparison with those from the wild because, as he concluded, these animals did not exert their intellect, instincts, and senses as much as did animals in the wild. However, it was not until the 1960s that the first controlled studies in animals demonstrated that enriching the environmental condition in which they were confined could alter both the chemistry and anatomy of the cerebral cortex and, in turn, improve the animals' memory and learning ability.

In these early experiments only the brains of young animals were studied. Although many were impressed to learn that the cerebral cortex could increase its thickness in response to enriched living conditions, they raised the question about whether enrichment might similarly affect older animals. Once middle-aged rats' brains showed positive responses to enrichment, the next step was to experiment with very

old animals. Once again, increases in cortical thickness were found. It then became important to discover what was responsible for these changes.

One step at a time, the level of morphological changes—from neuronal soma size, to number and length of dendrites, to types and numbers of dendritic spines, to synaptic thickening, to capillary diameter, and to glial types and numbers—was examined. Age, gender, duration of exposure, etc. were critical variables that had to be tested in new experiments.

Most of the basic data reported on the enrichment paradigm and its impact on brain and behavior have accumulated through studies on the rat. Effects of enriched and impoverished environments on the nerve cells and their neurotransmitters in the cerebral cortex have now been generalized to several mammalian and avian species (Rosenzweig and Bennett 1996). Some corroborating studies mentioned herein involved cats and monkeys, as well as isolated studies in human subjects. For example, Jacobs et al. (1993) using an isolated portion of the human cerebral cortex responsible for word understanding, Wernicke's area, compared the effects of enrichment in tissue from deceased individuals who had had a college education and from those who had had only a high school education. They demonstrated that the nerve cells in the college-educated showed more dendrites than those in the latter. (Tissue was obtained from the Veterans' Hospital in west Los Angeles.) Experiments on human tissue frequently support the data obtained from studies in the rat, and, in turn, benefit from these animal studies. We can now safely say that the basic concept of brain changes in response to enrichment holds true for a wide variety of animals and for humans.

1. *The Effects of Enrichment on the Cerebral Cortex*

What do we mean by *enrichment* for the rats that have served as the animal of choice for most of these studies? Thirty-six Long-Evans rats were sorted into three experimental conditions using 12 animals in each group: (a) enriched, (b) standard, or (c) impoverished environments. All animals had free access to food and water and similar lighting conditions. Eventually, it was determined that animals maintained in their respective environments from the age of 30 days to 60 days developed the most extensive cerebral cortical changes. For the enriched environment, the 12 animals lived together in a large cage ($70 \times 70 \times 46$ cm) and were provided five or six objects to explore and climb upon (e.g., wheels, ladders, small mazes). The objects were changed two to three times a week to provide newness and challenge; the frequent replacement of objects is an essential component of the enriched condition. The combination of 'friends' and 'toys' was established early on by Krech as vital to qualify the experiential environment as 'enriched' (Krech et al. 1960). For the standard environment, the animals were housed three to a small cage ($20 \times 20 \times 32$ cm) with no exploratory objects. For the impoverished environment, one animal remained alone in a small cage with no exploratory objects.

The numbers of animals placed in these separate conditions were based on the manner in which the routine housing was established in the rat colony. Three rats in a cage has been considered standard for all experimental work over the decades. Since prior to these experiments no one had designed studies to examine brain changes in response to different environmental conditions, the decisions about what represented 'impoverishment' and what represented 'enrichment' was more arbitrarily than scientifically reasoned.

After 30 days in their respective environments, all animals were anesthetized before the brains were removed for comparison among the three groups. Twenty micra frozen sections were cut and stained, and the thickness of the frontal, parietal, and occipital cortices were measured. Results indicated clearly that the cortex from the enriched group had increased in thickness compared with that living in standard conditions, whereas the brains from the impoverished group decreased compared to the standard. Because the nerve cells were farther apart in the enriched vs. the impoverished brains, it was thought that the major component of the brain changes due to enrichment had to do with alterations in the dendritic branching. With more detailed studies, the cortical thickness increases were found to be due to several factors, including increased nerve cell size, number and length of dendrites, dendritic spines, and length of postsynaptic thickening as measured on electron microscopic pictures of synapses (Diamond et al. 1964, Diamond 1988).

In the initial experiments designed to explore the impact of an enriched environment on the brain of postweaned rats, only enriched and impoverished groups were used. Rats were maintained in their respective environments from 25 to 105 days of age because there were no available data on how long it would take to create chemical or structural changes in the cortex. Chemical and anatomical measurements taken from these animals showed significant differences between the two groups in cortical thickness, cortical weight, acetylcholinesterase, cholinesterase, protein, and hexokinase levels (Bennett et al. 1964, Diamond et al. 1964). In these initial experiments, however, it was not clear if the changes were due to enrichment or impoverishment because there were no standard conditions established as controls.

Nonetheless, the differences in cortical thickness with this 80-day exposure to the two environmental conditions were not as great as during the 30-day exposure. Consequently, in subsequent experiments, the period of exposure to the experimental conditions was reduced from 80 days to 30 days, then 15 days,

seven days, and finally to four days. At each of these intervals, animals from the enriched environment showed increases in cerebral cortical thickness in some areas but not in others. For example, in the male animals exposed for 80 days to enriched conditions, the somatosensory cortex did not show significant changes, whereas male animals exposed for 30 days did develop significant differences in the somatosensory cortex. The occipital cortex showed significant changes for both the 80- and the 30-day experiments, but, again, the differences were greater at 30 days than at 80 days. It is possible that the longer exposure served to increase cortical thickness in the early days of enrichment but that over time the environmental condition became monotonous and this effect decreased. In later experiments the experimental conditions were modified to try to establish what the major factors were that created the observed cortical changes. For example, was the effect associated with the number of rats exposed or to the presence of stimulus objects?

The new conditions included one rat living alone in the large enrichment cage with the objects that were changed several times each week. The cortices of these rats did not show a significant effect of enrichment. Twelve rats living together in the large cage without the stimulus objects did not show as great an effect as 12 rats living with the stimulus objects. In other words, the combination of social conditions and frequent exposure to new stimulus objects was necessary for the animals to gain the full effect of enrichment.

Establishing what constitutes 'enrichment' for human beings is more problematic. Not only are controlled experiments not feasible, but no two human brains are identical. Individuals differ in their genetic backgrounds and environmental inputs. Furthermore, what is considered enrichment for one individual may be quite different for another. Yet, as mentioned earlier, the enrichment effect was evident in Wernicke's area from measurements of the amount of dendritic branching in brain tissue from college-educated individuals versus that from high school-educated people. The basic finding of dendritic growth in response to environmental stimulation appears in all brains studied to date. It would appear that newness and challenge are important for the human cortex as well as for that of animals.

2. *Independent Variables: Age and Gender*

Among the many variables researchers must consider as they seek to understand and accurately interpret the effects of enrichment on the brain, age and gender are important considerations. Enrichment has been shown to enhance many aspects of cortical structure at any age—from prenatal to extremely old rats (904 days of age). The amount of change varies with the age of the animal. For example, when a 30-day-old rat is put in an enriched environment for four days, the effects are not as pronounced as they are in the 60-day-old rat maintained in enriched conditions for four days. Is four days too short a time for the very young animal to adjust and benefit from enrichment? A young animal maintained for 30 days in an impoverished environment shows reduced morphological development of its cortex when compared to that of an adult animal maintained in impoverished conditions for 30 days. In further age-related experiments, another component was added to the enrichment conditions of old rats. Despite significant increases in the length of the dendrites in the brains of 600-day-old rats that had been placed in an enriched environment for 30 days (600 to 630 days), several of the old rats in this population died.

To determine whether the enrichment conditions could be modified to extend the animals' lifespan, the investigators added a new component: hand-holding the rats each day for several minutes while the cages were cleaned. In an attempt to increase the lifespan of the rats, rats were placed three to a cage after weaning at 25 days of age, and maintained in these standard conditions until they reached 766 days, at which time half went into enriched conditions until they reached 904 days of age and half stayed in the standard conditions. The only variable added was the daily hand-holding of the rats as they aged. Is it possible that handling the rats had extended their lifespan? Indeed, many investigators have been amazed that these rats survived to 904 days of age. The 904-day-old rats in enriched conditions developed a cortex significantly thicker than the cortex of rats living in the standard conditions (Diamond 1988). These experiments offered support to the thesis that the cerebral cortex is capable of responding positively to an enriched environment at *any* age.

Experiments comparing the effects of enrichment on male and female brains are few. Most enrichment studies have been carried out on male brains to avoid the compounding factors associated with the estrous cycle. In one study focused on gender, the female neocortex was found to respond differently from the male neocortex exposed to the same type of enrichment conditions (Diamond 1988). The male showed significant changes in cortical thickness in the occipital cortex, but no significant changes in the somatosensory cortex. (Although the right cerebral cortex in the brain of the male rat is thicker than the left, especially in the visual or occipital region, an enriched environment appears to alter both the right and left cortex similarly.) In the female, the thickness of the occipital cortex increased significantly in response to enrichment, although not as much as in the male, but the thickness of the somatosensory cortex increased significantly more in the female than in the male. In a follow-up experiment, however, in which obstacles were piled up in front of the female's food cup to provide a greater challenge to her already enriched

environment, the thickness of the occipital cortex increased as much as did that of the male without the additional challenge.

In rats whose testes were removed, either at birth or at 30 days of age before the rats were placed in an enriched environment for 30 days, the increases observed in cortical thickness were similar to those of their littermates with intact testes (Diamond 1988). These findings suggested that testosterone is not implicated in the increases in cortical thickness observed in the brains of rats living in enriched environments. Since sex differences were evident in the responses of the animals to enrichment, interest was now focused on the brains of pregnant rats, in which the concentrations of sex steroid hormonal concentrations are greatly altered. The brains of female rats living in the enriched environment from 60 to 90 days and then becoming pregnant and returning to enrichment until 116 days of age were compared between nonpregnant and pregnant animals living in an impoverished environment for the same time periods. When animals from the two groups were autopsied at 116 days, no significant differences in cortical thickness were found. Evidently, pregnancy has an effect on the cerebral cortex regardless of whether the environment is impoverished or enriched.

These initial experiments, all of which were replicated, clearly indicate gender differences in the brain's response to enrichment. Having dealt with the independent variables, we turn to the impact of dependent variables in the enrichment paradigm. For these studies, one must look at: duration of exposure, brain anatomy and chemistry, presence of lesions or fetal neocortical grafts, negative air ions, stress, physical activity, and nutrition, as well as behavioral effects. These are discussed in turn below.

2.1 Duration

The duration of exposure to the enriched environment is clearly a significant dependent variable that must be factored into research in this area. As short a period as 40 minutes of enrichment has been found to produce significant changes in RNA and in the wet weight of cerebral cortical tissue sampled. One day of enrichment was insufficient to produce measurable changes in cortical thickness, whereas four consecutive days of exposure (from 60 to 64 days of age) to an enriched environment did produce significant increases in cortical thickness, but only in the visual association cortex (area 18) (Diamond 1988).

When young adult rats were exposed to 30 days of enrichment, however, the entire dorsal cortex, including frontal, parietal, and occipital cortices, increased in thickness. Extending the duration of the stay in enriched conditions to 80 days did not produce any greater increase in cortical thickness than that seen at 30 days (in fact, it was often even less); however, the longer the rat remained in the enriched conditions, the longer the cortex retained its increased dimensions following return to the standard environment (Bennett et al. 1974). When we looked at age-related differences in the context of duration of stay in the enriched environment, we found that old rats (766 days of age) placed in enriched conditions for 138 days showed an increase in cortical thickness that was quite similar to that observed in young adult rats (60 days of age) that had lived in enriched conditions for 30 days.

2.2 Anatomical and Chemical Components

Early experiments, and those to follow in subsequent years, again demonstrated significant differences in brain chemistry and anatomy associated with enriched living conditions. Anatomical increases include all of the structural constituents measured in the cerebral cortex to date, such as cortical thickness (Diamond et al. 1964), nerve cell soma size, nerve cell nuclear size (Diamond 1988), dendritic dimensions (Holloway 1966, Greenough et al. 1973), dendritic spines, synaptic size and number (Mollgaard et al. 1971, Black et al. 1990), number of glia, capillary diameter (Diamond 1988), dendritic number after lesions (McKenzie et al. 1990), and successful tissue grafts (Mattsson et al. 1997). Chemical increases include: total protein, RNA-to-DNA ratio, cholinesterase-to-acetylcholine ratio, Nerve Growth Factor mRNA, cyclic AMP, choline acetyltransferase, cortical polyamines, NMDA (N Methyl D Aspartate) receptors, and hexokinase, etc.

2.3 Lesions

Another variable has to do with the impact of enriched conditions on purposefully incurred brain lesions. In a 1990 study, 60-day-old rodents were exposed for 30 days to either an enriched or standard environment two days after having received a lesion in the left frontal cortex that created a motor dysfunction in the right forepaw. Animals living in the enriched condition showed significant increases in cortical dendritic branching in both hemispheres, the lesioned and the non-lesioned sides, along with a significant return of motor function in the right forepaw compared to those animals living in standard conditions (McKenzie et al. 1990).

2.4 Fetal Neocortical Graft

Similarly, providing an enriched environment to rats that had undergone fetal neocortical grafts one week

after lesioning was found to improve behavior and to reduce the atrophy in the thalamus, a major structure beneath the cortex that supplies neural input to the cortex (Mattsson et al. 1997). The fact that the fetal neocortical graft when placed in the lesioned cerebral cortex could prevent atrophy in the underlying thalamus as a consequence of enrichment is of great interest to researchers considering the future possibility of using such grafts for brain-damaged individuals.

2.5 Air Ions

The possibility that physical environmental stimuli other than those classically regarded as 'sensory' could have an effect on the brain was tested experimentally by exposing rats living in enriched or standard environments to high concentrations of negative air ions. The experiments were undertaken to determine whether the effect of negative ions on serotonin, the putative second messenger cyclic-AMP, and on cyclic GMP in the cerebral cortex, differ depending on whether the animals lived in enriched or standard conditions. Studies demonstrated that rats placed in the enriched environment in the presence of enhanced negative air ions (ion density of 1×105) showed a significant decrease in serotonin, an effect not found in the brains of animals living in standard conditions (Diamond et al. 1980). Measurements of cyclic AMP decreased as well in the brains of the animals living in the enriched conditions, but cyclic GMP did not. These results indicate the importance of considering air quality and atmospheric conditions in determining the brain's response to enrichment.

2.6 Stress

The presence or absence of stress represents yet another variable to be taken into consideration in such studies, certainly so in any extrapolation of these findings to humans. Stress is a major factor in contemporary, fast-moving urban life. Crowding, for example, is deemed stressful under conditions where competition for space or food is likely. Experiments were set up to assess the effect of crowding on the brains of rats maintained in an enriched environment. To create a condition in which crowding would be experienced as stressful, 36 rats were placed in an enrichment cage usually housing only 12 rats, and kept there for 30 days. The results indicated that, compared with rats living in standard conditions, the thickness of the medial occipital cortex increased significantly whether the enrichment cage housed 12 or 36 animals (Diamond et al. 1987). One hypothesis to come from this study was that the animals' interaction with the toys might be diverting their attention or entertaining them sufficiently to mitigate the stress of the crowded condition.

Chronic stress has been reported by Meaney et al. (1988) to produce excess glucocorticoids, which are toxic to neurons—especially those of the hippocampus. Aged rats are particularly vulnerable to chronic stress. The investigations of Meaney showed that enriching the living conditions of old rats, or handling them in their infancy, helps to prevent stress-related hippocampal damage.

It is possible that stress can be produced by increasing the frequency with which the various objects in the enrichment cage are changed. In all previous studies, objects had been replaced daily or at least several times each week. Then the question was asked whether increasing the frequency of changing the objects would further increase the growth of the cortical thickness, or, alternatively, would it be experienced as a stress factor, given that the animals were inhibited from interacting with them in the more leisurely manner to which they were accustomed? For these experiments, rats 60 to 90 days of age found their objects changed every hour for three hours on four nights of each week for four consecutive weeks. Under this regime, the cerebral cortical thickness did not grow significantly compared to cortices from rats whose objects were changed several times each week for four weeks (Diamond unpublished).

Corticosteroids, released under stress, have been shown to reduce cortical thickness and future experiments would be necessary to compare differences in corticosteroid levels in animals exposed to these differing conditions.

2.7 Behavior

Psychologists have known for a long time that early experience influences the adult performance of an animal. In experiments in the 1950s (Bingham and Griffths 1952, Forgays and Forgays 1952) investigators were interested in determining how much experience in complex environments was necessary to produce a highly intelligent adult animal and when, specifically, during early life these experiences had to occur. These studies showed that all of the animals maintained in enriched conditions were better problem-solvers than those with no enrichment; however, in some other occasions, using other tests, enriched rats did not perform significantly better than controls.

One of the most robust effects of environmental enrichment on the behavior of rats appears in the areas of learning and memory. Investigators (York et al. 1989, Kempermann et al. 1997) studying the effects of enrichment in the rat brain have reported that new nerve cells develop in the adult dentate gyrus, an area dealing with recent memory processing. In the York

experiments the rats were 60 to 90 days of age (truly adult animals) during the enrichment experience, whereas in the Kempermann experiments the mice were 21 to 40 days of age. These findings are significant because neurogenesis had not previously been found in the cerebral cortex of the mammalian adult. Earlier studies had found that enriched environments stimulate the growth of dendrites in the dentate gyrus, and only in female rats (Juraska et al. 1985).

2.8 Physical Activity

One component of enrichment is the physical exercise involved in the animals' having to move about the cage, interacting with and climbing upon the novel objects. These activities appear to influence the motor cortex as well as the hippocampus. Olsson et al. (1994) showed that rats living in enriched environments at 50 days of age showed higher expression of the gene-encoding glucocorticoid receptors and induction of genes for Nerve Growth Factors in the hippocampus.

2.9 Nutrition

Nutrition is clearly an important variable to consider in all studies dealing with brain and behavior. Environmental enrichment and impoverishment have pronounced effects on nutritionally deficient animals. One study compared the effects of environmental enrichment on the offspring of mother rats living on protein-rich or protein-deficient diets during pregnancy (Carughi et al. 1990). The protein-rich diet proved beneficial for the healthy development of the cerebral cortical dendrites in young rats and even more so when combined with an enriched environment.

The cerebral cortical dendrites in rat pups from mothers with a protein-deficient diet were significantly less well developed than those of their counterparts, but, of greater importance, the cortex from the protein-deficient animals did not significantly increase with enrichment. However, when protein-deficient pups were fed a protein-rich diet and maintained in an enriched environment during their early postnatal life, cortical development improved almost to the level seen in rat pups from mothers on a high-protein diet during pregnancy followed by postnatal enrichment. These data are very encouraging, because they suggest the possibility of making up for lost brain growth during pregnancy by enriching both the diet and the environmental conditions during the postnatal period.

Another dietary factor significant to optimal brain function is glucose. The brain depends almost exclusively on glucose for its energy. Synapses use a great deal of energy and glucose supplies this energy. Although we know that different parts of the brain use glucose at different rates, to learn which of 30 discrete brain regions were most active in adult rats placed in enriched living conditions from 57 to 87 days of age, we studied their radioactive glucose uptake during this 30-day period and compared it with that of rats raised in standard conditions (Diamond 1988). Again, the cerebral cortex showed the greatest differences between enriched and nonenriched groups, but, surprisingly, of the two groups, glucose uptake was lower in rats maintained in enriched conditions. We concluded from this finding that glucose uptake is more efficient in the brain of animals living in enriched environments. Out of the 30 areas of the brain measured, including the cortex, only one area showed significantly greater glucose uptake in the enriched animals: the corpus callosum, specifically, the large mass of axons connecting the nerve cells between the two cerebral hemispheres. Could the axons forming the corpus callosum from the nerve cells in the cerebral cortex be more active than the nerve cell bodies from which they arise? Yet the right and left cerebral cortices show comparable cortical thickness increases with enrichment due to the effects on dendritic branching, but now the data show that the rates of glucose utilization in both the frontal and parietal cortices were 13 percent lower in the enriched rats than in the standard control rats, a paradox to be untangled in the future.

3. Methodological Issues Associated with Enrichment Research in Humans

Of the vast number of animal studies that yield results of interest to human research, studies on the impact of an enriched environment on brain development and behavior can be of enormous interest to humans. Despite similarities in some key respects between the brain of the rat and other mammals, replicating or extrapolating from anatomical and chemical studies conducted in animals is fraught with difficulty, for obvious reasons. Not only is it not presently possible to control all of the experimental variables at work in humans, but the diversity and complexity of human experience militates against designing experiences comparable to those used with lower animals. Nevertheless, these studies and those few human studies that have been done suggest that there are measurable benefits to enriching an individual's environment in whatever terms that individual perceives his immediate environment as enriched. At the very least, this work indicates that there are many opportunities for enhancing brain activity and behavior at all ages, and that they can have pronounced effects throughout the lifespan.

Brain Stimulation Reward

1. *The Discovery and its Context*

Brain stimulation reward was discovered in 1953 by James Olds and Peter Milner (1954; see also Olds 1973, Milner 1989), who had come to McGill University to work with D. O. Hebb, inspired by his groundbreaking theoretical work. In contrast to the dominant behaviorist orthodoxies of the day, which isolated psychology from the emerging disciplines of neuroscience and cognitive psychology, Hebb's views linked brain, mind, and behavior.

New findings and ideas about the neural bases of motivation and reinforcement provided a rich context for the discovery of BSR (Valenstein 1973). For example, the demonstration that lesions of different hypothalamic nuclei could lead either to massive overeating or starvation contributed to a seminal physiologically based theory of motivation (Stellar 1954). In that era, English-speaking investigators became familiar with Hess' use of electrical stimulation to map the hypothalamic control of autonomic outflow and behavior. Among Hess' observations were stimulation-elicited responses suggesting states of rage or fear. Shortly before Olds and Milner's discovery, Delgado, Roberts and Miller (Delgado et al. 1954) showed that cats would learn to escape electrical stimulation of certain deep forebrain structures. An-

other key component of the context was research linking brainstem circuitry to the control of arousal and vigilance. The pattern of connections between nerve cells in the brainstem region of interest was seen as net-like ('reticulated'); thus the region was dubbed the 'reticular formation.'

At the time that Olds joined Hebb's group, Milner and Seth Sharpless, another graduate student, had developed a theory linking reticular activation to positive reinforcement, the process by which desirable outcomes strengthen the behaviors that produce them. However, their experimental tests of this idea proved disappointing: if anything, the rats tended to avoid locations in a maze where stimulation of the reticular formation had been delivered.

A strikingly different reaction was noted in a rat prepared by Olds, in which the electrode somehow missed its reticular-formation target and ended up instead in the basal forebrain. This subject returned repeatedly to the location where stimulation had been delivered. The behavior of this rat was readily shown to be the product of learning. As the experimenters altered the location in the maze where the stimulation was delivered, the animal's behavior changed accordingly, and it directed its searching towards the site where it had most recently hit pay dirt. Within hours of the initial discovery, Olds succeeded in training the rat to press a lever that triggered delivery of the stimulation. This animal worked indefatigably to stimulate its own brain; such behavior has since been termed 'intracranial self-stimulation' (ICSS).

In the initial report published by Olds and Milner (Olds and Milner 1954), they presciently discuss their findings 'as possibly laying a methodological foundation for a physiological study of the mechanisms of reward.' Indeed, their paper was the well-spring for thousands of subsequent experiments.

Why did the report by Olds and Milner have such a large and enduring impact? Perhaps paramount is the promise their results offered that psychological phenomena such as learning, reinforcement, and motivation could be investigated fruitfully by physiological means. The authors also pointed out that the phenomenon of BSR could be used to distinguish between competing behavioral theories. For example, a prominent theory at the time held that reinforcement arose from the reduction of a drive, such as the abatement of hunger. This view is not easily reconciled with the findings that rewarding stimulation of many sites arouses the animal rather than calming it and that stimulation of some BSR sites can also induce sated animals to engage in consummatory behaviors such as eating and drinking.

2. *Lines of Inquiry*

Many of the principal questions about BSR can be subdivided under the headings, 'where,' 'why,' and 'how.' The 'where' questions include the mapping of BSR sites in the brain, the identity of the key neural populations, and the interconnections between these cells. The 'why' questions concern the functional significance of the phenomenon: how is BSR related to the rewarding effects of natural stimuli and of habit-forming drugs? The 'how' questions are mechanistic in nature: what set of neural and psychological processes translate the transient stream of nerve impulses elicited by the stimulation into goal-directed behavior and an enduring record of the rewarding effect?

2.1 *Where?*

The sites where BSR can be produced occupy a substantial proportion of the brain volume. Positive sites are distributed from the olfactory bulbs, at the front of the brain, to the nucleus of the solitary tract, at the back, and are found both in cortical and subcortical regions of the forebrain.

The identification of the cells underlying BSR continues to be a major challenge. Progress has been made in characterizing such neurons (Shizgal and Murray 1989; Yeomans 1990; Shizgal 1997), but their identity has not yet been established firmly at any BSR site. The best-characterized sites lie along two major pathways, the medial forebrain bundle (MFB) and fibers coursing near the mid-line of the brainstem. In both cases, the neurons that carry the reward-related signal away from the electrode tip include cells with relatively fast-conducting, longitudinally oriented, myelinated axons. This characterization narrows down the field of plausible candidates, but it leaves open many possibilities.

Lesions of several structures have been shown to weaken the rewarding effect. For example, following damage to a basal forebrain region that includes the sub-lenticular extended amygdala, the strength of MFB stimulation must be increased markedly in order to support self-stimulation. However, there is substantial across-subject variation in the effect of these and other lesions on ICSS. Explanations of this variability have been offered but have not yet been substantiated (Shizgal 1997).

Pharmacological methods have implicated several neurotransmitter systems in BSR. There is a large body of evidence tying dopamine-containing neurons to the rewarding effect (Wise and Rompré 1989). For example, manipulations that enhance transmission in these cells potentiate BSR and manipulations that decrease dopaminergic neurotransmission weaken the rewarding effect. The dopamine-containing neurons that project from the ventral tegmental area of the midbrain to the nucleus accumbens, a structure at the base of the anterior forebrain, have been singled out as particularly important. The modulation of BSR by manipulation of acetylcholine- and serotonin-containing neurons in the brainstem may be due to facilitatory and inhibitory interactions of these cells with dopaminergic neurons. Despite the considerable evidence

linking dopaminergic neurons to BSR, the nature of their contribution has not yet been established firmly. The directly activated neurons responsible for self-stimulation of the MFB and periaqueductal gray include non-dopaminergic cells (Shizgal and Murray 1989). Do dopaminergic neurons relay the output of the directly activated neurons to later stages of the circuitry or do the dopaminergic neurons serve to gate transmission at key synapses? Difficulty in reconciling certain key findings is a further indication that the last word about the dopaminergic contribution to BSR has not yet been written. For example, injection into the nucleus accumbens of dopamine receptor blockers decreases the effectiveness of rewarding MFB stimulation (Nakajima and O'Regan 1991), yet failure to detect release of dopamine in the nucleus accumbens following prolonged self-stimulation of the MFB has been reported, despite the use of very sensitive measurement methods (Garris et al. 1999).

2.2 *Why?*

A rat may spend hours on end doing little else but pressing a lever to deliver brief trains of electrical pulses to MFB neurons. Showing few signs of fatigue or habituation, the rat continues to approach and vigorously press the lever. If the lever is in a large enclosure and the rat is displaced to a distant corner, it will gallop back immediately. What is it about the brief burst of nerve impulses triggered by the electrode that causes the rat to focus so resolutely on obtaining more stimulation?

Since the early days of research on BSR, it has been suspected that the stimulation mimics effects of natural goal objects, such as food and water. Indeed, MFB stimulation has been shown to compete with, summate with, and substitute for rewards such as sugar solutions or food pellets. Differing views have been offered as to the nature of the effects that the stimulation mimics. For example, it has been argued that the stimulation mimics the overall utility of natural goal objects rather than specific sensory attributes such as texture, taste, and temperature (Shizgal 1999). This view is based on evidence that BSR is represented by a unidimensional neural code and that natural rewards of different types (e.g., solutions of sugar or salt) can summate with the rewarding effect of stimulating a single brain site. However, it has also been shown that food or water deprivation can alter preference between stimulation of different brain sites (Gallistel and Beagley 1971) and that the potentiating effect of chronic food restriction is seen only at some MFB sites (Blundell and Herberg 1969). Moreover, the fat-signaling hormone, leptin, has opposite effects on self-stimulation of different brain sites, depending on whether or not the rewarding effect is sensitive to chronic food restriction (Fulton et al. 2000). The unidimensional coding hypothesis could be reconciled with such findings if different subsets of neurons represented the utility of different categories of natural goal objects and the outputs of these multiple populations of cells converged onto a final common path.

Much work has been done to assess the effects on BSR of drugs such as cocaine, amphetamine, heroin, and nicotine (Wise 1996). These drugs have been shown to increase the effectiveness of the rewarding stimulation; reward effectiveness has also been shown to decrease during drug withdrawal. Such findings suggest that the neural circuitry responsible for BSR may play an important role in the habit-forming effects of drugs. Results of a study employing functional magnetic resonance imaging are consistent with such a view. Regions containing cells suspected of contributing to the rewarding effect of MFB stimulation in rats, such as the sub-lenticular extended amygdala and nucleus accumbens, showed activation during the expectation and/or the experience of cocaine-induced euphoria in humans (Breiter et al. 1997).

2.3 *How?*

The signal injected by the stimulating electrode can be regarded as having two destinations. The first is in the real-time control of ongoing behavior. This is illustrated particularly clearly in the case of electrodes that produce 'pure' rewarding effects without recruiting significant aversive effects as well. If the experimenter delivers a prolonged stimulation train through such an electrode and then turns it off, the rat will immediately turn it back on. Such observations have led theorists to link BSR with homing mechanisms that potentiate ongoing behaviors yielding high payoffs while terminating behaviors with negative outcomes. In such a view, the electrode activates the neural circuitry that estimates ongoing payoffs so as to signal a high return (Shizgal 1999).

The results of numerous experiments demonstrate that information about the strength of the rewarding effect is stored. This can be seen informally in the eagerness of experimental subjects to gain entry to the test cage and formally in the dependence of approach tendencies on the strength of the stimulation delivered on preceding trials. Thus, it has been argued that the second destination of the signal injected by the stimulating electrode is a memory record of some kind (Gallistel, Stellar et al. 1974).

3. *Methodological Issues*

In order to identify the neurons responsible for the rewarding effect, the investigator must have a good *a priori* sense of the quarry. Thus, methods for inferring characteristics of the reward signal and the neurons that produce it are of paramount importance to identifying the cells responsible for BSR (Yeomans 1990). Another aspect of the problem of reward

measurement concerns the distinction between performance and competence. When a rat ceases to respond for BSR following a lesion or administration of a drug, has the value of the BSR decreased or is the subject simply having trouble performing the required response? Practical approaches for distinguishing changes in performance capacity from changes in reward have been developed (Miliaressis et al. 1986), and these methods appear far superior to those used in the early days of research on BSR.

Research on the determinants of instrumental performance has evolved in parallel with work on BSR. Since the pioneering work of Olds and Milner, the 'matching law' was introduced (Davison and McCarthy 1988), offering a reasoned basis for inferring the strength of reward from performance. According to the matching law, the investment of behavior in competing activities is proportional to their relative payoffs. If so, relative reward strengths can be inferred from indices of performance such as time allocation or response rates. Although ideas based on the matching law have been applied to the scaling of BSR (Gallistel and Leon 1991), the validity of the law remains controversial. One promising line of attack extends the matching law by application of ideas from microeconomics, in particular the theories of consumer choice and labor supply (Kagel et al. 1995).

In parallel with the development of scaling methods, there has been dramatic progress in the development of physical methods for observing and manipulating neural activity. Methods for measuring the activity of single neurons and the release of neurotransmitters in behaving subjects have been applied successfully to the study of BSR. A wide array of lesion methods is now available, including methods for targeting specific neurotransmitter systems and for damaging cells on the basis of their projection fields. The promise of applying these methods to the study of BSR is far from having been exhausted. Dramatic progress has also been made in neuropharmacology, providing investigators with precise descriptions of receptor types and distributions, and increasingly selective tools for manipulating neurotransmission. Application of techniques from molecular biology has been used to visualize neurons activated by rewarding stimulation, and new methods for genetic manipulation promise very specific means of testing the roles in BSR played by particular neurotransmitters and receptors.

4. Future Directions

One likely direction for future work on BSR would combine advances in the scaling of reward with new techniques for measuring and manipulating neural activity. Such work offers the promise of achieving a fundamental goal that has as yet proved elusive: identifying the directly activated neurons responsible for the rewarding effect. Finding these cells would provide a solid base from which to trace inputs and outputs, to test theories of the natural function of the circuitry underlying BSR, and to determine how dopaminergic neurons contribute to BSR.

Electrical brain stimulation provides fine control over the timing and strength of reward, thus rendering BSR a promising tool for investigating basic questions in the decision and behavioral sciences. For example, there is a lively debate in decision science concerning the role of temporal patterning in the evaluation and choice of hedonic stimuli. This issue can be addressed in laboratory animals via the BSR paradigm.

The development of functional brain imaging methods has seeded many fruitful collaborations between cognitive scientists and neurobiologists studying human subjects. Applying these methods in behaving laboratory animals should make it possible to map neural activation evoked by rewarding brain stimulation and to compare it to the distribution of activation induced by natural rewards.

Solving the puzzle of BSR has likely proved harder than was anticipated in the heady years following the initial discovery. However, progress continues to be made, and there are grounds for cautious optimism concerning future prospects. Working out the mechanisms and circuitry underlying this intriguing phenomenon promises to pay rich dividends for our understanding of the neural foundations of both adaptive and maladaptive behaviors.

British Cultural Studies

One of the markers of contemporary studies in the humanities and social sciences is the close, critical attention directed onto the mass media and popular culture. British cultural studies, emerging out of the expanded English university system in the 1970s, were among the first to develop and broadly disseminate the methodologies and approaches which made such attention possible. Focusing initially on the relations between language and ideology through the close analysis of media texts, before diversifying into a broad range of interdisciplinary activities—cultural theory, cultural history, ethnography, media studies, and the analysis of the social construction of gender, race and identity—British cultural studies has played a fundamental role in establishing the conceptual and theoretical agenda for studies of popular cultural forms and practices.

1. *The Analysis of Popular Culture*

Academic disciplines in the humanities and social sciences took some time to accept the need to understand properly the power and influence of the mass media in Western societies. The spread of a transnational commercial popular culture, apparently disconnected from specific local cultures and disseminated through advertising and marketing, was seen by many in the academy as a threat to traditional or civilized values which should simply be repudiated. Within the British university system until the end of the 1960s, the task of analyzing and evaluating popular culture had been taken on by the discipline of English. However, the methods supplied by training in literary studies were suited for making esthetic and moral distinctions that proved inappropriate as a means of understanding the appeal of popular cultural forms such as film, television, or popular music. It was gradually acknowledged that popular cultural forms served a very different social function for their audiences than that served by high art for its audiences. Cultural studies was a product of the consequent recognition of the necessity of finding new ways of understanding the specific social functions of popular culture. Although it was partly a product of literary studies, the methods it developed had to be very different.

The starting points for this project are usually seen (Turner 1996) to be Richard Hoggart's account of the clash between an 'organic' English working class culture and mass mediated popular culture, *The Uses of Literacy* (1958), and Raymond Williams' history of cultural change in an industrializing England, *Culture and Society 1780–1950* (1958). The debates generated by these books set the conditions within which Hoggart established the Centre for Contemporary Cultural Studies (CCCS) at the University of Birmingham in 1964. In 1968, he was succeeded as Director of the CCCS by Stuart Hall, who played a major role in developing methods of analysis for popular cultural forms over the next two decades. In particular, Hall's work during the 1970s provided a very important conduit through which theoretical developments from France, by Barthes around post-Saussurean semiotics and by Althusser around the workings of ideology (Hall 1977), reached an English readership.

Initially, the analyses of popular culture which emerged from this tradition were highly political critiques of the ways ideology was embedded in language. Close analysis of media 'texts' (specific examples of media practice exposed to detailed study)

was employed as means of explaining how social understandings were carried and reinforced by the mass media, and how these social understandings were structurally inclined to be those supported by the state or the interests of market capitalism (Hall et al. 1978). However, by the latter half of the 1980s, British cultural studies had distanced itself from the notion that the media was simply a means of reinforcing the ideological interests of capital or the state. Instead, it had acknowledged the alternative possibilities suggested by such writers as Dick Hebdige (1979) during the late 1970s and began to investigate how popular cultural forms might also serve the interests of those who consume them. This produced a more positive reading of popular culture, and a more nuanced and contingent set of expectations about the specific interests served by popular cultural forms at particular historical conjunctures (Fiske 1987). Among the results of this focus over the 1980s was a significant expansion of the field, as a broad range of studies of television, popular music, the print media, fashion, media audiences, and youth subcultures were published, and as cultural studies established itself at undergraduate and graduate level in universities in the UK, the USA, Canada, Australia, and elsewhere. As the various forms of cultural studies proliferated (borrowing methods from history and anthropology as well as literary studies and sociology), the relative distinctiveness of the British tradition began to dissipate.

By the early 1990s, this reorientation of the field and modes of analysis had exposed cultural studies to the accusation of 'cultural populism' (McGuigan 1992): of complicity with the media and cultural industries that reduced its capacity to provide a critical analysis of the interests these industries served. This provoked a further reassessment of the study of popular culture which served to reassert the complicated set of understandings required: to understand how popular cultural forms worked as communication; to understand the competing political potentials implicit in the consumption of popular culture; and to understand how the political economy of the media and cultural industries operates as a determining frame around the relations between producers and consumers.

Crucial to the development of the analysis of popular culture within this tradition has been the focus on the media product as a 'text,' and the complementary insistence on the importance of understanding the processes through which these texts are consumed by audiences.

2. *Texts and Audiences*

The idea of treating media products as 'texts' comes from literary studies but the early means of doing so came from semiotics (see, for example, *Semiotics*). Semiotics was especially useful for two reasons. First, while it was interpretative as well as descriptive, it did not produce an aesthetic or moral evaluation of the text and was thus differentiated from the only other discipline where textual analysis was highly developed—literary studies. Second, it was the first method which offered the means for analyzing all forms of communication—written, verbal, and visual, either singly or in conjunction with other forms. As a result, semiotics enabled the detailed and comparatively objective analysis of popular cultural products such as advertising, television news, and newspaper layouts.

For most of the 1970s and much of the 1980s, British cultural studies busied itself with developing modes of textual analysis from a combination of semiotics, certain aspects of film theory, and Althusserian theories of ideology. The interest in the text was initially in critically unraveling its carriage of ideology. This slowly gave way to an attention that was more intrinsically interested in the text or genre of texts under examination—the appeal of soap opera, for example, or the construction of the news. Such work initially assumed that the readings generated by the cultural studies critic were immanent in the text, repeating an elitist assumption also made within literary studies that the critic had a privileged insight into what the 'true meanings' of popular culture might be.

The flaws behind this assumption were addressed by a number of interventions, the most significant being Hall's argument that the process of encoding or producing the text was separate and different from the process of decoding or 'reading' the text (1980). Indeed, he argued that there were at least three kinds of reading positions consumers might take when decoding the text. Consumers might simply accept what was described as the 'preferred' meaning; that is, the meaning apparently preferred by the producers or senders of the message or what is often referred to in the literature as the 'dominant' meaning. They might take an 'oppositional' position, which flatly rejects or subverts what they nevertheless would recognize as the preferred reading in order to construct their own, alternative reading of the message. Or they might produce a 'negotiated' reading, developed out of a relatively complicated consideration of the preferred reading and its alternatives. Hall's schema emphasized the contingency of the act of consumption, the varying ways in which audiences might understand any text. In practice, it was accepted, most would develop a negotiated reading rather than either of the other two options. This also emphasized how individualized the processes might be through which culture constructs its meanings. Consequently, cultural studies began to focus on these broader cultural processes rather than the processes of the texts themselves; this in turn was a shift away from the opinion of the critic and towards a serious consideration of the evidence from the audience.

Research into audiences' understanding of texts had occurred within the CCCS during the late 1970s, and the Centre's interest in subcultures had also produced a number of studies which used the methods of ethnography as a means of investigating how subcultural groups made sense of their social experiences (Hobson 1980, Willis 1977). However, it was not until Ien Ang's innovative analysis of fans of the US soap opera, *Dallas* (1985), that audience studies began the process of becoming a fundamental component of the practice of cultural studies. Ang's study used the letters from a group of *Dallas* fans both as texts to be analyzed and as ethnographic evidence which helped substantiate the nature of the soap opera's appeal to, for instance, intelligent and educated women who, at that time, would not have been reckoned to belong to the target audience for that kind of television. Something of an explosion of audience studies occurred, usually claiming to be in some way 'ethnographic' (that is, in this context, involving some direct observation of the group under analysis). The appropriation of what was a much reduced version of their research methodology provoked stern critiques from social science disciplines where the established protocols of ethnography were taken more seriously and employed more rigorously.

While the trend for what one might call 'thin' ethnography eventually waned, the usefulness of ethnography as a means of examining not only media audiences but other cultural formations has been accepted in cultural studies. David Morley (1986, 1992) moved audience studies away from largely providing a complementary strategy for those trying to understand the workings of media texts, and situated it as a means of, for instance, understanding the function of television within the home, and its implication in the web of social relations involving age and gender that made up families' everyday lives (see *Audiences*).

3. *Representation and Identity*

While the above account might imply that cultural studies' interest in the text has been displaced by the focus on audiences, there is at least one area where that is not true. Textual analysis in cultural studies was initially almost an end in itself; the development of a process which could unpack the construction of meaning within, particularly, media texts was rightly seen as a significant methodological advance. As a result, for quite some time, the performance of textual analysis was a dominant genre of research and writing within the literature of the field. As the authority of the critic was challenged by audience studies, however, the point and practice of textual analysis had to change.

Cultural studies had always been interested in how the world was 're-presented' to us in other forms: as images, as sounds, as writing, and as narrative. The influence of poststructuralist theories of language and culture situated representation as our only access to the real: we understood the world through languages, and through the ways in which it is represented to us. The problem of culture for many, therefore, is overwhelmingly the problem of representation.

One of the shifts in approach emerging from the mid-1980s interest in the audience was a focus on how cultural identity was represented. Feminist cultural studies was the primary instigator here, with its emphasis on how women's lives were determined and constrained by the dominant representational patterns within which the feminine is constructed (Franklin et al. 1991). The interest in identity as a contingent product of representation, and of the need for minority groups to therefore regard their representation as a political issue, becomes a major concern for cultural studies theory and a major genre of textual analysis.

It is also probably the location where the two complementary streams of British cultural studies—on the production and textual side, and on the consumption or audience side—have been most effectively and productively combined (Hall 1997). The focus on the representation of particular minority groups, and the interrogation of the effect of that representation upon particular examples of those groups, is precisely the territory that feminist cultural studies has developed. It has also been taken up by other groups—gays and lesbians, ethnic and racial minorities, diasporean communities—as a means of understanding the construction of their identities, and of contesting the political effects of that construction through a critique of the representational patterns involved. Finally, in the 1990s, the focus on representation has assisted in opening up the issue of the construction of national identity for British cultural studies.

4. *The Politics of British Cultural Studies*

One of the ways in which British cultural studies have conceptualized their project is to see it as inherently political. That is, British cultural studies set out to understand how culture works in order to intervene in that process and produce change. Williams, Hall, and other key figures were identified with New Left Marxism, and had played the roles of activitists within British politics. The process of developing the field, the work of 'theoretical clarification,' as it was called, has routinely addressed the problem of how to make academic knowledge matter within contemporary party politics. Indeed, when Hall (1988) addressed the problem of the Left's incapacity to combat the working class alignment with (then) Prime Minister Margaret Thatcher's policies, he presented it as an issue both for party policy and cultural theory.

The centrality of politics to the British cultural studies project is among the factors which may still

differentiate it from those more recent cultural studies traditions which have developed, for instance, in the USA. Indeed, among the concerns expressed by Hall and others about the success British cultural studies achieved in exporting itself to the USA at the end of the 1980s was the likely displacement of politics from the theoretical field. The widespread pattern of institutionalization of cultural studies, in the UK and elsewhere, has also been proposed as a threat to this fundamental principle. Similarly, if a little paradoxically given its direct engagement with political institutions, the incorporation of cultural studies academics into the process of state policy formation, particularly in the UK and Australia, and the consequent interest in the related field of cultural policy studies (Bennett 1998), has been criticized as a form of co-option.

The politics of British cultural studies itself is not without its blind spots, of course. It was reluctant to admit feminist concerns and paid little attention to issues of race, ethnicity or nationality until the 1990s. Its resistance to empirical research methods has exposed it to criticism from within the social sciences. However, its determination to make a highly theoretical enterprise prove itself in the material world of practical politics continues to mark it out as a distinctive intellectual and social project.

Broadbent, Donald Eric (1926–93)

During the second half of the twentieth century Donald Broadbent's research and theories, communicated in 247 publications, including four books, shaped the direction of applied human experimental psychology. In Britain he exerted a broader influence, fostering the entire subject of psychology by publicly representing it as a significant science. He achieved this through advice on appointments to many influential chairs of departments and public committees and through representations to funding bodies that secured recognition, and thus funding for academic and applied psychology and, later, particularly for cognitive science. His influence continues through the careers of his many research students and postdoctoral collaborators. His death, distressingly soon after his retirement, deprived his family and friends of emotional and intellectual comfort and support, and curtailed sharp insights on how the intellectual history of the subject of psychology may determine its future.

Donald described a boyhood troubled by sharply fluctuating family fortunes, the early loss of a father whose talents greatly exceeded his educational and social opportunities, and the determination of his mother that Donald should transcend similar problems by gaining a scholarship to a prestigious public school, Winchester. There he found the physical sciences dispiriting because of the volume of existing knowledge to be mastered before any original work was possible. Nevertheless, a brief wartime course in engineering arguably provided the skills and mindset that developed his particular slant on psychology. He was called up to the RAF, where pilot training in the USA forced recognition that poor engineering design causes catastrophic human errors. Also that, in a

richer society than postwar Britain, these problems were beginning to be addressed by a profession to which he too might aspire. Experience of RAF personnel selection intensified his conviction of the value of occupational psychology, and he resumed his interrupted undergraduate career at Pembroke College, Cambridge. Here, against the strong advice of his tutors, he read psychology in Sir Frederick Bartlett's Department.

This was then, arguably, the best place in the world for him to be. Bartlett, and all his staff, had distinguished themselves in applied human factors research and personnel selection during the war, and so gained respect from other scientists for what was then a minute and misunderstood discipline. The Cambridge department was uniquely in the mainstream of new ideas. Donald has described it as an intellectually 'explosive' environment, similar to that in the Cavendish laboratories and the 'Bun Shop' pub just across Downing Street, where DNA was being discussed. Among the volatile ingredients were the immediate local legacy of Kenneth Craik's seminal applications of control theory to human performance; William Hick's brilliant use of Shannon and Weaver's new information theory to model decision making and his interpretation of its use in the recent wartime work of Egan, Garner, and Pierce; the speculative computational neuropsychology of Hebb's (1949) 'Organisation of Behaviour,' and demonstrations by Grey Walter and Ross Ashby that automata theory could simulate and explain the behaviour of simple organisms. This paradigm shift was still imperceptible anywhere else in Europe. After gaining a first-class degree, Donald had to explain to Bartlett that he could not afford to follow his advice to support himself independently to work on any problem that interested him. So he was appointed as a member of scientific staff at the Medical Research Council Applied Psychology Research Unit (APRU) in Cambridge, which Bartlett had founded and Norman Mackworth then directed.

The APRU was funded to solve applied problems for government agencies, principally the Royal Navy, who determined the research agenda. Mackworth asked Donald to work on noise, both as an obstacle to effective speech communication and a factor in attentional distraction, arousal, and stress. Noise became a main theme of Donald's research, from his first paper, 'Some effects of noise on visual performance' in 1951, to a concluding review, 'Human Performance and Noise,' published with Dylan Jones just before Broadbent's retirement 40 years later. It brought an exceptionally congenial and fruitful early collaboration with Peter Ladefoged on speech perception, and a lifelong interest in auditory psychophysics, and in the subjective and objective measurement of the effects of noise and other stressors on human comfort and performance. Most importantly, it provided applied problems that cued Donald's seminal work on auditory multitasking and dichotic listening, which crystallized in his pivotal achievement, his book *Perception and Communication* (Broadbent 1958).

Modern readers appreciate immediately that the remarkable impact of this book came partly from a wonderful lucidity of style and inspired choice of illustrative metaphors that clarifies difficult arguments. It is now impossible to convey its fresh delight for his contemporaries. For all outside a small circle in Cambridge this was the first insight into how an entirely new style of conceptual models, derived loosely from information-flow diagrams used by computer scientists, could make sense of exciting new discoveries in momentary and sustained selective attention, short-term memory, arousal, and the effects of stress. The subtext was that the dominant conceptual framework of S–R connectionism could not possibly account for these new data. Donald's next book, *Behaviour* (Broadbent 1961) illustrates his recognition of the power of the zeitgeist that *Perception and Communication* had to exorcise. It showed how the behaviorist framework derived from animal learning experiments had become inconsistent internally, and that much of the data it had engendered could now be reinterpreted usefully in terms of simple cybernetic models such as those currently being suggested by scientists such as Tony Deutsch and Stuart Sutherland.

In 1958 Donald was appointed director of the APU and attacked energetically the hard tasks he inherited, and even harder ones that he set himself. The funding base had to be widened beyond insecure reliance on Royal Navy contracts. Civilian clients, such as the Post Office, the Department of Transport, British Rail, and the Royal Mint were, arduously, brought to recognize practical benefits from human factors research. Part of a self-imposed task of improving public understanding and support in the UK for a tiny and misapprehended subject was public appearances on radio and television. Effective representation of psychology through and within the British Association for the Advancement of Science, work with committees and boards of the MRC and the other, newer, Research Councils enlarged academic respect, and secured better funding for psychology in Britain. Similar efforts in the British Psychological Society and the Experimental Psychology Society brought him presidency of both bodies—and membership of even more committees. There was also the day-to-day administration of a rapidly expanding, and increasingly demanding, unit.

Donald always insisted that it would have been impossible to continue his personal research without Margaret Gregory, who began to be his lifelong collaborator in 1961, and his wife in 1972. Apart from a diversity of papers on auditory and visual selective attention, decision processes and stress, his main work during the 1960s became reinterpretation of data from vigilance tasks in terms of the new metric of Tanner

and Swets' Signal Detection Theory. Donald and Margaret found that small shifts in operator bias, which could be related neatly to maintenance of arousal and motivation, brought about counter-intuitively large changes in patterns of errors. This suggested fresh ways of analyzing the effects on sustained attention of stressors such as fatigue and noise, and of personality variables such as introversion and extraversion. It also led to the speculations on distinctions between selective perceptual sensitization for particular signals and preparatory bias for particular responses that became central to his next book, the monumental *Decision and Stress* (Broadbent 1971), and guided much of his later research. However, administrative loads and personal problems became overwhelming. A sabbatical at All Souls College, Oxford allowed personal reassessment and completion of 'Decision and Stress' which appeared in 1971. Perhaps election to the Royal Society also brought new confidence in public esteem for his individual contributions, independently of the background successes of the unit he had built up. He gave three years' notice of resignation, and in 1974 moved to the Department of Experimental Psychology in Oxford, which was then emerging into a period of pre-eminence in Britain under Larry Weiskrantz. Here, until his retirement in 1991, he at last had his chance to follow Bartlett's advice to work full time on whatever problems he wished.

Decision and Stress achieved immediate widespread respect for its scholarship and incomprehension of its message. Its central theme is a model for the way information is processed, remembered, and retrieved, expressed metaphorically as a distinction between 'pigeonholing' and 'categorization.' At first sight this seems as helpful as all Donald's other heuristic devices, but generations of students have failed to discover precisely what it means. It seems partly to contrast control of attention by selective tuning of perceptual, or attentional, sensitivity, and by response bias. It is stressed that these functional processes must be guided 'from the top down,' by the complex mental representations that people make of their environments, their momentary and continuing goals, and of the information that they need and the actions that they must perform to achieve these, rather than from 'the bottom up' by passive assimilation of sensory input. There is still no better reference source for the entire body of experimental work in applied experimental psychology between 1958 and 1970, but the metaphor did not provide the necessary guiding thread through this vast literature, or extract from it messages as concise and fruitful as those that *Perception and Communication* had drawn from no more than 20 key papers. Hindsight shows that the real problem was the familiar one in any rapidly developing science: the style of models that had been so successful in 1958 no longer worked for the new data base that they had generated. Issues of the inevitably increasing clumsiness of explanatory frameworks as further data accumulate, and of the best level of description at which to work, cut deep in applied cognitive psychology.

For the rest of his working life, Donald continued his commentary on intellectual navigation between finicky debates about the increasingly sterile details of models based on single experimental paradigms, and theoretical frameworks that are so general that it is unclear what they explain or how they can be tested. This was one of the themes of his William James lectures at Harvard, published as *In Defence of Empirical Psychology* (Broadbent 1973). A background stimulus was a fashion, during the 1970s, for rejection of empiricism in favour of 'cognitivist' descriptions. Donald's response to the new 'cognitive psychology' named, but not defined, by Neisser in 1966, had been cautiously tepid. He feared that it might encourage less gifted practitioners to a psychology based on pseudophilosophical speculation about phenomenology rather than on empirical evidence. This motivated an expression of concern at these trends in British psychology in a paper 'In defence of empirical psychology' (Broadbent 1970) published in the *Bulletin of the British Psychological Society*. Donald detested academic affectation, particularly grandiloquent posturing to win the generous hearts of students who had not yet been given the critical apparatus necessary to distinguish efflorescing cults of personality from the necessary tool kit of methodology and hard-won information in a science that many of them had resisted opposition to be able to study. He saw a threat to civilized values when, as he said, 'If one doesn't argue from evidence it must come to bludgeons.' Perhaps much of his distaste came from what he called a puritanical streak, which took him directly athwart the spirit of the 1970s: 'I decided then, and still believe, that self-realisation and the development of personal experience are neither dignified nor respectable goals in life, that most of the world lives within extremely tight economic margins and that positions of privilege, (such as the conduct of psychological research) demand obligations in return.'

During the 1970s and 1980s he commented shrewdly on early connectionist models by McClelland and Rumelhardt, on parallels between human experts and expert computer systems, and became concerned with levels, hierarchies and the locus of control, and the effects of emotional states and personality traits on selective attention and decision making. He resonated to the strong neuroscience bias that Larry Weiskrantz had brought to the Oxford University Department. He proposed a 'Maltese Cross' model to describe interactions between modality-based memory subsystems and their mutual control to achieve selective attention. Empirical research continued on a remarkable breadth of topics. Work on how the emotional valence of words affects the speed with which they can be recognized, on more general problems of word perception, on visual perceptual selectivity under

stress and distraction with Margaret Broadbent and Sue Gathercole, on the processing of rapid strings of successive visual stimuli, and on grouping effects in short-term memory with other distinguished collaborators.

Donald never lost the determination to apply psychology to economically and socially useful ends, and to enrich theory by studying complex real-life tasks rather than artificially simple experimental paradigms. With Diane Berry he investigated how managers develop and use mental representations of the systems that they try to control, providing empirical evidence that their decisions are affected strongly by assumptions, biases, and even computational procedures, which they do not articulate, and of which they may even remain unaware. Parallel work on errors and lapses took place in hospital wards and on automobile production lines, in collaboration with his student Peter Cooper, and with Dennis Gath of the Oxford University Department of Psychiatry. It is a pity that this work has gained far less attention than it deserves, because it teaches precisely those lessons of empirical methodology and acceptance of social responsibility that he most wished to pass on.

Donald felt that his so-called 'puritanical streak' discomforted his younger colleagues, but this was not quite the issue. He could not endure gladly the company of people whom he took to be insincere, or perverse, in their determination to avoid recognition of logical weaknesses in their positions, but he was always as fair and generous to them as he could force himself to be. Discomfort did not come from his humane responses but from glimpses of the considerable effort that they sometimes cost him. His intellectual acuity was often intimidating, as was occasional looming impatience with remarks or behaviour that he interpreted as histrionic or unkind. His genuine shyness was disconcerting in one so obviously, and exceedingly, clever and eminent, and sometimes compounded problems of communication, but his underlying kindliness was unmistakable, totally reliable, and amply assuaged any occasional unease. He was frugal with praise, perhaps because he was suspicious of merely verbal gestures, but he was endlessly generous and sensitively proactive in offering practical help. It is excellent that he retired sure of the intellectual esteem of his colleagues and students, but sad that he remained unaware that he also earned far more affection than he ever realized.

Broadcasting: General

Broadcasting refers to the social application of two related technologies of communication; radio and, later, television. Radio broadcasting, which began in the USA and Europe in the early 1920s, was a by-product of wireless telephony which was in turn an extension of wired telephony and telegraphy. All earlier electronic technologies of communication, whether wired or wire less, were designed expressly to transmit messages from point A to a distant receiver at point B. They were conceived as closed systems whose information was only for specific senders and receivers. Wireless telephony was developed as an extension of wired telephony with the obvious advantage that it could transmit messages to distant points (to ships at sea, for instance, or to armies in the field) that could not be linked by wire. However, this new technology had an apparent drawback. Anyone within range of the transmitted wireless signal could also 'tap into' the message if they had appropriate equipment. This became a major problem for all contending armies in World War I, all of whom used wireless telephony to maintain links between headquarters and their fronts and all of whom were obliged to design sophisticated codes to encrypt their messages which otherwise would give information to the enemy. It was only after the Great War that the *broadcast* effect of wireless telephony, which scattered its message across a wide radius, began to be exploited as a quite new kind of communication for general social purposes.

Radio broadcasting became a popular hobby, in the USA and Europe, in the early twentieth century. The technology was, in principle, a two-way system of transmission, permitting live interaction between two sender-receivers. In countless suburban bedrooms and garden sheds male members of the household, young and old, became enthusiastic radio 'hams.' Some put out programs of music at particular times to which

others, within range of reception, could tune in and listen. At the same time the electronics industry, then in its infancy, began to perceive the possibilities of a market for the sale of radio receiving equipment, but this presupposed that there was something to which purchasers of sets might listen. Broadcasting as we know it today began with the separation of transmission and reception. People would buy radio sets that only received, but could not transmit a broadcast signal, if there was something 'in the air' to which they could tune their receiving set and listen.

Simple though this sounds it contains issues of enormous complexity. The delivery of broadcast services depends on technological, legal, political, economic, and cultural factors all of which are enmeshed in each other. Take the most basic. How is a broadcast program service to be financed? The pay mechanism for other informational or entertainment services is obvious; you pay for the newspaper or at the box office for entry to the cinema or concert hall. But radio and television developed as services delivered to households, rather like gas or water. People paid for their radio sets. But how could they be made to pay for what they listened to? Today the 'box office' mechanism is in place and receivers of cable and satellite services operate on a pay-per-channel or pay-per-view principle. But for many years terrestrial broadcasting was a 'free to air' service, and the cost of the program service was met either by the sale of on-air advertising or by some kind of license fee, an annual charge levied and collected by central government on households with radio or television sets. In the USA broadcasting developed via the first route: as a commercial system funded by advertising and sponsorship revenue. In Europe, and classically in Great Britain, broadcasting developed as a public service, funded by a license fee which was levied by the Post Office, a department of state.

These two alternative models for the delivery of broadcast services have defined the first two 'ages' of broadcasting; the first age being the radio era, the dominant broadcast medium until the beginning of the 1950s in the USA and the end of the 1950s in Europe, when it was surpassed by 'the age of television.' Separately and together broadcast radio and television expanded worldwide in the second half of the twentieth century to become truly global systems of communication. The broadcast services that developed in the USA and Britain in the 1930s, and which today are still major players in an increasingly complex media environment, form the focus of this article.

Although radio broadcasting started up in different ways in different countries the nature of the program service on offer turns out to be everywhere the same: a mix of information and entertainment delivered through the day (and night) day by day and every day. The nature of this service imposes fundamental constraints upon the agencies that deliver it. Broadcasting is labor intensive. The delivery of news is a complex, costly affair if the broadcaster is in the business of actually gathering and producing the news that it transmits, and the same is true of broadcast entertainment, if it draws on professional, 'star' talent, and especially if it produces fictional drama. Thus we find, in early histories, that although radio started up in many places as a small local service, sooner or later there was a process of convergence whereby national systems of broadcasting developed—the commercial networks in the USA, and the British Broadcasting Corporation (BBC) and similar public service institutions in Europe and elsewhere. This convergence was driven largely by the necessary economies of scale that underpin the delivery of labor-intensive program services to very large audiences through the day and continuously.

When broadcasting began, electricity was a very new energy source that was not widely available throughout societies. In the 1920s most houses were wired only for electric light. In the 1930s they began to be wired for mains electricity so that electric appliances could run from them. But before the World War II, the 'wired home' as we know it today was restricted largely to urban centers and more affluent households. Electric goods such as cookers, refrigerators, record players, and washing machines only became widely available throughout societies in the 1950s. The development of a culture in which radio and television sets were part of everyday existence for everyone was part of the more general social process whereby domestic life was transformed in the twentieth century, as the home increasingly became the primary focus of leisure, relaxation, and entertainment across all social sectors.

But why should people want to listen to radio or watch television? First, it should be something that is easily available for them to do. Second, it should be something that they will want to go on doing. The availability of broadcast services is, in the first place, a technological matter. On the one hand there is the delivery of the signal, and on the other, the design of the receiving equipment. In terms of transmission there are two key issues: distance and quality. The greater the reach of the signal the more economic the delivery of the service. But at the same time the quality of the signal must be such that listening or watching is of sustained high standard, free of technical 'noise,' fade or interference. In terms of the receiving equipment it must be simple and easy to use and not liable to go wrong or to need frequent renovation.

It took time to resolve these basic problems. Early transmitters sent out a low-power signal with a reach of no more than 20 miles. Soon more powerful transmitters could transmit over much greater distances, but coverage of a continent such as the USA required a vast network of transmitters and telephone 'long lines' to relay the signal over thousands of miles. At the same time interference from neighboring

stations was initially a serious problem in both Europe and the USA where it was known as 'the chaos of the ether.' The Federal Radio Commission was established in 1927 as a central regulatory body responsible for the allocation of station frequencies across the whole of the United States. In Europe continent-wide agreement on the number of frequencies allowed to each nation state was reached by the leading broadcasters from 16 countries at Geneva in 1926 and formally ratified by their governments at the Prague Conference in 1929. The BBC which, until then had been broadcasting on 20 different frequencies, agreed to halve this number and undertook a fundamental redesign of its services, aiming to achieve nation-wide coverage with five high-powered twin transmitters strategically sited throughout the United Kingdom.

While these matters were being resolved the radio set as we know it today began to emerge. The earliest radio sets were sold as kits of electronic equipment which required some knowledge to assemble and some skill to tune in and pick up a signal. As a domestic good, rather than a scientific hobby, the radio set needed to be not only simple to use but acceptable to look at. It must appear as part of the domestic space in which it was situated. By the 1930s radio sets with a frequency tuner and volume control and housed in a molded plastic case were in mass production, and became the biggest selling electric appliance designed for domestic use. By 1939, 75 percent of British households had a radio, far ahead of the electric iron and carpet cleaner which were the next most purchased electric appliances.

What then did people want to listen to, having purchased their radio set? The whole of the broadcasting industry worldwide exists in order to deliver something that will make people turn on their receiving sets and keep them on. What is involved in this? We must first understand the basic characteristic of both radio and television as *time-based* media. When you turn on the set you expect there to be something to listen to or watch whenever you do so, not just occasionally or only at certain times. There must, in fact, always be something 'on' for listeners and viewers. So that from the start broadcasters were impelled to provide a service that ran continuously through the day and into the evening, and eventually all through the night as well. The most fundamental problem facing broadcasters is how to fill *air time*. How do you supply a program service that will run day in day out and through the day and night without ceasing?

Let us link this to the expectations of listeners and viewers. What did people want to listen to? What did they get? Radio in its very early days was a hit-and-miss amateurish affair. It could supply talking voices and music drawn from whatever local resources the harassed station operator could muster, and that usually was not very much. There was a demand from the start, everywhere, for broadcasting to link people to the centers of existing public life from which the vast majority were, of necessity, excluded. The time base of broadcast media is real time, *now*. The real-time property of radio and television meant that, from the start, listeners and viewers could in principle be linked to major events even as they happened: to a baseball or soccer game, a presidential inauguration, a royal wedding, a major 'breaking' news event live and as it happened. More generally, broadcasting could connect listeners to hitherto inaccessible cultural resources. Before radio only a tiny minority had ever heard a full symphony orchestra playing the classical repertoire. By the mid-1930s the Boston Symphony Orchestra, the Manchester Hallé, or the Berlin Philharmonic could be presented on air and heard throughout the land. Contemporary urban, urbane music—jazz, swing, dance music live from night clubs and smart metropolitan hotels—resounded in places far removed from big city life.

The demand for access to these things was irresistible and everywhere impelled broadcasting to centralize and concentrate its resources in order to provide high-cost entertainment, news, and access to great events for rapidly growing listening publics. At the same time broadcasting was compelled to invent new forms of entertainment that could meet the insatiable demands of continuous daily program services. Before broadcasting professional entertainers (singers, comedians) made their living by repeating the same limited repertoire as they toured the country, appearing in local variety theatres or concert halls. Star performers were signed up for radio only to discover that after one or two appearances they were burned out. Their repertoire, which sufficed for a lifetime of performing to audiences of at most hundreds, did not bear repetition anywhere after it had been heard once, simultaneously, by millions. Thus, the basic production problem that broadcasting faced was to discover serial formats that permitted the indefinite repetition of the same basic material yet which would be different each and every time. Key inventions in this respect were the serialized 'never ending' fictional narrative (or soap opera), and the 'situation comedy' which allowed for endless variations on the same basic comic theme. In time program formatting would extend to news, game shows, quizzes, and talk shows. Today all broadcasting, with the exception of singular live-to-air events (and even these are routinized in American news programs), is formatted on a principle that allows any program, in principle, to run indefinitely.

Program formatting is one key solution to the fundamental problems which time-based daily media pose for broadcasters. The other, and intimately linked to this, is scheduling. Scheduling is to do with the sequencing of programs through the day, and is crucial to the familiarity of daily broadcast services. This familiarity is given by the ways in programs are so arranged that they appear, as it seems to us, on the

right channel on the right day at the right time of day (or night) and go on for the right length of time. The routinization of schedules into settled, knowable sequences was accomplished by the 1930s and has the effect of adjusting the times of broadcasting to the times of daily life and its routines. Thus, the time of broadcasting interacts with and supports the temporal structures of day-to-day life in modern societies. The time of any program is always attuned to the time of day. Early morning radio and television shows have names like *Good Morning America*, *Today*, or *The Big Breakfast Show* and the fundamental task they perform is that of orienting whole populations to the ordinary business of the day ahead. What has happened since yesterday? What is happening now or later today? What's the weather and the traffic like 'out there'? What's the time? (It's time to get going). In dealing with all this such shows are not just *at* a certain time of day. They are *for* that time. The schedules are not just one damned thing after another, but have a temporal dynamic; not just the time of day, but time through the day: time to go to work and time to return (drive time and its attendant programs) and time to relax.

There is never 'empty' time in broadcasting. It is always filled with something going on. In the world as shown by broadcasting things are always happening, and thus what radio and television have accomplished unobtrusively is the routinization of history, day by day and every day. The formatting of programs and schedules combine to overcome the problem of the ever same (about which there is nothing to say). Broadcasting is characterized by difference in sameness. Radio and television combine and interact with each other (the times for listening and watching are not the same) to respecify each and every day as *this* day in which this is happening and these things are going on. Each day is like any other day and yet it is particular.

Particular for whom? Broadcasting began by separating production and transmission from reception. In so doing it created quite new kinds of audience, thereby redefining the character of public life and the boundaries between public and private existence. An audience usually is understood as a collectively gathered for some common purpose of witnessing, for instance, a concert, a play, or a movie. To be an audience member is to be present at a public event of some kind. Participation in public life, before broadcasting, had of necessity demanded some investment of time, effort, and often money. It meant journeying to the location or building dedicated to the event. It meant, moreover that the audience was always a particular kind of public, constituted by the nature of the occasion: a church congregation, a football crowd, a cinema audience. Now, via radio and television, the world 'out there'—the great world of public events and persons—entered into the spaces of everyday existence for untold millions. Whereas previously public life had been available only to particular and self-selecting publics, it now became generally available to a new kind of general public equivalent, on certain occasions, to the whole society and today even the whole world. Events themselves, hitherto discrete and catering to specific 'taste publics,' now became part of a shared common life enjoyed by millions who beforehand—of necessity or lack of interest, time, or money—had not participated in them. The common culture of broadcasting is defined by its nonexclusive, 'free to air,' general availability. Radio and television straddle two worlds: the great world of public life and affairs and the private worlds of individual social members. These two worlds are quite distinct and separate. Before broadcasting the horizon of concern for most ordinary social members extended no further than the immediate environment in which they dwelt. Public life and affairs were, for the majority, remote from day-to-day existence and impinged upon it only occasionally and unexpectedly. But broadcasting links these two worlds, routinely and continuously. How does it do this?

In an obvious way what links the public world of broadcasting and the private worlds of viewers and listeners is speech; the on-air talk that goes out on radio and television every day. This talk is, by now, so familiar and seemingly natural that it is hard to see that the question of how to address their audience was once a crucial issue for broadcasters. Broadcasting, as we have noted, separates production and reception. Broadcast talk is produced in the studio or on location but, either way, is always heard elsewhere. This means that although broadcasters control the talk which they produce, they cannot control how their absent audiences will react to that talk. This is more generally true of all live-to-air events and occasions broadcast either from the studio or on location. Live and present audiences in any event are called upon to adjust their behaviors to the nature of the occasion which is controlled and managed by the public speaker-performers. But no such constraints fall upon listeners or viewers. Thus, the key to understanding the communicative character of broadcasting is to see that the relationship between broadcasters and audiences is essentially noncoercive, because the former cannot control the behavior of the latter.

What are the consequences of this? It reverses the prevailing norms of public life in which audiences are required to adjust their behaviours to the nature of the occasion. This means, in effect, that they submit to being controlled by the performers who manage the performance. Broadcasters learnt that on the contrary they must adjust their behaviours to chime in with the situations and circumstances of listeners and viewers. Overwhelmingly watching and listening are not collective 'mass' activities. It is true that, in the early years of radio when only few people had sets, certain public events and ceremonies were relayed by loudspeakers in public spaces in which thousands congregated to

listen. Fascist radio was used in this way, in the 1930s, in Germany and Italy. Today the crowds at a major sporting event or ceremony may have simultaneous access to coverage of that at which they are present via giant television screens. But by and large people in the past listened to radio and today watch television in, as we say, 'the privacy of their own homes.' Viewing and listening are not work-related activities but are linked to what we think of as 'free time,' to leisure, and domesticity. Moreover, they are essentially individual activities which may be shared with family or friends.

In such circumstances, how would one expect to be spoken to? Most forms of public speech have some propagandist or persuasive aim. But in the contexts of domestic life and leisure people do not want to be preached to or lectured at when they turn on the television or radio. They want to relax and they expect to be spoken to as equals, and as individuals in their own right, not as anonymous members of a collectivity. Thus, the communicative style of broadcasting on radio and television everywhere came to orient itself to the norms of ordinary conversation, or talk. Those norms, in turn, have unobtrusively transformed the character of public life and entertainment in the twentieth century.

Consider the transformation of singing by the microphone. The microphone is a technology that amplifies and relays sound. It is fundamental to the recording and broadcasting industries. Before its invention the norms of public singing in Europe and America were defined by the requirements of opera, in which the voice had to project over a full orchestra and to the farthest reaches of large opera houses. In this style of singing, necessarily, the power and vocal range of the voice were especially prized. The operatic voice was designed specifically for performance to live, mass audiences of hundreds if not thousands.

When, in the early years of broadcasting, such singers came to the microphone to perform they almost short circuited the equipment when they gave voice. It was discovered immediately that to produce their sound on air or on disc the singers needed to be positioned several feet away from the microphone. However, a new style of singing began to develop which exploited the potential of the microphone. Here the singer stood close to the mike and, instead of bellowing, seemingly spoke or whispered into it. This 'talking' voice repersonalised singing. The crooner did not need a trained operatic voice in order to perform. He or she sang in their own, natural voice. So that what you heard was the voice *of* Bing Crosby or Frank Sinatra and they sang as if to you alone. Crooning brought intimacy into the public domain: instead of loudness, softness; instead of singing to many, singing to one; instead of the impersonal, the personal; instead of extraordinary, ordinary voices. For the singing voice, broadcasting and the record industry made sincerity the authenticating measure of intimacy as it was transposed from the private into the public domain. Just as the movie (and later, television) close-up offers to countless millions an intimate access to the human face and an exchange of looks hitherto available only between lovers or a parent and their little child, so close-miked singing produces similar effects for us as we listen.

The transformation of singing by the microphone is indicative of a much more general process whereby the personal norms of interpersonal life—of intimacy, sincerity, and authenticity—have been transposed into the public domain. Franklin Roosevelt was the first major political leader to exploit these communicative characteristics. His 'fireside chats' with American listeners in the 1930s were the reverse of the fiery public rhetoric of European dictators. They exploited the intimacy of broadcasting and established a more egalitarian relationship with the electorate. In the course of the twentieth broadcasting has become folded inextricably into the political process everywhere. It provides politicians with unparalleled access to those they wish to influence and, reciprocally, it makes them visible to their constituencies in ways that were hitherto impossible.

The growing involvement of politics with broadcasting is a decisive characteristic of the age of television in the second half of the twentieth century. Television makes politicians visible, and in close-up, and thus the management of visibility becomes increasingly important for them. Viewers judge by appearance and performance, as much as the substance of policy or the soundness of argument. They evaluate the person as well as the policies. The famous Nixon–Kennedy debate on television in 1960 was perhaps the defining moment when politicians, not just in America, came to realise that they must attend to their self-presentation and image on television if they wished to win electoral support. Margaret Thatcher, before she came to power in 1979, had a make-over, largely for television, which involved restyling her hair, her wardrobe, and her voice. Image management has become increasingly important in the last quarter of the twentieth century as individual politicians, parties, and governments all seek to put the best spin on themselves and their activities as they appear on television.

1. Coda

In *Waiting for the Rain*, written in 1975, the Zimbabwean novelist, Charles Mungoshi, describes the astonishment of Sekuru, an old man who lives up country, when he hears his grandson's transistor radio. He is amazed to hear his own language, Shona, magically emanating from this small black box and wonders (to the vast amusement of his city dwelling grandson) if the voices he hears are spirits who somehow live inside it. He listens to what the voice is saying:

> 'And to end the news, here are the main points again. Israeli troops have bombed an oil dump in the Suez Canal area. President Karanga has been shot dead. Rebel soldiers are still searching for President Bomba who escaped after a successful coup at dawn … '
> 'What's all this?'
> 'It's the news, Sekuru.'
> 'Where is all this happening?'
> 'All over the world, Sekuru. All over the world.'

The technologies of broadcasting, through their live immediacy, make the world available *as* the world. But it is not just that what is happening in the world now becomes generally available with an unprecedented immediacy. The relationship between events and their telling changes. History *is* this relationship. Unless a happening is brought to articulation—made into, reported, and recorded as a tellable story—it has no historic significance. Narrative is the discovery *of* the historical. It is this that has been routinized, on a daily basis, by modern news media. But radio and television have a specific temporal dynamic that earlier news media did not possess.

In written news stories (in news photographs or film) there is a necessary, inevitable gap between events as they happen and their postproduction as record or narrative. The temporality of written history moves on an axis from present to past. The time of the event and the time of its telling are always moving away from each other, and hence history is always the history of a receding past. But with radio and television the time of the event and the time of its telling coincide. Both exist in the same phenomenal real-time now. Broadcasting does not stand apart from the events that it covers. It is caught up in them, interacting with what is happening and, on ocasion, affecting how they unfold in real present time. This was widely noted in the dramatic sequence of events, in one country after another, as communism collapsed in Russia and Eastern Europe at the end of the 1980s. In these events television did not merely show what was happening. It contributed to what was happening. In this way broadcasting contributes to the making of history rather than acting merely as its recording angel. The temporal axis of both event and narrative in live broadcasting is one that moves from present to future. History is no longer 'then.' It is 'now.' It is no longer 'there,' but 'here.' The now-and-then, the here-and-there come together in the live immediacy of broadcast news and events which are structured in expectancy of what is to come.

Thus, the real-time basis of radio and television is a specific kind of temporality in which individual lives and the historical life of societies intersect with and interact upon each other routinely in the common public, available now of daily ratio and television output. How they do so is everywhere a matter of continuing concern. The impact of broadcasting on all our lives has been from the start and will continue to be something that is argued over and evaluated positively or negatively from many differing perspectives all over the world. But this in itself is indicative of what broadcasting has delivered unobtrusively in the course of the twentieth century: a world in which the past and the future come together and encounter each other in the live, immediate, unfolding now as a common, available world of concern.

Broadcasting: Regulation

By *regulation* we refer to political decisions and legal and economic instruments by which broadcasting activities are governed. These instruments include laws, rules, statutes, concessions, licenses, and traditions that make up the legal and economic framework; that is, the *regulatory regimes* within which broadcasting activities are carried out. Broadcasting regulations are outcomes of political decisions on broadcasting policy. Naturally, the regulation of broadcasting activities differs in time and space. First and foremost, broadcasting regulations vary between countries, as they reflect *national* political, cultural, social, and economic conditions. Still, in 2000, when the globalization of the media industry has become

conspicuous, is it fair to state that regulation of broadcasting to a considerable degree remains within the hands of individual states. This is true even if we consider the attempts of international organizations to establish international regulations for transnational television and trade in audiovisual products.

1. Distinctive Criteria

One main distinction between regulatory systems can be drawn between *democratic* and *authoritarian* states, which typically will regulate broadcasting differently with regard to freedom of expression but not necessarily with regard to ownership and market behavior. That is, the systems will vary according to the editorial freedom granted to media institutions: in democratic systems, the media are guaranteed a high degree of autonomy, editorial freedom, and freedom from censorship, persecution, and sanctions. Authoritarian states have generally repressive politics towards the media: either the media become instruments for the incumbent regimes, or they are heavily censored. The distinction between authoritarian and democratic not coincidental with the degree of state intervention but is characterized by the *distance* between authorities and media institutions in terms of editorial influence. To illustrate: there are many examples of state-owned broadcasting institutions that have or have had a national monopoly and which have had a high degree of editorial freedom (e.g., the British Broadcasting Corporation (BBC); the Swedish Broadcasting Corporation, Sveriges Radio), the Japanese Broadcasting of postwar Japan, NHK). There are also examples of countries where privately owned and market-driven broadcasting institutions have been heavily censored and worked as instruments of authoritarian governments, such as was the case with Brazilian Globo during the military government in the 1960s.

Another main distinction can be drawn between states with a *free-market economy* and states with a more *interventionist* tradition. The first type tends towards regulating broadcasting as an industry with the objective of securing competition and avoiding market failure. The latter type of states tends to regard broadcasting and other communications as a *public good*. Accordingly, *broadcasting policy* or *broadcasting legislation* in these countries is a more common term than regulation. In most European countries the state has owned and run broadcasting institutions operating with a national monopoly or duopoly. In these countries, there were few or no distinctions between the state as the regulator of broadcasting markets and the state as actor in the broadcasting sector. Instead, media policy and broadcasting policy were treated as a central topic within the larger area of *cultural policy*; that is, together with political issues related to maintaining and strengthening national identities, language, history, and culture. As such, in Europe broadcasting was and to a large extent still is an area considered as a sector for production of cultural goods more than cultural commodities.

In countries with a less interventionist tradition, such as the USA, the willingness to place broadcasting under cultural policy has been less prevalent. Broadcasting and other media activities are regarded as an area for free enterprise; that is, as a *market* for exchange of audiovisual products. Ideally, markets should regulate themselves, but since problems such as scarcity of frequencies, dominance of one or a few actors, and over-establishment led to market failure, broadcasting markets have been regulated with respect to *entrance* and *dominance*.

2. Regulatory Models: Public Service, Market Regulations, and Mixed Systems

2.1 Broadcasting Regulated as a Public Service

In Western Europe, broadcasting was early regulated as a *public service*; that is, as a service provided by the state or a publicly regulated institution. Public services are goods provided to the entire population on fairly equal conditions and that should be accessible for all at a relatively low cost. Most European countries centralized their broadcasting services in one or a few institutions either when broadcasting was introduced in the national context or shortly after. The discourse on public service broadcasting sometimes seems to imply that there exists *one* model, yet it is worth noting that a number of different systems and institutions are subsumed under the concept. The public service model thus varied from country to country, reflecting the cultural and political characteristics of different countries (Skogerbø 1996). In some, but not all, European countries they held a national monopoly and provided universal coverage and a program menu consisting of enlightenment, education, and entertainment that should appeal to different social and cultural groups. In some countries, license fees were the sole source of revenues for the public broadcasters; in others they drew their incomes from advertising or collected revenues from both these sources.

Accordingly, public broadcasting institutions were designed to cater to a diverse number of national interests (management of scarce resources, security, education, nation-building, news) as they were set up in many European countries in the 1920s and 1930s. In that period, the use of centralized institutions in order to solve problems that were regarded as in the national interest was quite common, especially in Europe and in particular in communications. Many countries had centralized telegraph and telephone services, and if not, the idea that communication services should be provided on a universal basis was widespread.

Within the public service model, there was room for quite large variations. Not all countries had a centralized broadcasting institution. The Dutch public

service system, for instance, incorporates a number of different broadcasters that have in common that they are affiliated with the traditional social *pillars* of Dutch society; that is, the religious and social cleavages that until the 1960s divided Dutch society into a number of strictly separate groups. Each of these groups or pillars established 'broadcasting societies' that were allowed the right to operate their own radio station and, at a later stage, produced programs for television. These broadcasters had the right to collect license fees, and from 1967 they also had revenues from advertising, allocated according to a complicated system. In 1967, a broadcaster providing news and sports was established in order to provide independent programming (*Nederlandse Omroep Stichting*, NOS), too. The allocation of, first, radio frequencies and later 'windows' on the national television channels to 'broadcasting societies' took care of the needs to cater to different audience segments, whereas NOS provided the audience with common references to the national culture, politics, and society.

2.2 Broadcasting Regulation as Market Regulation

Whereas the regulation of broadcasting as a public service can be said to be a European invention that has been exported to a number of other countries in Africa and Asia, the model of regulating of broadcasting as a competitive industry has its deepest roots in the USA. In the USA, a distinct *broadcasting policy* was never formulated. According to some scholars and judges the First Amendment of the American Constitution (which states that the federal government shall 'make no law abridging freedom of speech, or of the press' prohibits even a government's statement of broadcast goals and protects as far as possible the rights of private persons and even private corporations in the marketplace to speak as they choose. The European invention of vesting the responsibility for production of diverse programs in one or a few public institutions was adverse to the American conception that diversity and pluralism is a product of freedom of expression interpreted as freedom to establish media institutions.

Regulations were implemented in order to prevent, or rather to avoid, 'chaos on the ether' that resulted from the shortage of frequencies and lack of regulation in the 1920s. In the USA, the early period of chaos led to implementation of a regulatory regime aimed at correcting market failure in the form of chaos and scarcity, and to avoid monopolization and dominance. The networks, however, soon dominated national broadcasting whereas in the local and regional areas hundreds of radio and television stations operated.

The Communications Act that was implemented in 1934 was the backbone of broadcasting regulations in the USA. The act set up the regime that was in power until the late 1990s, and more or less defined the framework within which the American media and broadcasting industry was to develop. Broadcasters were regulated according to *dominance* in the market by the restrictions on ownership in terms of how many radio and television stations that could be owned by one company or individual; by *entry* regulations that foreclosed the networks from dominating program production and that divided broadcasting and communications into separate markets. As in all other countries, the legislation was amended and adapted to changing circumstances but these principles remained in force until the Communications Act of 1996 replaced them.

The Communications Act of 1996 has been regarded as a major liberalization of the communications market in the USA, and has influenced market developments within the country as well as outside. Basically, the new legislation removed most of the entry barriers between different markets, most notably between the telephone market and broadcasting market, and lifted or relaxed ownership restrictions on radio and television stations. In effect, these changes were aimed at opening and establishing *one* communications market, taking into account that the changes in information technologies had undermined the rationale for implementing different regulations for, for example, broadcasting and telecommunications.

The model of regulating broadcasting by means of the market has been adopted in other countries too, although the specific regulations vary. In Europe, Luxembourg was the exception to the dominance of the public service system. In Latin America, many countries adopted commercial systems, among them Brazil and Mexico.

2.3 Mixed Systems

If the pure public service model and the pure market regulation model are considered two opposite poles, it also becomes evident that there are a number of countries that have adopted hybrid variants or mixed models; that is, some system combining public service models with markets models. Canada and Australia are states that early set up mixed systems, Britain introduced its duopoly consisting of the BBC and the independent broadcasters in 1956, and most other European countries followed suit during the 1960s and 1970s. The Scandinavian countries and Belgium were the last countries to introduce nationwide commercial broadcasters in the early 1990s, the so-called *hybrid channels*. Hybrid channels are private broadcasters granted the privilege of tapping the national advertising market in return for complying with public service obligations concerning programming and coverage. The group of mixed systems is large, diverse, and increasing, reflecting technological as well as political changes in the broadcasting sector.

3. Research into Broadcasting Regulations

3.1 Research on Broadcasting Regulations before 1980

As a field of systematic research, the politics and regulation of broadcasting have developed gradually from the 1970s onwards. Although the broadcasting industry and the broadcasting institutions received much attention from the moment they were established, research into broadcasting regulation and the variations of broadcasting regimes were not studied systematically until the 1980s onwards. There are several explanations for this. The first and most obvious one is that communication studies in many countries were not established as a separate academic field. To the degree that there existed a research tradition on media politics in general and broadcasting regulation in particular, studies tended to be either descriptive country studies accounting for one specific broadcasting system, or they were efforts to typologize regulatory regimes across the world by a set of simple criteria, such as degree of state intervention as opposed to the degree of privatization, or the existence of commercial broadcasters as opposed to noncommercial systems.

Examples of such typologies that gained much attention were the book *Four Theories of the Press* by Siebert et al. (1956) who, writing from a liberal perspective at the peak of the Cold War, divided the world into two main categories of regulatory regimes, liberal with a contemporary variant termed 'social responsible' and authoritarian with the correspondent communist model. In spite of the fact that the model did not encompass variants such as the public broadcasters, the book, probably because of its simplicity, remained a standard reference in central textbooks (e.g., McQuail 1994) for several decades. Williams presented another typology in his book *Communications* (1960). Williams distinguished between authoritarian, commercial, and democratic systems. This was also an effort to set up a universal typology over media regimes, with the exception that Williams argued that fully democratic regimes were nonexistent and needed to be established. Both typologies were prescriptive rather than descriptive and did not in any detail describe the conditions under which different regulatory systems developed.

The relative stability of national regimes between 1950 and 1970 probably contributed to the lack of studies investigating, comparing, and contrasting national broadcasting systems in order to arrive at more precise models. In spite of the fact that television in this period replaced radio as the dominant electronic mass medium in most of the Western world, the introduction of the new medium in general did not change the existing regulatory regimes. In countries that had a national monopoly on broadcasting, television services were opened within the existing institution (e.g., Britain, Scandinavia), in countries that had a commercial system television services were provided by the existing actors (USA), and in authoritarian states television was controlled and used as an instrument for government propaganda in the same way as radio and newspapers.

3.2 Research on Broadcasting Regulations 1980–2000

As a research area, media politics and regulation had its breakthrough in the late 1980s. The increased interest among media researchers for studies of the political and regulatory aspects of the media replaced the preoccupation with power and influence of media institutions, media corporations, and media content that dominated research in political communication in the preceding periods. The 1980s initiated a period of major changes in broadcasting structures and markets all over the world leading to a liberalization of broadcasting markets, entrance of transnational television channels, and a diversification of national broadcasting structures. As a direct consequence, media politics and regulations were moved high on the agenda not only for national policy makers but were also discussed on regional and international forums such as the Council of Europe, the European Union, the World Trade Organization, and UNESCO. These changes, which were conceived of as dramatic by the research community as well as the legislators, spurred a renewed interest into describing and evaluating the processes.

One of the outcomes of renewed interest into media regulation was an increase in the number of *comparative studies* of broadcasting regulation. Whereas research into broadcasting typically had meant country studies, the late 1980s and 1990s saw an upsurge of works that compared and contrasted national systems (e.g., Sepstrup 1989, Siune and Truetzschler 1992, Syvertsen 1992, Humphreys 1996, Hoffmann-Riem 1998, McQuail and Siune 1998). These studies put different systems in relief to each other and reconceptualized the characteristics of national systems into general models, such as the coining of the 'public service broadcasting' model as an analytical concept in the early 1990s.

There exists a number of different attempts to grasp the characteristics of the public service system. The British Broadcasting Research Unit (BRU) assembled a list of eight characteristics, whereas the British political communication researcher Jay Blumler operated with six characteristics. Both were attempts at creating a conceptual tool that could be applied to the different national variants of public service broadcasters. The problem with these lists, however, was the fact that they were too complex and included criteria that applied to some but not all variants of what were conceived of as public service systems.

Another problem was that these criteria did not encompass the subsumption of the newcomers to the public service system—the hybrid channels—under the concept.

An alternative concept of public service broadcasting as a specific regulatory model was set forth by the Norwegian researcher Trine Syvertsen, who, on the basis of a comparison between the British Broadcasting Corporation and the Norwegian Broadcasting Corporation, described public service broadcasting as a reciprocal system between the broadcasting institution and the state. This model is described in terms of a *contract* that grants public broadcasters *privileges* from the state and in return for which the broadcasters take on a set of *obligations* (Syvertsen 1992). The privileges consist, mostly, of being given an exclusive position on the market, such as a monopoly on national terrestrial broadcasting, exclusive access to the license fee, or as in the case of the hybrid channels, exclusive access to the advertising market on national terrestrial broadcasting. The obligations consist, varying between national contexts, of providing universal access to the programs for the entire population, providing a diverse program menu, catering for the interests of majority and minority groups, and strengthening national culture and identities, to mention some of the commonest ideas.

Syvertsen's model allows for the national variations in the public service model. The fact that regulating broadcasting as a public service did not mean that identical models were set up in several countries, rather that each country tried to design a system of publicly governed broadcasting within the frames of external constraints and national characteristics (Skogerbø 1996) is also a feature that has been emphasized during the 1990s (Humphreys 1996, Hoffmann-Riem 1998, Smith and Patterson 1998). The model has also proven productive as it incorporates changes in the political developments of the public service systems.

At the beginning of the twenty-first century there is also an increasing amount of research on globalization of the media industry and the following regionalization and internationalization of regulatory regimes for broadcasting. Globalization can be interpreted as the outcome of a number of different processes, among them the digitization and convergence of different technological domains, such as broadcasting, print and publishing, information technology, and telecommunications. Liberalization of national broadcasting and telecommunications markets that started in the early 1980s contributed to transforming the communications industry into a global industrial sector. These developments have led to an increased focus both on the processes of change, on the causes, and on the effects that they have had on national and regional regulatory regimes.

In Europe, the efforts by the European Union to establish a common regulatory regime for transnational television have been followed critically and discussed extensively. A similar process took place in the Council of Europe culminating in the *European Convention on Transfrontier Television*. These international regulations subsumed a hitherto unregulated emerging industry of transnational satellite and cable television under a common regional regime. Similar provisions are baked into other regional trade agreements (e.g., North American Free Trade Agreement (NAFTA). A theme specific to the European debate on broadcasting regulations, however, was the objectives laid out in the Green Paper on *Television Without Frontiers* that was published by the European Union in 1984 as a precursor to the Directive with the same title that was adopted in 1991. The Green Paper stated that the attempt to harmonize broadcasting regulation across Europe was one of several ways to create a basis for a common European identity and a common European culture. These attempts were debated hotly in the European political community, and have also been an issue for research and debate among European media researchers. The gist of the academic debate was a profound skepticism towards the idea that international regulations could create the basis for a common European identity (e.g., Morley and Robins 1995, Schlesinger 1997). The early 1990s also displayed a conspicuous clash of interests between the USA and the European Union regarding regulation of trade in audiovisual products, of which television programs are a major part, that have attracted interest from scholars as well as political actors. The closing of the Uruguay Round in the negotiations on the General Agreement on Tariffs and Trade (GATT) threatened to break down because of major conflicts of interest between these two parties.

In the late 1990s less attention was given to these issues mostly owing to the fact that European agencies turned their attention to attempts at setting up a regulatory regime that adapted to the emerging *convergence* of infrastructure, services, and markets between broadcasting, telecommunications, publishing, and information technology. The changes foreseen were that the separate regulatory regimes for broadcasting and telecommunications could no longer be maintained, and should be replaced by one common regime for all types of communications.

4. *Methodological Issues*

The study of media politics and regulations is still a young field within communication research. During the 1990s the number of empirical studies comparing different national broadcasting systems has increased markedly. This development also signals that there is a methodological reorientation in the field, emphasizing descriptive and explanatory analyses of a few cases at the expense of normative evaluation of universal models. The comparison of national systems yields

insights into the conditions that have shaped broadcasting institutions and provides insights necessary to understand the current political conflicts on how to regulate broadcasting under new conditions, both nationally and internationally. In media studies there is a long tradition for adopting an implicit, not explicit, normative (critical or liberal) approach when phenomena are analyzed, which sometimes has created problems of analytical clarity. With the increased focus on comparisons, these problems may be overcome, as normative judgments will have to be made more explicit.

Buddhism

Of the world's three great missionary religions (Buddhism, Christianity, and Islam), Buddhism is the oldest. It was one of a number of universalist soteriologies which emerged in the Gangetic plain of north India in the sixth and fifth centuries BCE along with cities and kingdoms. It spread throughout Asia between 250 BCE and 1200 CE. Thereafter it began to go into decline in some places, eventually dying out in India, the land of its birth; in other places it went through cycles of decline and revival, culminating in newly invigorated and often innovative revivals in the modern era. In the nineteenth century—partly because of perceived similarities to and contrasts with Christianity—it proved to be powerfully attractive to many Westerners, an attraction that continued and grew in the twentieth century. But there are also underlying differences between Christianity and Buddhism which, when overlooked, lead to serious misunderstandings.

From a sociological point of view Buddhism can be seen as an individualist and humanist soteriology (salvation religion) which developed a variety of communal forms and worldly orientations in different settings. It has legitimated many elaborate hierarchies; in modern times, many Asian intellectuals interpret it as an early form of egalitarian socialism. For many, meditation is the heart of Buddhism (Carrithers 1983); in other places and times elaborate ritual has been, and remains, more important. Some see vegetarianism as central to Buddhism; many Buddhists eat meat. Everywhere Buddhism is centrally concerned with death and salvation; but in some places, notably (but by no means only) in East Asia, Buddhist temples have become deeply involved in providing rituals for worldly protection and winning personal advantages. Most Buddhists take very seriously the notion of rebirth in accordance with the morality of one's actions, but in East Asia the influence of Confucianism means that moral notions are usually divorced from the idea of rebirth.

1. The Buddha, his Teaching (Dharma), and his Community (Sangha)

Buddhist tradition is unanimous that the Buddha was born in Lumbini in southern Nepal and died, aged 80, in Kushinagara, India. The Theravada tradition maintains that he died in 543 BCE, and this date has become widely accepted by Buddhists: in 1956 the 2500th anniversary of the Buddha's death was celebrated in Nepal with delegations from around the world. Western historians of Buddhism have long rejected this date as too early and thus many textbooks give dates between 486 and 460 BCE. Recently it has been argued that the correct date is probably around 400 BCE.

'The Buddha' means 'the awakened one'; the historical Buddha's family name was Gautama and his personal name was Siddhartha. Buddhists believe that in principle anyone can become enlightened and teach others, and that there have been many other Buddhas in different world ages and in different worlds. According to the tradition, the Buddha's father knew from a prophecy that his son might abandon his kingdom to become a great spiritual teacher and

therefore isolated him within the palace, attempting to surround him with nothing but pleasure and ease. One day, however, he managed to escape and saw an old man, a sick man, and a corpse. These 'three signs' alerted him to the existence of suffering and death, and he resolved to seek a way beyond them. He left the palace at night, cut off his own hair, abandoned his clothes, sent away his servant and horse, and set out to seek enlightenment. He spent six years experimenting with different teachers, before coming to see that mortification of the body was as bad as self-indulgence. He realized that a Middle Way was necessary—eating once a day, enough to maintain the body without overindulgence—and this led him to attain Enlightenment in Bodh Gaya, India, at the age of 35. Being enlightened—an aim that he shared with other renouncers of the time—means escape from the otherwise endless cycle of rebirths.

He gave his first sermon, to his first five disciples, in Sarnath, near Banaras in India, on the Four Noble Truths: the existence of suffering, the arising (cause) of suffering, the end of suffering (nirvana), and the path to achieve it. Nirvana is the 'blowing out' of the passion, hatred, and delusion with which we are on fire (and from which we suffer). The metaphor of the fire refers to Brahmanical thinking: the Buddha took over much of the the Brahmans' vocabulary while radically changing its meaning by ethicizing and universalizing it. The path to nirvana consisted of three stages: morality, meditation, and wisdom. In order to practise the second two stages, and to attempt to attain enlightenment in this life, it was (until modern times) usually thought necessary to renounce the world, that is, to abandon, like the Buddha himself, the life of a householder, and live with other celibates, monks or nuns. The role of lay people was to practise morality and to support monks and nuns; by doing so they could improve their karmic state and attain better rebirths in future, eventually going on to attain enlightenment themselves. Later many Theravada Buddhists came to believe that the world had declined to such an extent that even monks and nuns could not attain enlightenment, and they too should seek better rebirths.

At his death the Buddha entered full nirvana and was not reborn. His remains were cremated and the ashes were divided between eight different lay groups and enshrined in *stupa*s. Later the remains of other prominent Buddhist clerics were similarly enshrined and these places, or smaller *caitya*s modeled on them, became the characteristic places of Buddhist worship.

To facilitate a life of self-control and meditation, the Buddha founded his Sangha or Monastic Community. All Buddhists 'take refuge in' the Three Jewels, which are the Buddha, the Dharma (his Teaching), and the Sangha. Members of the Sangha are governed by 227 Vinaya rules (in the Theravada tradition; other traditions have 250 or more). The rules cover the correct behaviour of monks (the nuns have their own Vinaya, with even more rules). This way of life appealed mainly to those of high status: although there were low-caste converts within the Sangha, high castes predominated. It was, as Max Weber (1958 [1916–17], p. 371) remarked, a 'genteel'(*vornehm*) soteriology.

Every fortnight monks are supposed to come together to confess any infractions of the rules and then to recite the rules together. However, in Theravada Buddhism there was originally little enforceable hierarchy. Monks do not promise to obey anyone. Deference is owed on the basis of seniority to monks who were ordained earlier than themselves, and to one's teachers, but that is all. Ecclesiastical hierarchies have emerged in many Buddhist countries, but they are not prescribed in the Vinaya.

Despite the fact that in practice monks frequently maintain close ties with their kin and often carry on secular occupations, the institution of celibacy was to have weighty consequences for the societies which adopted the Buddha's teaching. In Tibet it is estimated that before the 1950s 10–12 percent of the male population were monks, and a further 10–15 percent were non-celibate Buddhist practitioners. In Tibet and the Theravada countries the history, as written in the premodern period, was the history of the Sangha. The issue of monastic property, and its transmission, is important in all Buddhist countries, with a variety of solutions being adopted.

By the standards of his day, the Buddha's teaching was individualistic, humanist, egalitarian, and rationalist. It was individualistic in that individual persons had their own karmic trajectory, which they could work to better by good actions or to harm by bad. There was no question of any higher power or other person granting salvation. It was humanist in that it debunked the Brahmans' claims to higher purity and spiritual status on the basis of their birth; it denied the efficacy of ritual (especially animal sacrifice), ecstatic trance, or worshipping gods in order to obtain salvation. Only one's own efforts will do. It was egalitarian in that all human beings have an equal chance to start out on this path (and humans are superior to gods in this respect: gods, though powerful, have to be reborn as humans to have a chance of achieving nirvana). It was rationalist in that the Buddha favored openness (in contrast to the secretiveness of the Brahmans, whose learning was available only to other Brahmans); and he stressed the need to try out doctrines for oneself and a rational ethic of helpfulness to others.

Thus modernist reformers in the nineteenth and early twentieth centuries could relatively easily represent Buddhism as a rational and scientific belief system, as a philosophy and not a religion, as unconcerned with the existence of God or gods, and as implying social reform and development. However, most Buddhists have believed in gods, have practised ritual in order to overcome misfortune and in order to benefit the dead, have regarded their faith as a religion,

and have accepted socio-religious hierarchies. All the evidence is that these practices are as old as Buddhism itself, and the modernist interpretation of Buddhism should be viewed as just that: as modernist and as an interpretation.

2. *The Spread of Buddhism*

At the beginning Buddhism was just one of many different schools of renunciatory philosophy. With its universalism and its teaching of careful attention, it seems to have appealed to townspeople and merchants, and to have spread with them throughout the Indian subcontinent. It emerged to prominence through the actions of the Emperor Ashoka (reigned c. 268 BCE to 239 BCE) who ruled most of present-day India. Though he protected all religions within his realm, his inscriptions advocate the Buddhist virtues of non-violence, hard work, and consideration for others. He may well have seen Buddhism as a means of binding his enormous Empire together and he sent out Buddhist missionaries in all directions, including to West Asia (Middle East). Buddhist tradition remembers Ashoka as the ideal Buddhist ruler and he became the model for many subsequent rulers attempting to reform the Sangha.

As Buddhism spread, different schools and ordination traditions emerged naturally simply through geographical separation. The Buddha's teachings were preserved orally. This explains their repetitious character: they were only preserved because monks learned to recite them, and preservation of the canon quickly became a prime raison d'être of monastics. Writing probably did not yet exist in the Buddha's day. The earliest compilations of teachings were not systematically written down until the first century BCE, by which time they had long been organized into three 'baskets' (*pitaka*): the Sutta Pitaka, preserving the Buddha's teachings; the Vinaya Pitaka, preserving his rulings on the way of life of the Sangha; and the Abhidhamma Pitaka, which claims to present the teaching literally and systematically, and dates from after Buddhism was already established. (On internal evidence some of the Sutta Pitaka and much of the Vinaya Pitaka must also post-date the Buddha himself.) From time to time monks would come together to chant and check on each other's recitations. The early Buddhist councils were about fixing the Buddhist canon and debating minor differences that had arisen over monastic discipline. As far as the Buddhist laity was concerned, the central teachings were encapsulated in narratives about the Buddha's life, and particularly those concerning his 550 past lives contained in scriptures known as Jatakas and Avadanas; many of the latter were composed much later than the canon.

Among the many early Buddhist traditions, one was the Theravada, meaning 'doctrine of the elders,' so-called because they considered themselves the most conservative. This is now found in South-East Asia and Sri Lanka. Other schools had more adherents in India, especially in the north-west from which China and Tibet received their missions, but Buddhism in what is now Pakistan, Kashmir, and Central Asia died out after the arrival of Islam. Consequently Theravada Buddhism is the only form of pre-Mahayana Buddhism to survive into the modern world.

Although there are some disagreements, the vast mass of Theravada scriptures, preserved in the Pali language, are shared and agreed upon in the Theravada countries. Pali was close to the local vernaculars of the Buddha's environment and the Buddha rejected use of the Brahmans' holy language, Sanskrit, because of his policy of openness. But as Buddhism spread, and as the spoken languages of north India evolved, Pali quickly became a purely scriptural and liturgical language, just like Sanskrit, and lay people became dependent on monks to expound the teaching to them.

2.1 *Mahayana Buddhism*

Around the turn of the common era an entirely new form of Buddhism arose in north-west India called the Mahayana. This is conventionally translated as 'The Great Vehicle' but equally means 'the great path or way.' It introduced a whole raft of new scriptures, now composed in Sanskrit, which were supposed to date from the time of the Buddha himself; some claimed to have been hidden by him until people would be ready for them. The Mahayana reinterpreted the term *bodhisattva*, which for non-Mahayanists essentially means 'a future Buddha.' Mahayana Buddhism posited the existence of numerous powerful, celestial *bodhisattva*s. The most important of these was Avalokiteshvara, the embodiment of compassion, who would appear to people in their hour of need and save them. In China he was thought of as female and became the goddess Kwan Yin (Kannon in Japan). The Mahayana, unlike earlier forms of Buddhism, was most definitely based on a cult of the book: by this time scriptures were holy objects to be enshrined and worshipped as well as read.

The Mahayana introduced a revolution into the moral code of Buddhism, because it encouraged all Buddhists, whether monks or lay people, to aspire themselves to become Buddhas: this is called 'taking the *bodhisattva* vow.' Selfless service to others is part of this path; thus non-Mahayana Buddhists are said to be following the 'Hinayana' or Lesser Way. Great stress is laid on the Buddha's doctrine of 'skill in means' i.e., adapting the teaching to the level of the hearers. This, together with the philosophical teaching

of the essential 'emptiness' of all worldly phenomena, acted as a charter for developing new forms of ritual to attract lay Buddhists and non-Buddhists onto the path. These doctrines also served to legitimate the relaxation of some monastic rules e.g., the ban on monks' handling gold and silver.

Mahayana Buddhism did not reject the pantheon, the scriptures, or the monastic discipline of earlier Buddhism; it simply added further scriptures and objects of worship. Two of its most influential scriptures were the Lotus Sutra (Saddharma-Pundarika) and the Perfection of Wisdom (Prajna-Paramita). It was primarily in this form that Buddhism then spread to China, Tibet, Mongolia, Japan, Korea, and northern Vietnam.

2.2 *Vajrayana* (*Tantric*) *Buddhism*

There was a still later current which is known as Vajrayana or Tantric Buddhism. This is based on scriptures known as Tantras, which appeared in India between 400 CE and 900 CE primarily within Hinduism and Buddhism. (In fact, there were several successive waves of Buddhist Tantras.) These scriptures were esoteric, placed great emphasis on ritual, and used magical and antinomian symbols and practices, which, they claimed, enabled the spiritual seeker to achieve rapid results not possible by other methods under the guidance of a guru. The earlier forms of Tantric Buddhism spread to China and Japan (and are still carried on in Japan by the Tendai and Shingon sects). Later forms of Tantrism, once found from India to China, survive today only as part of Tibetan and Nepalese (Newar) Buddhist traditions. The very latest Tantric Buddhist scripture, the Kalachakra, can be dated to the early eleventh century and, very unusually, contains numerous references to Islam.

The development of the Tantric (Vajrayana) Buddhism encouraged the emergence of Buddhist priests, that is to say, full-time ritual specialists devoted to the religious needs of lay people, who are frequently married and pass on their position to their sons. Such specialists are found in Tibet, Nepal, and Japan. The ideology of Tantric Buddhism attaches paramount importance to the guru. He is frequently included alongside the Three Jewels of Buddhism or identified with the Buddha himself. In order to receive the full Tantric teachings it is necessary to take special initiations (Skt. *diksa*); celibacy is not a prerequisite; in fact, given the sexual nature of much of the symbolism and some of the practices, it may be an impediment. Thus Tantric Buddhism introduced a criterion of spiritual hierarchy that was sometimes in conflict with the monk/lay distinction, and at the very least served to undermine it. The necessity of a guru introduced a clear rationale for hierarchy among clerics. However, Tantric Buddhism, just like Mahayana Buddhism before it, did not reject what had gone before, but rather added to it; Tantric Buddhism therefore became the esoteric heart of a highly complex and layered set of traditions. Different schools and teachers disagreed on what exact place to give it. Monastic practice continued to be important in most forms of Buddhism. Tantrism has often been interpreted as a 'tribal,' peripheral, or 'shamanic' form of religion: however, whatever its origins, within Buddhism Tantrism was a highly sophisticated, learned, and scholastic tradition that attempted to tap some of the power of popular practices, both for salvation and for worldly benefits, while maintaining an elite distance from them.

2.3 *Later Developments*

In East Asia whole sects of Mahayana Buddhism grew up devoted to a particular scripture, a development which did not occur in India or Tibet. Thus, in Japan there are sects whose primary allegiance is to the Lotus Sutra, practising a devotional Buddhism, while others, e.g., the Shingon, have as their core practice the Tantric ritual of fire sacrifice, and yet others (the various Zen sects) focus on meditation. However, the Tendai attempts to teach and combine all the scriptures, while holding the Lotus Sutra to the final and highest truth. In Japan, until the Meiji restoration, most Buddhist practitioners were celibate, except those of the Jodo Shinshu, founded by Shinran (1173–1263); it was one of the most radical sects focused on the worship of the Amida Buddha of the Western paradise (Pure Land): simply uttering obeisance to Amida was all that was required for salvation; all other rules (including celibacy) were beside the point. A strong opponent of Shinran was Nichiren (1222–1282), who advocated devotion to the Lotus Sutra and mounted vituperative attacks on Buddhists who did not agree with him.

In Tibet yet another innovation, dating from the 13th century, was the institution of reincarnate lamas (teachers), of whom the most famous is the Dalai Lama. The first Dalai Lama lived in the sixteenth century; the present Dalai Lama is the fourteenth. When a Dalai Lama dies, after the interbirth period his successor is sought according to the indications of the state oracle. The boy chosen is believed to be both the reincarnation of the previous Dalai Lama and of the *bodhisattva* Avalokiteshvara, the special protector of Tibet. There are many other reincarnate lamas throughout Tibet and in neighboring areas where Tibetan Buddhism is practised.

2.4 *The Contemporary Situation*

Nowadays Theravada Buddhism is practised in Burma, Thailand, Laos, Cambodia, and Sri Lanka. Tibet was and is a stronghold of both Mahayana and

Vajrayana Buddhism, with both married and (more prestigious) celibate practitioners. Chinese Buddhism was predominantly non-Tantric Mahayana of various sorts, as are Korean and Vietnamese Buddhism. In East Asia generally different sects grew up on the basis of different Mahayana scriptures; thus in Japan there are both Tantric (Shingon, Tendai) and non-Tantric Mahayana schools, and even a tiny school (the Ritsu) based entirely on the practice of the monastic code. Thus when new religious movements arose in this century in Japan, naturally some were strongly Buddhist: some, like Soka Gakkai and Reiyukai, have spread through missionary activity to many different countries. The Tibetan diaspora has carried Tibetan Buddhism around the globe as well, and Theravada Buddhists have also proselytized widely. There have also been attempts to build a global ecumenical Buddhist movement.

There is a striking contrast between the Theravada countries plus Tibet, where Buddhism became the dominant cultural tradition and came eventually to define a nationality, and East Asia, where Buddhism, though at periods dominant and favored by the elite, never achieved unquestioned acceptance. In China, Japan, and Korea the influence of Confucianism and Daoism meant that Buddhists often had to defend celibacy against the argument that it undermined society; by contrast the spiritual value of avoiding marriage and reproduction is rarely questioned in South Asia and Buddhist Southeast Asia.

3. *Buddhism and Political Authority*

Although a minority of the first generations of monks chose to wander for nine months of the year, most later monks and nuns settled in monasteries, working at preserving the scriptures and serving the laity. Buddhist monasteries rapidly acquired economic assets, and some were wealthy, owning villages, buying and selling land, and involved in trade. Property brought problems, requiring managers, both lay and monastic (in Theravada Buddhism monks are not supposed to handle money). On the other hand, monks and nuns are obliged to act as 'a field of merit' and accept whatever the laity offer them. The suspicion that many were only interested in a comfortable and secure life, free from labor in the fields, was common.

A king was meant to be the foremost layman of the kingdom and ensure the purity and safety of the Sangha. All ordinations took place under his authority. Following the example of Ashoka, kings were supposed to expel monks who broke the rules or fomented splits within the Sangha. It has been argued by Samuel (1993) that it was the relative strength of the monarchy in Southeast Asia which enabled Theravada to remain dominant and prevented other sects, based on the Mahayana scriptures for example, from becoming established. By contrast, in Tibet the effective political control of Lhasa never spread far beyond the heartland, thus enabling a rich variety of Buddhist philosophies and schools to flourish, including many that gave a much greater emphasis than the dominant Gelukpa sect to shamanic and non-celibate practice.

Buddhist kings were faced with the problem that simply in order to carry out their duty as a king—protecting the people, maintaining order—they had to commit sins (primarily killing) and were therefore disbarred from attaining salvation. At the same time, in both Theravada and Mahayana countries, the king is often regarded as a *bodhisattva* (Buddha-to-be). Ashoka is remembered as having killed many enemies in war in Kalinga, and then, after becoming full of remorse, vowed not to do it again. But other ideal kings either do one or the other, and in Sri Lanka the heroes of the Sinhalese chronicles (composed by monks) are those kings, Dutthagamani (101–77 BCE) and Parakkamabahu I (1153–86), who fought on behalf of Buddhism. The Sangha offered a way out: earning merit to counterbalance their sins though supporting the Sangha. At the same time, one of the most popular and (for Buddhists) most poignant Jataka (Rebirth) stories tells how King Vessantara (the Buddha in a previous life) renounced and gave away, not only his kingdom and wealth, but his wife and children as well.

In short, the Sangha enabled the king to legitimate himself in the eyes of the people, and refused to ordain fugitives from royal justice. In return, the king supported the Sangha, granting it land and other privileges, and when necessary carried out purifications, suppressed noncanonical innovations, and supported revivals. Only in Tibet did the Sangha eventually take over and *become* the state.

4. *Religious Specialists and the Laity*

Lay Buddhists take the Five Precepts: undertakings not to take life, not to steal, not to commit sexual wrongdoing, not to lie, and not to take intoxicants which lead to carelessness and the breaking of the other four precepts. On special days lay people take the Eight Precepts: this includes the Five (while interpreting the third to mean a complete cessation of sexual activity), and adds three others: not to eat after midday, not to adorn oneself or go to entertainments, and not use luxurious beds (i.e., to sleep on the floor). In this way lay people, mostly women, take up the same discipline as a monastic novice, but on a temporary basis.

The Buddhist laity do not have to foreswear all other religious relationships. Providing they approach the gods for mere worldly matters, this is usually of no concern to the monks, and has nothing to do with their faith in Buddhism as a path to salvation. It is hard for Buddhist laity to continue to practise animal sacrifice but even this is done by some Buddhists in Tibet,

Nepal, and Thailand in what they define as non-Buddhist contexts.

The facts that Buddhism is centred so firmly on salvation and the afterlife, and that lay Buddhists almost inevitably have other, worldly interests, mean that 'Buddhism in real life is *accretive*' (Gombrich 1971, p. 49, original emphasis). Buddhism always coexists—often in a structured hierarchy that places the Buddha at the top of the pantheon—with other religious systems which satisfy the worldly needs of ordinary Buddhists. Thus when Theravada Buddhists celebrate the harvest, seek a cure for illness, or get married, they do so in a non-Buddhist idiom with the help of non-Buddhist specialists (Tambiah 1970). Hindu gods are included in the Buddhist pantheon as powerful spirits, subordinate to the Buddha, and travelled with Buddhism to other parts of Asia where they were sometimes identified with local deities, all of whom became part of the Buddhist cosmology.

This soteriological focus explains why, traditionally, there is no such thing as a Buddhist wedding ceremony, although pious lay people may optionally invite a monk or monks to chant and be fed after the ceremony. Even in Mahayana countries the close relationship between Buddhism and death continues. In Japan death ritual is almost exclusively a Buddhist concern, whereas birth and marriage are celebrated in a Shinto idiom. However, many Buddhist temples in East Asia also offer help for worldly needs; and in Nepal, among the Newars, Buddhist priests have even established a complete set of Buddhist life-cycle rituals, including marriage.

This interrelationship between Buddhism and other systems has frequently been mislabelled 'syncretism' by Western observers using an exclusivist definition of religion. But this is an ethnocentric judgement which ignores the fact that Buddhist lay people who worship non-Buddhist spirits or gods do nothing wrong, providing they do not do so in the hope of obtaining salvation. Ironically, however, modernist Buddhists have themselves adopted the Western-derived exclusivist definition of religion in their attempts to reform what they see as backwardness and superstition.

The radical individualism of the Buddha's message was socially and psychologically hard to accept. Most Buddhists, including monks, have wished to make some kind of offering to benefit their dead parents, for example. The ritualized offering of merit to others, which may include dead relatives, is common in all forms of Buddhism. In Theravada Buddhism the canonical explanation of the protective chanting ritual performed for the dead is that the dead can only benefit if they happen to be in the form of ghosts and happen to be nearby so that they can gain merit from listening. That such an abstruse justification might not be shared by all lay people can easily be imagined. In a similar way, many lay people have a straightforwardly magical attitude to the use of Buddhist amulets. Mahayana Buddhist specialists do not insist so unequivocally on maintaining a rationalist, commemorative explanation of Buddhist rituals; but they agree that the magical attitude corresponds to the lowest level of understanding.

5. *Reforms, Revivals, and National Identity*

Buddhism has always been subject to cycles of decline and reform. All forms of institutionalized Buddhism experience a tension between well-endowed institutions, which specialize in scholarship and ritual, on the one hand, and wandering or forest-dwelling monks or practitioners, on the other. Frequently, the laity (including the elite) perceive the freelance practitioners as closer to the Buddhist ideal and beat a path to their door. Over time, and thanks to the donations they cannot refuse, the freelancers themselves become well endowed, and inspire a further cycle of reform aimed at recapturing true asceticism and/or meditative practice.

5.1 *The Rise of Buddhist Modernism*

In the nineteenth and twentieth centuries, faced everywhere with competition from Christian missionaries and taking advantage of the new technology of the printing press, reform movements took a new and sometimes overtly political turn. Buddhist institutions experienced very different trajectories depending on the country. In Japan Buddhism had been closely tied to the state in pre-Meiji times and Buddhist priests had been responsible for government record keeping; after 1868 Buddhism was forcibly separated from Shintoism (with mixed religious sites being forced to choose one or other identity) and much land was expropriated (Ketelaar 1990). In China and Tibet, Buddhism, like all autonomous civil institutions, suffered enormously under Communist rule, being permitted a limited revival in the 1980s and 1990s.

The Theravada countries have experienced a new form of rationalist, scripturalist Buddhism which has been dubbed Buddhist modernism or Protestant Buddhism (Gombrich and Obeyesekere 1988). In Sri Lanka this was was a protest both against the Protestant missionaries and against traditional Theravada Buddhism: it criticized monks for being unlearned ritualists, for being inactive on issues of social and political concern, for not practising meditation, and for encouraging superstition. More positively, it stood for universal literacy, Buddhist Sunday schools, and a middle-class morality of strict monogamy and hard work. It sought to base Buddhist teachings strictly on the Pali canon, and to purify practice of anything that could be dubbed Hindu or Mahayana influence. It stressed the scientific nature of Buddhist teachings, often claiming that major scientific advances were already to be found in the Pali

canon. In Sri Lanka it also aimed to make Buddhists proud to be Buddhist, and to defend their cultural and religious heritage against the inroads of the Protestant missionaries who confidently predicted that in fifty years' time the Buddha would have gone the same way as Wodin and Thor. The rise of Protestant Buddhism went hand in hand, therefore, with the emergence of Sinhala nationalism. The Sinhalese race-nation came to be defined in terms of its Buddhism, and Buddhist historical chronicles were taken to demonstrate its long association with, and right to dominate, the island. The key figure in this Buddhist revival in Sri Lanka was Don David Hewawitarana (1864–1933), who took the title Anagarika Dharmapala, founded the Maha Bodhi Society, and campaigned ceaselessly to awaken the Sinhalese to their religious and nationalist mission.

5.2 Western Views of Buddhism and the Protestant/Catholic Parallel

The story of Buddhist revival in Sri Lanka intersects crucially with the story of the Western discovery of Buddhism. Many of the Victorians had a deep sympathy for Buddhism, because they thought it was, like Christianity, a simple and rational faith founded by a pure-hearted reformer. Edwin Arnold's poem, *The Light of Asia* (1879), had an enormous impact. Counter-attacking Christian apologists dubbed Buddhism 'nihilistic' and 'anti-life.'

There was a pervasive tendency, which has lasted up to the present in some quarters, to view Mahayana and Theravada Buddhisms as the equivalent of Roman Catholicism and Protestantism within Christianity. (Hostile descriptions of Buddhism borrowed a well-worn vocabulary, honed in many Protestant descriptions of Catholicism, in which the words 'priestcraft,' 'superstition,' and 'mumbo-jumbo' loomed large.) It is true that Mahayana Buddhism has a baroque pantheon, numerous elaborate rituals, and more elaborate priestly hierarchies; but the contrast was exaggerated by adopting the modernist interpretation of Theravada Buddhism as a simple, rationalist philosophy whose only ritual was the commemoration of its founder. The parallel breaks down as a serious tool of analysis for several reasons:

(1) historically Theravada Buddhism represents the earlier form, against which Mahayana rebelled;

(2) Theravada Buddhism is traditionally built on monasticism, and therefore on spiritual hierarchy, and it is modernist Buddhism which has introduced a Protestant-style belief in the equality of all believers;

(3) the scriptures of the Theravada were preserved in Pali, and it is only in the modern period that they began to be translated into the vernaculars;

(4) the worship of relics is very important in Theravada Buddhism, and sponsoring their worship has been an important source of legitimacy for rulers, both traditionally and in the modern period;

(5) traditionally Theravada Buddhists believed that nirvana was impossible to attain at present, because of the degeneracy of the age, which made the quest for salvation considerably less urgent than in Protestantism.

These differences between Protestantism and actually existing Theravada Buddhism were obvious to those Westerners, such as Madame Blavatsky and Colonel Olcott, founders of the Theosophical Society, who travelled to India in search of the wisdom of the East. Olcott came to Sri Lanka in 1880 and set about reforming Buddhism, so that it could become what they claimed it had always been. It was Olcott who first set up Buddhist schools, drew up a Buddhist catechism and encouraged the annual celebration of the Buddha's enlightenment with Buddhist carols. He was instrumental in the setting up of Buddhist Sunday schools and the Young Men's and Young Women's Buddhist Associations. He also designed the Buddhist flag which is now flown around the world. It was Olcott and Blavatsky who first encouraged Dharmapala. Many of the early Buddhist revivalists were Theosophists as well. Dharmapala, along with D. T. Suzuki, who first popularized Zen in the West, and Vivekananda, the leader of neo-Hindu revivalism, attended the 1893 World Parliament of Religions in Chicago, a key event in the history of Buddhist modernism.

5.3 Government Control in Thailand

In Thailand, which avoided European colonialism, modernist reforms were, by contrast, largely a top-down process. The reforming King Rama IV (Mongkut) (reigned 1852–68) had spent 27 years a monk before ascending the throne. He emphasized strict adherence to the Pali canon, excluding later, popular works that encouraged the laity to view the Buddha as a miracle worker. It was Mongkut's monastery that was the center of what was to become the Dhammayutika Nikaya, a new monastic order that stressed adherence to the Vinaya rules. Increasing centralization led in Thailand to the Sangha Act of 1902, by which the government took effective control not just of the royal monasteries in the capital but, for the first time, of all monasteries and monks in Thailand. A national exam syllabus was established with textbooks written by Rama IV's son and the king's half-brother, Prince Wachirayan, who himself became the Supreme Patriarch of the Thai Sangha in 1910. In Thailand, but not in Sri Lanka, it is the custom for all young men to spend at least 2–3 months as a monk, around the age of 20. (In Burma temporary ordination tends to be taken much younger, and can last anything from a day to several years.) Giving up the status of monk and returning to lay life is not seen

as in any way shameful; many men spend 10 or more years receiving an education as a monk, and then return to lay life. One consequence of tightening up monastic education was that monasteries, which had previously had a monopoly on learning and literacy, had to stick to a more strictly religious curriculum, and many forms of knowledge—medicine, astrology, history writing—that had been passed on in them, now found a home outside.

5.4 Buddhism and National Identity

As in Sri Lanka, the reform of Buddhism in Thailand was intimately tied to the construction of a sense of national identity. Muslim and Christian minorities have not been persecuted, but Buddhism receives official backing. However, the detailed government control of religion has meant that, when dissident movements arise, it is faced with the difficult choice between suppressing them in line with its traditional responsibility for the purity of Buddhism, and permitting them in the name of religious freedom.

In Burma, Thailand, and Sri Lanka the relationship between the ruling elite, the people, and Buddhism was so close that it is possible to speak of proto-nationalism there even before the modern period; that is to say, the people were defined in terms of their adherence to Buddhism and any ruler who failed to protect Buddhism could not be accepted as legitimate. Certainly, when the modern period dawned and nation-states were created, it was hard to be accepted as a Burmese or a Thai unless one professed Theravada Buddhism, and many of the ethnic troubles of Sri Lanka have flowed from the fact that most Sinhalese Buddhists feel the same way.

There is a similarly tight connection between Tibetan nationalism and Buddhism, but in other Mahayana countries the position is very different. In Japan, Buddhism was persecuted as a foreign religion in the 1870s, and in Korea restrictions were continuous from 1392 until the twentieth century: the ruling Choson dynasty, which based itself on Confucian ideas, banned Buddhist monasteries from the major towns.

5.5 Lay Meditation and the Movement for Female Ordination

The rise of the lay meditation movement marked a major change in Buddhist practice in the twentieth century. Traditionally few monks meditated. Most performed ritual services for the laity and some studied the scriptures. Highest status went to learned monks in urban centres or to rare forest meditators. Lay life was thought to be incompatible with meditation. Part of the modernization of the religion has seen meditation being taught to the laity, often by laymen and women. For many middle-class Buddhists, this means that they bypass monasteries altogether and base their religious practice in meditation centers. Burma led the way in the development of meditation for the laity, and Vipassana (insight) meditation has spread throughout the world; for example, the efforts of an ethnic Indian born in Burma, S. N. Goenka, have been very influential well beyond the community of those born Buddhist. Zen Buddhism has perhaps been even more influential in the West, though whether the popular understanding of it accords with the way it is practised in East Asia is open to question. In India Bhimrao Ambedkar, leader of India's Untouchables and one of the framers of India's Constitution, began a major movement of social liberation by urging his followers to embrace Buddhism and converting himself at the end of his life in 1956 (Zelliot 1992).

Just as the Buddhist laity in general are not as submissive to monastic authority as they once were, so there has been a general movement for the emancipation of women in Buddhism. Historically the order of nuns has always been subordinate to monks, the highest ranking nun being considered, formally, as inferior to the most junior monk. Furthermore, within Theravada countries the nun's ordination tradition died out in the eleventh century (Sri Lanka) and thirteenth century (Burma): since five nuns are needed to ordain a new one, the formal status of nun was no longer available to women. All that they could do was to take the Ten Precepts, like a monastic novice, on a permanent basis, and live a celibate life, a precarious and unprestigious possibility attractive mainly to widows (though often also done by elderly men). As part of the revival of Buddhism in the Theravada countries, many women started to adopt a more monastic way of life and to be treated as fully fledged nuns. In the 1980s and 1990s Western feminist Buddhists have argued that Theravada women should take full ordination from the Chinese tradition where it has been preserved, and some have done so. This has been extremely controversial; many of those (mainly men) who have opposed them doing so argue that they should thereby become Mahayanists or refrain from calling themselves nuns. While the theological objections are very different, the issue arouses similar passions to the ordination of women priests in the West.

Buddhism and Gender

Studies on Buddhism and gender can be divided into two categories. First, scholars are beginning to look into historical Buddhism, both to ascertain the history of women in Buddhism and to find out what classical Buddhist texts say about gender. Second, some contemporary Buddhists are re-evaluating their tradition and suggesting changes that would make their religion more equitable both in terms of gender and in terms of sexual orientation.

As is the case for all major religions, scholars who want to explore topics related to Buddhism and gender inherited androcentric scholarship about a male-dominated religion. There is no question that Buddhism was historically male-dominated, and remains so in most of its contemporary forms. And there is no question that until recently, scholars who studied Buddhism studied Buddhist men and ignored Buddhist women, for the most part. Buddhist studies and Buddhist constructive thought are both relatively conservative enterprises; therefore gender studies in Buddhism are less developed than is the case for other religions, especially Christianity.

Because the conceptual framework for gender studies evolved in the context of Western thought, care must be taken in applying that conceptual framework to Buddhism. It is easy to misinterpret or misrepresent Buddhist ideas and practices about gender by assuming that they mean the same things in a Buddhist context as they would in a Western context. For example, the popular assumption that it is 'bad karma' to be a woman can easily be taken to mean that women are 'bad' or evil, an assumption common in some forms of Western religions. But in a Buddhist context, the meaning of this assumption is that women are less fortunate than men precisely because of limitations placed on them by male-dominated cultures—an assessment with which Western feminists would agree!

1. Traditional Buddhist Understandings of Gender: Historical Perspectives

Despite the varied, often contradictory statements about gender found in classical Buddhist texts and throughout Buddhist history, several generalizations are tenable. There have been two major themes and one minor theme that have dominated Buddhist teachings and practices surrounding gender in all periods of Buddhist history, in all schools of Buddhism, and in all Buddhist cultures.

The first theme is that gender is irrelevant, 'something about which weak worldlings are confused,' to paraphrase a common scriptural theme. This strand of Buddhist thought is found in the textual traditions of all forms of Buddhism, though it is strongest in Indian Mahayana texts, which began to be written about five hundred years after the historical Buddha, and in Indian and Tibetan Vajrayana texts, which date from several centuries later. Though there are many variants of this theme, all of them proclaim that a person's gender is irrelevant to their understanding of Buddhist teachings and ability to attain enlightenment.

The second theme contradicts the first, declaring that gender matters a great deal and that it is far more fortunate to be reborn as a man than as a woman. The texts that present this point of view very clearly recognize that women's lives were far more circumscribed and difficult than men's lives in the cultural settings with which they were familiar. Cultural limitations on women's ability to study Buddhist teachings and practice Buddhist meditation were only the most onerous of their burdens. In addition, women were required always to be formally subordinate to male authority, even if they were nuns, and most women faced heavy domestic and childbearing responsibilities. The men who evaluated this situation came to the conclusion that women were, indeed, quite unfortunate. They explained this misfortune by means of common teachings about rebirth, according to which one's present life, filled with positive or negative circumstances, resulted from actions (*karma*) done in past lives. Thus, people who commit negative acts are reborn as women rather than men, with all the difficulties outlined above. Some have even claimed that there is no gender inequity in classical Buddhism because it teaches that 'deserving' women are reborn as men in future lives. Indeed, even in contemporary times, Buddhist women in some cultures engage in religious practices that would help them be reborn as men in the future.

The third, more minor theme in Buddhist literature is a strand of misogyny, or fear and hatred of women, that runs through Buddhist texts. This theme is especially strong in the writings of male monastics and in those forms of Buddhism that most valued celibacy. Thus it is no surprise that this theme is strong in the earliest Buddhist literature which describes the life of the Buddha and his immediate disciples. Significantly, some forms of Tibetan Vajrayana Buddhism specifically forbid their followers from disparaging women. This command clearly indicates the prevalence of antiwomen rhetoric in Buddhist contexts, but it is also noteworthy that some Buddhists authorities condemned that practice by prohibiting their followers from indulging in such prejudice.

How can these contradictory positions on gender be reconciled, if at all? Most knowledgeable Buddhists would conclude that the first view is the most normative for Buddhists. It is clearly in accord with the major teachings of Buddhism, whereas the second and third views actually contradict the most basic teachings of Buddhism. However, the second view is far more prevalent and popular among ordinary followers of Buddhism. Far more problematic is that all Buddhists institutions, especially the highly valued monasteries and universities, were organized in accord with the second, rather than the first view. Sex segregation was almost complete and men received far more of the education and livelihood provided by monasteries and universities than did women. So complete was the favoring of men's institutions over women's that the once flourishing nuns' order died out in all parts of the Buddhist world except China and Korea. In the other parts of the Buddhist world, only a much less prestigious form of lay ordination for women survived.

2. Key Buddhist Doctrines and Gender

Given this historical legacy, contemporary Buddhist analysts concerned with gender have studied the classical doctrines of Buddhist tradition, asking what implications they might have for contemporary gender issues, especially gender inequity and controversies surrounding sexual orientation. These contemporary analysts are especially concerned with finding firm doctrinal foundations for suggesting changes in traditional Buddhist practices that favor men over women and assume heterosexuality.

All forms of Buddhism trace human misery to grasping or clinging, and state that the most basic and pain-producing form of grasping is clinging to belief in a fixed and permanent underlying core of selfhood—what is called 'soul' in many religions. This is the famous doctrine of *anatman*, frequently translated as egolessness or 'no-self,' which is often the most confusing Buddhist idea to insiders and outsiders alike. Nevertheless, traditional Buddhist doctrine is firm and clear. There is no permanent, independent, real self that can be found by any means at all; the practice of positing such a self and acting as if there were such a self is the ultimate cause of all human suffering.

Thus, according to Buddhism, there is not even a permanent enduring sexless soul attached to any individual's existence, let alone any permanent, real, or lasting identity based on gender. Thus fixed norms

regarding gender roles or stereotypes based on gender are completely contradictory with the most basic Buddhist doctrines, which means that tenacious, emotionally intense clinging to those gender norms and stereotypes is even more inappropriate. Furthermore, the suffering experienced both by those who do not conform to gender norms, as well as those who do, is to be expected if clinging to rigid and fixed norms about gender persists. All that classical Buddhist doctrines would seem to warrant is a recognition that someone is male or female biologically, but that no inherent or necessary implications about appropriate behavior and psychology can be attached to that biology.

This doctrine of *anatman* is common to all forms of Buddhism. Mahayana Buddhism, which began to develop about 500 years after the Buddha, includes doctrines that reinforce the implications of early Buddhist doctrines and texts that specifically state that gender is irrelevant to one's ability to attain enlightenment—Buddhism's highest goal. Briefly, the central Mahayana doctrine of emptiness (*shunyata*) states that not only does a fixed permanent self not exist, but that nothing whatsoever has any permanent, fixed, or independent and real existence. Therefore, one should cling to nothing whatsoever; texts about emptiness state explicitly that gender does not inherently exist and is, therefore, irrelevant to the religious life. Some schools of Mahayana Buddhism also propose the doctrine of Buddha-nature, which claims that everything is potentially enlightened Buddha. All that needs to occur is for beings to realize this indwelling Buddha-nature. Schools of Buddhism that hold this doctrine commonly assert that all sentient beings, including all women and men, are equally endowed with Buddha-nature. Thus, these two Mahayana doctrines, when combined, assert that gender traits do not exist inherently and the men and women are equally endowed with the only trait that matters—indwelling Buddhahood.

3. *Contemporary Issues and Suggestions*

Contemporary analysts of Buddhism and gender have concluded that when Buddhist institutional practice regarding gender and Buddhist doctrines pertinent to gender are placed side by side, a massive contradiction is obvious. Thus it is no surprise that objections to practices of gender inequity in traditional Buddhism have come from many quarters, both Asian and Western, in the late twentieth century. Important factors in this development have been the rapidity with which Buddhism is becoming a religion of choice for Western intellectuals and the rise of Western feminism, which has resulted in a vigorous Buddhist feminist movement.

For many, the most obvious issue is the status of Buddhist nuns throughout the Buddhist world. For traditional Buddhism, monasticism is the preferred lifestyle and the prestige of monastics can hardly be exaggerated. Thus, a reliable marker of gender equity, at least in more traditional forms of Buddhism, is the presence of a flourishing community of well-educated nuns. In contemporary Taiwan and Korea, this is the case, but the situation is not so sanguine in other parts of the Buddhist world. Only the novice ordination has survived in Tibetan Buddhism and in Therevada Buddhism, even that has been lost. All that remains is an informal lay ordination for women, who then wear distinctive robes, but not of the ochre color that is the time-sanctioned mark of a Buddhist monastic. In addition, these novice or lay nuns are rarely well educated in classical Buddhist disciplines and often become mainly servants of the monastery.

How to reinstitute the nuns' ordination has been discussed by many; the mechanics of doing so are not difficult and ordinations have been offered by those Buddhist communities that still retain the ability to ordain nuns. However, in many cases, changes have not yet occurred while male monastic authorities investigate sectarian differences and the legitimacy of the ordination lineages being offered. In the meanwhile, especially among Tibetan Buddhists in exile, the status of novice nuns is improving and they are being taught disciplines not usually taught to nuns in the past. In Theravada countries, there are vigorous pro-ordination movements and some Theravadin women go abroad to receive monastic ordination. However, simply reviving nuns' ordination will not address all the issues brought up by contemporary analyses of Buddhism and gender. The monastic rulebook subordinates all nuns to all monks, with no regard for seniority or accomplishments, thus reduplicating the gender hierarchy of the societies in which Buddhism developed.

In Western countries, where Buddhism is rapidly spreading, monastic issues are less central to the daily concerns of most Buddhists. They have not become, and do not expect to become, monks and nuns, and whether monasticism will become part of Western Buddhisms remains an open question. Following a pattern more common in Japanese Buddhisms than in other Asian Buddhisms, even the most serious Western Buddhist practitioners remain laypersons, usually attempting to combine the demanding meditation and study programs of serious Buddhist practice with careers and family life. What is distinctive about Western Buddhism is that women are just as enthusiastic in such pursuits as are men. In many meditation programs, the number of women participants is as high as, or even higher than, the number of men participants, and, at least in some Buddhist denominations, the teacher is as likely to be a woman as a man. This is a radical departure from traditional Asian practices. If this pattern of lay Buddhists being seriously involved in Buddhist study and practice persists and becomes the norm for Western Buddhism, it will represent a significant paradigm shift in the 2500

year history of Buddhism, not only because of the role women are playing, but also because of the role laypeople are playing.

For both Western and Asian Buddhism, perhaps the key issue determining whether or not gender equity becomes the Buddhist norm is the presence or absence of women teachers at the highest ranks. Buddhism is more dependent on the teacher–student relationship than are most religions and in this nontheistic religion, no authority is higher than the heads of teaching lineages. In the past, such authorities have, with very few exceptions, been men, which has probably contributed more to the persistent gender inequity of Buddhism than any other single factor. As was discussed above, in both Asian and Western contexts, large numbers of Buddhist women are becoming better educated than in the past. In many forms of Western Buddhism, women are common among the senior teachers at the penultimate ranks, but very few women have been authorized to teach at the highest level, especially among those who practice Tibetan forms of Buddhism. American Zen Buddhists now authorize women as independent teachers somewhat more frequently and there are a significant number of women teachers in the Vipassana movement as well.

The presence of women teachers is important for several reasons beyond the requirement for equal opportunity. First is the importance of role models and the subtle messages communicated to newcomers by the presence or absence of members of various groups in leadership positions. More important is the fact that Buddhist teachers have an enormous impact on the development of the tradition. Like all religions, Buddhism is open-ended and unfinished, and the evolution of Buddhism largely depends upon the teachers of any given generation. No matter how realized and accomplished a woman may be as a meditator or philosopher, if she does not teach, she will have no impact on the development of Buddhist thought and practice. The lack of women teachers in the past explains why the insights of women's culture have not been integrated into Buddhist thought previously. They will not become part of Buddhist tradition until large numbers of women are authorized as teachers and speak in their own voices.

In fact, it could be argued that the androcentric character of inherited Buddhist thought and institutions is largely due to such an absence of women functioning as teachers. All periods of Buddhist history do record some highly accomplished women and probably there were many more, memories of whom were lost due to androcentric record-keeping practices. But we rarely encounter stories of them as teachers either in the monastic or the yogic traditions and few texts have been attributed to them.

The intersection of Buddhism, especially Western Buddhism, with the current attention to issues of gender promises to rectify this situation. Especially beginning with the decade of the 1990s, many thoughtful and innovative books and articles have been written on the topic of Buddhism and gender. Many of the authors of these texts openly identify as practicing Buddhists seeking to make their tradition more equitable. In this emerging body of literature, women who have begun to voice their concerns as Buddhist teachers focus on many issues relevant to the lifestyles of lay women practitioners, such as shared domestic responsibilities and arrangements for children at meditation programs. They have explored the importance of community (*sangha*) in Buddhist life and discussed alternative forms of community. They also have searched the historical records looking for accomplished women of the past whose stories had been lost to Buddhist collective memory. A matter of critical importance for many has been translating traditional Buddhist liturgies into gender-neutral and gender-inclusive language. Finally, some have contemplated the visual imagery common in Buddhist settings and sought to rectify the overwhelming preponderance of male images in the typical Buddhist meditation hall or sacred site.

More recently, the topic of sexual orientation has also begun to be discussed publicly in Buddhist circles. Because Buddhism has always required celibacy for its monastics and has not devised strict and detailed law codes governing the everyday behavior of its laity, the topic has not received significant formal attention in the past. The codes of behavior for monks and nuns would forbid homosexual activity simply through the precise and detailed descriptions of forbidden sexual activities. It is difficult to obtain much information historically about homosexual practices of lay Buddhists. But in contemporary times, especially among Western Buddhists, concern that Buddhism recognize the legitimacy of homosexuality has become an important issue. Because Western Buddhism is usually socially liberal, Western Buddhists are generally accepting of their gay and lesbian peers, and a number of important spokespersons for Western Buddhism are gay or lesbian. However, on the basis of relatively obscure traditional norms about forbidden sexual practices, some Asian teachers have objected to the practice of homosexuality, though not to homosexual sexual orientation. To date, less has been written on the topic of gender as an issue of sexual orientation than on the topic of gender as an issue of equity between men and women. With the growing realization that gender is an omnipresent facet of all peoples' experience, not something only women possess, it will no longer be possible to limit discussions of Buddhism and gender to issues of women's place in Buddhism. Such a development will signal a major conceptual breakthrough, for nothing is more indicative of androcentrism than the tendency to collapse the categories of 'gender' and 'women.'

Budgeting and Anticipatory Management

All organizations must:

(a) coordinate the way resources will be used by the various (often specialized) decision makers; and

(b) learn from the observed deviations between intended and actual.

They need these two activities in order to create value for their stockholders by increasing the probability of satisfying their key stakeholders such as customers, employees, suppliers, and any outside agency granting the organization the right to continue to operate.

For the past 75 years or more, budgets have been the prime instrument in providing such a process of *ex ante* coordination and *ex post* analysis. They did so by defining, often from 'above' (the leadership sends a 'command'), the actions that are likely to lead to goal achievement, combined with *ex post* evaluation of variances or deviations from plan ('control' to bring conformance).

A budget is generally defined as a formal document that quantifies an organization's plan for achieving its goal (Jiambalvo 2001). A budget, in other words, is a description of the financial implications of a sequence of coordinated actions and specialized targets that will allow an organization to achieve its objectives in a changing environment. Most budgets, until recently, assumed implicitly, once the budget had been defined—i.e., the actions and targets selected—that uncertainty about the environment could be essentially 'ignored' for a period of implementation (and the managers were expected to manage to the budget and not necessarily to pay attention to the competitive environment). Frequently, such a period used to be about 12 months and has recently frequently been reduced to six and, in certain cases, three or four months, given the turbulence of the competitive environment. However, many behavioral habits about managing to the budget have been kept alive, and many still try to 'achieve the budget,' thus still assuming the estimate made some 6 to 18 months before is still valid. A budget is in itself a fundamental document and budgeting an essential process in the operation of any organization.

How the budget has been used in practice has led to many abuses and negative effects. This short article will define the principles of budgeting and 'budgets' before showing the limitations of current practice and will explore how the 'concept' (i.e., a tool to support ongoing adaptive anticipation or anticipatory management) ought to be used today to meet current economic and competitive challenges.

1. A Philosophy of Anticipation

'As for the future, your task is not to forsee it, but to enable it' (Antoine de Saint Exupery in *Le Petit Prince*) and, to do so means to be able to mobilize all resources in the organization continuously to adapt to and exploit new opportunities that appear. This means the path to 'success' cannot be completely defined before hand.

Despite such an observation, 'command and control' are still the most commonly used form of management, essentially in contradiction to the reactivity and agility required for success in a competitive world. It seems odd that command-and-control-type budgets still occupy such an important

role in the ways of coordinating the behavior of decision makers. The whole organization, and especially its management team collectively, must continuously update the best way to create value for stakeholders in continuously changing competitive environments.

Budgets and the budgeting activity (process of establishing and validating action plans) are processes and procedures that aim at contributing to the creation of value. A budget is a statement—a declaration—of actions intended to be carried out by several organizational decision makers in a coordinated way. Action plans are needed in both 'for profit' and 'not for profit' organizations. A budget reflects the answers the organization and its leadership give at one point in time (and it may possibly be a valid answer only for a short period of time) to one key question: how are we going to go from where we are to where we want to be? A budget and budgeting process are one of the key ways through which energies are mobilized and channeled for the successful implementation of the business strategic intent.

We will first identify the purposes and the process of creation of the budget, then the key requirements for the budget to be an effective tool that fulfills its promises, before elaborating on the criticisms that have been formulated about budgets and their current use.

2. *Purposes of Budgets and of Budgeting Processes*

The budgeting process and budgets contribute to the process of anticipation in that they:

(a) Provide a forum in which the various organizational members (who do not have identical skills, experience, and expertise) can identify and share their views of opportunities and threats to the value creation process of the business or organization.

(b) Provide a locus for the construction of a shared business model (identify the key success factors and how they interact in creating the success of the firm).

(c) Allow management to discuss, select, and communicate values (to guide behavior), intent (defining what value creation or success means), and plans (coordinated sequence of interlocked actions and identification of resources created and consumed).

(d) Create a forum for coordinated decision making between actors that may otherwise act in a disconnected fashion that would result from their referring to different business models. For example, the sales manager might consider developing sales at a rate that might not be compatible with the action plan imagined by the manufacturing manager (who foresees difficulties in bringing the required new technology on line) or with the action plan of the financial manager (who would rather increase the dividends than finance the increase in working capital that the increased sales might create).

(e) Provide for the development of transfunctional action plans describing how to achieve continuous alignment of the firm or organization 'behavior' with competitive pressures.

(f) Identify what resources are needed at what time. Resources ought not be limited to tangible or financially measurable resources: know-how, intellectual capital, customer, supplier or employee loyalty, morale, image and style, etc. are resources that must be used appropriately to create and maintain long term success.

(g) Allow for the identification and allocation of the business' scarce resources required to carry out the action plan effectively and efficiently.

(h) Reinforce a structure of delegation, devolution and, 'subsidiarity' in co-locating 'rights to make decisions' (on the use of resources) and knowledge and in supporting initiative and autonomy while maintaining coordination. The term subsidiarity is not in the dictionaries we have consulted. It is, however, a commonly used term in the context of the partition of rights between States and the leadership—executive and legislative—of the European Union (EU). We use it here in the same logic to refer to the fundamental idea behind the word as it is used in the EU dialogues: decision making should be as close as possible to the 'customer' or to the market, i.e., any unnecessary attempt at going up in the delegation chain to reach a decision is slowing down the organization's reaction and runs the risk of creating a solution which is maladapted to the need.

(i) Help build commitment by individuals or groups of individuals to achieving time-based results that move the organization in the desired direction. Note that the principle is to obtain commitment to a result and not necessarily to the way through which this result is to be achieved. This aspect is the source of great misuse of budgets in that many organizations confuse 'commitment to the use of resources as agreed upon' for 'commitment to results.' Often the source of confusion is due to a combination of lack of trust on the part of the supervisor and lack of self-confidence on the part of the subordinate.

(j) Contribute to establishing benchmarks for performance measurement and evaluation (for both business units and individuals). Here again it is important to draw attention to the fact that the benchmarks need not be limited to financial measures of results or resource consumption.

(k) Provide a basis for learning from deviations. This aspect has often been misunderstood to mean that conformance to the plan is expected. Since, by definition, no plan can be perfect, conformance for its own sake can be a source of non-competitiveness.

(l) Create a context for the deliberate management of performance improvement.

(m) Allow for the forecasting of cash flow needs on the basis of the action plans that have been retained (cash is an essential scarce resource in any organization and must be monitored at all times).

(n) Offer a process for an ongoing estimation of year-end financial results and more specifically EPS & ROE for commercial organizations.

This whole array of purposes cannot be broken down and each aspect dealt with separately. They are all to be pursued simultaneously.

3. *The Budgeting Cycle*

Generally, the budgeting process follows a pre-established sequence but many iterations are possible with today's simulation instruments:

(a) Identify and communicate estimated future demand and markets conditions and business environment evolution to establish for every participant the hypotheses that all should assume in researching their contribution to the action plans. Such a task should, most of the time, originate with upper management that holds a bird's eye view of the whole business.

(b) Jointly identify threats, opportunities, weaknesses, and strengths of the organization in the perceived (or declared) future environment.

(c) Identify and evaluate the various possible action plans (sales, production, sourcing, human resources, innovation and investments, R&D, etc.) and verify their compatibility with both intent or goals and resources.

(d) Repeat the process until compatibility is obtained and acceptance by everyone in the organization has been secured (this step may require the superior to act as a binding arbitrator to avoid subordinates wasting time in useless battles). An arbitrator listens to all parties, reflects on the best collective solution, and selects a preferred course of action that is both explained and justified to all parties who must adhere to it.

(e) Once the budget or action plan is established, results are matched against expected (intermediate or final) results and the analysis of differences (or deviations) leads to learning and thus a reevaluation of the appropriateness of the action plan and its possible updating.

4. *Components of an Action Plan*

An action plan reflects the answers of the concerned persons to at least the following questions:

(a) Where are we and why do we need to do 'something' (understand the cause of the action plan by identifying a possible gap between where we are and where we are headed, and where we think we ought to be, given the intent or goals of the firm or organization)?

(b) What is the 'intention' behind doing something?

(c) How does whatever will be done relate to the achievement of the firm's mission?

(d) Who are the various actors who need to be involved (basis for both the richness of analysis and delegation in the implementation process)? An action plan is always teamwork, even though each person on the team is personally responsible for one 'component' of the plan, often overlapping with someone else's. For example, an action plan aimed at 'generating orders that the firm can deliver to the customer's satisfaction and that help the firm grow' will require, for example, the cooperation of such specialized managers as: sales manager, sales people, marketing manager, production scheduling, assembly manager, legal department, sourcing manager, management accountant, etc. If the plan were not the result of an agreement between all these required skill holders, it would have little chance of success.

(e) What causal model (also known as business model) do the 'team members' agree on to help them identify the 'action variables' they will activate through their decisions and behavior?

(f) What possible actions can be envisioned? (it is important to review several possible alternatives critically).

(g) Which one will we choose, and why? What will we actually do in this action plan?

(h) How will we do it? What process? What resources will be consumed and created and when? What delegation structure will be developed, etc.?

(i) Are the required and generated resources coherent with the availability and needs of the organization? If the answer is negative, there must be a return for adjustment to any or all questions (a) through (h).

(j) Why will we do it this way? What were the alternatives' pros and cons? How realistic is the alternative selected and how realistic were the other ones? What are the risks attached to each alternative and especially the one selected?

(k) Coherence with strategic intent, strategy, and other action plans.

(l) Expected impact of the selected actions (several may apply simultaneously):

(i) development of a competitive advantage;

(ii) ambitious yet realistic: placing the organization under tension;

(iii) challenging the ways of thinking; and

(iv) all of the above or other.

(m) When will these actions be carried out (calendar of actions)?

(n) How often will these action need to be carried out (if it is a recurring action plan)? This is an important point as a multistage action plan allows for better learning and continuous adjustment.

(o) To what do each of the actors actually commit (intermediate or final results, non-financial indicators, relationships, dates, intensity, etc.)?

(p) How will the achievement of the commitments

be measured? There are at least three domains for which measures should be agreed upon beforehand by all parties involved in the action plan. These measures will serve as a basis for learning from deviations and for continuously updating the action plan so that it remains aligned with the intention selected, if it is still the right one):

(i) Process, i.e., the way the action plan should and does unfold during implementation (the equivalent aerospace term would be 'trajectory'):

evolution of the conditions that created the need for the action;

resource productivity and effectiveness;

resources consumed and created;

organization and relationships between actors;

mastery over risks identified in step (j);

efficiency of use of resources; etc.

(ii) Progress (against the time scale selected by the actors in the plan to state by which date the target will be achieved):

timing: date of start, selection of milestones, date of expected completion;

positioning of progress on a PERT diagram;

validation of the critical path;

definition of the method of calculation of the percentage achievement; etc.

(iii) Impact:

effect of actions on objectives and key performance indicators (KPIs) for both short and long term; and

evaluation of the continued relevance of the intent.

(q) What priority should be given to this action plan and how much of the firm will be involved (if applicable)?

Traditional budgeting seems to have focused essentially on steps (h) and (i) and therefore has led to a very partial view of what is meant by an action plan. Essential to the effectiveness of the budgeting process is the measurement system evoked in step (p). The measures should be balanced between areas of expertise, perspectives, and time horizons and allow simultaneously both effective implementation and continuous validation of the relevance of the whole action plan given the evolution of the competitive environment. Budgeting and processes of anticipation link, therefore, directly to the area of management now commonly described as the Balanced Score Card or *Tableau de Bord*.

5. *Budget Process Requirements*

5.1 *A Sense of Direction*

There must be goals that preexist the beginning of the budgeting process. Each goal must have a time frame and be a milestone towards achieving the organization's mission or intent. In specifying its goals, the organization states who the stakeholders are that are taken into consideration.

5.2 *A Continuously Updated Shared Causal Model*

Decision makers and personnel must be able to understand some key 'cause and effect' relationships that affect the organization's output or performance. The budget rests on the identification of a causal model that helps understand what consequences might obtain from what actions in the perceived competitive environment. Much time is needed in a business to identify and maintain the model(s) or causal representations that will help understand how we could go from point X to point Y in the map of opportunities.

5.3 *A Monitoring System*

The monitoring system must be able to tell managers how well they are 'getting there' from 'here.' Some of the measures must be anticipatory or leading in the sense that they allow the managers to anticipate inappropriate or unacceptable results and therefore head off the undesired trend through appropriate corrective actions, while other measures are more historical and serve to keep track of what has been achieved.

5.4 *A Set of Criteria for Trade-off between Goal Achievement and Resource Consumption and Creation*

Whether the trade-off will be carried out in economic terms only or using other criteria such as market share, employee satisfaction, or citizenship of the firm, the firm needs to have some kind of preference ordering system that will allow for the identification of a preferred way each time a choice is to be made. It is, however, very difficult in any multi-person setting to come to an agreement on criteria for preference ordering. This difficulty should not prevent the managers from encouraging participation and expression on the part of everyone in the organization since that is the only way to open dialogue and communicate values and orientations.

5.5 *Above All, a Budget Requires Trust Between Participants*

A budget is grounded in delegation. Each person holds responsibility for a 'piece of the action' and must be able to count on the others doing what they promised to do. That promise includes a very crucial element: let others, who depend on the achievement of a milestone or of a result, know as early as feasible (through shared leading indicators) the actual changes in the probability to fulfill commitments. Budgets therefore require trust between participants (both vertically and laterally) and self-confidence combined with a reasonable willingness to take risks and not adhere to a prewritten script.

6. Budgets, 'Opportunity Gap,' and 'Performance Gap'

In projecting itself into the future, any organization faces two simultaneous challenges:

(a) Improve the 'productivity' (effectiveness and efficiency) of resources consumed in carrying out currently retained action plans.

(b) Identify new opportunities for continued growth that will require modification of current action plans and possibly the development of entirely new ones. Opportunities have a limited lifespan. If no new opportunities are identified and addressed, the organization will cease to grow and will decline into oblivion. Single-purpose organizations such as the March of Dimes or the Tennessee Valley Authority in the US have had to reorganize their mission completely to continue existing. A long-lasting organization such as the Kirin Beer Brewery in Japan is always reinventing itself because product attractiveness has a time limit and customers tend to be fickle unless the producer changes with the evolution of customer tastes.

We define the first challenge as that of managing the 'performance gap' while we will call the second one that of managing the 'opportunity gap.' As business environments grow turbulent, the continued relevance of any given action plan is less and less likely. Simultaneously, the need for continuous identification of new opportunities grows greater.

Figure 1 shows that, at any point in the continuum of turbulence, the required anticipation effort of an organization is always broken into two parts: managing the performance gap (increasing effectiveness and efficiency) and managing the opportunity gap (preparing the organization for the future). At each point on such a continuum, managers need to be able to hold two very different mental maps simultaneously, in differing proportions, as shown in the two 'wedges' at the top of Fig. 1. The coexistence of such differing relations to time and to uncertainty is not an easy task and the budgeting process offers a forum where these two mental maps can coexist.

Figure 1
The tools of anticipation change with the level of turbulence

The effectiveness of the system requires that at each level of turbulence (competitive environment) the manager and the supporting processes take into account the appropriate mix of attention paid to the performance gap and to the opportunity gap. At each level of turbulence, different tools (including the ones relevant at the previous level of turbulence) meet the requirements of management. If the world is very stable, a simple scorecard about past results will suffice as the next action plan is a mere extrapolation or adaptation of the previous one. As the world becomes less stable, 'budgets' answering the question 'what will we do?' suffice to help the firm project itself into the future in a coherent way. The critical issue is to limit the action to have a balance between the resources available (increased by the resources created by the action plan) and the resources needed by the action plan. That vision of 'budgets' is still quite prevalent, as mentioned previously, despite the fact that turbulence conditions make it appropriate no longer.

When the world becomes really very turbulent, a business requires two simultaneous tools: contingent planning (answering the question 'what will we do if?') and 'surprise management' which seeks an answer to the question 'how can we organize ourselves now to be reactive, innovative, and able to operate under future conditions we cannot even imagine right now'? Contingent planning is largely about understanding the relationships between possibilities in the world in which the organization operates and lining up possible 'baskets of competence' for each identified discrete possibility, while surprise management is essentially about understanding relationships between internal capabilities and how they can be mobilized.

If we go from a less turbulent to a most turbulent environment, the first three phases described in Fig. 1 refer to various degrees of extrapolation (the past is full of information relevant for the future), while the last phase, once again, completely changes the mode of thinking. It also forces management to hold simultaneously two mental maps because the future cannot be forecasted.

Turbulence affects each level of responsibility differently in the organization. To a large extent, it is the responsibility of a superior to 'filter' some of the uncertainties and turbulence she or he faces for his or her subordinate. The higher the person is in an organization, the higher the degree of uncertainty she or he has to deal with. Therefore, the higher the person is, the more her or his anticipation efforts should be addressing the 'opportunity gap.' As Fig. 2 shows, even at the top of the organization, although the effort

Figure 2
The effort is applied differently depending on the level of the individual in the hierarchy

of the individual is dedicated essentially to the management of the opportunity gap, there is still a part of the effort that is addressing the performance gap (effectiveness and efficiency).

As individual N moves from the bottom to the top of the organization, her or his preoccupation is more and more with the efficiency and effectiveness of the organization, but there is always a non-negligible preoccupation with some form of attention paid to the opportunity gap, recognizing that new opportunities can be identified at all levels of the organization.

7. Current Budgeting Practice is not Always Aligned with the Principles

As mentioned previously, it is a challenge to build a budgeting process that considers the issue of competitiveness not only from the point of view of the performance gap (efficiency and effectiveness, cost control, etc.) but also from that of the opportunity gap. The causes for such a difficulty can be traced to the following elements:

Objectives and processes to get to the target are often defined only *in* and *on* financial terms.

Partition of the process to achieve the target tends to be only hierarchical and functionally defined instead of being developed along the lines of transfunctional business processes.

The processes of alignment, dialogue, and team building through the budget construction are frequently ignored and the exercise is too often reduced to a scarce resource allocation leading to competitive behavior between organizational entities that ought to cooperate to serve the stakeholders best.

Value creation is mostly defined in terms of financial profit.

The time horizon of an action plan should be linked to the business cycle but is based, too often, on fiscal year constraints (which are defined by reporting needs and have little link with the need to have visibility of the future). Budgeting should be carried out almost as an ongoing process, provided information technology makes it economically feasible. Budgeting is a state of mind. The budget construction should be reengineered in most firms to take as little time as is possible (for example, by concentrating on the relationships in the causal model and on leading descriptors of the status of these relationships). If the budget were an ongoing process, frequent debates would take place that would continuously replace the firm on the most appropriate trajectory or path to its objectives and targets, thus developing confidence and commitment on the part of all in the organization.

Many times the budget has been highjacked as a substitute for an anticipatory form of financial accounting used in estimating year-end accounting results of the firm so that management can comfort stockholders about forecasted profit.

Focus is more on cost reduction than cost management (the 'right' cost is not always the least cost: costs are driven by product and process design, and by people eliminating non-value-adding activities).

Most action plans assume, usually erroneously, that costs are driven by the volume of sales and that costs are best controlled at the point where they can be measured (Lebas 1996). This leads to conformance budget (focused on resource allocation) thus limiting initiative and customer satisfaction.

Many budget processes merge and confuse anticipating and defining benchmarks for reward systems (especially if the latter are based on conformance with resource consumption) thus creating gaming behavior and budget slack which immobilize resources uselessly. Budget slack occurs when managers overestimate resource consumption or required effort and underestimate value created with the customers. Managers indulge in such behavior because most of the time they do not trust the leadership either to allocate resources or support action plans that are compatible with the manager's perception. Such behaviors immobilize resources and prevent the exploitation of opportunities. A performance management tool called 'flexible budgeting' consists in identifying clearly, before the fact, the areas of uncertainty each manager is responsible for (and which ones are not under her or his control) and in recalculating, after the facts are known, the elements of the action plan (consumption of resources as well as outcome or output) that would have been determined had the 'uncontrollable' elements been forecasted with pinpoint accuracy. Such an approach allows for total freedom in really anticipating because the manager knows she or he does not have to take precautions (through the building of budget slack) to cover risks she or he cannot control.

Often, the budgeting process does not implicate everyone and thus a frequent reaction is to consider that 'spending' resources allocated in the context of an

action plan becomes the objective rather than continuously validating the alignment with the intent of the plan of the actions that led to the original allocation.

The main weaknesses of many budget processes currently in place in organizations is that they are not built on a well thought-out system of:

(a) shared representations;

(b) subsidiarity and delegation which would rest on trust in people's ability to make the right decision at the right time, as close to the point of need as possible;

(c) representation of the firm as a network of business processes; and

(d) customer orientation.

8. *In Conclusion*

Anticipatory tools today are not constrained by the fiscal time-horizon; they are rolling and cover a period often closely related to product lifecycles. Anticipatory practices recognize the preeminence of the human aspect in the success of business processes. Choosing the right people and motivating them in well- thought-out processes make for satisfied customers who, in the end, drive the financials of the firm. Such a sequence requires flexibility and continuous adaptation.

Table 1 summarizes the main characteristics of the traditional and the 'new budgeting' approaches in a synthetic format. Budgets and budgeting processes, as they have been used in supporting the development of businesses since the end of World War I and mainly since the post World War II economic boom, seem to have reached their limit. New ways are emerging in coordinating energies in the firm to exploit opportunities. We have described their common denominator by outlining what is required to fulfill that purpose. What we have called new budgeting is far from being settled and probably never will be. Businesses are experimenting in many parts of the world; no solution seems, to date, to be vastly superior to any other, however. Firms like Svenska Handelbanken, Volvo Cars, or Skandia in Sweden, Schlumberger, Air Liquide, or Bull Computers in France, Borealis in Denmark, Boots the Chemist in the United Kingdom, or Sprint in the US have abandoned or are abandoning the 'old budget' approaches and inventing the 'new budgeting' (Hope and Fraser 1999). The real revolution is that we are entering an era of continuous adaptation and learning. Businesses need to adapt the tools too, and the 'budget' is not spared here. Because they have to be completely reinvented, budget processes should be even more fascinating to students, management researchers, and managers alike than they were before.

Table 1
Comparison of traditional and new budgeting (adapted from CAM-I Europe 1994, Lebas 1996)

	Traditional budgeting	'New' budgeting
Purpose	Financial performance forecast	Create and protect value
Structure	Multiple cost centers	Business processes
Resources measured	Costs only	Cost, quality, time, motivation, intellectual capital, loyalty, etc.
Resources view	Scarce, need to be partitioned	Can be obtained if creates value
Classification	General ledger items	Activity resource needs
Approach	Top-down command and control	Emerging and adaptive business process options
Objective	Control and minimize resource consumption	Create customer value through coordinated transverse activities
Mechanism	Historic costs extrapolation	Activity relationships and causality
Cost drivers	Single: output volume	Volume, product design, customer value offering, etc.
Data quality	Internal: implied accounting precision	Internal and external: ok to have approximation and non financial
Cost focus	Cost center spending	Hidden costs consumption
Logic	Simple and mechanical	Complex and dynamic
Reporting and time frame	Periodic and *ex post* analytical	Continuous, flexible, and explanatory
Responsibility	Budget holders	Process team
Deviation/variance	Return to conformance	Understand, learn, and adapt
Behavior induced	Competition	Cooperation
Rewards	Linked to conformance to budget	Linked to outcome long term coherence with strategic intent
Status	Entrenched and well known	Rare and still experimental
Vision	Incremental and bureaucratic	Radical and creative

Budgeting: Political Science Aspects

Budgeting is a process by which governments allocate public resources to bureaucracies and client groups. This process usually takes place on an annual basis, involves procedural rules and institutional arrangements, often invokes intense political conflict, and, together with taxation, forms the basis for fiscal and macroeconomic policy. Because it fundamentally determines political winners and losers through its allocative function, budgetary processes and outcomes serve as distinct guide to a political state's philosophy of government. The act of budgeting, therefore, lies at the heart of politics and government.

1. *The Study of Budgeting*

Budgeting may be studied from several perspectives. From the vantage point of professional schools of public administration, the practical elements of budgeting include the actual drafting and formatting of budget documents, the application of cost-benefit and other tools of program analysis, the projection of revenues and expenditures, the division of spending into its operational and capital components, and the management and implementation of programs funded by the budget. Economists principally focus on the macroeconomic consequences of budgeting, such as the effects of deficit spending on interest rates, inflation, the crowding out of private investment, foreign exchange rates, and national debt management. At a more microeconomic level, economists may also consider the effectiveness of specific programs funded in the budget, such as determining the influence of public jobs programs on the labor market. These questions may also be of interest to and directly addressed by political scientists, but the centrality of political science research looks at budgeting as a guide to a broader analysis of politics, relations between institutions, the behavior of political actors within those institutions and specific public policies.

2. *Budgeting as Incrementalism*

Modern theoretical understandings of budgeting begin with the idea of 'incrementalism.' Formulated in the late 1960s, incrementalism attempts to explain how budgetary decisions are made, how budgetary actors carry out their roles, and what the consequences are for politics by structuring budgetary decisions in one form as compared to alternative ones (Wildavsky 1964, Fenno 1966). Incrementalism is grounded in certain assumptions about human nature, that people are inherently limited by cognitive, time and resource constraints from being truly rational and synoptic in their ability to make budgetary decisions. Budgetary actors 'muddle through' and 'satisfice' rather than 'optimize.' They are constrained from making decisions in the way that microeconomically rational consumers might, where all information sources and alternatives are weighed before a decision is reached. To compensate, these actors rely on 'aids to calculation'. In particular, instead of reviewing the entire budget to determine what is funded, the focus of analytical and political decision making is on the annual change, or increment, in spending. The budget base, or last year's spending, is taken as a given, and the politics of budgeting revolve around determining the size of incremental 'fair shares' allocated to budgetary claimants.

Incrementalism takes into account the role of institutions and actors within those institutions. Budgeting is regarded as a decentralized, 'bottom-up process,' where budget proposals emerge from within executive branch agencies. These agencies in turn act as 'advocates' for larger increments before the Appropriations Committees in the House of Representatives and the Senate. Committee members evaluate these funding claims and act according to a set of behavioral norms. The House Appropriations Committee, for example, operates as the 'guardian of the purse,' while the Senate committee acts as a 'court of appeals.' The overarching norm is that budgets should be balanced.

Incrementalism views budgeting above all else as a political activity, and it gives limited consideration to notions of administrative efficiency or economic rationality in the determination of budgetary out-

comes. Both agencies and politicians instead rely upon incremental aids to calculation. For bureaucrats, incrementalism implies stability and long-term growth in resources. For politicians, incrementalism reduces societal tension and political conflict, as interested groups quickly learn that once their claims are included as part of the budget base, they may count on regular, presumably growing increments.

3. *Challenges to Incrementalism*

Critics of incrementalism soon argued that the model had become obsolete. First, alternative methods of budgeting came into vogue that directly challenged incrementalism's assumptions of limited human rationality and constrained organizational resources. Zero-Based Budgeting (ZBB) and then program budgeting in the form of Planning-Program-Budgeting Systems (PPBS) were designed to improve the choices of decision makers (Schick 1966). The supporters of ZBB declared that the entire budget, rather than just the increment, could be analyzed each year by breaking up the budget into discrete 'decision units' and then reprioritized and reassembled. The defenders of PPBS argued that multiyear planning rather than annual increments enabled decision makers to set broad programmatic goals.

Second, incrementalism, its critics claimed, neglected to account for the rise in entitlement spending, generally focused on the nondefense share of the budget, and ignored the role of the president in setting the budgetary agenda and in shaping outcomes. Where incrementalism depended upon budgetary growth for its conflict-reducing fair shares and growing budget bases, the rise of deficit spending, recessions and ideological demands for reductions in the size of the public sector, caused governments to engage in 'decrementalism' rather than incrementalism. Instead of providing for orderly budgetary growth, by the mid- and late 1970s, governments confronted the highly difficult political task of cutback budgeting.

Throughout the 1980s and 1990s, political scientists noted that governments throughout the world coped with fiscal stress by adapting similar budgetary techniques (Schick 1986, 1988). Budgeting became more centralized, 'top-down' and 'front-loaded' to reduce the influence of interest groups and budgetary claimants. Macrobudgetary guidelines set at the beginning of the budgetary process constrained micro-decisions during the remainder of the process. Governments employed hard targets, ceilings and caps to limit spending; calculated long-term inflationary and program costs through baseline budgeting; created new legislative committees and support agencies to impose greater oversight on the budgetary process; enacted budget resolutions and reconciliation to control entitlements; and strengthened the powers of finance ministers in constraining agency spending demands. Budget balancing reasserted itself as the focus of American politics, and these efforts at deficit reduction were characterized by the enactment of the Balanced Budget and Emergency Deficit Control Act of 1985, better known as Gramm–Rudman–Hollings, the Budget Enforcement Act of 1990, and the Balanced Budget Agreement of 1997 (Savage 1988, White and Wildavsky 1989). In Europe, the 1992 Maastricht Treaty imposed deficit and debt targets on countries seeking to join the European Monetary Union (von Hagen 1992, Wildavsky and Zapico-Goni 1993).

These changes in law not only altered budgetary decisions and institutional arrangements, they signaled a retreat from governments pursuing an activist fiscal policy through budgetary deficits. Spending might indeed violate caps and targets, but these expenditures were often incorporated into the budget through accounting gimmicks, rather than some publicly justified notion of employing Keynesian budgets to stimulate aggregate demand. In this sense, the drive towards deficit reduction and balanced budgets reflected the ascendancy of moderate and conservative governments and the pressures of globalization on public policies.

4. *The Rational Choice Approach To Budgeting*

Since the early 1980s, many political scientists have come to rely upon economically inspired rational choice models, rather than incrementalism's social psychological approach to study budgeting. The basic assumption of rational choice is that political actors rationally seek to maximize their self-interest. Holding power is central to political self-interest, and in democratically elected governments this means being re-elected. Consequently, political institutions and public policies, including budgetary processes and outcomes, are structured by politicians for electoral purposes.

Symptomatic of re-election budgeting is pork-barrel spending, where members direct appropriations to their states and districts to win political credit with their constituents. Pork-barrel projects are also allocated as 'side payments' to create coalitions of legislators in sufficient numbers to pass legislation. Depending upon the model, the size of these coalitions of legislators vary from 'minimum winning coalitions' that contain a majority plus one legislator, to 'universal coalitions,' where all legislators who want a project are given one. The budget is therefore characterized by programs where projects are provided for each legislative district. As a result of pork-barrel spending, the government spends money on economically dubious projects that create large, systemic budget deficits with what are presumed to be negative consequences for the macroeconomy (Shepsle and Weingast 1981).

Like incrementalism, the basic rational choice model has not gone unchallenged. Although politicians do engage in pork-barrel spending, the cost of

these 'distributive' projects is simply insufficient to account for the huge budget deficits incurred by the industrialized democracies in the 1980s and 1990s. Entitlement spending, principally in the form of pensions and health care expenditures, rather than pork-barrel spending is clearly the primary source of budgetary growth. The rise of large-scale deficit spending in the USA, moreover, may also be traced to stagflation, recession, tight monetary policy, tax cuts and the buildup in defense spending during the 1980s. Furthermore, politicians in many countries have risked their own re-election chances by pursuing politically costly fiscal policies, including cutbacks in distributive spending, in order to reduce these deficits.

The minimum winning and universal coalition elements of the rational choice models, which have usually been expressed in formal, mathematical terms, have also been challenged on empirical grounds. Individual, nonentitlement government programs appear to benefit only a limited number of legislative districts. Even when bundled together for purposes of creating voting coalitions, most program 'portfolios' fail to provide universal benefits for all districts. While the rational choice assumes that pork-barrel budgeting takes place for re-election purposes, individual constituents overwhelmingly receive their government benefits from entitlement and general benefit programs, not low visibility pork-barrel funding (Stein and Bickers 1995).

5. *Institutions, Divided Government and Budgeting*

Where rational choice, with its focus on institutions, and incrementalism, which examines roles and norms, experience some convergence is in the analysis of divided government's effect on budgeting. Political institutions and roles within those institutions matter. Empirical evidence indicates that when competing political parties control the executive and legislative branches of government, these governments experience greater difficulties in controlling budget deficits and expenditures than unified ones (Alesina and Rosenthal 1995). Leftist parties spend more than rightist parties, and both parties differ in their spending priorities. Changes in the American budgetary process since 1974 enhanced the power of the parties to set overall budget and fiscal priorities, though the detailed spending decisions remain the prerogative of the committee system. When control of the government is divided, these priorities conflict and fiscal stalemate likely results. Similarly, the more unified and conservative the government, the greater the priority is budget balance (Kiewiet and McCubbins 1991).

Incrementalists add that divided government also influences the advocate and guardian roles of budget makers. Whereas the early incremental models regarded specific roles as enduring, the behavior of budgetary actors during the rise of divided government indicated they were in fact mutable (Cox et al. 1993). When rightist parties control the executive branch, for example, the executive becomes less of an advocate of spending and more of a guardian or protector of perceived budgetary excess. The more leftist oriented the House Appropriations Committee becomes, the less its emphasis on guardianship, particularly in the presence of a conservative executive. A decreasing level of guardianship is associated with the growing size of budget deficits. The Senate Appropriations Committee, meanwhile, tends to remain in its role as a court of budgetary appeals.

6. *Budgeting and Political Science*

Incrementalism and rational choice theories have, despite their limitations, greatly contributed to political science's analysis of the institutional forces and politics that create budgets. These two theories also offer important policy implications of budgeting. Incrementalism, for example, points to the norm of balanced budgets as a reoccurring policy goal of American politics. Rational choice, for instance, accounts for the continued presence of often wasteful pork-barrel spending, which threaten the success of government programs and public policies.

Burckhardt, Jacob (1818–97)

Jacob Burckhardt was born in Basle, Switzerland on 25 February 1818 as the son of the pastor of Basle cathedral. At first he studied theology in Basle, although after a religious crisis he changed to history and history of art, and continued his studies in Bonn and Berlin from 1841 to 1843. He was most influenced, especially in Berlin, by Franz Kugler, Johann Gustav Droysen, August Boeckh, and Leopold Ranke. He habilitated at Basle in 1844, held lectures in history and history of art there, and edited the 'Basler Zeitung' from 1843 to 1845. After the uprisings in Switzerland of 1844–5, an early manifestation of the midcentury revolutionary unrest in Europe, his previously liberal political outlook changed into a decided conservatism. With this he turned away from his political and publishing activities in favor of the 'education of old Europe.' In 1855 he was appointed to a chair at the technical university of Zurich, and in 1858 at Basle, where he taught history until 1886, and history of art from 1874 to 1893. In 1860 he stopped publishing and concentrated on his lectures, although he completed a number of manuscripts after this point. He died in Basle on August 8, 1897.

Jacob Burckhardt's historical writing can be understood as a critical diagnosis of the present. This found its most clear expression in his lectures on the history of the revolutionary era and *Über das Studium der Geschichte* (*On the Study of History*) as well as in references to the present throughout his work. Burckhardt rejected the liberal historians' optimism in progress, and saw a danger for his ideal of culture in the contemporary processes of mechanization, industrialization, and fundamental democratization. He also felt the modern development of large states to be a threat, particularly that of the new German Reich from 1871, and he made accurate prognoses of the political catastrophes of the twentieth century. However, his historical pessimism was in contradiction at least to his early religiously influenced opinions on and admiration of art. In numerous long tours through Italy he worked on the basis of his extensive works on art history, and these journeys through Italy, France, and The Netherlands remained an important part of his life until his old age. In 1855 he published *Cicerone. Eine Anleitung zum Genuß der Kunstwerke Italiens* (*Cicerone. An Introduction to Enjoying Italy's Art*), a work which visitors to Italy interested in art still use today. In 1867 his work, *Kunst der Renaissance* (*Art of the Renaissance*), was brought out by his friend Wilhelm Lübke. In this work he deliberately avoided a history of the artists themselves and instead concentrated on a 'history of art according to functions.' His late masterpiece *Erinnerungen an Rubens* (*Memories of Rubens*) was published from his papers after his death, in which the re-evaluation of the Baroque which he had completed in his later years found its expression. His portrayal of Renaissance art had an important influence on the educated German public's reception of the Renaissance and Italy. With his concept of a history of art ordered according to functions he guided the emerging study of art on to new methodological paths.

Burckhardt's basic historiographical principles are most clearly illustrated in his introductory lecture *On the Study of History*, which he held three times between 1868 and 1873, and which his nephew Jacob Oeri edited and published in 1905 under the now famous title *Welthistorische Betrachtungen* (*Reflections on History*). Burckhardt drew up his images of the historical world from a universal historical perspective, assuming three basic human needs: (a) the political (state), (b) the 'metaphysical' (religion), and the 'critical' (culture). In this scheme of 'potencies' he relativized the importance of the nation and the nation state in conscious contrast to German historicism, and allotted an equally important role to culture as the expression of human spontaneity as to the 'stable' powers of state and religion. As culture he understood 'the quintessence of all that which has come into existence spontaneously for the promotion of material life, and as the expression of the spiritual and emotional–traditional life, all social gathering, all technologies, arts, writing and sciences.' Burckhardt thereby rediscovered an enlightenment tradition of cultural history, and consolidated it in that he saw the polarity of freedom and violence in a developed form not only in state and religion, but also in culture. However, the potencies theory also enabled him to relativize the stress on a typological basis. The interaction of the three potencies adds depth and complexity to historical reality, as Burckhardt experienced it.

In his three historical masterpieces, *Die Zeit Constantins des Großen* (*The Age of Constantine*), (1853), *Die Kultur der Renaissance in Italien* (*The Civilisation of the Renaissance in Italy*) (1860) and *Die griechische Kulturgeschichte* (*The Cultural History of Greece*) (*3 volumes, 1898–1900*) Burckhardt varied the potencies scheme in that he added a further definition

of culture to state and religion. Culture is then the entirety of the achievements of a human creative urge, which is, however, permanently under threat of being destroyed. In all three works Burckhardt assumes a state of acute breakdown of authority and an increased societal and moral antagonism. In this latent chaos the respective forms of state and religion represent the relatively stable potencies, which, however, remain fragile because the 'spirit' strives persistently as a 'subversive,' as a destructive, and also creative ancient force, to bring forth new forms.

In *The Civilisation of the Renaissance* Burckhardt focused on Italy of the the fifthteenth and early sixteenth century, in contrast to Sismondi and Michelet, and thereby lent the term 'Renaissance' the temporal and geographical boundaries it has retained up to the present day. Burckhardt drafted the image of an epoch in the sway of violence and crime, lawlessness and tyranny, in which, however, equally the rational calculation of seizing and retaining power became established and so created the specific modern form of the 'state as artform.' The Humanists established themselves alongside the tyrants as a temporally specific human type, in whom the modern individual was embodied just as it was in the rulers. For Burkhardt they were the 'most obvious examples and victims of unbridled subjectivity' with a new intensity and sophistication of emotional life as well as a new method of rationalizing their relationship to the world. In *The Cultural History of Greece* Burckhardt describes similarly to the image of the state in *The Civilisation of the Renaissance* the Greek state, the polis, as a place of 'state slavery of the individual' in which democracy degenerated into a tyranny of the majority. Burckhardt developed the principle of agon as an essential structural feature of life in the Greek polis, the competition between individuals, yet also the bitter struggle of the poleis against one another. This principle does have destructive effects, yet at the same time it brings about the preconditions for the development of cultural freedom and a singular creative wealth. In Burckhardt's view the Greek form of religion was, however, just as constitutive as the principle of agon, as it knew neither theology, theocracy nor the rule of priests, unlike the states of the old orient, and so enabled a free development of spiritual life. As leading experts on ancient history criticized sharply, Burckhardt made a decisive contribution to the demythologization of the neohumanist–idealist reception of Greece with his portrayal of Greek society.

Burckhardt's greatest success by far among his audience, apart from *Cicerone*, was with *The Civilisation of the Renaissance in Italy*. This is due to a consciously narrative and nonscientific diction, the consistency of his analysis and references to contemporary society kept continuously alive in the subtext, which consistently refer to the dialectic of the rationalization of the individual relation to the world and the development of modern subjectivity. Burckhardt hereby made an important contribution to a structural analysis of the modern age. He overcame the thought of individuality of German historicism with his typological thinking, which orders material according to the aspect of 'cultural importance,' and anticipated Max Weber's cultural historical method. The potencies theory is reminiscent of the conception of equal systems which, however, exercise an influence over each other, or of historical areas of reality in modern sociology (Talcott Parsons for example). Burckhardt's potencies theory differs though, in that economy and society are not taken into account, and in the important position of religion and the specific function of culture, among other factors. Nor did Burckhardt, who always portrayed himself as an unsystematic thinker, develop a 'historical method.' Yet he did make an essential contribution to both the theoretical and methodological reflection of historical research. He analyzed the relationship of prejudice and historical judgement and the effects of the emancipation of knowledge from political rule and religious belief more precisely than most of his contemporaries. In the accelerated social and cultural change of the 'Revolutionary Age' he discovered an elementary compensatory need for the preservation of traditions. He encountered every tendency to political–social instrumentalization of historical knowledge, out of progressive or conservative interest, with extreme skepticism. In conscious contrast to the contemporary professionalization of historical science he retained an older, personal understanding of learning and education. Historical education should not contribute to an alteration of the outer reality, but widen the mental horizon of those seeking knowledge. With this maxim, his independent cultural historical method, and his art of portrayal he not only in fact influenced the educational horizon of those interested in history to a great degree, but also had a stimulating effect on the increasingly specialized areas of historical science (ancient history, modern history, history of art).

Bureaucracy and Bureaucratization

Bureaucracy has several meanings, some positive, most negative. The sociologist Max Weber (1946) coined the term 'bureaucracy' and treated it as synonymous with rational organization: bureaucracy embodies the ideals of rational–legal authority, under which all decisions, except executive decisions, are based on rules that are internally consistent and stable over time. Political scientists tend to think of bureaucracy as governance by bureaus having the following characteristics: bureaus are large, are staffed by full-time employees who have careers within the organization, and rely on budget allocations rather than revenues from sales since their outputs cannot be priced in voluntary *quid pro quo* transactions in the market (Downs 1967, Wilson 1989). There is a third definition of bureaucracy, which is far less flattering: bureaucracy is inefficient organization, is inherently antidemocratic, cannot adapt to change, and, worse, exacerbates its own errors (Crozier 1964). Discussions of bureaucracy tend to be ideologically tinged. The political left emphasizes the rationality and neutrality of government while downplaying the power of bureaucracy itself, while the right uses bureaucracy as an epithet or shibboleth and focuses on bureaucracy's antidemocratic tendencies and inefficiencies. Outside of academic circles, the rightist view of bureaucracy as inefficient and antidemocratic administration prevails. At least in the USA, very few positive references to bureaucracy can be found in the press. For most people, bureaucracy is unbusinesslike administration, an epithet or an accusation.

1. Bureaucracy vs. Traditional Organizations

Weber's analysis of bureaucracy begins by comparing the structure of bureaucracies with traditional organizations. This comparison is made along four dimensions: differentiation, integration, constraints, and incentives.

Compared to traditional organizations, bureaucracies are highly differentiated. There is horizontal division of labor: jobs are specialized and responsibilities are strictly delimited. There is vertical division of labor as well: there are higher and lower offices, the latter subordinate to the former, all of which are ultimately accountable to the head of the organization. Perhaps most importantly, there is a clear differentiation of official duties from personal interests and obligations, what Weber calls separation of home from office. Traditional organizations, by contrast, are undifferentiated. They do not delimit responsibilities, do not separate higher from lower offices, and do not distinguish personal from official capacities-instead, the organization mirrors the stratification system of the larger community (Dibble 1965).

Compared to traditional organizations, bureaucracies have numerous integrating mechanisms, among them written rules and regulations, procedures for selection and advancement of officials, and a specialized administrative staff charged with maintaining these rules and procedures. Written rules, formal procedures, and specialized administrative staffs are largely absent from traditional organizations—actions taken by traditional organizations need not be consistent.

Compared to traditional organizations, bureaucracies constrain the conduct of officials while offering powerful incentives for compliance. There are several types of constraints: actions must be justified in terms of the larger purposes of the organization; actions must be guided by the norm of impersonality, that is, detachment and objectivity is required in all decisions; and advancement is contingent on contributing to the purposes of the organization. Traditional organizations have no distinctive purposes apart from the purposes of the people participating in them; norms of impersonality and objectivity are practically nonexistent because the organization and the community are indistinct; and there is no possibility of advancement within the organization because, again, stratification within the organization is determined by the stratification of the community.

The incentives offered by bureaucracies include the prospect of a lifetime career, salaries paid in cash rather than in kind, and (in Europe if not the USA) a modicum of prestige attached to the status of the official. Careers, salaries, and prestige based on position within the organization do not exist under traditional administration. The elements of differentiation, integration, constraints, and incentives render bureaucracies more powerful than traditional organizations yet more responsive to central authority. The

power of bureaucracies results from their capacity for coordinated action. Traditional organizations are incapable of coordinating large-scale action, except temporarily when the interests of elites coincide. The responsiveness of bureaucracies to central authority arises from top-down control of ultimate decision premises, the policies and objectives of the organization, which is impossible in traditional organizations where authority is fragmented. Paradoxically, the same elements that make bureaucracies powerful yet responsive to central authority render individual bureaucrats nearly powerless. Limited responsibilities, subordination to higher authority, and numerous rules and regulations, as well as the norm of impersonality deprive bureaucrats of latitude in decision-making. The powerlessness of individual bureaucrats, moreover, is exacerbated by their dependence on the organization for their income and social standing. Weber claims that the capacity for coordinated action, responsiveness to central authority, and dependence of individual bureaucrats on the organization promote administrative efficiency. 'Precision, speed, unambiguity, knowledge of the files, continuity, discretion, unity, strict subordination, reduction of friction and of material and personal costs—these are raised to the optimum point in the strictly bureaucratic administration...' (Weber 1946, p. 214). The context in which Weber was writing is critical. Weber was not comparing modern businesses with bureaucracies. Rather, he was comparing bureaucracies capable of coordinated large-scale action with traditional organizations that were not.

2. *Bureaucracy vs. Business Administration*

Many of the elements of bureaucracy identified by Weber are present in modern business organizations, but some are not. Like bureaucracies, large businesses are highly differentiated—jobs are specialized, a chain of command runs from higher to lower offices, and people are expected to ignore personal interest when acting in their official capacities. As in bureaucracies, many of the integrative mechanisms used are also present in large businesses, among them written regulations, procedures governing selection and advancement (today called human resource management), and specialized administrative staff. And similar constraints operate in bureaucracies and businesses—actions must be justified by the purposes (today called strategy) of the organization, norms of impersonality prevail, and advancement depends on contributing to the organization's purposes. The similarity of the administrative structures of bureaucracies and business firms occurs for several reasons. Many administrative practices arise from bounded rationality limits, people's limited capacity to make and execute complicated decisions. No one person is capable of assembling an airplane or winning a war. Instead, complicated activities are coordinated through administrative hierarchies that transform broad decision premises (maximize shareholder value, win the war) into specific programs of action (marketing plans, battle plans) and guided by general rules that people accept as conditions of employment (Simon 1976).

Research on organizational structures also shows that organizational size is the principal determinant of administrative structure for both bureaucracies and businesses (Blau and Schoenherr 1971). Both bureaucracies and businesses, moreover, are constrained by norms of rationality, which means that people expect to find a chain of command, consistent rules and purposes, and rewards based on qualifications and accomplishments whether or not they are technically necessary (Meyer and Rowan 1977).

In other respects, however, businesses and bureaucracies have evolved differently in the last 50 years. Public and private administration were similar at the time Weber was writing in the early 1900s. Much of the US public sector was modeled explicitly after the private sector at that time. It is not accidental that the reform movement in the USA, which called for governmental administration devoid of politics (or, to use another term, 'businesslike' administration), coincided with the emergence of scientific management, which called for rational selection, training, and supervision within firms. Nor is it accidental that in the 1940s, the same theory of administration was believed to apply to public- and private-sector enterprises (Gulick and Urwick 1937). Public and private organizations have diverged in the last 50 years, however. Divergences have occurred in several domains, most notably in organizational design, accounting practices, and incentives and performance measurement. With respect to organizational design, firms now choose from among diverse organizational designs. Many larger firms have alternated between functional and divisional organizational designs, that is, between designs where the principal units are specialized by function (such as purchasing, manufacturing, and sales) so as to maximize scale economies, and designs where the principal units are self-contained businesses containing a full array of functions so as to focus attention on bottom-line objectives. Some firms have experimented with matrix organization, where people report to both product and functional managers, and still other firms have more complicated designs where some functions are centralized while others are dispersed across geographic or product units. Public bureaucracies, in contrast to business firms, exhibit very little variety in organizational design. Almost all remain organized by function as they were 90 years ago. To be sure, some central government functions have been decentralized to local governments (this is called 'loadshedding' in the USA), contracted to the private sector, or privatized outright, but the core organizational design for public bureaucracies remains functional.

With respect to accounting, public-sector agencies have departed substantially from business practice. At the beginning of the twentieth century, public entities issued consolidated financial reports and maintained capital accounts just like private businesses. Consolidated accounting gave way to much more complicated fund accounting during the 1920s, when it was believed necessary to segregate revenues and expenditures intended for different purposes into separate funds. Capital accounting has all but disappeared from the public sector—few governments distinguish between current and capital expenditures—though accounting for long-term indebtedness is retained because it is required by creditors.

With respect to incentives and performance measurement, public sector bureaucracies face more complicated issues than private businesses and, as a consequence, appear to lag substantially behind business. Businesses use several approaches to measure and reward performance. To begin with, most publicly-held businesses define performance as total return to shareholders and reward performance so defined using techniques like value-based management. Under value-based management, executive compensation is based largely on gains in share prices, and the compensation of middle managers is based on a metric (for example, return on invested capital or economic value added) believed to drive shareholder value. The non-financial drivers of financial performance are captured in measures of internal process and customer satisfaction. Moreover, firms' internal operations are gauged against industry benchmarks assembled by third parties, usually consultants or trade associations. There is no analog to total shareholder returns in the public sector, at least none that can be easily measured—the electoral process is a coarser measure of performance than the stock market, and it is difficult to reward civil servants for electoral performance. Public agencies are taking some initial steps toward measuring non-financial performance by setting objectives and gauging progress toward them—performance measurement of this sort is part of the initiative, in the USA, to 'reinvent government' (Osborne and Gaebler 1992) and also by measuring customer (constituent) satisfaction. Even so, competitive performance assessment hardly exists for government—the concept of benchmarking has not yet penetrated the public sector. In the USA, at least, performance comparisons across governmental units are strongly resisted, mainly on the grounds that the functions and outputs of governmental units cannot be compared across jurisdictions.

3. *Liabilities of Bureaucracy*

There is widespread agreement that bureaucracies suffer some liabilities in comparison with business. Many of these liabilities of bureaucracy are systemic in that they arise from the structure of bureaucracy rather than from people's predilections. Sociologists and political scientists have focused on what they call dysfunctions of bureaucracy, among them displacement of goals, so-called vicious circles in which dysfunctions feed on one another, and spiraling bureaucratic growth. Economists, by contrast, have drawn attention to the efficiency disadvantages of bureaucracies as compared to firms, asking whether, in general, nonmarket transactions are inefficient compared to market transactions, and, specifically, whether the funding of bureaucracies through budgets rather than market transactions results in overproduction of bureaucratic services. These potential liabilities of bureaucracy should be reviewed *seriatim*.

3.1 *Displacement of Goals*

Bureaucracies are known for rigid adherence to rules and procedures, even when rules and procedures appear to impede the objectives of the organization. The notion of goal displacement provides both a description and an explanation for this seemingly nonrational conduct. Goal displacement, following Robert K. Merton (1958), describes the process whereby means become ends in themselves, or 'an instrumental value becomes a terminal value'. The displacement of goals is especially acute in settings—such as bureaucracies—where the following conditions exist: the technical competence of officials consists of knowledge of the rules; advancement is contingent on adherence to the rules; and peer pressure reinforces the norm of impersonality, which requires rules and procedures to be applied with equal force in all cases. What is important is that goal displacement, at least as originally conceived, argues that bureaucracies are efficient in general—under conditions anticipated by their rules and procedures—but inefficient in circumstances that cannot be anticipated. The implications of goal displacement for innovation and new product development have been realized only gradually: bureaucracy can be antithetical to innovation.

3.2 *Vicious Circles*

A more thorough critique of bureaucracy argues that dysfunctions are normal rather than exceptional and, moreover, that dysfunctions accumulate over time such that organizational stasis is the expected outcome. The elements of the vicious circle of bureaucratic dysfunctions are impersonal rules that seek to limit the discretion of individual workers, centralization of remaining decisions, isolation of workers from their immediate supervisors as a consequence of limited decision-making authority, and the exercise of unofficial power in arenas where uncertainty remains.

Thus, as Michel Crozier observes (1964), maintenance people exercise undue influence in state-owned factories because their work is inherently unpredictable and cannot be governed by rules. The logic of vicious circles, it should be pointed out, yields several consequences. To begin, new rules will arise to eliminate whatever islands of power remain in the organization, but these rules will trigger further centralization, isolation, and power plays as new sources of uncertainty arise. Additionally, to the extent that the organization is opened to uncertainties arising externally, line managers have the opportunity to reassert power that would otherwise erode through the dynamics of vicious circles. External crisis, in other words, may be an antidote to bureaucracies' tendency toward rigidity over time.

3.3 Spiraling Growth

Bureaucratic systems also tend toward growth, other things being equal (Meyer 1985). Until recently, growth of government and of administrative staff in private firms was endemic. The causes of growth lie in several factors, but chief among them are people's motives for constructing organizations in the first place. People construct formal organizations in order to rationalize or make sense of otherwise uncertain environments; organizations, in fact, succeed at making the world more sensible; as a consequence, there is continuous construction of bureaucracy and hence bureaucratic growth as people attempt to perfect their rationalization of an inherently uncertain world. Three comments are in order.

(a) The logic of bureaucratic growth is built into neoclassical administrative theory developed by Simon (1976) and others. Irreducible uncertainty in the environment, in conjunction with the belief that administrative organization can rationalize uncertainty, will result in continuous growth in administration.

(b) The growth imperative is so strong that deliberate campaigns to 'downsize' or 'restructure' organizations must be launched in order to achieve meaningful reductions in staff.

(c) Inefficiency. Economists have asked persistently without resolution whether bureaucracies are inherently less efficient than private-sector enterprises. Several answers have been proffered, none fully satisfactory.

From the 1940s to the present time, the Austrian school of economics, von Mises (1944) and others, have argued that any departure from market principles yields both inefficient transactions and antidemocratic tendencies. This position has proved difficult to reconcile with contemporary transaction-cost theories (Williamson 1975), which argue that hierarchies may be more efficient than markets under some circumstances. In the 1970s, the efficiency question was cast somewhat differently: might bureaus, which depend on budgets for their sustenance, overproduce compared to firms subject to the discipline of the market? (Niskanen 1971) Here too the answer was equivocal, as analysis showed that rent-maximizing monopolists would have similar incentives to overproduce whether they were located in public bureaucracies or private firms. Despite the uncertain analytic underpinnings for the belief that bureaucracies are more apt to harbor inefficiencies than private-sector organizations, privatization of governmental functions is occurring rapidly and with positive results in many countries. It is unclear whether the liabilities of public bureaucracies are simply the liabilities of established organizations that have been shielded from extinction for too long, or whether bureaucracies suffer disadvantages in comparison with private organizations because of weak incentives and inconsistent objectives.

4. Research on Bureaucracy

Organizational research and research on bureaucracy were once synonymous or nearly so, as the bureaucratic model was believed descriptive of all organizations, for-profit, non-profit, and governmental. Case studies of bureaucracy written during the 1950s and 1960s encompassed government agencies and industrial firms alike as evidenced by titles like Gouldner's (1954) *Patterns of Industrial Bureaucracy*. Early quantitative research on organizations, such as the work originating at Aston University and the University of Chicago, focused mainly on relations among elements of organizational structure (size, hierarchy, administrative ratio, formalization, centralization, etc.) that flowed from the bureaucratic model implicitly if not explicitly. As attention shifted to external causes of organizational outcomes, however, the bureaucratic model has become less relevant to organizational theory. Thus, for example, the key causal variable in resource dependence models of organizations (Pfeffer and Salancik 1978) is control of strategic resources, which is more germane to businesses than to government bureaus. The key dependent variables in organizational population ecology (Hannan and Freeman 1984) are births and deaths of organizations, which are infrequent in the public sector (see Kaufman 1976). The new institutional theory of organizations has downplayed Weber's notion of bureaucracy as rational administration and has substituted for it the notion that all organizations, bureaucratic and nonbureaucratic alike but especially the former, pursue social approval or legitimation by appearing to be rational rather than actual efficiency outcomes. Almost alone among major organizational theorists, Philip Selznick argues that the problem of bureaucracy remains a central issue in organizational theory: '… the ideal of an effective, fair, and responsive bureaucracy remains elusive. Our society desperately needs organized ways of dealing with social problems; we cannot rely solely on market strategies. Yet the specter of bureaucracy

still haunts and repels, still saps public confidence and weakens support for collective action' (Selznick 1996, p. 276).

Several streams of research on bureaucracy remain, although they are at the periphery of organizational theory. One stream of research, largely in the field of public administration, focuses on the possibility of bureaucratic reform, of reducing the otherwise endemic dysfunctions of bureaucracy. This research does not promise solutions; quite the opposite, it finds bureaucratic dysfunctions intractable. For example, reform initiatives almost inevitably create new positions for people to oversee the reform, resulting in new layers of administration and 'thickening' of each layer (Light 1997). Decentralizing managerial authority in public bureaucracies is offset by a corresponding centralization of political authority, with little net improvement in efficiency or responsiveness (Maor 1999). Attempts to 'reinvent government' by reshaping bureaucracies into so-called performance-based organizations are usually frustrated by conflict over what the performance standards should be (Roberts 1997).

Another stream of research, pursued mainly by economists, focuses on the impact of incentives and performance standards on performance outcomes in bureaucracies. The tentative conclusions of this research are, again, unpromising. Only weak incentives are available in bureaucracies. Not only do bureaucracies perform multiple tasks, but they also answerable to multiple constituencies or, in the argot of agency theory, principals. Multiple tasks weaken incentives in all organizations because the outcomes of some tasks can be more readily observed than the outcomes of others. Multiple constituencies or principals, however, are unique to bureaucracies and further weaken incentives because each constituency will bargain separately with the bureaucracy (Dixit 1996). Specific performance standards built into legislation do discipline the behavior of bureaucrats somewhat, but measures of short-term results can work against long-term objectives and are frequently gamed (Heckman et al. 1997).

Bureaucracy, Sociology of

The word 'bureaucracy' has been, for a hundred years, one of the keywords of the social sciences. The problems of bureaucracy were one of the favorite battle grounds of intellectual debates in sociology and in political science. Curiously enough, bureaucracy is a very fuzzy word which does not correspond to an acceptable definition. There has never been a rigorous concept, nor a precise definition but this lack was itself a reason for its success since fuzziness provided scope of much debate.

The traditional meaning of bureaucracy seems to have been 'government by specialized and obedient bureaus.' This supposes the existence of a state apparatus composed of appointed, i.e., not elected, civil servants, organized in a hierarchy and reporting to the sovereign authority, originally to the king, then to the nation as represented by its elected representatives.

Bureaucratic power, in this definition, implies the '*Etat de droit*'—the state of law. At the same time, it rejects the citizen's direct participation. Parallel to this traditional use which may be relatively precise, another much broader meaning has gradually taken

hold and is related to the theory of bureaucratization. Bureaucratization means the rationalization of human activities into bureaucratic organizations, i.e., organizations arranged hierarchically and staffed by well trained obedient personnel. Bureaucratization supposes the concentration of bigger and bigger production units and the massive extension of the state apparatus. The theory is built upon a deterministic postulate: it is ineluctable because of the constraints of complexity and growth. Bureaucratic organizations are a necessity also because they look as if they were the only solution to our technical problems. But bureaucratization does not necessarily refer only to public organizations. The same trend can be found in all forms of activity, including industrial, commercial, social, or political organizations.

The two meanings of the word 'bureaucracy' are very often mistaken: the problem of political choice between electing and appointing office holders and the problem raised by the inevitability of new modern forms of organization which are necessarily bureaucratic. This confusion has been compounded by the emergence of a third, more popular, meaning. Bureaucracy, in common language, has become synonymous of dilatory procedures, clumsiness, routine, and procedural complications. Whatever the context, bureaucracy calls to mind the difficulty in adapting organizations or institutions to the needs and demands of the people they are meant to serve. Bureaucracy, in this context, is a permanent evil. The emotional content of the word in current language cannot be removed from the intellectual debate and this has prevented the emergence of a neutral scientific definition.

One cannot discuss the growth of bureaucratic forms of organization as a natural phenomenon since it means the growth of an evil. The confusion between these three different meanings has created one of the basic nightmares of social forecasting. If one admits that the rise of big and complex organizations will inevitably encourage the development of nondemocratic forms of management and government and the proliferation of dehumanizing experiences for employees and for customers, one will have to predict the end of our unresponsive civilization or the coming of a redemptory crisis.

Logically however, there is no real link of causality between these different facts which are, on the other hand, only partially acceptable. Research in social sciences over the last fifty years has focused on disentangling the summary logic results of such confusion and has provided empirical data with which to answer the various questions that the ideological debate has raised:

Is the concentration of productive and administrative activities in large units really inevitable?

Does it carry with it a bureaucratic model of management? Other models of managing people may be possible.

Is there a strong link between these bureaucratic models and the evils of routine and alienation about which the ordinary citizen complains?

Is there a link between the concentration of organizations and the evolution of the model of political authority?

Three intellectual currents have successively emerged from these major questions. The first of these is the Weberian current which appeared between 1900 and 1930. Max Weber was both the instigator and the person who formulated its most refined form. Drawing on a rich philosophy of history and a rationalistic view of human relations, he built a well documented and sensible analysis of the evolution of the models of organization and their basic consequences. A second more empirical wave, emerged in the 1930s and 1940s in the US and a few years later in Europe. Based on observations of the reality of contemporary organizations and of the way it was experienced by employees and managers, it has focused especially on the gap between theory and reality and has thus developed facts and interpretations about the 'dysfunctions' of the Weberian model. Since the 1960s, a new wave has emerged. This acknowledged the gap between theory and practice but has sought to understand the system which results from the pressure of managers on employees so that they will comply with the theoretical model and from the pressure of employees who succeed in changing this model when adjusting to it. This neo-rationalist analysis makes it possible to put bureaucratic forms into the perspective of a broader postindustrial model, for which rationalization is no longer the dominant logic.

Not only is it difficult to recognize the partial inefficiency of bureaucratic organization, but it becomes now indispensable to conceive and put into practice nonbureaucratic organizations that could be efficient and profitable. In such a new context, at a time when more and more activities are appearing, the traditional dilemma of bureaucracy tends to decline in the public debate. However, we can observe a new cleavage between public administration, which has become the domain of a more sophisticated analysis of public choice, and business firms, whose complexity of management escapes the simple dilemma of the traditional debate.

1. The Weberian Ideal Type

The reigning concept of bureaucracy has been shaped by the success of large scale organizations in the 1900s, be they American and German corporations, state apparatuses, or the organization of social democratic parties in Europe. Max Weber, the founder of the theory of bureaucracy, was especially influenced by the achievements of the Prussian state and its mirror image, German social democracy. For Weber, the ideal type of a bureaucratic organization, similar to

the Prussian state, comes from the combination of a legal rational model of social control and a hierarchical model of organizational authority.

This national specificity was neglected since the model was rational and could be used to understand all modern administrations. The emergence of the bureaucratic form was the consequence of disenchantment (*Entzauberung*) with the world, the basic characteristic of modern societies. Max Weber's theory is basically historical. We have moved from a patrimonial to a charismatic concept of authority, and then to a rational-legal one.

The rational-legal order requires that functions, rules, and procedures be impersonal. Agents (civil servants) must be specialized and well-trained and they must report to superiors within a hierarchical system. Order could be exercised by a collegial type of organization but Weber believed in the superiority of the pure bureaucratic type, which was monocratic. Its success, he thought, was unavoidable, in the same way that machine tools had proved a success in mass production industry. This type of organization, which started in traditional public service organization, invaded big capitalist enterprises and went on to conquer hospitals, political parties and churches as well.

Weber perceived, especially at the end of his life, the dangers of servility which may come from such a system and which may, as a consequence, undermine democracy but he never questioned its technical efficiency. At the same time, a young union official, Robert Michels, who was active in Italy and Germany, pushed this reasoning further. Starting with an analysis of the mechanism of power in labor unions and social democratic parties, he formulated another law, the iron law of oligarchy. According to Michels, militants who wanted to bring deep social transformations, had to operate through collective action which means organizations, i.e., bureaucracies. But, the existence of bureaucracies was not compatible with democratic goals and values, which were the only justification of collective action. This proved to be a tragic dilemma and led to one of the great political debates in Europe and in the world about ends and means.

But the weakness in Weber's reasoning, i.e., his implicit admiration for the infallible superiority of the bureaucratic machine, was never questioned. The great political leaders and thinkers of the revolutionary period of the 1930s believed in the machine. For them, the problem lay in seizing power, not exercising it. They thought that, once the state power was taken over by the proletariat, no basic problem would ever exist. The results were appalling but the leaders and thinkers of the revolutionary effervescence of the 1920s and 1930s were blind to them. They reacted by emphasizing the danger of a catastrophic term of human society and thus revolutionary pessimism became the dominant model of the period and developed into arguments for the coming revolution. The logic was very simple. By exaggerating the danger of the evolution of oppression, one is pushed to a desperate wager: either socialism, or the coming of barbary. Because of this contradiction, one calls for revolution which will dialectically overcome the problem.

The revolutionary current was, of course, a minority current, but its cultural success made a profound impact on society and on its politics. It can still be found as an overtone in the best-selling social novels from the 'iron heel' of Jack London to James Burnham, the era of organizers and even in William H Whyte Jr.'s *The Organization Man*.

2. *The New Paradigm of Dysfunctions*

According to the rationalist theory, it was argued that evolution would establish the dominance of the bureaucratic form of organization, as it was the only form able to provide the stability and predictability which was needed in the modern world. Using this logic, one could try to predict the development, conditions, and consequences of its evolution.

The deep trauma of the Great Depression disturbed these confident beliefs in the US and led to new and quite different research questioning this theory. Gradually, a new paradigm developed around the concept of dysfunctions, based on the discovery of the severe gap that existed between employees' behavior in reality and behavior as prescribed by the model. New authors showed that bureaucracy was not as effective as the rationalist model predicted, and sought to understand why this was happening and what were the mechanisms of ineffectiveness.

The new dysfunction paradigm can be summarized in the following way. Decisions taken from a rational perspective bring about a chain of secondary consequences that run counter to the established objectives. This very practical logic was so pervasive that the negative properties of the bureaucratic model were stabilized into 'dysfunctions' that were as characteristic of the bureaucratic model as its rational capacities of action.

The emergence of this new approach was stimulated by the discovery of the importance of the human factor in the way organizations function, as seen from Western Electric's experience at Hawthorne. It was also echoed the political discussion about ends and means which had raged in revolutionary and reformist circles in Europe. The seminal contribution in this line was Robert K Merton's article (1936) on 'The unexpected consequences of purposeful action,' in which Merton argued that the discipline necessary to obtain the standardized behavior indispensable to achieving the objectives in a bureaucratic structure would provoke a major displacement of goals among the civil servants, who would behave in a ritualistic manner.

What was to be means to attain the end became an end in itself. This brought about a strong rigidity which prevented civil servants from responding realistically to the concrete demands of their tasks. The caste behavior of civil servants thus created a basic gap with the public which accounted for the ineffectiveness of their action and prevented the attainment of agreed official goals.

Empirical research carried out during the 1940s and early 1950s by American sociologists and in the 1950s by European sociologists provided a number of cases validating this reasoning. The bureaucratic model of action created behavioral rigidities among subordinates who had to apply the bureaucratic rules. This created conflicts between superiors and subordinates and between performers and their public, and introduced a need for control and regulation. Thus the unexpected consequences and the dysfunctions of the bureaucratic model tend to reinforce the model.

Why does such a model persist since it is not effective? Alvin Gouldner (1954) has shown that it reduces tensions generated by subordination and control but, at the same time, it maintains their existence.

3. *The Neo-rationalists*

The first proponents of bureaucratic rationality borrowed without questioning the experience of Taylorian engineers who considered the members of an organization as mere cogs in the machine. Against this very narrow view, the proponents of the dysfunction paradigm saw them as affective human beings whose behavior was influenced by the conditions they were enduring.

At the end of the 1950s, a new wave of analysis developed into a real reversal of perspective, in which each human being was recognized as also being a free and active human agent inside the organization. This led to a new theory of action and the re-emergence of the problem of power.

The new theory of action resulted from consideration of a new approach: decision analysis. Herbert Simon was the inspirer of this breakthrough. He questioned the principle of the 'one best way,' according to which, once an objective is established, there is only one best way to attain it. The engineer's job is to discover and to calculate that best way. After analyzing the practice of decision-making in different settings, Simon showed conclusively that human beings—and engineers are human beings—were incapable of reaching the one best way because there was no absolute rationality. Rationality is bound by the costs of information and even more by the limitation of cognitive problems. The discovery of these limitative problems led Simon to propose a new theory of limited rationality. Since human beings are incapable to reach absolute rationality, they will stop their search when they will reach a 'satisfying' rationality. With his colleague, James C March, they applied this model to the field of organization and bureaucracy. Their book *Organizations* was a real landmark. According to this new perspective, it was possible to return to rational analysis. Human relations analysis cannot be placed in opposition to rational analysis but can be integrated with it inasmuch as it will define the conditions based on which the satisfying point can be calculated.

Meanwhile a new theory of power relations was being formulated based on game theory and using experimental research on groups. Political science became the cutting edge of research. The battleground shifted from bureaucracy to public problems.

4. *The Decline of the Bureaucratic Paradigm*

If one wishes to summarize the state of research and the major trends, it seems quite clear that the bureaucratic paradigm is no longer central to sociology and political science. But past research on bureaucracy has given rise to a number of connecting fields:

(a) First of all, the debate has moved from the questioning of the trend towards bureaucratization to analysis of the complexity of new large scale organizations that cannot work under the principles of hierarchical authority at the time of NTIL, networking and constant restructuring.

(b) A new cleavage has developed between public organizations and other organizations. Public organizations are less dominated by organizational paradigm as decentralization and subsidiarity. Debates turn around public policy problems, costs-advantage 'techniques,' accountability, and evaluation.

(c) In private organizations, the basic paradigm has become more managerial. After a long period during which the basic problems centered on strategy, from the end of the 1980s, the basic paradigm has been applied to the functioning of the internal system. The principle of hierarchical authority as the central axis of organizational order is now being questioned more effectively. With the progress of information technology, the argument for a nonhierarchical, lateral principle of organization has partially won. Re-engineering has proved to be essential for the re-development of organizations.

(d) The most promising fields are now to be found in the experience of intervention and change and the roles of innovators and change agents.

One may surmise however that bureaucracy will reemerge as an active field of research. The problems of implementing new practices of cost-advantage calculus and evaluation cannot be solved simply by imposing best practices because they are more rational. It becomes a problem of innovation in a bureaucratic setting, i.e., a problem of restructuring bureaucracy. The same is true of re-engineering in private organizations. Intervention requires understanding bureaucratic resistance. The strategy of

change brings us back—at least partially—to the old debate on dysfunctions.

Bureaucratization and Bureaucracy, History of

Bureaucratization is a process, and the term in itself thus refers to a historical development. It is, however, used in several distinct meanings, some of which refer to moral and political values, which are endangered by a growth of bureaucracy according to a common belief. As a descriptive term, apart from its evaluative content, bureaucratization may mean: (a) a growth of numbers of administrators and administrative organs between points of reference; (b) a growth in administrative complication in the handling of matters; and (c) an increase in administrative competence and independence and in the functional division of administration. These three definitions may be inter-related, though this is not necessarily the case. The third one comes close to the analysis first made by Max Weber of the development of a bureaucratic principle (Weber 1922).

There is also a great difference in the reference of the term in different contexts. Here one may distinguish first (a) a reference to state administration only or (b) a reference to any sort of administration, whether public or private.

A third distinction may also be made. Sometimes the term bureaucratization is used in regard to states and societies irrespective of their political system. On other occasions the use is restricted to states and societies where a separation is made, at least in principle, between political and administrative duties and responsibilities. The latter limited scope of the term is, of course, much more related to the near history than to past centuries, with the nineteenth century as an intermediate period when this separation first came to be more commonly observed.

The different aspects of the concept of bureaucratization and their close relationship to political ideals regarding the scope of state interference in relation to citizen's rights and the division of responsibility between politicians and bureaucrats make it difficult to use the concept in historical and social science analysis. Yet, in regard to changes in power and control, it covers an important reality, which has to be differentiated from the use of administration in general. The following account goes out from Weber's analysis combined with the distinction between political and administrative responsibilities.

1. From Antiquity to the Nineteenth Century

There is a striking difference between the state of Egypt in the Antiquity, or the Mesopotamian empires of Babylon and Assur, or Rome compared to the Medieval states of Europe including the vast empire of Charles the Great. This difference has to do with the ambitions of the state. While delegation to subprinces was the rule in the feudal system that emerged in medieval Europe, the state was in principle centralized as to the important decisions in the early empires. It is often said that these empires were highly bureaucratized. The Russian historian of the Antiquity Michail I. Rostovcev in the first half of the twentieth century wrote several books in which he tried to show that the process of bureaucratization was going on in Egypt,

the Hellenistic Empires and the Roman Empire (Rostovcev 1936–8, 1941, 1957). In spite of his brilliance his views are not current among ancient historians of today. Some would rather stress the limits of state power in the Antiquity and others the specific structure of the ancient system of government in different parts of the world. What was common to these regions was the fusion of politics with administration. No real difference was made, and only the king or emperor exerted a political power meant to express a deliberate policy. He headed an organization where the highest officials had some political duties but their policy-making had mostly to be concealed under administrative clothing. Further down in the hierarchy, the administrative chores were the real occupation of the employees. Often, administrators were neither full-timers nor independent, and regulations tended to vary with the will of the ruler. Further, it is important that the state in the Antiquity was highly centralized and that no clear difference was made between public law and private law until the late Roman Empire and, thus, no real limit was set between state obligations and rights and a private sector. Mostly the kings and emperors commanded only 'their' servants and demanded only what belonged to them, though if these relations were of private or public nature was often not quite clear. This 'bureaucratic' state was, thus, vague in its boundaries but, as a centralized state, it needed an efficient bureaucracy. It is hardly evident that bureaucracy should have grown or extended its procedures from one period to another or from one empire to another during the period before AD 400.

China was in many ways the same sort of bureaucratic-political state as imperial Rome but the Chinese system started earlier and continued in the dynasties all up to the end of the empire in 1911. The Confucian class of state servants was hierarchically ordered under the emperor, who had the political power in his hands. No real delegation of political power was used, but rather a blend of political and administrative obligations, which included a strict rule regimen. The bureaucracy was organized in a refined system already in the Ch'in and Han dynasties (221 BC–220 AD). There were ministries and ministers, but even these, and some senior officials or 'excellencies' who were the highest in rank, could influence policy via their channels to the emperor. Their responsibilities did not include the task to form a policy even for the field for which they were responsible. Hierarchy was enormously developed both within each ministry or office and also in the country as a whole. Local administration took place via organs in at least five different levels. Yet, it will seem that all political decision-making stayed with the emperor in spite of a system of checks and balances within the bureaucracy (Loewe 1986, Bielenstein 1986).

The politico-bureaucratic system of China, Egypt and imperial Rome under the Antiquity did not change in principle, which makes it difficult to use the term bureaucratization in each of the cases. The fundamental structure of bureaucratic government did not develop even though specific modifications were introduced in the division of tasks and responsibilities. Except in China, Korea and Japan, a fundamental debureaucratization took place in the centuries after AD 400. In the nomad empires of which the one of the Mongols was by far the most extensive, virtually no bureaucracy existed. When the Mongols had taken China, the Chinese system of government became theirs but not in the parts of the empire that broke away from Mongol China. Bureaucracy was also kept small in the Arab and Islamic states, which were rapidly formed in the seventh to tenth centuries. European feudal princes had very few officials who were employed to administer and such officials seldom had a full time employment for their administrative work and they could almost never rely on a rule system, which might ensure a field for decision-making without interference and with some autonomy. Only within the Catholic Church a system resembling a bureaucracy survived.

Only with the rise of central power in the fifteenth to seventeenth centuries administrative institutions grew again in Western Europe, and in Eastern Europe the same system existed for much longer, in Russia until 1905 and partly until 1917. There are many similarities between this system of bureaucratic forms of government and the one of ancient China and Rome. A specific instruction for future bureaucrats emerged. Universities played a role in this, and China had such educational institutions from an early date. In Europe two different types of reforms increased the theoretical competence of the bureaucracy. First, in centralized monarchies there was a need for educated secretaries and fiscal employees, who could master the subtleties of foreign and internal relations and international and national law. This need was partly met through recruitment of low-estate university men, who were sometimes promoted into nobility (the 'noblesse de robe'). Second, nobles who wanted to preserve to nobles influential posts in the immediate vicinity of central power, arranged specific educational institutions for young nobles, to make them fit for bureaucratic leadership. It also became customary to send young nobles to universities in a tour over Europe to polish their education in a fitting way. Centralized monarchy in this manner again made bureaucracy important in the European way of handling public affairs. The well-functioning of the administration of the state was a pre-condition for efficiency in foreign policy and warfare, and these were the ultimate aims of most of these monarchies (Raeff 1983). In the middle of the seventeenth century military entrepreneurs were finally made servants of the state and a military bureaucracy evolved. Later 'cameralism', the 'science' of civil administration, developed mainly in the German states (Mann 1986/1993). The relatively

poor Swedish state became a power of significance partly because of the efficiency of its bureaucratic apparatus, organized in 'collegia' defined according to functional criteria, and with (in principle) salaried employees. This organization impressed Peter I of Russia, so that he reformed the Russian bureaucracy according to the same model, soon modified by his successors (Peterson 1979, Shepelyov 1999).

The new European bureaucracies represented some innovations in the process of a bureaucratization of state and society. Some of the state bureaucrats of the seventeenth and eighteenth centuries had a real full-time employment and were salaried for their services. Rule systems were given to ensure that the administrations worked in an efficient manner and on a daily basis. A formalized routine of handling incoming matters and a hierarchical organization were intended to give the rational flow of work, which was the aim of the monarchs who set them up. However, obstacles to a rational decision-making process were universal. In Russia, complaints were common that copying in triplicate and more, of documents took a long time and slowed down the process (Shepelyov 1999). The heads of administrations also had a privileged position and were normally not regarded as bound by regulations in the same way as the lower echelons of bureaucracy. Often salaries were paid to nominal civil servants that were allowed to employ substitutes to perform the real duties. Finally, autonomy was restricted in the bureaucracies. Top bureaucrats often combined a role as a counselor to the monarch with the administrative leadership. Lower bureaucratic strata of course tried to observe the wishes of their superiors. This tended to mean that political considerations and political ambitions mixed into the work of the bureaucracy and this was regarded as natural (Yeroshkin 1997). As long as no ambition was found to separate politics and administration and to differentiate, for example, between a minister and a head of an administration, this seems to have been unavoidable.

2. *Bureaucratization and Parliamentary Politics from the Early Nineteenth to the End of the Twentieth Century*

The development of bureaucratization took a new turn from the nineteenth century in Europe and the US and, because of European imperialism and the domination of these countries in world politics and economy this new turn made a global impact. The first half of the century was filled with parliamentary and bureaucratic reforms and the second half saw different stages of democratization take place. Politics and bureaucracy thus became centers of societal change. Constitutional rule was the first political demand from the 'left' (relative to the political scale of the time) all over Europe, and its fundamental issue was to get rid of 'despotism' in the form of monarchic rule through bureaucracy. This demand meant to give a decisive influence to elected bodies at least in fiscal and educational matters. It became usual to contrast bureaucratic and political responsibilities.

In this situation, during the first half of the nineteenth century, a long-standing request for reform of the civil service in several countries was finally agreed to in several countries. In Germany, France and Britain these demands led to results and extensive reforms of their civil service took place (Mann 1986/1993, Gillis 1971, Charle 1980, Thuillier 1980, Campbell 1955, Mackenzie and Grove 1957). These reforms had as their main objectives to reduce or get rid of nepotism in the appointment of personnel, to abolish corruption and thus to establish a certain independence and objectivity among bureaucrats. Those who have investigated these reforms have not contended that they were entirely successful in their aims, but it is generally said that a huge improvement took place. Since these days West European bureaucracy has established a reputation for being normally impartial and honest.

During part of the nineteenth century when the ideas of economic liberalism flourished, state intervention was normally confined to a restricted area, though practice never conformed to theory. When the security of the state or vital interests of common nature to the whole society were at stake, the state should intervene. This meant that military purposes were generally excluded from the restriction for the state to engage in economic activities and also some public education for the supply of civil servants and, in fact, common interests could be extended into new fields. In principle, however, the civil servants had to protect state interests through legal means and the military to protect such interests through means of force and violence. The bureaucracy in the strict sense thus was an instrument for a 'legal domination,' one of the forms of power acknowledged by Max Weber. During most of the nineteenth century bureaucracy was regarded with distrust by the liberal forces in Europe and America and its growth was seen as an evil. Conservatives, with another evaluation of law and legal forms, tended to appreciate bureaucracy as a counterweight to democratic rule and as a guarantor of equal treatment and long-term obligations of the state system. This did not imply, however, that conservatives generally were favorably inclined to any growth of bureaucracy but, rather, that they wanted it to be strong and limited.

What holds for the bureaucratic development in Europe and the US is not valid for the European colonies. The European powers pursued another policy in their colonies, which were ruled almost entirely through bureaucracy. Real political bodies existed only in the 'mother' countries and the bureaucracy in the colonies were responsible to the

governments in their political center and, indirectly to their political mandators. Political elements in the colonies were few, elected bodies had little or no influence of the administration and, most important, administration and military power were closely united in terms of command and responsibility. For example, in India the heads of bureaucracy (the civil administration, Indian Civil Service) in each district were intertwined with the military forces in the districts. Though they were separate organizations they were used together, if required, in command and operations, and the military personnel was used to enforce the implementation of the regulations of the civil service. This system, slightly different in the colonies of different European powers, was based on bureaucratic rule in the colony. Thus, it differed completely from what was tolerated in the colonial states at home and it meant a bureaucratization, which was never only a legal domination but always also domination by violence.

At the close of the nineteenth century the economy of most European countries and North America started to grow rapidly after a protracted slump. Investments increased and trade and industry grew. As shown by Jürgen Kocka the structure of the industrial and commercial firms changed. Very big companies arose, and these companies met new organizational problems. The structure of the Siemens and Halske Company had been, earlier, one of a patrimonial type with an allegiance of the salaried employees to the owners directly. Their loyalty was ensured through bonuses and other benefits given on a personal basis from the members of the Siemens family. In the 1880s a total reorganization took place. The Company replaced the family. General regulations were given instead of personal instructions from the leadership. Benefits were regulated and depended on the firm (Kocka 1969). Although this may have been an unusually clear case, several other examples show that this type of impersonalized bureaucratization took place in many industrial and commercial enterprises during the late nineteenth and early twentieth century (Torstendahl 1991) (see *Business History*).

Not only did bureaucratization get an inroad in each company but industries also started to organize themselves into federations both as employers and as producers and traders. Such employer's associations and industrial organizations were intended to give support to their members through a general knowledge of industries and branches. This required an administrative staff. In this way private sector enterprises both as individual firms and as organizations of firms took a decisive step into a formal bureaucratization of their activities in the late nineteenth or early twentieth century. Thereby they also forced the states to act. It was impossible for states to rely only on their traditional administration, when organizations of industry made demands on the state and its policy. States had to engage competent personnel, in the first hand technically educated persons who could meet the demands from industry and trade. These new bureaucrats should also assist states in their demands on industry, in the first hand in questions of security—inspectors of ships, elevators, constructions, bridges, railroads etc. were engaged and organized into new administrative units. Security of labor became another source of state activity (Winkler 1974, Bruguière et al. 1985, Torstendahl 1991, Chap. 4). Voluntary organizations and, not least, parties were also drawn into the organizational mainstream and got a bureaucratic structure (Michels 1911).

It is well known that World War I (see *First World War, The*) meant an enormous growth of state intervention in the economy all over Europe. In order to make resources suffice for the most urgent needs the state had to regulate vast areas of the economy entailing an extensive bureaucratization. After the war most of the new administrations were abolished. The recollection of the war years and the large-scale bureaucratization of society during these years was, however, alive with many people and it formed a source of inspiration to some both on the left and the right (Rials 1977).

The reshaping of Europe after World War II (see *Second World War, The*) brought a new stage to bureaucratization: the social welfare administrations. They were foreshadowed in Scandinavia and France before the war but became a general phenomenon in West Europe only after the war. States then took the lead in the economies of European societies and, with or without nationalization of industries, wanted to carry through extensive planning. The variations between West European states were considerable in regard to political will. Enthusiasm for planning and welfare was great in the socialist and social democratic camps in countries like France, Britain, and Sweden (Rousso 1986; Rousso 1987, Morgan 1984) (see *Socialism: Historical Aspects*). In Germany and Italy, for a long period dominated by their Catholic and conservative parties, governments also accepted some state intervention. (Baring 1982, Mammarella 1985), accentuated with political change in the late 1960s. All over Western Europe administrations grew in size and importance.

Around the end of the 1960s complaints about bureaucratization had become numerous and bureaucracies had begun to behave independently of politicians, not any longer implementing political demands but also presenting more and more their own policies. (Aberbach et al. 1981, Mayntz and Scharpf 1975). This new phase of bureaucratization meant that politicians began a drive to reduce the influence of bureaucracy on policy-making. The cutting up of big administrations became usual in Europe and efforts to strengthen the influence of politicians in relation to bureaucracies were frequent in the 1970s and 1980s. Curtailed bureaucracies however, showed their tenacity through

branching off and re-establishing on a local or regional level. Political initiatives may have been transferred more to the politicians but in pursuing their policy politicians were dependent on negotiations with different interest groups and different bureaucratic bodies within the public sector. In the new negotiating economy bureaucracies played a distinctive role though mostly in the background or as participants in the groups forming policy solution in complete packages. Bureaucratization was no longer as obvious as earlier, but it did not mean that its development was reversed (Torstendahl 1991).

Outside of Western Europe strong presidential systems have often given rise to a different process of bureaucratization from the one in Western Europe. In the US the president is regarded as the head of the administration as well as the head of politics, while in Western Europe the two spheres have in principle been kept apart. Bureaucratization in Europe has meant that the superiority of politics over administration has been challenged through bureaucratic expansion, while in the US bureaucratization has meant, rather, the increasing influence of federal (public) decisions in the private sector of economy and life, balanced by the equally strong judicial sector. Strong presidential systems have arisen in many other countries in the period after World War II but often without the strong judiciary that exists in the US. Russia is one recent example.

The parallelism of the development of bureaucratization in Europe and North America—and in the twentieth century also Australia and New Zealand—thus became less visible after around 1950. Russia, on the other hand, has not made away with large parts of its bureaucracy from Soviet times after *perestroika* starting in 1985, which might have been expected. The strong presidential rule in new Russia relies heavily on the administrative organs, and these are still intertwined with the leadership of the privatized huge industrial conglomerates. In domestic matters the president is regarded and seems to regard himself more as the leader of an administration than as a political leader and he has no party to rely on. The Duma and the Federation Council (and their predecessors in the previous constitution) have little influence on the government and the administration. Bureaucratic rule is still prevailing, as in Soviet and Czarist times (Shevtsova 1999).

The process of bureaucratization in societies where a distinction is made between politics and bureaucracy has tended to develop in similar forms in different countries. The changes have been going in the same direction at approximately the same points of time. It will then seem that we meet the same type of dynamics and it is tempting to refer this to basic economic structures of these societies. This assumption might be well founded for the West European societies, for they have been fundamentally like each other. It is more difficult to say that it holds also for the US. It is still more difficult to transfer the argument to India, where bureaucratization of both the private and the public sector has been fairly similar to the process in Western Europe in spite of a different type of economy and another basic economic structure.

3. *Bureaucratization as a General Phenomenon and Object of Theory-making*

The interest in the problem of bureaucratization seems to have been directly dependent on the relation between politics and administration. In regard to the interest in bureaucracies surprisingly few books have been devoted to the process of bureaucratization as a general phenomenon (primarily Jacoby 1969, Rizzi 1939).

A wide literature has been produced on the bureaucratization of different parts of modern Western societies. Eisenstadt, with several investigations on bureaucratic developments, gave an overview of the literature in 1958, now somewhat outdated (Eisenstadt 1958). A general approach has been tried in regard to the bureaucratization of socialism (Hodges 1981) but most discussions of bureaucratization have been particular in regard to the selection of societies and time periods discussed.

Max Weber brought forward the basic criteria for a discussion of bureaucratization as a social phenomenon, answering to the need for rationalization in the sphere of government. His standpoint is often rendered as an inevitability of bureaucratization and an impossibility to evade the 'iron cage' of bureaucracy. This hardly makes justice to Weber's sophisticated argument about men's possibility to counteract what seem to be probable predictions (Mommsen 1974, 1989, Schluchter 1989). However, several critics of contemporary culture in post-World-War-II Europe and America have taken bureaucratization as their point of departure for a demand to change a development into a civilization run by administration.

R. Torstendahl

Burnout, Psychology of

Burnout is a psychological syndrome that develops in response to chronic emotional and interpersonal job stressors. The three defining components of this syndrome are: (a) exhaustion, (b) cynicism and detachment from the job, and (c) a sense of inefficacy and reduced accomplishment. Burnout impairs both personal and social functioning. While some people may quit the job as a result of burnout, others will stay on, but will only do the bare minimum rather than their very best. This decline in the quality of work and in both physical and psychological health can be costly—not just for the individual worker, but for everyone affected by that person.

1. Development of the Burnout Concept

The relationship that people have with their work, and the difficulties that can arise when that relationship goes awry, have been long recognized as a significant

phenomenon of the modern age. The use of the term 'burnout' for this phenomenon began to appear with some regularity in the 1970s in the USA, especially among people working in the human services. This popular usage was presaged by Greene's 1960 novel, *A Burnt Out Case*, in which a spiritually tormented and disillusioned architect quits his job and withdraws into the African jungle. Even earlier writing, both fictional and nonfictional, described similar phenomena (for example, the protagonist in Mann's *Buddenbrooks* (1900) displays the core features of burnout, including extreme fatigue and the loss of idealism and passion for one's job). What is noteworthy is that the importance of burnout as a social problem was identified by both practitioners and social commentators long before it became a focus of systematic study by researchers.

The evocative power of the burnout term to capture the realities of people's experiences in the workplace is what has made it both important and controversial in the research field. As the 'language of the people,' burnout was more grounded in the complexities of people's relationship to work, and gave new attention to some aspects of it. However, burnout was also derided as nonscholarly 'pop psychology.' Unlike other research on the workplace, which used a top-down approach derived from a scholarly theory, burnout research initially used a bottom-up or 'grass-roots' approach derived from people's workplace experiences. At first, the popular, nonacademic origins of burnout were more of a liability than an advantage. However, given the subsequent development of theoretical models and numerous empirical studies, the issue of research scholarship has now been laid to rest.

Research on burnout has gone through distinct phases of development. In the first, pioneering phase, the work was exploratory and had the goal of articulating the phenomenon of burnout. The initial articles appeared in the mid-1970s in the USA, and their primary contribution was to describe the basic phenomenon, give it the identifying name of 'burnout,' and show that it was not an uncommon response. This early writing was based on the experience of people working in human services and health care—occupations in which the goal is to provide aid and service to people in need. Such occupations are characterized by high levels of emotional and interpersonal stressors, so it is not surprising that the concern with burnout originated there. The initial articles were written by Freudenberger, a psychiatrist working in an alternative health care agency, and by Maslach, a social psychologist who was studying emotions in the workplace. Freudenberger (Freudenberger 1975, Freudenberger and Richelson 1980) provided direct accounts of the process by which he and others experienced emotional depletion and a loss of motivation and commitment, and he labeled it with a term being used colloquially to refer to the effects of chronic drug abuse: 'burnout.' Maslach (1976, 1982) interviewed a wide range of human services workers about the emotional stress of their job, and discovered that the coping strategies had important implications for people's professional identity and job behavior.

The clinical and social psychological perspectives of the initial articles influenced the nature of the first phase of burnout research. On the clinical side, the focus was on symptoms of burnout and on issues of mental health. On the social side, the focus was on the relationship between provider and recipient, and on the situational context of service occupations. Most of this initial research was descriptive and non-empirical—it was more qualitative in nature, using such techniques as interviews, case studies, and onsite observations.

In addition, this first phase was characterized by a strong applied orientation, which reflected the particular set of social, economic, historical, and cultural factors of the 1970s. Both Farber (1983) and Cherniss (1980) provided analyses of how these factors had influenced the professionalization of the human services in the USA, and had made it more difficult for people to find fulfillment and satisfaction in these careers. Burnout workshops became a primary mode of intervention, as exemplified in the work of Pines et al. (1981).

A second phase of burnout research developed in the 1980s, in which the emphasis shifted to more systematic empirical research. This work was more quantitative in nature, using questionnaire and survey methodology, and studying larger subject populations. A particular focus of this research was the assessment of burnout, and several different measures were developed. The scale that has had the strongest psychometric qualities and has been used in over 90 percent of the research studies is the Maslach Burnout Inventory (MBI) developed by Maslach and Jackson (see Maslach et al. 1996 for the most recent versions of this measure).

The shift to greater empiricism was accompanied by theoretical and methodological contributions from the field of industrial–organizational psychology. Burnout was viewed as a form of job stress, with links to such concepts as job satisfaction, organizational commitment, and turnover. The industrial–organizational approach, when combined with the prior work based in clinical and social psychology, generated a richer diversity of perspectives on burnout and strengthened the scholarly base via the use of standardized tools and research designs.

Another aspect of this empirical phase is that burnout extended beyond its original American borders. At first, the phenomenon drew attention in English-speaking countries, such as Canada and the UK. Soon articles, books, and research measures were translated into numerous languages, and subsequently research on burnout emerged in many countries of Europe, as well as Israel. Because burnout research in these countries started after the concept and measures

had been established in the USA, that work built on an already established theoretical and methodological base. Hence, the initial conceptual debate on burnout was less broad, and alternative measures were rarely developed. However, by the 1990s, the intellectual contributions of non-Anglo-Saxon authors in terms of theory, research, and intervention were considerable (most notable is the work of Schaufeli and his colleagues; see Schaufeli et al. 1993, Schaufeli and Enzmann 1998).

In the 1990s this empirical phase continued, but with several new directions. First, the concept of burnout was extended to occupations beyond the human services and education. Second, burnout research was enhanced by more sophisticated methodology and statistical tools. The complex relationships among organizational factors and the three components of burnout led to the use of structural models in much of burnout research (Leiter is the leading contributor here; see Leiter 1993), and also spurred developmental proposals of the merits of sequential versus phase models (for the latter, see Golembiewski and Munzenrider 1988).

A third direction has been the development of new theoretical perspectives on burnout. For example, burnout has been conceptualized as a lack of reciprocity in social exchanges, as emotional contagion, as a failed quest for existential meaning, and as a mismatch between person and job in six areas of worklife (see Schaufeli et al. 1993, Maslach and Leiter 1997). Another new development has been the focus on the opposite of burnout, namely the productive and fulfilling state of engagement with work. Engagement has been defined in terms of the positive end of the three dimensions of burnout (i.e., energy, involvement, and efficacy), but future research may suggest a more complex model of this phenomenon.

2. *A Research Overview*

The current body of research evidence yields a fairly consistent picture of the burnout phenomenon (see Schaufeli and Enzmann 1998 for the most recent review of this literature). Because burnout is a prolonged response to chronic job stressors, it tends to be fairly stable over time. It is an important mediator of the causal link between various job stressors and individual stress outcomes. The exhaustion component of burnout tends to predict the rise of cynicism, while the inefficacy component tends to develop independently.

2.1 *Contributing Factors to Burnout*

The primary antecedents of burnout are work overload (both quantitative and qualitative) and personal conflict at work. A lack of resources to manage job demands also contributes to burnout. The most critical of these resources have been social support among colleagues, and the opportunity to exercise control over one's work. Although the bulk of burnout research has focused on the organizational context in which people work, it has also considered a range of personal qualities. Burnout scores tend to be higher for people who have a less 'hardy' personality or a more external locus of control, or who score as 'neurotic' on the Five-Factor Model of personality. People who exhibit Type A behavior tend to be more prone to the exhaustion dimension of burnout. (See *Personality and Health*)

There are few consistent relationships of burnout with demographic characteristics. Although higher age seems to be associated with lower burnout, it is confounded with both years of experience and with survival bias. The only consistent gender difference is a tendency for men to score slightly higher on cynicism.

2.2 *Outcomes of Burnout*

The exhaustion component of burnout is more predictive of stress-related health outcomes than the other two components. These physiological correlates mirror those found with other indices of prolonged stress. Parallel findings have been found for the link between burnout and various forms of substance abuse.

In terms of mental, as opposed to physical, health, the link with burnout is more complex. It has been assumed that burnout may result in subsequent mental disabilities, and there is some evidence to link burnout with greater anxiety, irritability, and depression. However, an alternative argument is that burnout is itself a form of mental illness, rather than a cause of it. Some of this research has focused on the distinction between burnout and depression: burnout is job-related and situation-specific, as opposed to depression, which is general and context free.

Burnout has been associated with various forms of job withdrawal—absenteeism, intention to leave the job, and actual turnover. However, for people who stay on the job, burnout leads to lower productivity and effectiveness at work. Consequently, it is associated with decreased job satisfaction and a reduced commitment to the job or the organization.

People who are experiencing burnout can have a negative impact on their colleagues, both by causing greater personal conflict and by disrupting job tasks. Thus, burnout can be 'contagious' and perpetuate itself through informal interactions on the job. There is also some evidence that burnout has a negative 'spillover' effect on people's home life.

3. *Implications for Interventions*

The personal and organizational costs of burnout have generated various intervention strategies. Some try to treat burnout after it has occurred, while others focus on how to prevent burnout. The interest in job engagement has led to a focus on how to promote this

positive state (rather than just on how to reduce the negative state of burnout). Although some interventions have been implemented, there has been almost no evaluation of their effectiveness.

The primary emphasis has been on individual strategies to deal with burnout, rather than social or organizational ones, despite the fact that research has found that situational and organizational factors play a bigger role in burnout. Future progress in burnout interventions will depend on the development of strategies that focus on the job context as well as the people who work within it.

Business and Society: Social Accounting

To succeed, any modern business manager needs to understand all the interfaces between the business and wider society no less than all the internal operations of the business itself. For no business can survive, let alone flourish, unless it provides goods or services for which customers outside the business will be prepared to pay. Business success depends on meeting market demand. Awareness of market conditions and of how the market may be influenced is a key part of business management. In this article the various interfaces between businesses and their social context are briefly examined, using a form of analysis which has come to be known by the acronym SLEPT, in which the different letters stand respectively for the Social, Legal, Environmental, Political, and Technological factors influencing business organizations.

1. Social Factors

Market demand depends on the needs, desires, and interests of people in society, and knowledge of these is essential if a business is successfully to meet that demand. Such factors may be determined by the physical climate, by the language and culture, or by the demographic structure of a society. There is likely to be little demand, for example, for heavy overcoats in tropical countries, or for umbrellas in arid lands. In some cultural settings it is still rare for women to seek paid employment. In others the increase in life expectancy may have resulted in increasing demand for leisure activities for pensioners who have retired from employment. Changes to birth rates cause fluctuations in demand for goods and services required by children. These are examples of the ways in which knowledge of the market place will help a business entrepreneur to decide what goods to produce and offer for sale to meet demand.

Part of the cultural context of a business is the prevailing ethos or climate of moral opinion about what are right standards for business activity and trading. During the last two decades, such questions of business ethics have figured increasingly in public concern and on the agendas of business organizations. These highlight the need for complete probity and accountability in business, and for more openness in the operations of boards of directors. Ethical considerations may involve how a firm exploits its markets, how it obtains raw materials or cheap labour for its operations in different parts of the world, or how its activities affect the physical environment (which will be explored more fully in Sect. 3).

The ethical standing of a business will affect its public relations, which in turn may impact upon the demand for its products, one way or the other. Modern businesses, especially larger ones, pay increasing attention to their public relations and how their images—and the brand images of their products—appear to the general public. Part of that public image is determined by how a business is presented by the news media, part by the reputation which products have among customers, and part by the business' own public advertising of its products. No successful

business can ignore its need for a continual campaign to advertise its products, for in this way it can significantly influence market demand and maintain its share of markets with strong competition. The outlets for advertising are constantly spreading, using newspapers, magazines and journals, individual mail-shots, public hoardings, television and radio, and more recently, the Internet. This leads to the whole field of electronic commerce to be considered more fully in Sect. 5. At the same time, businesses need to be conducting market research, assessing public opinion about their existing products and exploring what other demands there are in the marketplace for potential new products. Market research enables a business to maintain direct links with any community where it seeks to trade.

The social factors relating to a business company have been recognized in many circles by introducing the concept of stakeholders of the company, who are all the groups of people with a legitimate interest in the operations of the company, not just the shareholders. Stakeholders equally include the employees of a business, the customers, local residents and communities, and representatives of environmental interests. For many years there have been schemes of co-ownership and copartnership which have involved employees in the actual ownership of companies. More recently, and particularly in the United States, some corporations have introduced special constitutional features so that there are boards with representation from all stakeholder groups. A growing number of large firms are now publishing regular social or environmental reports as a means of accounting to all their stakeholders; and independent professional bodies are now issuing reviews of whole industries in this way, such as the Turnbull Report of the Association of Chartered Accountants of England and Wales. These arrangements vary in their levels of formality, but they are all attempts to involve wider social interests in the decision-making processes of the company. The growth of consumerism and of specific organizations established to protect and further consumer interests has inevitably brought increasing pressures to bear on the decisions of many businesses.

2. *Legal Factors*

The framework for business activity in any society may be constrained by legal requirements in that society. As long ago as 1570, the English Parliament enacted a law requiring every member of the 'lower classes' over the age of six years to wear a woollen cap on Sundays and holidays. Such legislation would today be regarded as a gross infringement of personal freedom, but it was introduced to further the interests of the politically powerful sheep farmers and wool traders at the time.

In later centuries in Britain there was significant dismantling of such legal constraints on business, with the ending of the mercantile system and the growth of '*laissez faire*.' Free market economists like Adam Smith, Thomas Malthus, David Ricardo, and John Stuart Mill advocated the freeing of business markets from legal restraint and control, so that the 'invisible hand' of free market forces could determine the price levels at which supply would equal demand. It was maintained that the interests of both producers and consumers were optimised by the free play of market forces, and that this required the absence of legal constraints, to enable businesses best to serve society by pursuing their own interests as vigorously as possible.

During the last 180 years, however, the political pendulum has swung very much the other way. Acts of Parliament in Britain ended the slave trade, banned the employment of women and children in coal mines, and introduced legislation for the health and safety of employees in factories and other places of work. Other statutes provided for the registration of business companies, giving them legal entity as corporate bodies rather than partnerships of all their various owners, and limiting the financial liability of shareholders to what they paid for their shares. Increasingly under governments of differing political shades, more and more legislation has come into force in virtually all countries of the world which sets the standards and requirements to be observed in business trading. Business managers need a very full awareness of the legal framework in which they are operating, both of the statutes established by political processes and of the decisions of courts in applying those statutes and developing case law.

3. *Environmental Factors*

Concern for the health and safety of employees is one example of a limitation on business operations to curb the potentially harmful effects of those operations. Just as people within the workplace may be injured and exposed to health risk, so too the activities of a business, in both production and distribution, may be detrimental to people living in the vicinity, along transport routes, and in the community generally. The discharge of waste materials from industrial processes, be they solid, liquid, or gaseous, on to waste land, into rivers, or into the atmosphere can have harmful effects reaching far into other countries, and into the ozone layer above the atmosphere. There is global concern that raw materials are being depleted at rates which will restrict or even exhaust their availability for future generations. For instance, the rain forests of Brazil are being decimated by the worldwide demand for timber and paper. Similarly, known reserves of fossil fuels in the world are finite. Public opinion is increasingly aware of the environmental effects of business activities in the widest contexts and longest timescales, and there is growing demand that all economic activity

should be environmentally sustainable and without permanent damage to the planet.

Most goods supplied to the market today are packaged in some form, and difficulties may arise in the disposal of the packaging. Cardboard, paper, bottles, and some metallic containers can now be recycled for reuse, but containers made of some plastics have no future use. Manufacturers therefore need to be more aware of the environmental impact of the way they package their products. And in this age of the throw-away society, there are immense problems arising from the disposal of goods which are no longer of use to their owners. It is not easy for society to get rid of motor cars and household applicances which have outlived their useful lives, and there are limits to how the world can dispose of its growing mountains of rubbish. All such considerations challenge business operators to develop products which are easier to recycle or get rid of, or which will last much longer. Political pressures on governments will almost certainly lead to more legal constraints on business to meet these challenges.

4. *Political Factors*

Section 2 highlighted the ways in which business activities can be constrained by laws in force in society, and in most cases those laws are made, amended, or repealed through the established political processes of the country in question. Political structures vary between countries, and any business manager needs to understand the working of those structures in any country where the business has operations, in securing raw materials, in production, or in marketing and distribution. In countries which have democratic structures, a business needs to be constantly alert to what changes may come about in public policies. The programs of potential alternative governments need to be scrutinized and possibly influenced through the use of open democratic processes, so that when new laws are enacted they do not take the business by surprise and may be more helpful for the business than would otherwise have been the case.

Equally important is an understanding of the administrative processes of government through which laws and statutes are implemented. A business must be especially alert to the taxation implications of all its activities, and be ready to rearrange and retime those activities to reduce its tax liabilities. Similarly, the day-to-day administration of other departments and agencies of government may bear on the activities of a business, and it is essential for the manager to have an easy means of communication with appropriate public servants in order to sort out any problems which may crop up for the business. The best means of cooperation in this respect will vary from country to country, but one general principle is that all representations to officials must be open and never underhand nor illegal.

5. *Technological Factors*

In Sect. 1 it was noted that technological changes provide another important influence on how a business is run, introducing new products to be manufactured, new methods of manufacturing them, new means of packaging and distribution, new methods of advertising and marketing, and new means of communication to be employed in all operations. The pace of technological change appears to be accelerating all the time, and the contemporary electronic revolution in communicating information is introducing a new way of business life for all large organizations. The mobile phone, the fax, and email enable decisions to be taken and implemented instantly.

Technological changes can bring vast benefits to producers and consumers alike, but they may also pose difficult problems, particularly in the management of human resources. As old machinery becomes obsolete, staff need to be retrained to use new technology or redeployed to new activities because the new technology is not so labor-intensive. Many new machines take the place of people, so it is not unusual for established workforces to resist the introduction of new technology, and industrial relations may become fraught. Nowhere was this shown more dramatically than in the English newspaper industry in the 1980s, when decisions to introduce new technology for print-setting led to mass picketing and some violence at Wapping in east London.

At the same time, the modern revolution in electronic communications enables many more people to work at home in more conducive surroundings and avoiding the traffic congestion associated with commuting to work. Word processors, fax machines, and emails enable the workforces of many businesses to be geographically scattered, with many individuals working on a contract or consultancy basis on tasks which had previously to be done in central offices. Add to all this new technology the far-reaching potential of the Internet, and it becomes possible for more and more business to be conducted electronically, with consumers ordering, and paying for, goods on the Internet; the effectiveness of such commerce depends partly on the strength and security of computer systems, and partly on the reliability of networks used for the prompt distribution of goods.

6. *Social Accounting*

Whereas the foregoing description of the interfaces between business and society was in terms of the links between an individual business and its social context, social accounting is more concerned with macroeconomics, involving a study of how whole industries and institutions relate to the wider economy and society, and of how the production of goods and services, income formation, and income distribution relate to each other. Social accounting techniques have

been widely applied in the fast developing economies of the third world, such as Iran, Malaysia, Sri Lanka, Pakistan, Indonesia, Ecuador, and Swaziland.

In the application of these techniques, Social Accounting Models, or SAMs, can be constructed for specific countries and used as integrated databases for understanding the effects of national economic policies. While the British Treasury has used Economic Models for over a quarter of a century, in most of the less developed countries similar SAMs have now been built, varying greatly according to the economic characteristics of local economic conditions. Such models may be diagrammatically represented as shown in the literature, and are increasingly used in the formation of public economic policy.

Social accounting concerns microeconomics as well, since a growing number of corporations are now active in social accounting, auditing and reporting. They publish social and environmental reports on a yearly basis, which provide detailed information about the relations with their stakeholders, such as investors, employees, consumers, suppliers, central and local governments, and environmental associations. Financial rating agencies evaluate firms not only in terms of their economic and financial performance, but also in terms of their social, ecological and ethical performance.

Business History

Strictly speaking, Business History (company history) as the history of private and/or public corporations with specific legal structures must be distinguished from Entrepreneurial History (business biography), the history of entrepreneurially active personalities. In the first instance, the concern is with the development of organizations in which questions of economic success loom paramount. In the second case, the object of study is a certain social type and/or individual personality whose behavior inside and outside of the enterprise can be researched, for example, in its social, cultural, or political effects. In practice, however, institutional and biographical approaches tend to overlap. This article starts out by sketching the history of the subject, above all in the USA and in Europe, before then going on to a discussion of contemporary methods and approaches.

1. History of the Academic Discipline

Modern business and/or entrepreneurial history has two sources: First, the need of corporations and businessmen for image cultivation and self-affirmation, which has brought forth an increasing number of commissioned biographies and company histories, as well as autobiographical accounts. Business History received academic impetus above all from the German Historical School of Economics. This school questioned the explanatory power of classic liberalism and attempted to replace it through alternative concepts in which long-term perspectives as well as the entrepreneur played a key role in explaining economic growth. Of primary significance was the work of the German scholars Gustav Schmoller, Werner Sombart, and Lujo Brentano.

Against this theoretical background, scholars around 1900 began to write academic business histories, thus establishing a counterweight to the celebratory usage to which these chronicles had been put in the last third of the nineteenth century initially by banks and publishing houses, soon thereafter by the large industrial firms. Both genres were reacting to the mounting criticism of the conduct and profits of the more successful businessmen. In such a way, business history served, among other things, to legitimize a rising social class that was rapidly acquiring both affluence and influence. In 1912 Richard Ehrenberg, whose *History of the Siemens Brothers* (1906) was one of the first company histories based on archival documents, collaborated with Hugo Racine on *The Worker Families of Krupp*, which defended the company politics of the Ruhr's heavy industry sector. Also during this period was the founding of the first systematically organized business archives (Krupp 1905, Siemens 1907. In Great Britain in 1904, George Unwin published his pioneering work on the origins of the modern enterprise, which traced the decline of the guilds through to the emergence of functionally differentiated management structures in the seventeenth century.

Academic approaches to business history received a further impulse from the History of Technology and the burgeoning field of 'management studies' which specialized in private enterprise. Here historical methods were combined with the self-promotional interests of new academic disciplines. Both fields of study wanted not only to secure their academic standing, but also harboured naive hopes—from a modern perspec-

tive—of being able to derive general laws of historical development.

In nineteenth-century America there appeared numerous non-academic business histories in which banks, canal and railroad companies were the leading players. The subject first established itself academically in the 1920s with the Graduate School of Business Administration of Harvard University, which sought to use Business History for training purposes. Future managers were to be trained through an analysis of historical case studies and through a comparison of past and current methods of executive leadership. With the appointment of Norman Gras to the first ever chair for Business History in 1927, Harvard laid the groundwork for the institutionalization of American business history. There subsequently appeared such periodicals as the *Journal of Economic and Business History*, 1928–32; *Bulletin of the Business Historical Society*, 1938–53; and *Business History Review*, since 1954. In his magnum opus *Business and Capitalism*, inspired by the work of Sombart, Ehrenberg, and Unwin, Gras (1939) divided the economic history of America into various stages, naming them for each period's distinctive business type: petty, mercantile, industrial, financial, and national capitalism. The *Casebook in American Business History*, which Gras co-authored with his Harvard colleague Henrietta M. Larson, also appeared in 1939. In 1948 Larson published an extensive bibliography in her *Guide to Business History*. Already the year before, with the registration of the *Business History Foundation*, Gras and Larson had gone a step further down the road to firmly establishing their discipline. In 1954 the *Business History Conference* was founded, which has remained the subject's central American organization to the present day.

The subject received an additional stimulus through the favourable reception of Joseph Schumpeter's ideas, which stressed the dynamic innovations of entrepreneurs as the driving force of economic development. Following his programmatic address to the Economic History Association, Schumpeter himself helped in establishing the Research Center in Entrepreneurial History (1948–58), funded by the Rockefeller Foundation and the Carnegie Corporation. Its first director Arthur H. Cole, along with Thomas C. Cochran, Leland H. Jenks and the German economist Fritz Redlich, grouped their work around the concept of 'entrepreneurship,' and anchored it in a broader social context. The Center also published its own journal, *Explorations in Entrepreneurial History*. In 1959, after 10 years, Cole summarized the Center's most significant findings, which went far beyond those of mere biographical studies. The main emphasis was on the development of entrepreneurial typologies, as well as on the relation of the entrepreneur to the corporation and its environment.

As of the 1940s, more and more American universities, colleges, and business schools introduced courses and chairs in Business History. In Germany, the discipline has been unable to achieve a similar rank within the academic canon, and is primarily taught by history and economics faculties under the rubric of economic and social history.

Appearing in the mid-1950s were many periodicals that reflected a growing interest in the subject, such as *Business History* (1956, UK), *Tradition* (1956, West Germany; since 1978 *Zeitschrift für Unternehmensgeschichte*), *Technology and Culture* (1958, USA), and *Histoire des Entreprises* (1958, France). Ironically, *Business History* remained a force even when its object of study was undergoing severe periods of crisis. In the wake of the student movements of the 1960s, entrepreneurs and companies were subjected to harsh criticism. Then in the 1970s the pioneer countries of the industrial age lapsed into a structural crisis that within a few years had shrunk those long dominant sectors of mining, iron, steel, and textiles. These upheavals led to the founding of numerous museums and business archives that have since become lively research sites. Added to this were newly established academic organizations such as Germany's *Gesellschaft für Unternehmensgeschichte* (Society for Business History, est. 1976).

At the same time, *Business History* began to subdivide, there emerging special organizations and journals for individual aspects of the field, sporting names such as *Accounting*: *Business and Financial History* (1991), *Financial History Review* (1994) and *Journal of Industrial History* (1998). By contrast, the successor of *Business and Economic History Review* (1962–99), *Enterprise and Society* (2000), began to pose questions whose impulse came from the broader fields of social and cultural history. And since 1998, the *European Yearbook of Business History* has likewise represented a wide thematic outlook.

Due to the regional embeddedness, further initiatives arose that not infrequently culminated in the founding of museums and archives. Prominent examples are the Centre for Business History in Scotland (Glasgow), the Hagley Museum and its affiliated Center for the History of Business, Technology, and Society in Wilmington, Delaware (USA), and the Society for Westphalian Economic History in Germany's Ruhr district. In the 1990s, various international organizations were founded, such as the European Association for Banking History (1990), the European Business History Association (1994), and the Society for European Business History (1997).

2. *Methods and Approaches of Business History*

From the moment it entered academia, *Business History* began to borrow methodologies from neighbouring disciplines, particularly economics and management studies, but also from history, sociology, political science, and ethnology. Equally variegated are the research areas and methodologies of modern

business history. Roughly speaking, one can distinguish nine new areas of study:

2.1 The Enterprise as a Commercial Endeavour

In an analysis of the commercial success of firms, the instruments of management studies are of primary importance. Costs, investments, yield, cash-flow, and profit margins are studied over prolonged periods. Company development is essentially traced with the help of in-house accounting files—themselves objects of research, as the methods of accounting have been subject to historical change. The external relations of the enterprise are only of marginal interest, or are treated indirectly. However, in the same way as trade cycles, fiscal, legal, or political intervention show up in the final balance sheet.

2.2 Finance Capital and Industrial Production

Stimulated chiefly by Rudolf Hilferding's thesis of the dominance of big banks over industry, the relationship between the financial and the industrial sectors is likewise an object of analysis. For European and American industrialization, it has been revealed that banks and money markets at first played only a subordinate role in the financing of business. However, when these firms reached certain growth thresholds—for example, merging with or investing in capital-intensive technologies—external funding was required, in which way they would enter into a close relationship to the banks.

Of Great Britain it is said that between 1880 and 1930 London financial institutions neglected industrial interests, thus hindering the modernization and concentration of the country's industrial base. This was in contrast to the big banks of Paris and Berlin. On the other hand, Collins sees the aloofness of the money market to industry as a consequence rather than a cause of slow corporate growth. Davis argues that the American money market circa 1900 was less efficiently organized than its British counterpart, and the selective access to credits explains the concentration of capital in the hands of multi-millionaires like Rockefeller and Carnegie. By comparison, Chandler emphasizes the dominance of internally-generated cash-flow as the result of successful integration. Case studies on the close relationship between big banks and industry in Germany show that one cannot speak of a general ascendancy of financial institutions.

2.3 Businesses as Innovators and Users of Technology

Technological innovations, either self-generated or initiated from outside the firm, are central to the development of many enterprises. Thus, *Business History* undertook the description of technical processes; however, these were often uncritical lists of glorious inventions and paeans to the genius of the particular entrepreneur. The new *Business History* discusses questions as to the timely application of technical innovations or their adequacy for specific conditions of production and sales. In the debate on the decline of that pioneer of the Industrial Revolution, Great Britain, comparative investigations have been particularly enlightening. While some researchers brand the British businessman's clinging to outdated technology as a failing, others see this as perfectly rational behavior in view of fundamental differences in the market as well as in the conditions of supplies and sales (Wengenroth 1986).

The mass production technology that had been suitable for the large and relatively homogenous American market and a predominantly unskilled labor force was non-transferable—at least with the same level of success—to the completely different economic terrain of Europe. It is also not always an advantage to be in the forefront of technological innovation. Wait and see—then imitate. Later investments in more mature technologies has proven itself in many ways a superior strategy, especially for countries lagging behind the pioneers of industrial development.

Further significant themes in this field are: mechanisms of technology transfer, research and development, the relationship of companies and academic research, as well as the social, economic, and mounting ecological consequences of technical progress (Hounshell 1984).

2.4 Organizational Capability and Comparative Advantage

Belonging to the central themes of *Business History* is the quest for the optimal organizational structure with respect to strategy, technology, and the market. It were along these very lines that Alfred D. Chandler of the Harvard Business School forwarded theses that were to preoccupy entire generations of scholars. In Chandler's first major work, *Strategy and Structure* (1962), he asserted that changes in the 'market-cum-technological environment' modify the 'basic long-term goals and objectives of an enterprise,' which themselves determine the shape of the company's organization. It was Chandler's (1977) *The Visible Hand* which stressed the superior performance of managers i.e., salaried entrepreneurs, in comparison to the owner-entrepreneuer. His third notable work, *Scale and Scope*, extended the study to Great Britain and Germany, concluding that differences in national competitiveness were the result of divergent utilization of economies of scale. In employing this approach, Chandler elevated the American model of managerial capitalism and its large-scale 'three-pronged investment in production, management, and marketing facilities' to a universal prescription for success.

Chandler's theses met with enthusiastic response. He had moved beyond the stage of individual case

studies in favour of a general paradigm for the analysis of industrial capitalism. At the same time, his claim to general validity provoked vehement protest. The ensuring debate was unusually productive, and issued most significantly in a criticism of Chandler's idealization of the American model of big industry. 'The usual Chandler bracketings apply. Labor, culture, state, politics, and all industrial activity outside the top 200 are set aside as secondary or irrelevant.' (Scranton 1991)

The latter point was especially raised by Michaele Piore and Charles Sabel who pointed to the viability of 'Historical Alternatives to Mass Production.' According to their 'theory of dualism,' mass production is not the only paradigm of industrial capitalism. Small-scale enterprises, always representing the majority of companies, were also able to operate successfully. The most efficient were those specializing in small market segments and using flexible production technologies as well as highly skilled labor. Fluctuations in demand and design could be easily coped with. In a way, this 'modern craft production' was a 'necessary complement to mass production' and explains the persistence of the small firm. Philip Scranton and Gary Herrigel have demonstrated for the USA and Germany respectively that multiple paths to industrial profit did coexist and that successful specialty production of small and medium-sized firms hinged on quality, differentiation, human skills, and local networks rather than on high throughput technologies and size.

Associated with this debate are questions concerning the optimal size of firms, the reasons for and success of mergers and acquisitions, the relation of transaction costs and corporate structure, as well as solutions to the principle-agent problem.

2.5 Multinationals in the Process of Internationalization and Globalization

Closely connected to the question of the appropriate organizational structures is the internationalization process within firms (Wilkins 1970, Jones 1996). Why do companies prefer foreign direct investments with direct control as opposed to portfolio investments or cooperation with independent foreign partners? Firms like Nobel and Vickers invested abroad in order to exploit those competitive advantages already acquired at home. By contrast, Shell and Lever secured access to vital raw materials. Others were desirous of skirting customs barriers, of operating more closely to the market, or securing foreign know-how, locational advantages, and subsidies.

Buckley and Casson maintain that excessive transaction costs are the main reason for substituting cross-border market cooperation through multinational hierarchical organization. Internalization is a superior method of coordination across national frontiers.

In addition, the detailed structures of these firms are examined i.e., the choice between sales and production subsidiaries or the emergence of particular types of firms like the Free Standing Company, which is characterized by a small corporate headquarter in the country of origin and the location of all productive assets abroad. Related hybrid structures such as joint ventures, cartels, and strategic alliances are also analyzed with the use of similar questions.

It is necessary to distinguish between internalization and globalization. Whereas international firms mainly operate from a national basis, global enterprises are difficult to locate precisely, distributing their activities over the entire globe both fiscally and in terms of market strategy and costs.

2.6 Firms as a Venue of Social Interaction

The history of work relations was given particular impetus by the classic school of social history. This school discovered that in the process of industrialization, many entrepreneuers rose from related occupations from which they derived important social and financial capital, as well as technological and/or organizational know-how. Their degree of social mobility has long been overestimated. Social history further asks how owners of capital, managers, employees and workers, and men and women organize their social relations within firms. In what ways are individual interests bound together organizationally, and how do they factor into the bargaining process? Thus the focal points of research are the history of unions, of worker participation of company social policy, and methods of in-house company relations.

Other objects of study are the mechanisms with which top management uses its power and control in the implementation of directives. In these, how is the principal-agent problem solved? That is, what way is the self-interest of manager-employees curbed with regard to the goals of the entire firm and the capital owners? Chandler, however, sees the rise of better educated managers bereft of family interests as one of the positive and decisive competitive advantages of the American model. He sees the main reason for the relative decline of British industry in its insistence on 'personal capitalism.' Numerous critics have warned against generalized statements concerning the different potential of managers and owner-entrepreneurs, respectively. There is little doubt, however, that outside of the USA the emergence of large company structures frequently coincided with the rise of managers who had no familial connection to the capital owners.

2.7 Corporations as Cultural Institutions

Firms are bearers of specific corporate cultures that play a key role in internal and external communication. As concerns the internal structure, it is a question of the 'software of organization,' of shared rules and values. While Chandler's work suggests that the formal structures—the 'hard facts of organi-

zation'—are decisive, proponents of cultural business history assert that internal integration and coordination is essentially dependent on the strength of the given corporate culture. This assures loyalty, team spirit, and communication skills, while also lowering transaction costs. It consolidates the results of long-term learning processes, especially firm-specific routines and tacit knowledge.

Corporate culture is frequently influenced by strong individuals, chiefly company founders, but also by external socio-cultural factors. Organizational traditions like the German bureaucracy (Kocka 1978), those of the military, or agrarian paternalism were especially effective in the industrialization process. Following mergers and takeovers, there is often a clash of cultures and incompatibility between differing value systems. Furthermore, it is precisely the strong corporate cultures that have a tendency to develop moments of inertia during which adaptation to external change is impeded. The research has shown that organically-evolved corporate cultures determine the inner quality of a company in essential ways. However, social engineering—i.e., the arbitrary, short-term modification of corporate cultures—is impossible.

Corporate culture is not only effective as an internal link of identity and cohesion, but also serves as an exogenous label and a seal of quality. It determines the firm's image in the customer's mind and in that of the broader public, as well as defining the self-projection of the enterprise and its advertised products. The image-forming power of corporate culture extends to brands that rationalize the communication process with customers, while also implying an adherence to quality standards. The strong trust of such arrangements is central to all forms of marketing, but can also be transformed into its diametrical opposite when that trust is abused.

2.8 Companies and Entrepreneurs as Political Actors

Modern companies operate within a regulated framework. The state establishes legal forms that superintend ownership laws and property rights, responsibilities, and information duties. Aside from company law, also of prime importance are labor law, wage law, environmental law, trade law, and tax law. Therefore it is in the vested interest of the firm to influence the development of regulatory frameworks and to involve itself in the political process. The range of its dealings extends from simple forms of lobbying to the participation in *coup d'états*.

Central themes are the effects of organized interests, the activity of companies in political parties, parliaments, administration, governments, the thin line between fund-raising activities and corruption, private-public partnerships, the sale of products to the state, the nationalization or privatization of enterprises, and the correlation between business goals and politics in general.

The view of the political role and ethical responsibility of the economy has gained in significance through research on the behavior of German and foreign businessmen in relation to the National Socialist regime. In reaction to the decades-long taboo placed on studies of the Nazi past, numerous works have now emerged rejecting ideologically-motivated generalizations and accusations, while at the same time confirming the deep involvement of many businessmen in National Socialism.

2.9 The Biographical Approach (Entrepreneurial History)

Entrepreneurial History is concerned with the people behind the strategic decisions. What socio-cultural variables determined their world view and thereby their business personality? Such questions were at first chiefly posed by biographical investigations that frequently sought to portray their subjects in heroic terms. Simultaneously, there was the counter-tradition of critical and even defamatory entrepreneurial biography.

Since the 1970s, social history has introduced quantifying methods into entrepreneurial biography. The great advantage of collective-biographical studies consists in the ability to distinguish between exceptional facts and general structures. Drawing upon selective and representative samples, they investigate heritage, education and upbringing, religion, marital and social status, financial circumstances, the chances of ennoblement and political influence (Augustine 1994, Berghoff and Möller 1994, Daumard 1987). One of the most heatedly discussed questions is whether European businessmen became gentrified by imitating the aristocracy and abandoning their own identity, a debate that has led to an overwhelming rejection of this thesis.

Emerging parallel to the wave of collective-biographical works have been several excellent academic compilations with a wealth of individual-biographical items (Jeremy 1984). With the current wave of historiography addressing everyday life and mentalités, individual-biographical methods are currently on the rise. Vivid and atmospheric narratives now complement more representative statements on general structures which are analyzed through statistical methods.

3. Conclusion

On the whole, despite its varying worldwide status, *Business History* is experiencing an unmistakable upsurge and continues to evolve and expand. As before, there is the ever present danger of a particularistic narrowing of the subject to a series of individual case studies often composed with an antiquarian mind-

set, and which enlarge on their theme with a wealth of material but with little regard for historical context. This unhappy state of affairs—typical of many commissioned studies—can only be countered through a determined commitment to macrohistorical and macroeconomic findings and the inclusion of theoretical approaches from related disciplines.

H. Berghoff

Business Law

1. Contracts

1.1 Elements

A contract is a legally enforceable promise. Formation of a valid contract generally requires four basic elements. First, there must be an agreement between the parties formed by an offer and acceptance of that offer. Second, the parties' promises must be supported by something of value, known as consideration. Third, both parties must have the capacity to enter into a contract. Fourth, the contract must have a purpose that is legal.

1.2 Intent to Be Bound

As business transactions have grown more complex, courts have wrestled with the issue of when preliminary negotiations have ripened into a contract (Farnsworth 1987). Perhaps the leading case arose out of Pennzoil Company's failed attempt to merge with Getty Oil Company (*Texaco, Inc. v. Pennzoil Co.* 1987). The court held that a five-page memorandum of

agreement, signed by the majority shareholders of Getty Oil and approved (but never signed) by the board, constituted a binding contract under New York law even though a definitive agreement for the $5 billion transaction was never signed.

In Japan, businesspersons are more likely to rely on oral contracts or on short contracts with a broad catch-all provision stating that the parties will consult in good faith to resolve any questions of interpretation or matters not covered by the contract (Yanagida et al. 1994). As a result, Japanese courts are more likely than their US counterparts to conclude that negotiations have ripened into a binding contract. In addition, as the Japanese High Court explained in a case decided in 1987:

> In the event that preparation between two parties progresses toward conclusion of an agreement and the first party comes to expect that the agreement will surely be concluded, the second party becomes obligated under the principles of good faith and trust to try to conclude the agreement, in order not to injure the expectation of the first party. Therefore, if the second party, in violation of its obligation, concludes that the agreement is undesirable [absent certain circumstances], it is liable for damages incurred by the first party as the result of its illegal acts (Yanagida et al. 1994).

US law imposes more limited precontractual liability under the doctrine of promissory estoppel for the out-of-pocket reliance damage suffered when one party reasonably and foreseeably relies on a promise made during negotiations.

1.3 Consideration

In most jurisdictions each side must provide something of value to form a valid contract. The thing of value, known as consideration, can be money, property, a promise, or a service. Consideration is present if a party agrees to do something that he or she is not otherwise legally required to do or if the party agrees to refrain from doing something that he or she was otherwise legally entitled to do. Courts usually will not scrutinize the value of the consideration, thus giving rise to the adage that even a peppercorn can be adequate consideration. Indeed, under Japanese law, there is no requirement for consideration at all.

1.4 Unconscionability

A court will refuse to enforce a contract if it is so oppressive or fundamentally unfair as to shock the conscience of the court. This doctrine of unconscionability dates back to Aristotelian theory and Roman law (Gordley 1981). The doctrine of *laesio enormis* provided a remedy when the contract price for the sale of goods deviated by at least half from the just price, defined as the market price for similar goods under similar circumstances. The German and French laws that relieve a party from its obligations under a contract that is not for the just price have their roots in this doctrine of *laesio enormis*. Similarly, in England and the United States, the general principle of freedom of contract has always been limited by the doctrine of unconscionability.

1.5 Genuineness of Assent

Even if a contract meets all the requirements of validity (agreement, consideration, capacity, and legality), a court will not enforce it if there has been no true 'meeting of the minds' between the parties. This may occur when there is fraud, duress, or a mistake of fact.

1.5.1 Fraud and duress. There is no meeting of the minds if a contract is tainted with fraud or if one party was forced to enter into it under duress. Thus, a contract is voidable, that is, subject to being undone by one or more parties, if one party induced another to enter into the contract by making false statements, by failing to disclose information when under a legal duty to do so (e.g., when the parties are partners), or by engaging in blackmail or extortion.

1.5.2 Mistake of fact. A contract is voidable if it was predicated on a substantial mistake of fact. For example, in the classic case *Raffles v. Wichelhaus* (1864), two parties had signed a contract in which Wichelhaus agreed to buy 125 bales of cotton to be brought by Raffles from India on a ship named *Peerless*. Unbeknownst to both parties, there were two ships named *Peerless* both sailing out of Bombay during the same year. Raffles meant the *Peerless* sailing in December, and Wichelhaus meant the *Peerless* sailing in October. When the cotton arrived in the later ship, Wichelhaus refused to complete the purchase, and Raffles sued for breach of contract. The court concluded that the mutual mistake of fact had resulted in there being no meeting of the minds and, therefore, no contract.

1.5.3 Mistake of judgment and commercial impracticability. While a mistake of fact makes a contract voidable, a mere mistake of judgment does not. Therefore, even if a party is mistaken about some aspect of what is bargained for, the contract is still enforceable. For example, the Wisconsin Supreme Court held that a contract to sell a stone for $1 was enforceable when neither party knew at the time that the stone was in fact a diamond (*Wood v. Boynton* 1885).

Some jurisdictions will relieve a party of its contractual obligations if performance is commercially

impracticable, that is, if performance is made financially impracticable by the occurrence of an event unforeseen by the contract (Eagan 1980).

1.6 Statutes of Fraud

1.6.1 United States. Although most oral contracts are enforceable, almost every state in the United States has statutes requiring that certain types of contracts be evidenced by some form of writing. These Statutes of Fraud require that any (a) contract for the transfer of any interest in real property (such as a deed, lease, or option to buy), (b) promise to pay the debt of another, (c) agreement that by its terms cannot be performed within a year, (d) prenuptial agreement (that is, an agreement entered into before marriage that sets forth the manner in which the parties' assets will be distributed and the support to which each party will be entitled in the event of divorce), and (e) contract for the sale of goods priced at $500 or more must be evidenced by some writing signed by the party against whom enforcement is being sought.

1.6.2 England, France, and other jurisdictions. Although the original Statute of Frauds was adopted in England in 1677, England has repealed all of it except the provisions relating to transfers of interests in land and promises to pay the debt of others. Many other countries that once had a Statute of Frauds have repealed all or parts of it. France, Japan, and other civil law countries never had a writing requirement.

1.7 Remedies

In the event that a valid contract is breached, the other party is entitled to monetary damages or to a court order requiring performance. The nonbreaching party is generally entitled to expectation damages, that is, such amount of money as is necessary to put the plaintiff in the cash position it would have been if the contract had been fulfilled.

Consequential damages, that is, compensation for losses that occur as a foreseeable result of the breach, are also often available. However, if the party suing for consequential damages has suffered lost profits that were not reasonably foreseeable or a natural consequence of the breach, then there will be no award of consequential damages.

2. Agency

Agency law specifies under what circumstances the contracts entered into by one party (the agent) will bind another (the principal) on whose behalf the agent is acting. Agency law also addresses the question of when the principal will be liable for the torts or civil wrongs of the agent. The employer/employee relationship (historically described as the master/servant relationship) is perhaps the most common type of agency in business settings.

2.1 Authority to Bind the Principal

A contract entered into by an agent on behalf of the principal is binding on the principal only if the agent had authority to enter into the contract or if the contract is later ratified by the principal. Authority to enter into a contract can be either actual or apparent. Actual authority can be given expressly or can be implied from the nature of the responsibilities the principal has given the agent to fulfill. Apparent authority exists when the principal, either directly or indirectly, leads a third party to believe that the agent has power to act on the principal's behalf. If a contract is one subject to the Statute of Frauds then, under the Equal Dignities Rule, execution of that contract by an agent would be binding on a principal only if the agent/principal relationship itself were embodied in a writing.

2.2 Respondeat Superior

Under the doctrine of *respondeat superior*, the principal is liable for any torts committed by the agent while acting within the scope of employment. A minor detour, whereby the agent deviates from the assigned task, is still considered to have been within the scope of employment unless the deviation is so great as to constitute a frolic, that is, an excursion that in no way furthers the business of the principal.

A principal is more likely to be responsible for activities that otherwise might be deemed frolics when the harm done by the agent was made possible by an instrumentality provided by the principal. For example, if the principal provides the agent a truck to drive, the principal is more likely to be responsible for automobile accidents occurring while the agent is driving the truck even if at the time of the accident the agent was not directly furthering the business of the principal. Similarly, courts have found the city liable when a police officer arrests then rapes a female suspect, because much of the police officer's power over the woman to begin with derived from the badge of office given by the city.

In Japan, the employer is not liable for the misdeeds of an employee if the employer exercised due care selecting the employee and supervising the employee's work or if the damages would have arisen even if due care had been exercised.

2.3 Employment Laws

Most jurisdictions have statutes and case law setting the minimum wage, imposing limits on the employ-

ment of children, and specifying whether an employee without a written employment contract is an employee at-will who can be terminated at any time for any or no reason, or an employee who can be fired only for just cause. In addition, in many jurisdictions, the employment relationship is subject to statutes banning discrimination based on race, color, national origin, religion, sex, or age. For example, effective April 1, 1999, Japan prohibited discrimination based on sex in the hiring of women. Previously, Japanese law banned sexual discrimination once the person was hired, but did not extend that protection to the hiring decision itself.

3. *Forms of Business Entities*

A third body of law fundamental to the conduct of business prescribes the types of entities by which business can be conducted. A business may be conducted as a sole proprietorship owned by one person, a general partnership, a limited partnership, a limited liability company, or a corporation.

3.1 *Corporations*

The most prevalent entity used for large businesses is the corporation. A corporation is a fictitious person that has capacity to enter into contracts and to hold property. The equity of a corporation, evidenced by shares of stock, is owned by the shareholders. The shareholders elect the board of directors, which has the responsibility for managing the corporation. The board elects the officers, such as the president, treasurer, and secretary, who report to the board and serve at its pleasure.

3.1.1 Corporate governance. The respective rights and obligations of shareholders, directors, and officers of a corporation are dictated by the statutes of the jurisdiction in which the corporation is formed. For example, in the state of Delaware, where more than half of the Fortune 500 companies are domiciled, the board of directors has broad latitude to determine when it is in the best interests of the corporation to rebuff a hostile takeover offer (Bagley 1999).

Jurisdictions vary significantly in their treatment of corporate stakeholders, such as employees, customers, suppliers, and communities. In large German corporations, co-determination statutes require that half of the supervisory board be elected by the employees and labor unions and councils. In Japan, boards traditionally included no nonexecutive directors and put the welfare of the employees before shareholder return. In the United States, shareholder primacy tends to be the rule, at least once a decision has been made to sell control of the corporation or to break it up (Bagley and Page 1999).

3.2 *Limited Liability*

A key advantage of a corporation is the limited liability it provides to its owners. Absent facts justifying piercing the corporate veil, such as the commingling of personal and corporate assets or the shareholders' disregard for the corporate form, the shareholders are not liable for the debts of the corporation. In contrast, in a general partnership, each of the general partners is personally liable for the debts and other obligations of the partnership. Similarly, the owner of a sole proprietorship is personally liable for all debts of the business. In a limited partnership, the managing partner has the same unlimited liability as a general partner in a general partnership, but the limited partners have no liability beyond their capital contribution unless they actively participate in management. In the case of a limited liability company, the owners (called members) have limited liability even if they are active in the management of the business.

3.3 *Tax Considerations*

The choice of business entity can often be driven by the different tax treatment accorded. For example, in the United States, a corporation is generally taxed as a separate entity so that the corporation pays tax on its income; when any corporate property, including dividends, is distributed to the shareholders, the shareholders pay a tax on those distributions. In contrast, with a limited liability company or a limited partnership, there is no entity-level tax; instead, the income earned by the firm is taxed directly to the owners even if in fact none of that income is distributed to them.

4. *Commercial Laws Governing the Sale of Goods, Negotiable Instruments, and Secured Lending Transactions*

Because of the key role played by purchases and sales of goods in virtually every type of business, many jurisdictions have specific statutes designed to facilitate sales transactions. Commercial laws also govern the creation and transfer of negotiable instruments and the lending of money secured by property.

4.1 *Uniform Commercial Code*

In the United States, every state other than Louisiana has adopted a version of the Uniform Commercial Code (UCC).

4.1.1 Sale of goods. The provisions in UCC Article 2 concerning the sale of goods eliminate many of the formalities required under the common law. For example, the UCC abolishes the 'mirror image rule,' which requires that an acceptance be identical in terms to the offer. Instead, the UCC acknowledges that sales transactions are often represented by an exchange of preprinted forms with additional or conflicting terms (the 'battle of the forms'), and it provides guidance as to which terms will be deemed to be part of the contract.

4.1.2 Negotiable instruments. Article 3 of the UCC governs negotiable instruments, including drafts, checks, notes, and certificates of deposit. The most common type of draft is a check: the writer of the check is the drawer; the bank on which the check is drawn is the drawee; and the person to whom the check is payable is the payee. Article 3 sets forth the requirements for negotiability: a writing signed by the maker or drawer containing a definite and unconditional promise or order to pay a fixed amount of money on demand or at a definite time. It also specifies what endorsements are required to negotiate an instrument payable to order, such as a check.

The UCC prescribes the rights given a holder in due course, i.e., the holder of a negotiable instrument who took it for value, in good faith, and without notice that it had been dishonored or that any person has a defense against or claim to it. Unlike an ordinary holder who has only those rights that the transferor had, a holder in due course takes the instrument free of most of the defenses and claims to which the transferor was subject.

4.1.3 Secured lending transactions. Article 9 of the UCC governs transactions in which payment of a debt is guaranteed, or secured, by property owned by the debtor. It permits the secured party to perfect its security interest by filing a financing statement or, in some cases, by possession of the collateral. In general, the first to perfect has priority over other third parties who may wish to have their debts satisfied out of the same collateral.

4.2 Convention on Contracts for the International Sale of Goods

Most sales of goods involving parties in more than one country are governed by the Convention on Contracts for the International Sale of Goods (CISG), unless the parties expressly opt out of CISG. Unlike the UCC, CISG requires that the terms of the acceptance mirror those of the offer. It provides that an offer is irrevocable if the offeror orally states that it is irrevocable, or if the offeree reasonably relies on the offer as being irrevocable. In contrast, the UCC requires that an irrevocable offer not supported by consideration be in writing. Under CISG, the parties must specify the price or provisions for its specification, whereas the UCC requires that only the quantity be specified.

Some commentators maintain that CISG imposes a duty for merchants to conduct themselves in good faith (Koneru 1997). If this interpretation is correct, then, for example, a buyer could not arbitrarily deny a seller's request for additional time to deliver goods. This contrasts sharply with the UCC's perfect tender rule, which permits a buyer to reject goods not conforming perfectly to the contract.

5. Product Liability

Most jurisdictions impose liability on the sellers of goods for defective products. For example, the Council of Ministers of the European Union adopted a directive in July 1985, which made manufacturers and producers strictly liable for injuries caused by defects in their products. Previously, all the member states other than France required the injured consumer to prove both negligence and privity of contract (Bagley 1999). In 1963, the Supreme Court of California became the first in the United States to impose strict liability for product defects as a matter of common law (*Greenman v. Yuba Power Products, Inc.* 1963).

In 1997, the American Law Institute (ALI) adopted the *Restatement (Third) of Torts: Product Liability*, which abandoned the notion of strict liability in defective design cases and imposed on the plaintiff the burden of proving that there was a defect in the product that could reasonably have been avoided by the use of an alternative design. Although judges often regard the ALI's Restatements as persuasive authority, they are free to ignore them. The Supreme Court of Connecticut declined to impose a burden on the plaintiff to prove a feasible alternative design (*Potter v. Chicago Pneumatic Tool Co.* 1997), and it remains to be seen whether other courts will adopt the Restatement (Third) view of product liability.

6. Intellectual Property

Intellectual property is any product or result of a mental process that is given legal protection against unauthorized use. It includes patents, copyrights, trademarks, and trade secrets.

6.1 Patents

A patent is a government-granted right to exclude others from making, using, or selling an invention for 20 years after the date the patent application is filed. A utility patent, the most common type of patent, protects any novel, useful, and nonobvious process,

machine, manufacture, or composition of matter. In the United States, human-made living organisms can be patented as can computer software.

6.1.1 Business process patents. In 1998, the US Court of Appeals for the Federal Circuit reversed prior precedent and held that a business process could be patented (*State Street Bank & Trust Co. v. Signature Fin. Group, Inc.* 1998). Several companies engaged in electronic commerce, including Amazon.com (with a patent on one-click technology for placing orders online) and Priceline (with a patent on using computers for reverse auctions whereby the buyer names a price and seeks a willing seller), filed suits in late 1999 to protect their methods of conducting electronic business. If upheld, these patents could chill innovation in the fast-moving market for electronic commerce.

6.2 Copyrights

Unlike a patent, which can protect an idea, a copyright protects original expressions fixed in a tangible medium, such as books, records, musical scores, and films. Although registration of a copyright gives the author certain additional rights, the copyright is created as soon as the work is fixed in a tangible medium of expression. Under the Berne Convention, most industrialized countries give persons with a copyright under the laws of another jurisdiction the same rights that a national would have under local law.

6.3 Trademarks

A trademark is a word, name, symbol, or device used by a manufacturer to identify and distinguish its goods from those manufactured by others and to indicate the source of the goods. Examples include Coca-Cola, Marlboro, and Nescafe. A service mark, such as Citigroup, is similar but is used in connection with services.

To avoid consumer confusion, trademarks are granted for a particular field of use, e.g., nonalcoholic beverages or automobiles. Thus, more than one company can register the same mark. The importance of a company's domain name, or electronic address, for Internet branding purposes and the fact that domain names contain no field-of-use restriction have required courts to consider when use of a trademark within a domain name constitutes trademark infringement. Courts have ruled against 'cybersquatters,' who register a trademarked name as a domain name to force the trademark owner to buy the domain name. They also have found infringement when the company using the domain name offers the same or similar products as the trademark owner or uses the name in a way that dilutes or tarnishes a famous mark. For example, Hasbro, owner of the trademark Candyland for a children's game, was able to force the owner of Candyland.com to stop using the domain name for a pornography site. Effective January 1, 2000, the U.S. Anticybersquatting Consumer Protection Act bans registration of domain names in bad faith.

6.4 Trade Secrets

A trade secret is information, including a formula, compilation, or process, that derives independent economic value from not being generally known and is the subject of reasonable efforts to maintain its secrecy. Perhaps the most famous trade secret is the formula for Coca-Cola. In response to perceived problems facing US businesses from foreign theft of trade secrets, the United States adopted the Economic Espionage Act in 1996, which imposes criminal liability (including fines and prison sentences) on any person who knowingly steals a trade secret or knowingly receives a wrongfully obtained trade secret.

In 1997, Volkswagen AG (VW) paid General Motors Corporation (GM) $100 million to settle allegations that VW's purchasing chief stole trade secrets, including plans for future GM models and car-building techniques, when he left GM to join VW. Under the emerging doctrine of inevitable disclosure, an employer can challenge a former employee's decision to work for a competitor if the new position would result in the inevitable disclosure or use of the former employee's trade secrets.

7. Other Laws Affecting the Legal Environment of Business

Other laws affecting the legal environment in which businesses operate include antitrust and competition law; environmental law; consumer protection laws; regulations governing the offer and sale of securities; and bankruptcy law.

7.1 Antitrust and Competition Law

The wide-ranging case brought in 1998 by the US Justice Department against Microsoft Corporation promises to help define how courts in the twenty-first century will apply the Sherman Act's 110-year ban on restraints of trade to the digital economy and its network effects, whereby the value of owning a product rises as other consumers own the same product. That case and others will have to wrestle with the question of how to reconcile the exclusionary rights arising out of intellectual property law with the bans on anticompetitive behavior and abuse of dominant position contained in such laws as the Sherman Act in the United States, Articles 85(1) and 85(2) of the Treaty of Rome in the European Union, and the Act Concerning Prohibition of Private Monopoly and Maintenance of Fair Trade in Japan.

7.2 Environmental Laws

In response to high-cost hazardous waste spills and clean-ups, a number of jurisdictions have adopted laws governing the storage, transport, and disposal of hazardous waste. The European Union has adopted the policy that the polluter pays with the objectives of protecting the quality of the environment and human health and promoting the prudent and rational utilization of natural resources. The United States imposes liability not only on the person who stored, transported, or disposed of the waste, but also on the owner or operator of the property at the time the waste is discovered.

7.3 Consumer Protection

Jurisdictions continue to adopt laws and regulations to protect consumers from deceptive sales practices and advertising. The rise of the Internet and the ease with which electronic databases can be used to collect personal data have sparked new concerns about privacy.

7.4 Securities Law

The United States has the most restrictive rules regarding the offer and sale of securities, such as common and preferred stock and bonds. Generally, any public offering of securities must be made pursuant to a registration statement declared effective by the Securities and Exchange Commission (SEC). The most important part of the registration statement is the prospectus, which contains detailed information about the company issuing the securities and its management, principal shareholders, business, and financial condition. The US laws provide civil and criminal penalties for any offer or sale of a security, regardless of whether it is registered, involving a misstatement of a material fact or an omission that makes the facts stated materially misleading. SEC Regulation S facilitates the offering of securities outside of the United States by US firms by exempting many such offerings from the burdensome US registration requirements that would be applicable if the securities were sold within the United States.

7.5 Bankruptcy Law

The principle that a debtor should be permitted to discharge certain debts has ancient roots. As early as 1400 BC, Mosaic Law required unconditional forgiveness of debts every seven years. The British Parliament under King Henry VIII passed a Bankruptcy Act in AD 1542 to regulate failing English merchants.

A key objective of bankruptcy law is to ensure that creditors and equity holders of financially distressed businesses are treated fairly in a judicial setting designed to ensure the efficient handling of claims. In general, creditors must be paid in full before equity holders receive anything.

The United States provides perhaps the most pro-debtor bankruptcy relief available. An insolvent firm in the United States generally can elect to liquidate its assets or to reorganize the business, often with the debtor still in control. In contrast, in Australia, creditors can force the liquidation of a company that cannot pay its debts even if the debtor argues that the business would be worth more as an operating whole. Some countries, such as Germany, do not provide for the complete discharge of debts in bankruptcy, only arrangements for their payment over time.

Campaigning: Political

At the microlevel, political campaigning involves an individual candidate attempting to win political office. At the macrolevel, political parties seek to gain seats in government for their partisans and ultimately to gain power or at least to share power in the relevant governmental arena. At each level decisions must be made about candidacies, organizations must be built, messages must be refined, strategies must be set, and the public must be convinced to support those waging a particular campaign. Only certain aspects of political campaigns are viewed by the public. Frequently, the actions taken away from public view are more determinative of success and failure.

1. The Choice of Candidates

Decisions about who will run for office involve decisions by potential candidates as to whether or not they will run and decisions by political parties, acting under a variety of rules, concerning who their candidates will be.

1.1 The Decision to Run

Individuals who run for political office must exhibit political ambition beyond the desire to simply serve their community. Campaigning for and serving in political office involves personal costs and public exposure that deter many from seeking office. However, even those ambitious for elective office must make decisions about what offices to seek and when to seek those offices (Jacobson and Kernell 1981). These decisions are based on a complex, often-implicit cost-benefit analysis. Potential candidates weigh the costs and benefits of both winning and losing. Their decision calculus can be summarized:

$$p_r = p_w\ (B_w - C_w) + p_l(B_l - C_l)$$

where p_r = probability of running; p_w = probability of winning; p_l = probability of losing; B_w = benefit of winning; C_w = cost of winning; B_l = benefit of losing; C_l = cost of losing.

The difficulty that potential candidates face in making these decisions relates to the uncertainty regarding virtually all of the relevant variables (Maisel 1986, Kazee 1994). Generally the rather obvious benefits far outweigh the costs of winning for those with the requisite political ambition; but costs must be weighed—loss of privacy, loss of time with family, frequently loss of income. Similarly, the evident costs of losing are almost always greater than the benefits; but some benefits do accrue to losers—making a name for oneself, building up good will with party officials. Beyond these broad generalizations, little is known about how specific candidates make individual decisions given the dazzling array of difficult-to-estimate variables (Maisel and Stone 1997).

1.2 Parties' Choices of Candidates

The ways in which political parties choose their candidates for office varies significantly from political system to political system and from party to party. The key variable in this aspect of the process relates to the extent to which party organization controls places on the ballot contrasted with voters acting independently. In the former, the process is often described as candidate recruitment, in the latter, candidate emergence.

At one extreme are those systems in which political parties slate their candidates for office, ranking candidates or placing them in safe constituencies. Most parties operating in electoral systems with proportional representation follow this procedure. It is also followed in systems with strong party systems, in which citizens vote more for parties than they do for individual candidates. Many European systems fit this description (Hix and Lord 1997).

At the other extreme are systems, of which the United States is prototypical, in which voters choose party candidates in primary elections. The shape of the electorate in primary elections varies considerably from polity to polity. In theory, primary elections are open only to members of one political party or another, but in actual practice how membership is defined varies according to local rules and can be quite restrictive or totally open. In either case, voters in the primary elections determine the party nominee, even if that nominee would not have been the choice of party officials (Maisel 1999).

Many systems are hybrids, with party officials and the voters sharing power. The US presidential nominating system stands as perhaps the most complex means of choosing party candidates. Delegates elected to national party conventions make the actual nom-

inations. Some delegates are selected because of their positions within the party or as elected officials with party affiliations; others are chosen at party meetings (or caucuses) held in local communities; still others are chosen by the voters in primary elections, based on lists of delegate candidates approved by the presidential campaigns they seek to support (Polsby and Wildavsky 2000, Wayne 2000).

2. The Campaign Organization

In polities with strong party systems, campaign organizations tend to be party-centered. In these cases, the voters cast their ballots for candidates as representatives of a party. The party defines the campaign message and communicates it to the voters. The party raises the money to fund the campaign, does the polling necessary to understand what the electorate is thinking, and structures the campaign strategy and tactics. Typically full-time, year-round party workers perform all these functions or they are contracted out to professionals.

Where strong party systems do not exist, individual candidates must build their own organizations. In these cases, candidates are most concerned with their own elections, not that of those who share this party label. Candidates choose campaign managers whose sole goal is victory for that one candidate. They build personal organizations to handle the important functions of campaigning—doing research to develop issue positions and to counter opponents' proposals; polling the public to ascertain perceptions of the candidate and reactions to strategies; writing speeches; communicating with the press; developing and placing advertisements; sending out direct mail appeals, telephoning and leafleting the district; scheduling and preparing for candidate appearances; and perhaps most important, raising money. For larger and more expensive campaigns, all of these functions are performed by paid workers or volunteers in a candidate's own organization, or bought with campaign contributions.

Recent campaign organizations have been less able to handle all of these functions, and two means of coping have emerged. For campaigns in smaller constituencies, the candidate often performs all of these functions him or herself. They are done more or less well depending on the skill of the candidate, the time available, the level of competition, and the sophistication that is expected in campaigning for office (Maisel 1999).

Even those with relatively high budget campaigns often find that they cannot hire staff to perform all of the necessary campaign activities. These candidates frequently turn to paid political consultants, experts from outside the campaign who specialize in certain aspects of the campaign process and sell their services to many campaigns during any election cycle. Firms specialize in media advertising, polling, direct mail, telephone banks, fundraising, and virtually every other aspect of campaigning; other firms are structured to take over all or many aspects of a campaign. Some work in particular geographic areas. Others are ready to sell their services anywhere throughout an entire nation or even internationally.

3. Defining Messages and Setting Strategy

A political campaign requires getting a message to voters. To do that, a candidate must define what the message is and must devise a strategy to reach the voters who will be swayed by that message. Again, how this is to be done varies with whether the campaign in question is party-centered or candidate-centered.

For party-centered campaigns, the message is the party platform, and the voters to be reached at those in the party's core constituency and others to whom the message might appeal in a particular year. Neither the message nor the strategy vary much from year to year, though marginal changes are made as the context changes—and these marginal changes might well spell the difference between victory and defeat.

For candidate-centered campaigns these decisions are among the most crucial. Candidates must decide whether to stick with the party message or to devise one of their own; they must decide what particular issues will play best to their voters; and they must figure out who precisely those voters are. Campaign strategists divide the electorate in a variety of ways—by demographic characteristics, by economic interests, by geographic locations. The goal is to use research and polling data to determine what appeals will work with which audiences and to have the candidate address those audiences appropriately. For incumbents seeking re-election, the strategic consideration often involves relying upon strengths demonstrated earlier. For challengers, the strategy must be to find an opponent's weakness and to emphasize one's own strengths.

Effective campaign strategies remain more art than science. Professional political campaigners know what has worked in the past. But many strategists learn those lessons. The successful strategists are those who can see how to change the approach as the context changes, as is often said in the military, 'not to refight the last war but to plan for the next one.'

4. Communicating with the Voters

To be effective, a political campaign must be able to send the message it has devised to the audience it has targeted. Campaign messages are communicated in two ways, through free media and paid media.

4.1 Free Media Coverage

Political campaigns seek free media coverage in whatever form they can, whenever they can. Candidates want to be reported on in newspapers and newsmagazines; they want to grant interviews on radio; they want their events covered on television. Free media coverage is advantageous not only because there is no cost but also because the viewer sees news coverage of a candidate as giving that candidate a sense of legitimacy; the candidate is seen as part of the day's news, not as part of a paid advertisement. However, free media is uncontrolled exposure. Campaign strategists can try to structure what topics will be covered—and campaigns are exploring increasingly sophisticated means to do this—but too frequently the message delivered is very different from the message the candidate seeks to convey.

4.2 Paid Media Advertising

The opposites apply to paid advertising. Paid media—whether in the form of television, radio, or print advertisements, of Internet sites, or of direct mail—is costly and is often viewed by the prospective voter as the slanted message it in fact is. However, these paid media also have the distinct advantage of allowing a candidate to emphasize exactly the message desired. These messages can be narrowcast, that is designed for and directed to specific target audiences. These ads can create images, discuss positions, or—increasingly in recent years—attack an opponent, all in precisely the way strategists feel will be most effective for a specified audience.

The critical concerns about political campaigns today relate to paid media. Many fear that effective political messages cannot be conveyed in 30-second advertisements, the medium preferred by advertising executives. Others complain that the emphasis on negative, attack advertising has poisoned the atmosphere that surrounds political life, keeping some of the best candidates from running (Ansolabehere and Iyengar 1995). Virtually everyone bemoans the exorbitant costs of campaigns, costs spurred by reliance on paid media. However, political campaigns will continue to rely on paid media so long as they are effective in communicating a candidate's message to the target audience; for that is the means to electoral success—the ultimate message of a campaign's effectiveness.

Campbell, Donald Thomas (1916–96)

Donald Thomas Campbell, born November 20, 1916 in Grass Lake, Michigan, died May 6, 1996 in Bethlehem, Pennsylvania, thus ending a career marked by an array of superlatives. Prolific scholar and author, original thinker, ebullient teacher with a notable twinkle in his eye, and generous colleague, Campbell was widely regarded as the most important social science methodologist of the twentieth Century. Several of Campbell's articles vie with one another as among the most widely cited pieces of social science scholarship. Repeatedly he coined phrases any one of which most scholars would be proud to have conceived, for example, 'quasi-experiments,' 'unobtrusive measures,' 'internal and external validity,' and 'plausible rival hypotheses.' His concepts are incorporated as fundamental in several fields—psychology, sociology, anthropology, organization and management sciences, public policy, evaluation, education, and philosophy—and in common use by scholars unaware of their inventor. Moreover, Campbell's welcoming and self-critical personal style, modeled on his scholarship, led him to embrace and examine all 'plausible rival hypotheses' and endeared him to students and colleagues alike.

Campbell received his B.A. (1939) and Ph.D. (1947), both in Psychology, from the University of California (Berkeley), and taught at several institutions, including

Ohio State University (1947–50), the University of Chicago (1950–53), Syracuse University (as N.Y. State Board of Regents Albert Schweitzer Professor, 1979–82) and Lehigh University (as Distinguished University Professor of Sociology-Anthropology, Psychology and Education, 1983–96), but the majority of his scholarly years were spent as professor of psychology at Northwestern University (1953–79) with which Campbell's name and reputation are 'permanently and inextricably co-identified' (Campbell 1981).

Campbell's honors include a Fulbright Visiting Professorship in Social Psychology at Oxford (1968), the Distinguished Scientific Contribution Award from the American Psychological Association (1969), election to the National Academy of Sciences and the American Academy of Arts & Sciences (1973), the Kurt Lewin Memorial Award from the Society for the Psychological Study of Social Issues (1974), presidency of the American Psychological Association (1975), the Williams James Lectureship at Harvard (1977), the Myrdal Prize in Science (1977), and the Distinguished Contribution Award from the American Educational Research Association (1981). In addition, two annual awards are given in his name: The Donald Campbell Award for Significant Research in Social Psychology (1982–) and the Donald Campbell Award from the Policy Studies Organization, to an 'outstanding methodological innovator in public policy studies' (1983–). Campbell received honorary degrees from numerous universities, including Oslo, Michigan, Chicago, and Southern California.

But Campbell felt most honored by the vast array of books dedicated to him, a list that grew steadily in several disciplines before and after his death.

1. *Major Contributions*

When he died, Campbell's resumé listed more than 230 published books, monographs, and articles. Any brief discussion of his contributions must necessarily focus on a few. Best known as a methodologist, with considerable scholarly work in the areas of experimental design, measurement, and social experimentation, Campbell is perhaps remembered especially for his explorations of the concept of validity. He was also a well-regarded epistemologist with a keen interest in the sociology of science. To each domain, Campbell brought his unique mind to bear on the problem of knowledge production. In a remarkable array of works, Campbell explored from several perspectives the inevitable fallibilities inherent in both observers and methods in accurately portraying the world.

In his earliest publication, 'The Indirect Assessment of Social Attitudes' (1950), Campbell evidenced an aspect of the interests that would become the overall focus of his scholarly life: the imperfections introduced by human observers and methods, including the scientific method, in the search for veridical description of the physical world and mechanisms for compensating for these errors. (Campbell later declared profound 'ambivalence' toward the use of disguised measures; see Kidder and Campbell 1970.) Campbell explored the sources and loci of bias and developed and refined methods for illustrating and for minimizing these biases. For example in Jacobs and Campbell (1961) he demonstrated how consensus in the 'reality' of an arbitrarily invented but shared group norm could persist over generations of experimental subjects. In a series of crosscultural explorations Campbell and co-workers (e.g., Segall et al. 1966) explored sources of validity and invalidity in perceptions of 'in-groups' and 'out-groups,' and the differential susceptibility to perceptual illusions between European and non-European cultures.

Campbell and Fiske (1959) published 'Convergent and Discriminant Validation by the Multitrait, Multimethod Matrix,' a complex and frequently cited analysis of the need for multiple measures of underlying constructs (traits) and of the need for the demonstrated capacity of methods to distinguish among traits if one is to minimize irrelevant measurement artifacts. Since every measure is partially invalid, multiple and distinctive methods are called for to yield a 'heterogeneity of irrelevancies.' Campbell and Fiske explored the value of simultaneously deploying maximally different measures of an underlying trait (in pursuit of convergent validation) and of different traits measured the same way (in pursuit of discriminant validation). Only by demonstrating that an underlying trait can be measured in various distinct ways and that the chosen measurement strategies distinguish among measured traits, can one minimize the impact of misleading artifacts.

By the early 1960s Campbell had established an enviable reputation for the vigor and reach of his campaign for advancing the methods and theory associated with issues of validity. His reputation was further advanced with the publication with (Campbell and Stanley 1963) of 'Experimental and Quasi-experimental Designs for Research,' a widely circulated work (elaborated as Cook and Campbell 1979) in which they popularized the terms 'internal' and 'external' validity:

> Internal validity is the basic minimum without which any experiment is uninterpretable: did in fact the experimental treatment make a difference in this specific experimental instance? External validity asks the question of generalizability: To what populations, setting, treatment variables, and measurement variables can this effect be generalized? (Campbell and Stanley 1963).

Another widely cited treatise, *Unobtrusive Measures: Non-reactive Research in the Social Sciences* (Webb et al. 1966) evolved during affable lunchtime conversations with colleagues from different departments. Over several years these colleagues sought to identify relatively unbiased, nonreactive ways of mea-

suring behavior. A frequently cited example describes ways a Chicago museum tried to identify the popularity of its exhibits. 'Obtrusive measures' included questioning visitors leaving the museum; an 'unobtrusive measure' was the frequency with which museum staff had to replace worn tiles in front of exhibits. By that index, the exhibit of baby chicks hatching live and wet from quivering eggs was by far the most popular.

Campbell's participation in an interdisciplinary conference spawned his brilliant foray into the sociology of science entitled 'Ethnocentrism of Disciplines: A Fishscale Model of Omniscience' (1969a). On reading a paper 'in an area of high relevance' to his own work by esteemed fellow social psychologist William McGuire, Campbell realized and then acknowledged that he had not 'read or read-at even half of McGuire's citations, and was not at all aware of the existence of another sizeable proportion' (Campbell 1969a). While many scholars might react with chagrin, Campbell instead reflected on how the 'highly arbitrary' organization of universities and academic fields skewed knowledge production:

> Thus anthropology is a hodgepodge of all novelties venturing into exotic lands—a hodgepodge of skin color, physical stature, agricultural practices, weapons, religious beliefs, kinship systems, history, archeology, and paleontology … Thus psychology is a hodgepodge of sensitive subjective biography, or brain operations, or school achievement testing, of factor analysis, of Markov process mathematics, of schizophrenic families, of laboratory experiments on group structure in which persons are anonymous … Thus economics is a hodgepodge of mathematics without data, of history of economic institutions without mathematics or theory, of an ideal model of psychological man … (Campbell 1969a)

Campbell took a breathtaking leap when he conceived the 'myth of unidisciplinary competence,' demonstrating how social, administrative, structural, and political supports which accrue over time around arbitrary disciplines ultimately create incentives that reinforce these arrangements and punish others of equal epistemological worth. Campbell detailed the inevitable consequence—biased knowledge production—and offered a model of 'interdisciplinary narrowness' for mitigating this 'ethnocentrism of disciplines.'

By the late 1960s, following Vietnam War protests, campus unrest, and a national focus on urban inequities, Campbell began trying conscientiously to influence the design, implementation, and evaluation of social policies. In 'Reforms as Experiments' (1969b) Campbell introduced a range of real-world quasi-experiments (attempts to approach the standards of experimentation even where random assignment of subjects to conditions is unachievable)—each tested against standards of 'internal and external validity'—to the practical world of social reform. That article frequently is cited as the most important single work in the field now known as 'program evaluation.'

In a brilliant tongue-in-cheek section of this article Campbell advised 'trapped administrators whose political predicament will not allow the risk of failure' how to capitalize on 'threats to validity' to assure positive results (Campbell 1969b). For example, were they to accept the occasional 'grateful testimonial' as if it were a representative outcome, to reserve interventions for carefully selected subpopulations most likely to succeed, and to eliminate from their analyses all those who prematurely quit the program, 'successful' program outcomes could be virtually assured.

Campbell continued in various fora to insist that social scientists have both obligations and opportunities to test the relevance of their theories and methods in the service of public good. In this, Campbell's unswerving concern was with the biases affecting the generation of knowledge. For example, in his too-infrequently cited 'Assessing the Impact of Planned Social Change' (1975) Campbell again displayed remarkable methodological and sociological insight in generalizing the problem of data validity in the policy arena in the following way:

> The more any quantitative social indicator is used for social decision-making, the more subject it will be to corruption pressures, and the more apt it will be to distort and corrupt the social processes it is intended to monitor (Campbell 1975).

Corrupted indicators remain a persistent and only vaguely explored source of real-world invalidity (e.g., Cochran et al. 1980).

Another highly influential, widely circulated piece went unpublished for nearly 20 years: in 'Methods for the Experimenting Society' Campbell attempted specifically to design a strategy for a society willing to test innovations and their intended effects. He argues for a society that would

> vigorously try out possible solutions to recurrent problems and would make hard-headed, multidimensional evaluations of outcomes, and when the evaluation of one reform showed it to have been ineffective or harmful, would move on to try other alternatives (Campbell, in Overman 1988).

Surveying the multitude of societal reforms underway at the time, many of which he endorsed (e.g., Alexander Dubcek in Czechoslovakia, Salvador Allende, in Chile), Campbell argued:

> There is no such (experimenting society, committed to reality testing, self-criticism, to avoiding self-deception) anywhere today. While all nations are engaged in trying out innovative reforms, none of them are yet organized to adequately evaluate the outcomes of these reforms (Overman 1988).

After specifying requirements of such an 'experimenting society' Campbell attempted in various ways to determine conditions under which these results might be achievable. For example, after Allende was assassinated in Chile, Campbell invited Chilean social scientist Ricardo Zuñiga to Northwestern University

specifically to reflect on the conditions that might allow vigorous, large-scale reforms to be tested.

Campbell made other major contributions in his application of evolutionary theory to the realm of ideas. Campbell, the eternal epistemologist, focused in particular on the joint operation of the 'blind-variation-and-selective-retention process fundamental to all inductive achievements, to all genuine increases in knowledge.' In his 'evolutionary epistemology,' which perhaps received its fullest flowering in his essay honoring Karl Popper (in Overman 1988), Campbell endorsed the natural selection paradigm for explaining the production of knowledge. Through the selective winnowing of ideas, Campbell argued, what survive over time are those ideas that are most meritorious, particularly as each is subjected to 'critical realism.' In his William James lectures, Campbell (1977) summarized his perspective in this way:

> I am a fallibilist and antifoundationalist. No part of our system of knowledge is immune to correction. There are no firm building blocks, either as indubitable and therefore valid axioms, or in any set of posits that are unequivocal once made. Nor are there any unequivocal experiences or explicit operations on which to found a certainty of communication in lieu of a certainty of knowing.
> I am some kind of a realist, some kind of a critical, hypothetical, corrigible, scientific realist. But I am against direct realism, naive realism, and epistemological complacency (Campbell, in Overman 1988).

2. *Legacy*

Campbell's legacy is vast and pronounced. It affects a wide range of social scientists as well as public policy scholars and practitioners, and is reflected in the work of hundreds of his students and more distant heirs. He introduced fundamentally new ways of thinking that are taken for granted today about how we perceive, discover, and assess accumulated knowledge. Many of his concepts are now fundamental throughout the social and policy sciences. Campbell is the most important intellectual figure in the history of evaluation research. The strategies he employed in 'Reforms as Experiments' for unearthing and illustrating threats to interpretations of policy implementation are an often-cited model for exploring complex data (see Tufte 1983).

In remarkably vivid, fetching but precise language, Campbell repeatedly captured the central importance of fallibilities inherent in human observers and their methods as they accumulate knowledge about the world, and thus of the importance of multiple perspectives, the triangulation of methods, and an open process whereby ideas are tested against one another to promote the winnowing effects of competition. Thus, in the James lectures, Campbell stated that

> We are cousins to the amoeba, and have received no direct revelation not shared with it. How then, indeed, could we know for certain? … Our only hope as competent knowers is that we be the heirs of a substantial set of well-winnowed propositions (Campbell, in Overman 1988).

In the heady intellectual mix he created and sustained, Campbell was known for changing his mind when persuaded by carefully tested evidence, and for challenging others to do the same. For example, over the years Campbell was persuaded by sociologist Howard S. Becker and others to appreciate the falsifiability of carefully wrought case studies, in spite of their failure to live up to his long-cherished methodological criteria (Campbell, in Overman 1988). In return, he prompted qualitatively-oriented colleagues to persist in reconsidering the validity claims inherent in their own work (see, for example, Becker 1986). For this open-mindedness, Campbell is revered by quantitative and qualitative methodologists alike (see Patton 1999).

Campbell also influenced legions of colleagues to reflect honestly on their own work. He talked and wrote openly about his own insecurities and frustrations, including how late in his career he began to write, droughts in his own productivity, his discomfort with the production pressure and relentless expectation of genius when he was a young assistant professor at the University of Chicago, his frequent bouts of depression, and the times when he believed his students and colleagues 'carried him.'

He explained his messy desk cheerfully by saying that he 'filed archeologically,' and as long as no one moved things around he could find whatever he wanted. Amazed colleagues would watch him reach into a pile and pull out the precise papers relevant to their discussions.

Although its publishers have sold thousands of copies of *Experimental and Quasi-Experimental Designs for Research* and students return to it year after year, Campbell never received any royalties; he asked only for unlimited copies to give freely to his colleagues.

Consideration of Campbell's legacy would be incomplete without a discussion of his personal style, for it, too, promoted the production of knowledge while providing his colleagues with a vital and successful paradigm. It would understate Campbell's colossal influence if there were no mention of his towering warmth, kindness, and generosity, and his deeply honest and self-critical perspective on his own work (Campbell 1981). Campbell was remarkably able to reflect on his own fallibilities and to create conditions that would model his epistemology, and improve both his work and the work of others. Examples are diverse and legendary: he would often send a requested reprint accompanied by a colleague's critical rejoinder. He was always in pursuit of contrary evidence and counter-intuitive examples, particularly if they confronted his own work. He encouraged students to write minority sections to project reports if they

disagreed with him or with an emerging majority. Campbell was resolutely encouraging of others and in fact was thought by some to 'suffer fools gladly.' He gave three grades: A, B, and incomplete. If the data collected in dissertations failed to support anticipated hypotheses, or failed to replicate published findings in the literature, Campbell urged students to write up the apparent reasons for the obtained results.

Over time, Campbell connected his early deep philosophical explorations to a program of practical work that will continue to guide generations of scholars and practitioners. Campbell lives on through his voluminous work in many fields, through his students, and through their adoption of his style.

Cancer-prone Personality, Type C

Type C has emerged as a behavioral pattern, coping style, or personality type that predisposes people to, or is a risk factor, in the onset and progression of cancer. Type C has been described as being over-cooperative, stoical or self-sacrificing, appeasing, unassertive, patient, avoiding conflict, compliant with external authorities, unexpressive, suppressing or denying negative emotions, self-sacrificing, and predisposed to experiencing hopelessness and depression (Bleiker 1995, Eysenck 1994, Temoshok 1990).

Since the mid-twentieth century, the contribution of psychosocial factors to cancer has been an important research topic. A search of the literature shows an exponential growth: while only nine publications appeared from 1951 to 1955, between 1995 to 1999 more than 300 hundred documents dealing with this topic have been published in scientific journals (Psychlit and Medline database). This article deals with the 'state of the art' of Type C and its role as a risk factor in the onset and progression of cancer.

1. Historical Overview

The belief that personality contributes to the etiology of disease is as old as the history of human thought. In the third millennium BC, Hippocrates stated that melancholic humor (caused by a surplus of black bile) caused cancer, and Galen (second century AD) observed that neoplasm was more likely to occur in melancholic and depressed than in sanguine women.

It is in the twentieth century that experimental evidence about relationships between cancer and personality are found. During the first half of the twentieth century, investigations were made from the perspective of psychoanalytical theory, and within the field of psychosomatic medicine. The most important

characteristics in cancer patients found through empirical research mentioned: loss of important relationships, inability to express negative emotions, tension concerning parental relationships, and sexual problems.

Finally, it is from the second half of the twentieth century that the role of behavioral and psychosocial conditions in the onset and progression of cancer has been investigated systematically in research programs, groups, and laboratories, following a track parallel to research in Type A, Coronary prone behavior. A good deal of clinical observations and research data has been produced about a systematic link between some psychosocial factors and cancer. At the same time, there have been comprehensive reviews of psycho-oncology research, and strong criticism of its methodological flaws. Thus, before presenting the main traits constituting Type C, the most important difficulties involved in its research will be discussed.

2. *Difficulties in the Study of Cancer-prone Personality, Type C*

Temoshok and Heller (1984) described Type C research in a very illustrative fashion, as 'comparing apples, oranges and fruit salad,' expressing its complexity and methodological difficulties. In other words it involves different constructs, assessed through different instruments, in different samples of subjects with different types of cancer and other diseases, and using different designs.

The heterogeneity of factors contributing to the noncomparability of psycho-oncology literature can be considered in the following ways: (a) the nature and measurement of psychological phenomena, (b) cancer characteristics (type, site, and stage in the process), (c) sample characteristics, and (d) designs used.

2.1 *The Nature and Measurement of Psychological Phenomena*

Personality type, coping style, stress or emotional response, or behavioral pattern are constructs with a variety of conceptualizations in psychology. This problematic issue has been overcome by Eysenck (1994); in short, the subject's response to a given stressful situation cannot be understood without taking into consideration their stressor perception and the behavioral pattern used in coping with stress—both are stable personality conditions.

To this conceptual problem, a methodological one should be added. As constructs, all types of variables must be operationalized through psychological measures. From semistructured interviews and projective techniques to well-developed questionnaires, hundreds of measures have been used in psycho-oncology research, which have different psychometric properties and different levels of generalizability, and their scores can, therefore, be generalized to different universes, presenting difficulties for the comparability of results. Over recent decades much more attention to Type C measurement has been paid, and these methodological problems have been partially overcome.

2.2 *Cancer Characteristics*

Cancer is not a homogeneous entity; both cancer types (melanoma, sarcoma, etc.) and cancer sites (lung, breast, skin, etc.) vary with regard to etiology, course, mortality, heritability, and risk factors. Also, cancer always implies a process, and psychological factors may act at different stages of this process; this fact introduces important research problems. For example Kreitler et al. (1993) stated that emotional repression may be a response to the threat posed by the cancer diagnosis. Several studies have dealt with the timing of psychological assessment and its relationship to cancer, but the relationships between psychosocial conditions and neoplastic processes require sophisticated and complex research designs, and these have yet to be fully developed.

2.3 *Subjects/Sample Characteristics*

Several authors have pointed out that sociodemographic variables may be associated with medical and environmental risk factors. Among sociodemographic characteristics, age seems to be the most important, since cancer incidence and prevalence increases with age, and several personality characteristics are also associated with age (e.g., introversion). When cancer groups are compared with other participants, age should be controlled (e.g., Fernández-Ballesteros et al. 1998).

In order to test the psychological risk factors of a given disease or illness through psychological covariation, comparison between healthy and ill subjects is not enough. It is essential to distinguish also between the target illness and other illnesses. Cancer patients have been compared, as well as with normal patients, with patients suffering from cardiovascular and digestive problems, chronic diseases and benign pathologies, and with accident victims, among others.

2.4 *Designs*

Science requires strategies or designs for testing hypotheses; that is, when and under what conditions units (subjects) will be observed and measured. Authors agree that the best design for studying a given risk factor is a prospective one. Subjects (recruited at random in the community or as a member of a given

group) are assessed in the relevant target behaviors and psychological constructs, and are monitored until some of them develop cancer and others do not. Also, in longitudinal studies subjects already diagnosed with cancer are monitored during different stages of the illness process, from diagnosis to progression, treatment, and survival or death.

In quasiprospective designs psychological evaluation is carried out before cancer diagnosis, but this period is usually very short. This type of design is commonly used within cancer prevention programs in which all subjects are assessed in psychosocial characteristics and, after diagnosis, subjects with cancer are monitored. This type of design has two main flaws: psychological characteristics are measured when subjects have already developed cancer, and subjects attending a prevention campaign cannot be considered to be in a neutral context. Furthermore, this situation is quite heterogeneous, since while several subjects may already be suspicious about lumps or lesions, others are merely participating in a preventive—or 'normal'—situation.

In retrospective designs, subjects already diagnosed or being treated for cancer are compared with control groups in a set of psychological characteristics. Such retrospective designs are highly criticized because they do not tell us whether psychological characteristics are the cause or the result of cancer (e.g., Kreitler et al. 1993).

All of these designs can be considered as 'descriptive' or 'correlational' research strategies. However, there are also experimental designs; in these, the 'independent' variable (a psychological or personality condition) is manipulated in order to measure its causal or functional relationship with the 'dependent' variable (cancer).

In sum, several of these conceptual and methodological problems have been overcome, while others continue to be the object of criticism.

3. *Personality Characteristics in Cancer Patients*

Evidence from prospective, quasiprospective, retrospective, and experimental studies converges on a set of psychological characteristics that seem to act in the onset and progression of all types of cancer. Let us examine these characteristics.

3.1 *Emotional Expression*

This appears to be at the core of Type C. That is, suppression, repression, inhibition and/or denial of negative emotions seem to be the central characteristics of the cancer-prone personality (see *Emotions and Health*). Cancer patients (in comparison to controls) are described as anti-emotional and alexitimic, with a tendency to control their negative feelings (mainly anger, aggressiveness, hostility); they report not feeling anger or irritation, and in their relationships they report avoiding arguments with others by using reason and logic, often contrary to their feelings. For example, in a quasiprospective study, within a breast cancer prevention program, Fernández-Ballesteros et al. (1997) compared the rationality (as well as other somatic characteristics) of healthy women ($N = 96$), women with benign breast disease ($N = 90$) and women with breast cancer ($N = 122$). Healthy women were matched with women with benign breast pathology or with breast cancer. All were assessed before diagnosis. Results show that women with breast cancer differed significantly from healthy women and those with benign breast pathology. Any other review on this topic yields the same results: emotional expression is one of the psychological hallmarks of cancer (Bleiker 1995, Eysenck 1994, Spiegel and Kato 1996, Temoshok 1990).

Unfortunately, however, experimental data does not describe the nature of these psychological characteristics, nor whether cancer subjects fail to perceive or feel their emotional internal physiological reactions or whether they simply fail to express them (verbally or otherwise).

3.2 *Depression*

Consideration of medical anamneses also suggests that depression is a frequent precursor of cancer; feelings of helplessness and hopelessness are also found in several studies. For example, the Western Electric Health longitudinal study monitored 2,020 employees with the purpose of investigating coronary disease risk factors. As a measure of personality and personal and social adjustment the Minnesota Multiphasic Personality Inventory (MMPI) was administered. At the 17-year follow-up, 4 percent had died of cancer. As reported by Shekelle et al. (1981), there was a twofold increase in the odds of death from cancer in men with psychological depression. This result was consistent across sites and types of cancer. Also, this association persisted after adjustments had been made for age, cigarette smoking, use of alcohol, family history of cancer, and occupational status (see *Depression*, *Hopelessness*, *Optimism*, *and Health*).

In spite of these impressive results, it is unclear whether these states are antecedents or consequences of cancer, and research data is inconsistent in this area.

3.3 *Interpersonal Style*

In the medical literature, cancer patients have been described by their doctors as 'extremely pleasant' in their interactions with them. There is evidence from retrospective, quasiprospective, and prospective studies, as well as from experimental studies, that cancer patients—in comparison to control subjects—yield significantly higher scores in tests assessing need

for harmony, self-sacrifice, and unassertiveness. For example, in a quasiprospective study Fernández-Ballesteros et al. (1998) compared, in terms of need for harmony (as well as rationality), three groups of women with breast cancer (before diagnosis (74), during treatment (105), and during the follow-up (132)) with healthy women. Both personality variables correctly classified 86 percent of the participants (87 percent of the breast cancer patients and 82 percent of the healthy participants) and, moreover, no significant differences in rationality and need for harmony were found to be related to the stage of the cancer process.

This behavioral pattern can be understood as a coping style for stressful situations, as a personality characteristic, or as a defense mechanism against anxiety.

3.4 Stressors, Stress, Strain, and Coping Mechanisms

Cancer patients' anamneses usually show that an antecedent of cancer disease is a subject's life event. However, as already mentioned, it is important to differentiate between the external stressor, the subject's appraisal and coping style, and the stress reaction (see *Stress and Health Research*). As underlined by several authors, stress is the response of a given subject to their perception of a stressor—a stimulus or situation perceived as threatening. Also, however, subjects have different mechanisms for coping with stress. For example, Cooper and Faragher (1993) pointed out that subjects who experienced a stressful situation they perceived as threatening had a significantly higher cancer risk. In a retrospective study, Watson et al. (1984) compared breast cancer patients and healthy controls. Breast cancer patients were more likely than controls to report a tendency to control emotional reactions, particularly anger.

However, evidence about psychosocial influences on cancer incidence and progression comes not only from descriptive studies—there are also important experimental results. For example, Grossarth-Maticek carried out an experimental study within the Heidelberg prospective study. In 1971, 1,026 healthy persons from a random sample of the population were assessed in a wide set of psychosocial and medical variables. Also, 1,537 subjects were selected on the basis of their increased psychosocial and clinical risk of cancer or cardiovascular or circulatory disease. Criteria used included chronic depression and hopelessness, chronic excitement and anger, heavy smoking, hypertension, high blood cholesterol, and high blood sugar. From the 1,537 high-risk subjects, 100 were selected who were thought to have an especially high risk of cancer (and also of CV disease). Half of these subjects were selected randomly and given psychological therapy intended to decrease the respective risk. This therapy, which has been called 'creative novation behaviour therapy,' was developed by Grossarth-Maticek and Eysenck (1990) on the basis of cancer-prone characteristics (emotional expression, assertiveness, coping, etc.), and it was attempted to manipulate them through behavior therapy techniques. In 1983, mortality and causes of death for the 2,563 subjects of the study were ascertained. Of the selected subjects, 38 percent of risk subjects had died, as compared to 10 percent of the random sample.

In the cancer therapy group deaths were significantly fewer than in the control group, and there were no deaths from cancer. In marked contrast, 60 percent of the deaths in the control group were from cancer. Although Grossarth-Maticek's studies have been criticized for certain methodological shortcomings (questionnaires used were not in a standard form, and there was no report on psychometric properties), their impressive results are in accordance with the well-established effects of psychosocial treatment, which significantly increases survival in cancer patients (e.g., Spiegel and Kato 1996).

From descriptive and experimental studies it can be summarized that cancer-prone or Type C personality is a psychological configuration with two main conditions: (a) suppression of negative emotions (such as anger and anxiety), which includes not only lack of verbal expression of emotions but also corresponding interpersonal behaviors and (b) inappropriate stress coping mechanisms, leading to feelings of hopelessness, helplessness, and depression.

Finally, what mechanisms can be assumed to link psychological characteristics with cancer?

3.5 Mechanisms that Link Psychological Factors with Cancer

From a mentalistic and/or dualistic perspective, psychological characteristics observed in cancer patients have been considered as though the 'soul' (or mental entities) were affecting the body. This position has been brought up to date through empirical evidence from both psychological and biological literature that support the relationship between personality and emotions and the autonomic, endocrinological and immune systems.

O'Leary (1990), in her review of stress response and the immune system, referred to the fact that chronic stress is associated with a suppression of the immune function, and that personality and coping styles may enhance or degrade the immune response. As pointed out by Spiegel and Kato (1996), chronic and acute stress are associated with reductions in various measures of the immune function, and, moreover, psychological intervention positively influences hallmarks of the immune system.

In sum, as Spiegel and Kato (1996) conclude, 'there is a nonrandom relationship among various psychosocial factors and cancer incidence and progression that can only partially (underline added) be explained by behavioral, structural, or biological factors.'

4. Conclusions

Throughout the twentieth century, the empirical study of the relationship between personality and cancer has been an important research topic. During the 1980s and 1990s, several conceptual and methodological problems have been overcome.

Various designs, assessment devices, and samples have shown that a set of psychological characteristics appears to play a role in cancer onset and progression. These characteristics can be reduced to the suppression of negative emotions and to inappropriate stress coping mechanisms. Much more attention should be paid to the psychological nature of these characteristics.

Psychological treatments (manipulating the above psychological characteristics) appear to act on the cancer process, preventing cancer onset and increasing patient survival possibilities.

Scientific literature supports the hypothesis of a link between personality characteristics, stress reaction coping styles and biological systems. That is, there is evidence of a connection between personality, stress and cancer, as well as between personality, stress, and the autonomic, endocrinological, and immune systems.

These psychological characteristics can be considered as cancer risk factors. Nevertheless, Type C or cancer-prone personality should be understood in terms of its synergic interaction with other genetic, biological, and environmental conditions.

Cancer: Psychosocial Aspects

1. Introduction

Psychosocial research in oncology has been conducted since the 1950s. The initial interest in cancer onset has changed, perhaps due to the many methodological problems, to research in psychosocial consequences of a cancer, and the impact of psychosocial factors in cancer progression. Although there are some studies, in several fields of research, which show negative results, most well-controlled studies have shown positive correlations between specific psychosocial factors and quality of life during cancer treatment, cancer progression, and survival.

2. Quality of Life in Cancer Patients

The concept of quality of life (QOL) was first referenced in *Index Medicus* in 1977. Since that time, it has emerged as an important concept in cancer research in the description of conditions in cancer diagnosis and treatment that make the quality of life of patients worse, and in the use of quality of life measurements for the evaluation of new methods of treatment. QOL is defined as a concept which refers to the individual's own perceptions about the degree of satisfaction with treatment, and ability to perform in their daily life. Although impairment in several dimensions of quality of life are primarily caused by biological aspects of the disease, psychosocial research has focused on psychosocial factors that additionally modulate the intensity of subjectively experienced impairments in quality of life. Extensive psychosocial research has been done with cancer patients in the

Figure 1
Learning model of classical conditioning, of anticipatory nausea and vomiting. See text for further details

initial phase of diagnosis and treatment, whereas little information is available about the problems and concerns that persist for long-term survivors. It can be assumed that, for all cancer survivors, what begins as a crisis involving diagnosis and treatment gradually becomes a chronic illness with life-long follow-up medical care, long-lasting psychological effects, and changes in social and employment relationships.

2.1 Physical Symptoms

2.1.1 Treatment-related nausea and vomiting. It is estimated that 75 percent of the patients receiving chemotherapy will suffer from nausea or vomiting in spite of an antiemetic therapy (Morrow 1992). Nearly 25 percent of patients suffer from so-called anticipatory nausea. In these cases nausea or vomiting occur prior to the infusion of chemotherapy and is triggered by particular special odors or situations similar to stimuli experienced in previous treatment. Whereas post-chemotherapy nausea and vomiting are caused by neuropharmacological agents, anticipatory nausea and vomiting are assumed to be caused by classical processes of conditioning. Neutral stimuli (e.g., the taste of a drink like cola) that were associated with the infusion of chemotherapy (cola was mixed into the antiemetic drug that was given prior to chemotherapy), will be associated with post-chemotherapy nausea. As a consequence, its taste will release nausea even if the neuropharmacological effects of chemotherapy have passed. Taste becomes a learned stimulus for anticipatory nausea or vomiting (see Fig. 1).

Several predictors were identified as high risk factors for the development of nausea and vomiting during cancer chemotherapy: (a) antiemetic drugs; (b) physiological factors, such as age, constitutional predisposition; and (c) psychological factors, such as treatment-related state anxiety or general psychological distress (Andrykowski and Gregg 1992). There are various hypothesized pathways by which a state of anxiety or distress may contribute to the experience of treatment-related nausea. First, due to the proximity of structures in the higher brain stem responsible for the release of vomiting, and noradrenergic structures that are influenced by anxiety and distress, it can be assumed that distress triggers release and intensity of nausea and vomiting through a higher noradrenergic activity. Second, it is well known from learning psychology that anxiety and distress may facilitate the process of classical conditioning. Therefore it can be assumed that distress may enhance the conditioned anticipatory nausea and vomiting.

2.1.2 Pain. Pain is one of the most prevalent physical complaints of cancer patients. Bonica published the most comprehensive overview in 1985 (see Fig. 2). Fifty to 70 percent of cancer patients suffer from pain syndromes during the late phases of their disease; 20 to 50 percent suffer from cancer- or treatment-related pain even in early phases of their disease. In 60 to 80 percent of the cases pain syndromes are attributable to the malignancy of the tumor (tumor compression, infiltration of nerves); in 10 to 25 percent they are long-term results following operation, chemo- or radiotherapy; in 3 to 10 percent of cases the pain syndromes can be assumed to be unrelated to the cancer or treatment (e.g., migraine, arthritis). In many cases, however, it is difficult to discover the main cause of pain. It can be assumed that several psychological factors, known modulators in nonmalignant pain also influence the intensity and aversiveness of cancer-related pain. Among others, factors of depression, chronic daily stress in private life or at work, maladaptive pain-related patterns of

Figure 2
Prevalence of pain in different cancer diagnoses (see Bonica 1985).

thought like catastrophizing or suppressive cognitions; maladaptive pain coping strategies belong to the most important psychological factors that contribute to the chronicity of pain, e.g., chronic low pack pain (Hasenbring 1998).

2.1.3 Fatigue. Only in the last years of the twentieth century did cancer research focus on fatigue as another cancer- or treatment-related physical complaint; a national survey in the USA showed a prevalence of problems with fatigue in 76 percent of 419 chemotherapy and/or radiation-treated patients, with impairment in walking, exercising, house cleaning, or climbing stairs (Curt 2000). Cancer-related fatigue had also a significant emotional component, with 90 percent of patients reporting that fatigue contributed to a loss of control, hopelessness, isolation, lack of motivation, sadness, and frustration. A significant number of patients also reported fatigue-related social impairment, which included difficulties in shopping, expressing intimacy with a loved one, playing with children, or spending time with friends. Curt has shown that the physician recommendations tended to be nonspecific: 40 percent of physicians recommended doing nothing, 37 percent prescribed rest. Further research should focus on the biological and psychological mechanisms by which fatigue is produced and maintained, in order to develop effective interdisciplinary treatment modalities.

2.2 Body Image

Impairments of body image are mostly a direct consequence of cancer treatment. Significant impairment was seen in patients with a tumor of the head, neck, or larynx; in breast cancer patients with a resection of the mamma; and in patients with colorectal cancer and an artificial anal/sphincter praeter. Between 10 and 56 percent of the breast cancer patients develop problems in sexuality and in their partnerships. More than 50 percent of the patients with cancer of the head or neck experience a decrease in self-esteem, combined with anxiety and depression, which leads to withdrawal and social isolation (Holland and Rowland 1998).

2.3 Physical Functioning
