Of the five kinds of failure to inform, two are highly objectionable. No informing typically means that subjects do not know they are participating in a study. False informing means lying or omitting vital details. Both approaches deny self-determination and invade privacy; the researcher extracts information that subjects might not wish to reveal.

The other three approaches somewhat respect subjects' autonomy and privacy. Informed consent to participate in one of several specified conditions

without knowing which condition will actually occur, means subjects can decide whether all of the possible conditions are acceptable hence whether to participate. Consent to deception means subjects know deception may occur. Waiver of informing involves no explicit warning about possible deception. Each of these approaches involves telling subjects what they will experience, and providing debriefing afterward.

2.2 Who Deceives?

The researcher is not necessarily the only deceiver. Third party deception may occur when social interaction is studied, as in research on therapeutic privilege where physicians are observed lying to patients when the truth is deemed harmful. Self-deception occurs when subjects fail to realize that the researcher views them from a different, critical, or unsympathetic perspective.

No informing and no consent, false informing, self-deception, and third-party deception, especially in field experiments, violate privacy, self-determination, and interpersonal trust. Worse, some deception is so convincing that subjects may reject debriefing. Alternatively, if deceived once, why should subjects believe the next thing they are told? However, in laboratory experiments employing such contrivances as bogus equipment and confederates, it usually is easy to demonstrate the deception and hence to debrief convincingly.

2.3 Devices of Deception

Three major devices of deception are: technical deception in which objects, equipment, or procedures are misrepresented; role deception or use of confederates; and implicit deception in which the research aim is so unlikely that subjects generate their own misleading assumptions. Such devices, *per se*, are harmless; they are commonly used in magic tricks and other forms of entertainment. But when combined with certain other features of deception research they may create distrust and cynicism.

2.4 The Research Topic

The most powerful determiner of unacceptability of deception is the degree of immorality and privacy of the behavior studied, the strength of induction, and the degree of upset caused by the combination of these factors.

(a) If the behavior studied is regarded as positive or neutral, deception is less objectionable than if the behavior is regarded as negative or immoral.

(b) The study of public behavior is more acceptable than the study of private or covert behavior.

(c) The study of naturally occurring or mildly induced behavior is more acceptable than use of powerful induction.

(d) To the extent that the research causes upset, it is likely to be considered objectionable.

Upset to subjects may arise from what they thought happened, or from debriefing that leaves them feeling foolish, or vulnerable. Public upset may arise from concern that science condones such procedures. Investigators, assistants, and confederates may be upset about their involvement.

To illustrate the importance of these factors, contrast Milgram's study of obedience with Isen and Levin's (1972) study of kindness. Their study involved no informing, no consent, no debriefing, role deception, and implicit deception. Yet generally it is regarded as a positive intervention, not as deception.

Isen and Levin (1972) studied the effects of positive versus neutral moods on by-stander intervention. Students studying in the library were selected randomly to be given a cookie or not, then given an opportunity to help another student (confederate) who 'accidentally' dropped an armful of books. Isen and Levin showed that people who feel good because of a lucky occurrence or the kindness of some passerby will return the kindness (to someone else) at the next opportunity, while control group members are more likely to ignore the minor mishap of another.

3. Indefensible Uses of Deception

An indefensible use of deception is to trick people into participation that they would find unacceptable if they correctly understood pertinent details of the research. Each culture or population has its own beliefs, values, and sensitivities; these must be respected. When full disclosure to subjects would invalidate the research, the investigator must find other ways to evaluate acceptability to the research population. For example, the researcher might ask surrogate subjects (i.e., peers of the subjects), to consider all relevant details of the research including its sponsorship and likely applications, identify any harmful, worrisome, or objectionable elements, and decide whether participation would be acceptable to them.

A flawed rationale for deception in laboratory settings is to promote spontaneous behavior. Laboratory subjects, especially college students, typically assume that deception is employed and engage in deceptive behavior of their own (Geller 1982). Subjects are respectful of consent procedures that request permission to withhold some information until after participation.

When the value of the research does not justify the risks and wrongs of deception (i.e., when valid knowledge can be obtained otherwise, the research design is flawed, or the research is trivial) deception is indefensible.

4. Debriefing: Dehoaxing and Desensitizing

Debriefing refers to the removal of the deception after research participation; it involves two processes: *dehoaxing* refers to removing any misunderstanding and demonstrating how the deception occurred. If technical deception was involved, an examination of the bogus device is in order. Role deception is dehoaxed by introducing subjects to the real person. Implicit deception is more difficult to dehoax since subjects essentially misinformed themselves; such subjects should be assured that anyone would misinterpret the situation and that the research was designed to produce misinterpretation. The explanation should enable subjects to feel that the research was reasonable, and that appropriate steps were taken to ensure subjects' privacy and safety. Subjects should be given the opportunity to ask questions and discuss the study, and to withdraw their data from the research, especially if private behavior was involved.

Desensitizing means detecting undesirable emotional consequences of the research and restoring subjects to a frame of mind at least as positive as before participation. For example, Milgram's subjects were induced to reveal information about themselves that upset them; it inflicted unflattering self-insight. Milgram desensitized his subjects by explaining that their behavior had been powerfully induced by a demanding supervisor, at a prestigious institution, etc., and that others in the same circumstances behaved similarly. Subjects were offered free psychotherapy sessions in which to examine their concerns and restore their self-assurance and sense of dignity. Since desensitizing efforts do not always succeed (Holmes 1976) studies should not damage self-esteem in the first place.

When studying persons whose typical behavior generally is regarded as negative, desensitizing is unnecessary and dehoaxing harmful. For example, young children typically take things they want. Researchers studying stealing in young children, e.g., by making coins available for stealing, should not tell the child the study was about stealing. The researcher's goal is not to shame, or to accelerate the child's moral development, but only to study how children behave. The researcher must also be mindful of the feedback given to parents. If parents are informed of their child's response, it must be in the context of information about typical behavior of children at that age, and about appropriate parental responses to stealing by children of that age.

5. Alternatives to Deception

This article began with four research objectives that might best be achieved using deception. These same objectives also sometimes can be achieved via simulation (in which subjects act as if the situation were real), or via ethnographic methods.

5.1 Simulations

In game simulations, subjects take roles under a particular set of rules. For example, mock trials have been convened using real jury candidates, real judges, and real cases, and they are highly realistic. Field simulations lack firm rules, use highly realistic staged settings, and encourage subjects to believe they are participating in a natural event. These can be so realistic that in simulation involving harmful behavior subjects may actually suffer harm. Role playing is, perhaps, the most practical simulation substitute for deception. The role player knows what illusions are created but is asked to act as if the situation were real. Geller (1982), using Milgram's equipment, had subjects role play the various conditions of Milgram's obedience experiment. He replicated Milgram's results!

5.2 Ethnographic or Participant Observation Methods

These methods, borrowed from cultural anthropology, coupled with self-report, are now often used to study sensitive behavior of people in their communities. The key to valid ethnography is not technical cleverness, but trust, rapport, knowledge, empathy with the culture studied, and good ethnographic interviewing skills.

Despite recent developments, heightened ethical sensitivities, and government regulation, deception continues to be used. Since 1969, lying to subjects first declined then increased. Human confederates have been partly replaced by computers. Little else has changed (Sieber et al. 1995). Whether use of deception will further tarnish the reputation of science probably depends on whether scientists attend creatively to respecting autonomy, providing appropriate debriefing, and selecting the most valid and least objectionable deception methods (see *Mentoring: Supervision of Young Researchers*; *Privacy of Individuals in Social Research: Confidentiality*; *Research Ethics: Research*).

Decision and Choice: Economic Psychology

1. Introduction

Economic psychology is best defined by what economic psychologists do. Typically, they are interdisciplinary social scientists who recognize that: (a) the economy powerfully influences individuals' lives, at the psychological level of feelings, thoughts, and behavior; (b) individuals' feelings, thoughts, and behavior are what make up economic life; and (c) there are many problems, both academic and practical, to which economics and psychology can both contribute despite their very different approaches and explanatory styles.

2. Relation of Economic Psychology to Other Research Areas

Thus economic psychology is not a branch of psychology, but the interdisciplinary study of the interface—or sometimes the gap—between economics and psychology. One of the most powerful and successful ways of looking at that interface has been through the study of economic decisions (see *Decision Research: Behavioral*), particularly in the areas of risky choice (see *Risk: Empirical Studies on Decision and Choice*), limitations on rationality (see *Bounded and Costly Rationality*), and intertemporal choice. So an article on economic psychology is fittingly placed in this section, alongside discussions of numerous other aspects of decision theory. But it is equally strongly linked to articles in this Encyclopedia devoted to economics (for example, to developmental, social, personality, and motivational psychology (for example, *Leisure, Psychology of* or *Poverty and Child Development*), to organizational and management studies (for example, *Customer Satisfaction* or *Marketing Strategies*), and indeed to others.

A few very distinguished researchers have moved freely between economics and psychology, and are recognized and respected in both disciplines. But many of them would be more likely to identify themselves as decision theorists than as economic psychologists: examples include Herbert Simon, Amos Tversky (see *Tversky, Amos (1937–96)*), Richard Thaler, and George Loewenstein. It is true in general that many more people do economic psychology than call themselves economic psychologists. Very similar approaches are taken not only in decision science, but also under other interdisciplinary names, such as behavioral economics, consumer science, or socioeconomics, and within particular branches of both psychology and economics (see *Behavioral Economics*; *Consumer Economics*; *Experimental Economics*). Because so many of these areas of research are represented elsewhere in this Encyclopedia, the remainder of this article will largely discuss the work of those who have explicitly thought of themselves as economic psychologists.

The first use of the phrase 'economic psychology' is thought to be in the work of the influential French social psychologist Gabriel Tarde (1902). But the modern development of economic psychology started from the work of the Hungarian-American Gestalt psychologist George Katona, summarized in his *Psychological Economics* (1975). Recent surveys of current research include Earl and Kemp (1999) and Webley et al. (2001).

3. Economic Behaviors of Individuals

Economic behaviors include, for example, work, buying, saving, giving, and gambling. Several of these have been subjects of intense research within psychology. Work, for example, is the subject of an entire branch of psychology, variously known as occupational psychology, industrial psychology, or work psychology, and a correspondingly large part of economics, labor economics. It is no accident, therefore, that many economic psychologists have concentrated on economic behaviors such as saving, giving, and paying (or avoiding) tax, which are left aside by the established subdisciplines. When economic psychologists look at topics such as work and buying, it is usually with the aim of integrating them with other aspects of economic life, rather than seeing them in isolation.

The study of saving and debt has been one of the most popular research areas for economic psychologists, for a number of reasons. First, it is macroeconomically important. Katona's consumer surveys focused on how much of their incomes consumers intended to spend rather than save, since quite small

changes in this 'propensity to consume' can tilt a modern economy into recession or inflation. Second, the problem of optimal intertemporal choice is theoretically interesting, and difficult: economists have often had to appeal to (usually speculative) psychological principles to reconcile their theories with some obvious macroeconomic facts. Third, it is important in the lives of individuals: making adequate provision for future life changes such as children's education or one's own retirement is a difficult and complex matter, while getting involved in serious debt or bankruptcy can be a personal disaster. Finally, the problems have proved tractable to psychological investigation. Wärneryd (1999) has summarized extensive research that has given us a thorough understanding of the psychological processes leading some people to save more than others. The psychology of debt has only come under investigation more recently, but it is already clear that, though debt is formally just the opposite of saving, the psychological processes involved are quite different.

The psychology of giving has attracted a smaller research literature, but a great deal of popular attention. Gifts illustrate in a vivid way a general principle: every gift is both an economic and a social transaction. Within any society there are well-understood, though usually unstated, social rules about what may be given to whom and on what occasions. For example, in the UK money is not an acceptable birthday gift from a young adult to his or her mother. Interestingly, the objections are felt more strongly by the potential donor than by the potential recipient.

Almost all economic behaviors involve money in some way. A central problem for economic psychologists has therefore been the psychology of money itself. The problem is the more acute because modern 'fiducial' money is inherently a psychological creation: it is valuable only because we all believe it is. Economic psychologists have investigated what makes 'good' money, from the kinds of coins that look and feel valuable to people, to the kinds of electronic payment that do not leave people feeling they are out of control of their spending. They have also investigated some of the unexpected behaviors people show towards money, for it seems to be a general rule that money attracts a certain amount of behavior that is disproportionate to its actual economic usefulness. Furnham and Argyle (1998) have collected much of the recent literature on the psychology of money.

4. *The Impact of the Economy on Individuals' Psychology*

At any moment, within any given economy, different individuals occupy different positions, from millionaire to beggar; even the most stable economy undergoes unpredictable macroeconomic changes, from growth to recession; some economies undergo massive transformations, as for example the 1990s transition from state socialism to market capitalism in Eastern and Central Europe and the former Soviet Union; within economies, individual industries and industrial sectors wax and wane; and across the globe there are huge variations between countries in people's average earnings, spending power, and standards of living. These many different dimensions of economic variation must have profound psychological consequences, yet the economy is traditionally ignored as an independent variable within psychology. Economic psychologists have sought to repair this omission.

A popular methodology has been to look at how children learn to function within the particular economy they are born into. This is known as the study of 'economic socialization' (Lunt and Furnham 1996). Many earlier studies took a cognitive stance, investigating how children's understanding of economic concepts improves with age. More recent work has tended to look at children's actual economic behavior, and has led us to realize that, as well as interacting directly with the adult economy, children have at least two other kinds of economic life. They are potent influences on the economic behavior of their entire households, both through their unarguable needs, and through their ability to influence their parents' consumer and occupational choices. In consequence, children are the target of major advertising and marketing campaigns, and the legitimacy and effectiveness of these has been keenly debated. Second, however, children live in an entire economic world of their own, involving exchange transactions that are at best tangentially related to the adult economy. They may show much more sophisticated economic understanding in these transactions than they reveal in the traditional studies of the development of economic understanding.

Another widespread approach to considering the economy as an independent variable has been comparative study, either cross-sectional or (more rarely) longitudinal. Cross-sectional studies include a series of impressive collaborative cross-national investigations, for example, of economic socialization (Leiser et al. 1990), of tax evasion (Webley et al. 1991), and of attitudes to the new, transnational Euro currency (Pepermans et al. 1998). The many institutional differences between nations mean that such comparisons can give a good insight into the effective economic variables producing differences between people.

Where such formal comparisons are not feasible, 'impact studies' have been popular: people in a particular economic position are interviewed or given psychometric tests to try to understand how they differ from more typical populations. Such studies have, for example, looked at the impact of the tourist economy on its host populations (Ap 1992), or at the kinds of coping behavior elicited by living in poverty within a wealthy society (Kempson et al. 1994).

5. The Vexed Question of Rational Self-interest

Economics as a discipline is dominated by a single theoretical idea: rational self-interest. Much of economics is theoretical, and much of its theory consists of working out what a rationally self-interested individual would do in a given situation. Psychology, by contrast, has no dominant theory, and its dominant research paradigm is to submit theoretical assertions to empirical test.

Unsurprisingly, two such different disciplines have made uncomfortable bedfellows. Furthermore, the empirical bias of psychologists has led them, as soon as they start to look at economic behavior, to question the economic assumption of rational self-interest. This means that a great deal of research in economic psychology has consisted of investigations by psychologists of the empirical accuracy of theories developed by economists. A smaller amount has consisted of the incorporation into economic theory of psychological principles.

Economic rationality is a protean concept; some have argued, indeed, that it is not a theory at all, more of a general language within which specific theories can be expressed. Economists are not necessarily impressed when psychologists find that, in artificial experiments, some percentage of individuals show a percentage variation from the truly rational behavior pattern: they protest that they are interested in predicting the broad trends of behavior in the great mass of people, so as to explain the performance of the economy as a whole—and they argue that many empirical deviations from rationality are second-order effects of little or no macroeconomic consequence.

Recognizing the various difficulties associated with a frontal assault on rationality assumptions, modern economic psychologists mostly do not test rationality assumptions directly, but rather try to build empirically valid models of the causation and consequences of economic behaviors. Popular causal variables include personality differences, attitudes, socialization experiences, and psychological disorders. All these variables can potentially cause different people, exposed to apparently identical economic situations, to react in different ways. They thus allow psychologists to account for some of the individual variation in behavior that remains when the obvious economic variables have been taken into account.

Cumulatively, of course, such studies can still constitute a powerful attack on the economic theory of rational self-interest. There are many ways of acting rationally in any given situation, depending on your knowledge, abilities, values, and goals. If most of the variation between people's economic behavior actually depends on which rational behavior people choose, and if this has to be predicted from psychological properties of the person, the role of economic psychology has to increase, while the role of rational theory as such has to decrease. How far that process will go remains uncertain; what unites economic psychologists is a belief, based on the fruitfulness of research so far, that it has to go further than it yet has.

Decision and Choice: Paradoxes of Choice

Choice paradoxes are cases where people make decisions that systematically violate the implications of a theory that is considered (at the time of the 'paradox') a viable representation of human decision-making. In the days of the classic paradoxes, a rational person's choices were thought to be normative and so paradoxes of choice also influenced theoreticians' ideas of what is rational. Results considered paradoxical from the viewpoint of one theory are explained by newer theories proposed to provide more accurate representations of decision-making. Modern paradoxes are violations of clearly stated premise or implications of a descriptive model.

1. The Classic Paradoxes

Before 1738, it was considered that a rational person should choose between gambles according to their expected values. The expected value (EV) of a gamble with n mutually exclusive and exhaustive possible outcomes can be written:

$$EV = \sum_{i=1}^{n} p_i x_i \tag{1}$$

where p_i and x_i are the probability and prize for outcome i.

1.1 St Petersburg Paradox Refutes EV

The St Petersburg paradox presents a case where scholars insisted that they would and should prefer a small amount of cash to a gamble with much higher EV. Consider the following gamble: a fair coin will be tossed and if the outcome is heads, the prize is \$2 and the game ends; however, if it is tails, the coin will be tossed again. If the second toss is then heads, the prize is \$4; if tails, the coin is tossed again, and the prize for heads doubles for each successive tails that occurs before heads. When heads occurs, the prize is awarded and the game ends. The EV of this St Petersburg gamble is infinite,

$$EV = \sum_{i=1}^{\infty} p_i x_i = \tfrac{1}{2}2 + \tfrac{1}{4}4 + \tfrac{1}{8}8 + \cdots = \infty$$

Therefore, if one prefers higher EV, then one should prefer this gamble to any finite amount of cash. Instead, most people say that they would prefer a small sum (e.g., \$15) rather than play this gamble once.

1.2 EU Explains St Petersburg Paradox

This paradox, or contradiction between EV and human judgment, was explained by Bernoulli (1738), who showed that if utility is a nonlinear function of wealth, then the expected utility (EU) of the gamble might indeed be less than the utility of a finite sum of cash. In EU theory:

$$EU = \sum_{i=1}^{n} p_i u(x_i) \tag{2}$$

Bernoulli went on to show that EU theory could explain why a pauper might be willing to sell a gamble to a wealthy person for less than its EV and why both would consider the exchange rational. He also explained the purchase and sales of insurance.

When von Neumann and Morgenstern (1947) developed axiomatic foundations of EU and when Savage (1954) developed subjective expected utility theory (SEU), generalizing EU to cases of uncertainty where objective probabilities are unspecified, violations of EV no longer seemed paradoxical. Risk-averse behavior (preferring sure cash over a gamble with the same or higher EV) and risk-seeking behavior (preferring the gamble over the EV in cash) could be explained by the shapes of the utility functions for different cases. It was not long, however, before new paradoxes were discovered that confounded EU and SEU.

1.3 The Paradoxes of Allais Violate EU

Allais suggested two-choice problems in which no utility function could be constructed that would explain choices (Allais and Hagen, 1979). The constant consequence paradox is illustrated with the following two choices:

A: \$1 million for sure

B: 0.01 probability to win \$0
0.89 probability to win \$1 million
0.10 probability to win \$5 million

A': 0.89 probability to win \$0
0.11 probability to win \$1 million

B': 0.90 probability to win \$0
0.10 probability to win \$5 million

Choices A versus B and A' versus B' differ only by changing the common consequence on a .89 chance to win \$1 million in both sides of the first choice to \$0 in the second choice. Many people preferred A to B and also preferred B' to A', contrary to EU.

Allais also proposed a constant ratio paradox, which can be illustrated as follows:

C: \$3,000 for sure

D: 0.20 probability to win \$0
0.80 probability to win \$4,000

C': 0.75 probability to win \$0
0.25 probability to win \$3,000

D': 0.80 probability to win \$0
0.20 probability to win \$4,000

Note that the probability to win is one-fourth in C' versus D', compared to C versus D. Many people persisted in choosing C over D and D' over C', contradicting EU theory.

1.4 SEU and the Ellsberg Paradoxes

Consider an option with n mutually exclusive and exhaustive events, where each event, E_i, leads to consequence C_i with subjective probability $S(E_i)$. Savage's (1954) SEU replaces probability, p_i, in Equation 2 with subjective probability, $S(E_i)$.

Although SEU has two subjective functions and may therefore seem hard to test, Ellsberg (1961)

Table 1
Choices illustrating Ellsberg paradox

Option	Payoffs for drawing a ball of each color		
	Red	*Blue*	*Green*
F	\$100	\$0	\$0
G	\$0	\$100	\$0
F′	\$100	\$0	\$100
G′	\$0	\$100	\$100

devised paradoxes contradicting SEU theory. Ellsberg's paradox can be illustrated as follows. Suppose there is an urn with 90 balls, 30 of which are *Red*, and 60 of which are either *Blue* or *Green*, in unknown proportion. Now consider Table 1.

A person who prefers F to G should also prefer F' to G', since the only difference is the (constant) consequence for a Green ball, which is the same within each choice. If a person prefers F to G, the theory implies that $S(Red) > S(Blue)$, and if that person prefers G' to F', then $S(Red) < S(Blue)$, a contradiction. Indeed, many people exhibited this paradoxical choice pattern even when confronted with this argument. One interpretation is that people are averse to ambiguity, as well as to risk. Others suggested that the decider might distrust that the urns are identical in both choices.

1.5 Paradoxical Risk Attitudes

In *EU* theory, the shape of the utility function determines risk attitudes. For example, for $x > 0$, if $u(x) = x^b$, then the person should be risk-averse if $b < 1$, and risk-seeking if $b > 1$. However, many people are both risk-seeking, when p is small, and risk-averse, when p is moderate to large. Furthermore, many people show risk-aversion for small probabilities of heavy losses (they buy insurance) and they accept risks to avoid certain or highly probable losses.

Whereas Allais considered paradoxical choices 'rational', and theory to be wrong, Savage considered paradoxical choices to be human 'errors' that should be corrected by theory. Many psychologists considered the contradiction between theory and behavior to mean that descriptive theory need not be rational. In this purely descriptive approach, a choice paradox is merely a clear contradiction between theory and human behavior.

Paradoxical risk attitudes and the Allais paradoxes can be described by a theory in which decision weights are a function of probabilities (Edwards 1954, Kahneman and Tversky 1979). Prospect theory (Kahneman and Tversky 1979) described many of the empirical phenomena known by the 1970s. However, this theory was restricted to gambles with no more than two non-zero payoffs and it included a number of seemingly *ad hoc* editing rules to avoid implications that were considered both irrational and empirically wrong.

2. Modern Theories and Paradoxes

During the 1980s, a number of investigators converged on an approach that used a weighting function of probability but did not have the problems of prospect theory (See reviews by Quiggin 1993, Luce 2000). This class of models includes rank-dependent expected utility (Quiggin 1993), rank- and sign-dependent utility theory (Luce 2000), and cumulative prospect theory (Tversky and Kahneman 1992, Wakker and Tversky 1993, Wu and Gonzalez 1998), among others.

2.1 Rank-dependent Expected Utility

For gambles with nonnegative consequences, the rank-dependent expected utility (RDEU) of a gamble can be written as follows:

$$RDEU(G) = \sum_{i=1}^{n}\left[W\left(\sum_{j=i}^{n} p_j\right) - W\left(\sum_{j=i+1}^{n} p_j\right)\right]u(x_i) \quad (3)$$

The consequences are ranked such that $0 \leqslant x_1 < x_2 < x_3 < \ldots < x_n$; and W is a strictly monotonic weighting function with $W(0) = 0$ and $W(1) = 1$. This representation (and its extensions to the cases of negative outcomes and uncertain events) can handle the classic paradoxes of Allais and Ellsberg.

However, new paradoxes were soon created to test if rank-dependent models are descriptive of choices that people make. The new paradoxes can be analyzed as the result of combinations of simpler properties.

2.2 Transitivity, Monotonicity, Coalescing, and Branch Independence

Transitivity holds if for all gambles, $A \succ B$ and $B \succ C$ implies $A \succ C$, where $A \succ B$ denotes A is preferred to B.

Monotonicity assumes that, if one consequence of a gamble is improved, holding everything else in the gamble constant, the gamble's utility is improved.

Coalescing holds that, if two (probability-consequence) branches of a gamble yield the same consequence, then such branches can be combined by adding their probabilities without affecting the gamble's utility. For example, (\$0, 0.8; \$100, 0.1; \$100, 0.1) ought to have the same utility as (\$0, 0.8; \$100, 0.2).

Branch independence is the assumption that if two gambles have a common consequence for a given state of the world with known probability, then the value of

the consequence on that common branch should have no effect on the preference order induced by other components of the gambles. Branch independence is weaker than Savage's (1954) 'sure thing' axiom because it does not presume coalescing. It was assumed as an editing rule by Kahneman and Tversky (1979).

Let $G = (x, p; y, q; z, r)$ represent the three-outcome gamble to win x with probability p, y with probability q, and z otherwise ($r = 1-p-q$), where $0 < x < y < z$. For such gambles, restricted branch independence implies,

$$(x, p; y, q; z, r) \succ (x', p; y', q; z, r)$$
$$\text{if and only if}$$
$$(x, p; y, q; z', r) \succ (x', p; y', q; z', r) \qquad (4)$$

where the branches are distinct, the probabilities are non-zero and they sum to 1. The term 'restricted' refers to the constraint that the probabilities and number of outcomes are fixed in all of the gambles. Although branch independence is implied by *EV*, *EU*, SEU, and certain other theories, it can be violated by RDEU (equation 3) if the common consequence (z or z') changes rank. However, if the common consequence maintains the same rank (i.e., the same cumulative probability), the case is termed comonotonic branch independence, which is implied by Eqn. 3.

One can view the constant consequence paradox of Allais as a violation of (non-comonotonic) restricted branch independence, coalescing, and transitivity. Thus, a theory that violates either branch independence (such as RDEU) or coalescing can explain this Allais paradox.

2.3 Paradoxical Violations of Branch Independence

RDEU (Eqn. (3)) accounts for the observed pattern of risk-seeking for small probabilities to win big prizes and risk-aversion for medium to large probabilities to win modest positive consequences (Tversky and Kahneman 1992). It also accounts for Allais paradoxes if the cumulative weighting function, W in Eqn. (4), has an inverse-S shape (Wu and Gonzalez 1998) in which a probability change near zero or 1 has a greater effect than the same change near 1/2.

However, Birnbaum and McIntosh (1996) reported a pattern of violation of branch independence opposite to the prediction of this inverse-S weighting function. This pattern can be illustrated as follows:

S: 0.80 probability to win \$2
0.10 probability to win \$40
0.10 probability to win \$44

R: 0.80 probability to win \$2
0.10 probability to win \$10
0.10 probability to win \$96

Choices S' and R' differ only in the consequence on the common branch of probability 0.8.

S': 0.10 probability to win \$40
0.10 probability to win \$44
0.80 probability to win \$110

R': 0.10 probability to win \$12
0.10 probability to win \$90
0.80 probability to win \$110

According to the inverse-S weighting function, RDEU implies that violations of branch independence should follow a pattern of $R \succ S$ and $S' \succ R'$. However, the opposite pattern occurs significantly more often than this pattern predicted by the weighting function of RDEU (see review in Birnbaum 1999). Although violations are compatible with Eqn. 3, the observed pattern of violations is the opposite of what was assumed in order to fit Allais paradoxes.

2.4 Configurally Weighted Utility Models

Birnbaum (1997) reviewed configural weight models that he and his colleagues had used in previous research. These models satisfy neither restricted branch independence nor coalescing. They reconcile data that seemed to imply the inverse-S and data that seemed to imply the opposite. Birnbaum's models and the RDEU class of models (Eqn. (3)) are related by being different special cases of the following configural weight model:

$$CWU(G) = \sum_{i=1}^{n} w(x_i, G)u(x_i) \qquad (5)$$

where $w(x_i, G)$ is the configural weight of consequence x_i in gamble G, and $u(x)$ is the utility function. In the transfer of attention exchange (TAX) model, lower-valued consequences 'tax' weight from higher valued ones. A simple version of this model, with $u(x) = x$ for $0 < x <$ \$150 has given a good approximation to empirical choices by undergraduates. In this model, the weight of a distinct branch (probability-consequence pair) is proportional to $p^{.7}$, which is modified by the configural tax. In two-outcome gambles, the lower branch takes 1/3 of the weight of the higher valued branch; in three-outcome gambles, any lower branch takes 1/4 of the weight of any higher-valued branch. Birnbaum (1997) proposed tests between this model and RDEU.

2.5 Paradoxical Violations of Stochastic Dominance and Event-splitting

Birnbaum (1997) proposed the following choice:

I: 0.05 probability to win \$12
0.05 probability to win \$14
0.90 probability to win \$96

J: 0.10 probability to win \$12
0.05 probability to win \$90
0.85 probability to win \$96

Gamble *I* stochastically dominates *J* because the probability of getting a higher prize than *t* given gamble *I* exceeds or equals that of gamble *J* for all *t*. *EV*, *EU*, and RDEU imply that people should choose *I* over *J*. The TAX model, fit to previous data, implies people will choose *J*.

Birnbaum and Navarrete (1998) tested this prediction and found that about 70 percent of college students violated stochastic dominance on this and similar choices, in violation of RDEU. RDEU implies coalescing, monotonicity, and transitivity, so it satisfies stochastic dominance. Configural weight models violate coalescing, and violate stochastic dominance for these cases.

According to the TAX model, it should be possible to eliminate the violations of stochastic dominance by event-splitting, as in the following choice:

IS: 0.05 probability to win \$12
0.05 probability to win \$14
0.05 probability to win \$96
0.85 probability to win \$96

JS: 0.05 probability to win \$12
0.05 probability to win \$12
0.05 probability to win \$90
0.85 probability to win \$96

Note that *IS* and *JS* are simply a split versions of *I* and *J*. According to coalescing (and thus RDEU), choices between *I* and *J* and between *IS* and *JS* are the same. More than half of the undergraduates tested chose *J* over *I and IS* over *JS*, contrary to coalescing (Birnbaum, 1999).

Wu (1994) found violations of tail independence, also called ordinal independence, which can be derived as a combination of coalescing, transitivity, and comonotonic branch independence.

2.6 Violations of Lower and Upper Cumulative Independence

To characterize the paradoxical relationship between evidence that appeared to imply an inverse-S weighting function and evidence that appeared to contradict it, Birnbaum (1997) deduced two new paradoxes, which he called lower and upper cumulative independence. Consider the following choice:

S: 0.80 probability to win \$2
0.10 probability to win \$40
0.10 probability to win \$44

R: 0.80 probability to win \$2
0.10 probability to win \$10
0.10 probability to win \$98

Now increase the common prize of \$2 to \$10 on the 0.8 branch of both gambles and coalesce it to the \$10 branch in *R*. Now, increase the consequence of \$40 to \$44 and coalesce it with the \$44 branch on the left. If a person preferred *S* to *R*, they should definitely prefer S'' to R'':

S'': 0.80 probability to win \$10
0.20 probability to win \$44

R'': 0.90 probability to win \$10
0.10 probability to win \$98

However, more people switch preference from *S* to R'' than from *R* to S'', contrary to monotonicity!

The following choice illustrates upper cumulative independence:

S': 0.10 probability to win \$40
0.10 probability to win \$44
0.80 probability to win \$110

R': 0.10 probability to win \$10
0.10 probability to win \$98
0.80 probability to win \$110

If a person prefers R' to S', then they should prefer R''' to S''':

S''': 0.20 probability to win \$40
0.80 probability to win \$110

R''': 0.10 probability to win \$10
0.90 probability to win \$98

Note that the common branch has been reduced in value to \$98 in both gambles, but the consequence of \$44 has been reduced to \$40 in gamble S''', which should make that gamble relatively worse. More people switched from R' to S''' than the opposite (Birnbaum 1999, Birnbaum and Navarrete 1998).

These modern paradoxes, which violate RDEU, were predicted by configural weight models. Undoubtedly, new paradoxes will be developed to confound new theories. Each new finding represents a phenomenon that must be explained by newer theories. Although some are pessimistic that any transitive theory will be able to explain all of the paradoxes, others continue the search for a theory that can explain the widest domain of behavior.

Decision and Choice: Random Utility Models of Choice and Response Time

Introduction

The task of choosing a single 'best' option from some available, potentially infinite set of options R has received considerable study in psychology and economics. Random utility models of choice account for the stochastic variability underlying these choices (i.e., the same choice is not necessarily made on repeated presentations of the same set of options) by assuming that there exist a random variable $U(x)$ for each option x and a joint probability measure for these random variables such that the probability of choosing a particular option x from the set of available options is equal to the probability that $U(x)$ takes on a value greater or equal to the values of all other random variables (e.g., see *Luce's Choice Axiom*; *Utility and Subjective Probability: Contemporary Theories*). The basic choice paradigm is extended here by considering, in addition to the option chosen, the point in time that a choice is made from the set of available options. The random utility model can be tailored to cover this situation by replacing the utility variable $U(x)$ by $V(x) = \phi[U(x)]$ (ϕ some monotonically decreasing transformation), where $V(x)$ can be interpreted as decision time for choosing option x, and by replacing the maximum utility rule by a minimum decision time rule: the option chosen is the one which happens to be associated with the minimum choice (or decision) time with respect to all options in the available set. This model will be referred to as 'horse race' random utility model.

A number of problems arise in the study of 'horse race' random utility models for choice and response time that have found only partial solutions: (a) What conditions on the observable choice probabilities and decision times are necessary and sufficient for a random utility representation? (b) What are the consequences of assuming stochastic independence between the time of choice and the identity of the option chosen, and which assumptions on the joint distribution function do imply this independence? (c) What are possible generalizations to other choice paradigms? The presentation here is partly based on Marley and Colonius 1992 and Marley 1992, 1989. Some related results (not explicitly referred to in the following) can be found in Bundesen 1993, Robertson and Strauss 1981, and Vorberg 1991.

1. 'Horse Race' Random Utility Models

Let $R = \{x, y, \ldots\}$ be a finite set of potential choice options (for an extension of the theory to infinite choice sets, see Resnick and Roy 1992); the subset X of R containing at least two elements is the currently available choice set. $T(X)$ is a random variable denoting the time at which a choice is made; and $C(X)$ is a random variable denoting the element chosen from X. For $t \geqslant 0$

$$P_X(x; t) = Pr[C(X) = x \cap T(X) > t]$$

is the probability that options x is chosen from X after time t, and $\{P_X(x; t)\colon x \in X \subseteq R\}$, or (R, P) for short, is called joint structure of choice probabilities and response times. (R, P) is called complete if it is defined for all subsets of X of $R$with $|X| \geqslant 2$.

A complete joint structure of choice probabilities and response times (R, P) is said to satisfy a '*horse race*' random utility model if for any $X \subseteq R$ with

$|X| \geqslant 2$ there exists a probability measure $Pr_X[\ ]$ such that for the collection of nonnegative random variables $\{V(x)\colon x \in X\}$

$$P_X(x;\, t) = Pr_X[t < V(x) < V(y)\colon y \in X \backslash \{x\}] \quad (1)$$

For simplicity, all distributions are assumed to be absolutely continuous, i.e., they must possess a density function. However, as observed in Resnick and Roy 1992, absolute continuity is not necessary for the results cited here. Note that with

$$\begin{aligned} P_X(x) &= \lim_{t \downarrow 0} Pr_X[t < V(x) < V(y)\colon y \in X \backslash \{x\}] \\ &= Pr_X[V(x) < V(y)\colon y \in X \backslash \{x\}] \end{aligned} \quad (2)$$

the collection of choice probabilities $\{P_X(x)\colon x \in X \subseteq R\}$ constitutes a system of choice probabilities with

$$P_X(x) = Pr_X[V(x) = \min\{V(y)\colon y \in X\}] \quad (3)$$

satisfying a random utility representation with min replacing the usual max.

In this article the problem of finding conditions on the—at least theoretically—observable choice probabilities and response time distributions that are necessary and sufficient for the existence of a particular representation in terms of a collection of underlying random variables is referred to as a characterization problem.

Given a (complete) joint structure of choice probabilities and response times, what conditions on the (survival) functions $P_X(x; t)$ are necessary and sufficient for the existence of a (possibly dependent) 'horse race' random utility representation for that joint structure?

A complete answer to this problem is still open. However, a number of results in special cases have been found.

1.1 Representation by Independent Random Variables

A partial answer is given by the following

Theorem 1 (Marley and Colonius 1992).

(a) For a collection of choice probabilities and response times $\{P_X(x;\, t)\colon x \in X\}$ on a fixed set X with $|X| \geqslant 2$, there exist independent random variables $V(x)$, $x \in X$, with unique distributions, such that Eqn. (1) holds provided $P_X(x;\, t)$ is absolutely continuous and positive for all $t \geqslant 0$.

(b) A complete joint structure of choice probabilities and response times (R, P) can be represented by an independent 'horse race' random utility model, with unique distributions, if the conditions of (a) hold and

$$\left[\sum_{y \in X} P_X(y;\, t)\right]^{-1} (\mathrm{d}/\mathrm{d}t) P_X(x,\, t) \quad (4)$$

is independent of $X \subseteq R$ for all $t \geqslant 0$.

Thus, given the above regularity conditions on the response time distributions, any set of choice probabilities and response times on a fixed finite set X can be represented by independent random variables such that the 'horse race' Eqn. (1) holds. Following Berman 1963 the proof of (a) is based on setting up a differential equation with the following unique solution in terms of the (survival) distributions of independent random variables

$$\begin{aligned} G_x^X(t) &\equiv Pr[V(x) > t] \\ &= \exp\left\{\int_0^t Pr[T(X) > s]^{-1}\, \mathrm{d}P_X(x;\, s)\right\} \\ &= \exp\left\{\int_0^t \left[\sum_{y \in X} P_X(y;\, s)\right]^{-1} \mathrm{d}P_X(x;\, s)\right\} \\ &= \exp\left\{\int_0^t \left[\prod_{y \in X} G_y^X(s)\right]^{-1} \mathrm{d}P_X(x;\, s)\right\} \end{aligned} \quad (5)$$

A related result, in the context of parallel-serial processing analysis, appears in Townsend 1976. Some of the above distributions, but not all, may be improper, i.e., they may have positive measure at infinity implying an infinite decision time for that alternative, even if the distribution of response time $T(X)$ is finite almost surely (see Dzhafarov 1993 for a related interpretation and further results under weaker conditions in a different context). Note that Theorem 1 (a) does not say that there always exists a unique set of independent random variables representing a complete joint structure of choice probabilities and response times irrespective of the subset X. The latter postulate is in fact paraphrased in Theorem 1 (b). Thus, the general characterization problem is still unsolved leaving open the possibility that for some joint structures no independent representation over all subsets X exists.

1.2 Hazard Rate Reformulation

In the theory of competing risks (e.g., David and Moeschburger 1978) the 'event' associated with each $x \in X$ is reinterpreted as a cause (e.g., of failure or death), and thus the selection $x \in X$ then corresponds

to the cause associated with x being the first to occur when X contains the possible causes. The instantaneous rate of failure from cause x when all causes in X act simultaneously, called cause-specific (or crude hazard rate), is defined as

$$h_x^X(t) = \lim_{\delta \downarrow 0} Pr[t < T(X) \leqslant t+\delta \cap C(x) = x | T(X) > t| \quad (6)$$

In the choice context this can be interpreted as the instantaneous rate of choosing option x from X at time t given that no choice was made before t. Provided that $Pr[T(X) > t] \neq 0$, going over to the unconditioned probability in Eqn. (6) gives

$$h_x^X(t) = [(-\mathrm{d}/\mathrm{d}t)P_X(x; t)] \Big/ \left(\sum_{y \in X} P_X(y; t) \right) \quad (7)$$

Note that the right hand side of Eqn. (7) agrees (except in sign) with that given in the statement of the Marley-Colonius Theorem (b). Thus, for a fixed set X, the crude hazard rate leads directly to the desired random variable representation by setting

$$Pr[V(x) > t] = \exp\left[-\int_0^t h_x^X(s)\, \mathrm{d}s \right] = G_x^X(t) \quad (8)$$

and for a common representation on all subsets X of R, h_a^X must not depend on X (as in part (b) of Theorem 1).

$P[T(X) > t]$ is commonly referred to as the overall survival distribution (for set X) with a corresponding overall hazard rate $h^X(t)$; i.e., by definition

$$h^X(t) = -\mathrm{d}/\mathrm{d}t\, Pr[T(X) > t]/Pr[T(X) > t] \quad (9)$$

and so from

$$Pr[T(X) > t] = \sum_{y \in X} P_X(y; t)$$

and Eqn. (7), it follows that

$$h^X(t) = \sum_{x \in X} h_x^X(t) \quad (10)$$

Thus, under the stated regularity conditions, the independent random variables $V(x)$, $x \in X$, constructed above can be used to generate the survival distributions $P_X(x; t)$. In competing risks theory this is a well-known result, often referred to as the 'non-identifiability problem.' It means that any set of competing risk data can be explained by some independent risk model which, in most empirical situations, appears to be unrealistic. One way to establish identifiability of a dependent model is to assume that the $V(x)$ follow some (flexible) parametric family, to estimate the parameters of the multivariate distribution, and to test for independence (Tsiatis 1975).

1.3 Independence of Option Chosen from Time of Choice

The following condition is often made in the competing risks theory and it turns out to be equivalent to a condition specifying a large family of random utility models. A joint structure of choice probabilities and response times (S, P) satisfies the proportional hazard rate (PHR) condition if and only if for any subset X of R there are constants $C_X(x)$ such that

$$h_x^X(t) = C_X(x) h^X(t) \quad (11)$$

where $h^X(t)$ is the overall hazard rate for $T(X)$ and $h_x^X(t)$ are the cause specific hazard rates. After some algebra,

$$P_X(x; t) = C_X(x) Pr[T(X) > t]$$

In particular, because $P_X(x) = \lim_{t \downarrow 0} P_X(x; t)$,

$$P_X(x; t) = Pr[C(X) = x] Pr[T(X) > t] \quad (12)$$

Reversing the steps leads to the following result (see Kochar and Proschan 1991).

Theorem 2. The proportional hazard rate condition (PHR) is equivalent to assuming stochastic independence between $T(X)$ and $C(X)$ for any $X \subseteq R$.

Intuitively, proportionality of the hazard rates means that the time of choice gives no information as to the identity of the element chosen, and vice versa. This seems like a rather strong assumption in an empirical context, and the following result concerning Luce's choice model (see *Luce's Choice Axiom*) supports this view. Luce's choice model holds for a system of choice probabilities $\{P_X(x)\colon x \in X \subseteq R\}$ provided there is a ratio scale v on R such that for $P_X(x) \neq 0, 1$

$$P_X(x) = \frac{v(x)}{\sum_{y \in X} v(y)} \quad (13)$$

For simplicity in the following, we assume that all choice probabilities are nonzero. The result can be

generalized when this is not the case by adding a connectivity and a transitivity condition (Luce 1959, Theorem 4, p. 25).

Theorem 3 (Marley and Colonius 1992). Consider a (complete) independent 'horse race' random utility model (R, P) where for each $x \in X \subseteq R$ with $|X| \geqslant 2$, $P_X(x; t)$ is positive and absolutely continuous for all $t > 0$. If $T(X)$ is stochastically independent of $C(X)$, then the choice probabilities satisfy Luce's choice model.

Given the known limited empirical validity of Luce's choice model in empirical preference situations, this result implies that one must study dependent 'horse race' random utility models as long as one is not willing to drop the assumption of independence between $T(X)$ and $C(X)$.

1.4 Generalized Stable Survival Functions

A large class of (possibly) dependent 'horse race' random utility models based on extreme value distributions can be generated from the concept of a generalized stable survival function.

For simplicity, in this section assume $R = \{x_1, \ldots, x_n\}$. We call

$$P_R(t_1, \ldots, t_n) = Pr[V(x_1) > t_1, \ldots, V(x_n) > t_n)$$

a (multivariate) survival function. P_R is called generalized stable if there is a strictly monotone decreasing function η and a constant $\mu > 0$ such that for all $\alpha > 0$, $t_i \geqslant 0$, $i = 1, \ldots, n$,

$$(\eta \circ P_R)(\alpha t_1, \ldots, \alpha t_n) = \alpha^{\mu}(\eta \circ P_R)(t_1, \ldots, t_n) \quad (14)$$

where $\circ$ denotes concatenation of functions. Letting $G_R = (\eta \circ P_R)$ this amounts to

$$G_R(\alpha t_1, \ldots, \alpha t_n) = \alpha^{\mu} G_R(t_1, \ldots, t_n)$$

i.e., G_R is homogeneous of degree μ. Furthermore, a survival function P_R is called a strictly monotone transform of a generalized stable survival function Q_R if there is a strictly monotone increasing function γ (of the random variables associated with Q_R) with $\gamma(0) = 0$, $\gamma(\infty) = \infty$ such that for $t_i \geqslant 0$, $i = 1, \ldots, n$,

$$P_R(t_1, \ldots, t_n) = Q_R(\gamma(t_1), \ldots, \gamma(t_n))$$

Theorem 4 (Marley 1989). Any 'horse race' random utility model that is generated by a strictly monotone transform of a generalized stable survival function is such that $T(X)$ is stochastically independent of $C(X)$ for any $X \subseteq R$.

As shown by way of an example in Resnick and Roy 1992 (Sect. 5) the converse of this result does not hold in general, i.e., independence between $T(X)$ and $C(X)$ does not lead back to the class of generalized stable survival functions. Robertson and Strauss 1981 show that the converse of Theorem 4 is true if the survival function P_R (or some strictly monotone transformation of it) belongs to the generalized Thurstone class: for $t_i \geqslant 0$, $i = 1, \ldots, n$,

$$P_R(t_1, \ldots, t_n) = P(u(x_1)t_1, \ldots, u(x_n)t_n)$$

where $u(x_i) \geqslant 0$ and P is a survival function that is independent of R.

2. General Feature Model

Marley 1989 presents a general class of models which lends itself easily to a process interpretation for the choice paradigm. With $R = \{x_1, \ldots, x_n\}$ suppose each option x_i has m (random) components. Thus, there is a matrix of random variables $(Z_{ik})_{i=1,\ldots,n}^{k=1,\ldots,m}$, and it is assumed that the previous random variables $V(x_i)$ are given by

$$V(x_i) = \min_{k=1,\ldots,m} Z_{ik}$$

In the process interpretation Z_{ik} corresponds to the 'time of occurrence' of feature (or dimension) $k$for option i, and that option is selected which has the earliest such event over all features (or dimensions). Thus, the survival function is

$$\begin{aligned} P(t_1, \ldots, t_n) &= Pr[V(x_1) > t_1, \ldots, V(x_n) > t_n] \\ &= Pr\left[\bigcap_{i=1}^{n} \{V(x_i) > t_i\}\right] \\ &= Pr\left[\bigcap_{i=1}^{n} \left\{\min_{k=1,\ldots,m} Z_{ik} > t_i\right\}\right] \\ &= Pr\left[\bigcap_{i=1}^{n} \bigcap_{k=1}^{m} \{Z_{ik} > t_i\}\right] \end{aligned} \quad (15)$$

For the survival function P to be generalized stable, restrictions must be placed on the distribution of the random variables Z_{ik}. However, no independence of $(Z_{i1}, \ldots, Z_{im})$ for distinct i, $1 \leqslant i \leqslant n$ is assumed as one might be able to give a 'process' interpretation of such dependencies.

Example: Multivariate exponential distribution (Marley 1989, Pickands 1981).

Let $A = (a_{ik})$ be a $n \times m$ matrix with non-negative and finite entries such that there is at least one positive value in each row, and no two values are identical in any column. Also, $Z_1, \ldots, Z_m$ are mutually independent random variables with standard exponential distri-

bution, i.e., $Pr[Z_k > t] = \exp(-t)$, and $V(x_1), \ldots, V(x_n)$ have components

$$V(x_i) = \min_{k=1,\ldots,m} \frac{Z_k}{a_{ik}} \tag{16}$$

Inserting this into Eqn. (15) yields the survival function

$$P(t_1, \ldots, t_n) = \exp - \left[\sum_{k=1}^{m} \max_{i=1,\ldots,n} a_{ik} t_i \right]$$

or,

$$-\ln P(t_1, \ldots, t_n) = \sum_{k=1}^{m} \max_{i=1,\ldots,n} a_{ik} t_i \tag{17}$$

With $G_R \equiv (-\ln \circ P)$ this clearly satisfies the condition of Theorem 4. Marley 1989 demonstrates how this model easily explains the standard 'bicycle/pony' or 'red bus/blue bus' examples that Luce's choice model cannot adequately represent.

3. Subset Choices

The above development can be extended to cases where one is allowed to choose a subset of 'acceptable' options from the set of available options rather than a single element (e.g., approval voting). Extending the previous notation, let $Q_X(Y; t)$, $t \geqslant 0$, be the probability that the nonempty subset $Y \in X$ is selected after time t, and assume that

$$Q_X(Y; t) = Pr[C(X) = Y \cap T(X) > t] \tag{18}$$

where (as before) $T(X)$ is a random variable denoting the time at which the subset choice is made, and $C(X)$ is a random variable denoting the subset chosen. Such a collection $\{Q_X(Y; t)\colon \emptyset \in Y \subseteq X \subseteq R\}$, or $\{R, Q\}$ for short, will be called a joint structure of transition probabilities and response times, and (R, Q) will be called complete if it is defined over all subsets of R, as before. A (complete) joint structure of transition probabilities and response times (R, Q) satisfies a random (subset) advantage model provided there exists for any $X \subseteq R$ a probability measure $Pr_X[\ ]$ such that for the collection of nonnegative random variables $\{V(Y)\colon \emptyset \subset Y \subseteq X \subseteq R\}$

$$Q_X(Y; t) = Pr_X[t < V(Y) < V(Z)\colon \text{ for all } Z \text{ with } \emptyset \subset Z \subseteq X, Z \neq Y] \tag{19}$$

If the $V(Y)$, for a fixed X, are independent, then the random (subset) advantage model is independent. The idea here is that some 'event' is associated with each non empty subset of the available choice set, and that the time of choice and the subset selected are determined by the occurrence of the first such event. As before, assuming absolute continuity,

$$Q_X(Y) = Pr_X[V(Y) < V(Z)\colon \text{ for all } Z \text{ with } \emptyset \subset Z \subseteq X, Z \neq Y] = \lim_{t \downarrow 0} Q_X(Y; t) \tag{20}$$

is the probability of selecting the subset Y of X. The following is an immediate result paralleling Theorem 1 (a).

Theorem 5 (Marley and Colonius 1992). A collection of transition probabilities and response times $\{Q_X(Y; t)\colon \emptyset \subset Y \subseteq X\}$ can be uniquely represented by an independent random (subset) advantage model provided $Q_X(Y; t)$, $\emptyset \subset Y \subseteq X$, are absolutely continuous and positive for all $t \geqslant 0$.

4. Structures of Transition Probabilities

Subset selection as defined in the preceding section might only be an intermediate stage in the determination of a single 'best' element by repeatedly selecting subsets from the subset determined in the previous subset selection. The class of Markovian transition structures has the recursive property

$$P_X(x) = \sum_{Y \subseteq X} Q_X(Y) P_Y(x) \tag{21}$$

However, Eqn. (21) is compatible with any set of choice probabilities, e.g., define

$$Q_X(Y) = \begin{cases} P_X(x) & \text{if } Y = \{x\} \\ 0 & \text{otherwise} \end{cases} \tag{22}$$

Thus, some restrictions must be put on the transition probabilities. The following *proportionality* condition leads to Tversky's 1972a, b elimination-by-aspects model (EBA):

$$\frac{Q_X(Y)}{Q_X(Z)} = \frac{\sum_{J \cap X = Y, \emptyset \subset J \subset R} Q_R(J)}{\sum_{J \cap X = Z, \emptyset \subset J \subset R} Q_R(J)} \tag{23}$$

for $\emptyset \subset Y, Z \subseteq R$, provided the denominators are both positive, and if one denominator vanishes, so does the other.

To formulate a generalization of Theorem 3 in the context of subset choices, the following plausible min-consistency constraint on the response time distri-

bution is needed which, however, does not constrain the distribution of the $V(Y)$ to have any specific form:

$$Pr_X[V(Y) \leqslant t] = Pr_R[\min\{V(J) | J \cap X = Y, \emptyset \subset J \subseteq R\} \leqslant t] \quad (24)$$

Theorem 6. (Marley and Colonius 1992). Consider an independent random (subset) advantage model (R, Q) where for each $\emptyset \subset Y \subseteq X \subseteq R$, $Q_X(Y; t)$ is absolutely continuous and positive for all $t \geqslant 0$ and $Q_X(Y)$ is nonzero. If the model satisfies min-consistency, and if the subset chosen, $C(Y)$, is independent of the time of choice, $T(Y)$, then the transition probabilities satisfy proportionality.

Thus, independence between $C(Y)$ and $T(Y)$ in this subset choice context leads to the transition probabilities of the EBA model paralleling the result (Theorem 3) for the single-element choice context with the special case of the EBA model, i.e., Luce's choice model. Finally, it has been shown (Marley 1989) that the general feature model can easily be adjusted such that it contains the EBA model as a special case with a generalized stable survival function where

$$-\ln P(t_1, \ldots, t_n) = \sum_{J \subseteq R} V_R(J) \max_{i \in J} t_i \quad (25)$$

where $V_R(J) \geqslant 0$ for all $J \subseteq R$.

5. Conclusions

The introduction of the notion of response (or decision) time into the random utility approach to modeling choice behavior has been very fruitful. It has brought about new insights into existing stochastic choice models and their characterizations, and it has generated new questions, many of which have only found partial solutions up to now.

Decision Biases, Cognitive Psychology of

Normative analyses of rational decision making dictate *a priori* how decisions ought to be made. Descriptive analyses of decision making are based on experimental studies and emphasize the role of information processing in people's decisions. The empirical evidence indicates that people's decisions are often at odds with the assumptions of the rational theory. The following describes some of the cognitive mechanisms that underlie decision behavior and cause it to depart form the normative benchmark, yielding systematic decision biases.

1. Normative and Descriptive Analyses

The study of decision making is an interdisciplinary enterprise involving economics, political science, and psychology, as well as statistics and philosophy. One

can distinguish two approaches to the analysis of decision making: normative and descriptive. Central to many of the social sciences is the normative approach, which assumes a rational decision maker with well-defined preferences. Every option is assumed to have a subjective 'utility' for the individual, a well-established position in his or her preference ordering (von Neumann and Morgenstern 1947). Because preferences are clear and stable they are expected to be invariant across normatively equivalent assessment methods ('procedure invariance'), and across logically equivalent ways of describing the options ('description invariance'). This conception, known as the rational theory of choice, is based primarily on *a priori* considerations and on normative assumptions rather than on empirical observation. Because the normative treatment specifies clear and compelling principles of rational behavior, it serves as a benchmark against which descriptive studies of decision making are compared.

The descriptive approach to individual decision making is based on empirical observation and experimental studies of choice behavior, which emphasize the role of information processing in people's decisions. The empirical evidence is that people's decisions often depart from the normative benchmark in systematic ways which can be viewed as decision biases. In essence, preferences appear to be formed, not merely revealed, during their elicitation, and their formation is often influenced by factors that ought not to matter from a normative perspective. The formation of preferences appears to depend on subtleties such as problem frame, method of elicitation, and the valuations and attitudes that these trigger. In what follows, selected empirical findings about individual decision making are presented and several cognitive psychological principles that underlie the decision-making process, and lead to systematic bias, are described.

2. *Diminishing Sensitivity, Risk Attitudes, and Frames*

Decisions are often 'risky' in the sense that their outcomes are not known with certainty. Presented with a choice between a risky prospect that offers a 50 percent chance to win $200 (otherwise nothing) and an alternative of receiving $100 for sure, most people prefer the sure gain over the gamble, although the two prospects have the same expected value. (Expected value is the sum of possible outcomes weighted by their probability of occurrence.) Preference for a sure outcome over a risky prospect of equal expected value is called *risk averse*; indeed, people tend to be risk averse when choosing between prospects with positive outcomes. The tendency towards risk aversion can be explained by the notion of diminishing sensitivity, first formalized by Daniel Bernoulli in 1738. Just as the impact of a candle is greater when it is brought into a dark room than into a room that is well lit so, suggested Bernoulli, the utility resulting from a small increase in wealth will be inversely proportional to the amount of wealth already in one's possession. It has since been assumed that people have a subjective utility function, and that preferences should be described using expected utility instead of expected value. According to expected utility, the worth of a gamble offering a 50 percent chance to win $200 (otherwise nothing) is 0.50 * u($200), where u is the person's concave utility function. (A function is concave or convex if a line joining two points on the curve lies entirely below or above the curve, respectively.) It follows from a concave function that the subjective value attached to a gain of $100 is more than 50 percent of the value attached to a gain of $200, which entails preference for the sure $100 gain and, hence, risk aversion.

Consider now a choice between losses. When asked to choose between a prospect that offers a 50 percent chance to lose $200 (otherwise nothing) and the alternative of losing $100 for sure, most people prefer to take an even chance at losing $200 or nothing over a sure $100 loss. This is because diminishing sensitivity applies to negative as well as to positive outcomes: the impact of an initial $100 loss is greater than that of the next $100. This results in a convex function for losses and a preference for risky prospects over sure outcomes of equal expected value, called *risk seeking*. With the exception of prospects that involve very small probabilities, risk aversion is generally observed in choices involving gains, whereas risk seeking tends to hold in choices involving losses.

These risk attitudes form part of prospect theory (Kahneman and Tversky 1979), an influential descriptive theory of choice, which incorporates an S-shaped value function that is concave for gains and convex for losses. This function is also steeper for losses than for gains: Thus, a loss of $X is more aversive than a gain of $X is attractive, which is known as *loss aversion*. In addition, prospect theory is defined on gains and losses rather than total wealth, which captures the fact that people typically treat outcomes as departures from a current reference point, rather than in terms of final assets. These properties seem compelling and unobjectionable, yet their combination can lead to problematic consequences.

In one example (Tversky and Kahneman 1986), respondents are asked to assume themselves $300 richer and invited to choose between a sure gain of $100 or an equal chance to win $200 or nothing. Alternatively, they are asked to assume themselves $500 richer, and made to choose between a sure loss of $100 and an equal chance to lose $200 or nothing. In accord with the properties described above, most subjects choosing between gains are risk averse and prefer the certain $100 gain, whereas most subjects choosing between losses are risk seeking, preferring the risky prospect over the sure $100 loss. The two

problems, however, are essentially identical: When the initial $300 or $500 wealth is added to the respective outcomes, both problems amount to a choice between $400 for sure vs. an even chance at $300 or $500. This notwithstanding, those choosing between what are framed as gains exhibit a preference for the former outcome, whereas those facing what are framed as losses prefer the latter. This is known as a *framing effect*. It occurs when alternative descriptions of what is essentially the same decision problem give rise to discrepant attitudes and to predictably different choices. Framing effects have been observed in dozens of studies involving economic, medical, and consumer decisions, among others.

3. *Loss Aversion and the Status Quo Bias*

A fundamental fact regarding people's reaction to outcomes is loss aversion: The loss of utility associated with giving up a good is greater than the utility associated with obtaining it (Tversky and Kahneman 1991). An immediate implication of loss aversion is that people will not accept an even chance to win or lose $X, because the loss of $X is more aversive than the gain of $X is attractive. Indeed, people are generally willing to accept an even-chance prospect only when the gain is substantially greater than (about twice as large as) the loss. Loss aversion entails that the loss of utility associated with giving up a good that is in our possession is generally greater than the utility gain associated with obtaining that good. This yields 'endowment effects,' wherein the mere possession of a good (thus viewing it as a potential loss) can lead to higher valuation of it than if it were not in one's possession (Kahneman et al. 1990).

A closely related manifestation of loss aversion is a general reluctance to trade, which is illustrated in a study (Knetsch 1989) in which subjects were divided into two groups: Half of the subjects were given a decorated mug, and the others were given a large bar of Swiss chocolate. Later, each subject was shown the alternative gift, and offered the opportunity to trade their gift for the other. Because the initial allocation of gifts was arbitrary and transaction costs minimal, economic theory predicts that about half the subjects should exchange their gifts. On the other hand, if losses loom larger than gains, then most participants will be reluctant to give up the gift in their possession (a loss) in order to obtain the other (a gain). Indeed, only 10 percent of the participants chose to trade their gifts. This contrasts sharply with the 50 percent predicted by standard economic analysis in which the value of a good does not change when it becomes part of one's endowment.

Loss aversion entails a strong tendency to maintain the status quo, because the disadvantages of departing from it loom larger than the advantages of its alternative (Samuelson and Zeckhauser 1988). A striking framing effect which relies on people's tendency to maintain the status quo has been observed in the context of insurance decisions, when New Jersey and Pennsylvania both introduced the option of a limited right to sue, which entitles automobile drivers to lower insurance rates. The two states differed, however, in what they offered consumers as the default option. New Jersey motorists had to acquire the full right to sue (transaction costs were minimal: a signature), whereas in Pennsylvania the full right to sue was the default. Presented with the choice, only about 20 percent of New Jersey drivers chose to acquire the full right to sue, while approximately 75 percent of Pennsylvania drivers chose to retain it. The difference in adoption rates due to the different frames had financial repercussions estimated at around $200 million dollars (Johnson et al. 1993).

Loss aversion promotes stability rather than change by inducing people to maintain their current position. Among other things, the reluctance to change induced by loss aversion can hinder the negotiated resolution of disputes. If each side to a dispute evaluates the opponent's concessions as gains and its own concessions as losses, then agreement will be hard to reach because each side will perceive itself as relinquishing more than it stands to gain.

4. *Compatibility and Reversals*

An important cognitive principle that relates the characteristics of stimuli to the ways in which people code the information and produce a response is the principle of compatibility. This principle has long been recognized by students of perception and motor control. It states that when stimuli and responses are mentally represented, the weight of a stimulus attribute is enhanced to the extent that it is compatible with the required response. Alternative methods of eliciting preference can thus lead to differential weighings of attributes and, consequently, to different choices.

In line with compatibility, for example, setting the price of a gamble is likely to emphasize payoffs more than probabilities because both the price and the payoffs are in monetary units (e.g., dollars). Consequently, a gamble's potential payoff will be weighted more heavily in a pricing task than in a choice between gambles. Consistent with this is the preference reversal phenomenon (Slovic and Lichtenstein 1983), wherein subjects choose a lottery that offers a greater chance to win over another which offers a higher payoff, but then price the latter higher than the former. This pattern has been observed in numerous experiments, including one involving professional gamblers in a Las Vegas casino (Lichtenstein and Slovic 1973), and another offering the equivalent of a month's salary to respon-

dents in the Peoples' Republic of China (Kachelmeier and Shehata 1992).

For another example, consider having to choose one of two options or, alternatively, having to reject one of two options. The two tasks are logically equivalent: If people prefer the first they should reject the second, and vice versa. However, because it is natural to select options based on their strengths, and to reject options based on their weaknesses, compatibility suggests that the strengths of options will loom larger when choosing, whereas options' weaknesses will be weighted more heavily when rejecting.

In one study (Shafir 1993), subjects were presented with pairs of options, one of which-–the 'enriched' option—had more strengths and more weaknesses than the other, 'impoverished' option. Because options' strengths are weighted more heavily when choosing than when rejecting, and their weaknesses are weighted more heavily when rejecting than when choosing, the enriched option was chosen and rejected relatively more often than the impoverished option. Contrary to procedure invariance, logically equivalent tasks give rise to predictably different choices.

5. *Independent and Comparative Evaluation*

Some procedures, such as pricing or rating, involve an independent evaluation of each option, whereas others, such as choice, are inherently comparative in nature. Independent vs. comparative procedures tend to highlight different aspects of options and can thus alter decision. As it turns out, people feel that some attributes (e.g., safety) are more important than others (e.g., cost). There is evidence that the attribute that is judged as more important looms larger in choice, where it can act as a tie-breaker, than in independent evaluation, where its comparative advantage is less prominent (Tversky et al. 1988). This can lead to systematic violations of invariance.

One study, for example, elicited people's support for interventions addressing environmental problems (Kahneman and Ritov 1994). One intervention concerned human health; for example, free medical checkups for farm workers facing the risk of skin cancer. The other concerned environmental protection: the contribution to a fund to provide safe breeding areas for Australian mammal species nearly wiped out by hunters. One group of respondents were asked to choose which of the two interventions they would rather support; a second group were presented with these one at a time and asked to determine the largest amount they would be willing to pay for each intervention. When asked to evaluate each intervention separately, respondents, who were predictably more moved by the hunted animals' plight than by mundane checkups, were willing to pay more, on average, for the safe breeding of the Australian mammals than for skin cancer checkups. However, when faced with a direct choice between these options, most subjects favored checkups for humans over safe breeding for animals. As expected, the issue viewed as more important (cancer in humans rather than breeding of animals) acquired greater prominence in choice, which involves direct comparison between issues, than in separate evaluation, where other considerations prove influential absent a direct comparison.

A related pattern emerges when attributes are difficult to gauge in isolation. Hsee (1996), for example, presented subjects with two second-hand music dictionaries, one with 20,000 entries and a slightly torn cover; the other with 10,000 entries and a cover that was like new. Subjects had little notion of how many entries to expect in a music dictionary. Under separate evaluation, they were willing to pay more for the dictionary with the new rather than the torn cover. When these were evaluated concurrently, however, most subjects obviously preferred the dictionary with twice as many entries, despite its inferior cover.

6. *Preferences Constructed in Context*

People do not always have clear and well-ordered preferences: Instead, they approach decisions as problems that need to be solved, and construct preferences that are influenced by the context of decision. Among other things, decision is thus biased by the ways in which the options are described and by the methods through which preference is elicited. Other aspects of decision that have been found to yield bias include the tendency to delay decision when choices are hard (Tversky and Shafir 1992), the regret anticipated when another option could prove superior (Bell 1982), the influence exerted by costs already incurred (Arkes and Blumer 1985), the effects of temporal separation on future decisions (Loewenstein and Elster 1992), the role of reasons and justification (Shafir et al. 1993, Tetlock 1992), and the occasional inability to predict future tastes or to remember past satisfaction (Kahneman 1994).

Decision biases have been documented in real settings and with experts; for example, in physicians' decisions regarding patient treatment (McNeil et al. 1982, Redelmeier and Shafir 1995), academics' retirement investment decisions (Benartzi and Thaler 1995), and taxi drivers' allocation of working hours (Camerer et al. 1997). Because these biases emerge from underlying cognitive mechanisms, they form an inherent part of the ways in which we process information and make decisions.

Decision Making (Naturalistic), Psychology of

Naturalistic decision-making (NDM) is the process by which people use their experience to make decisions in complex real-world environments. Many of these environments involve high levels of risk and time pressure, are dynamically changing, and have significant consequences for both the decision maker and others. They include domains such as firefighting, aviation, medicine, and nuclear power operations. Knowledge gained from experience on the part of the decision maker plays a key role in the decision process, because that knowledge is the basis for recognizing situations that require decisions to be made, in determining what information is relevant to the decision, and in deciding what would be an appropriate course of action.

Naturalistic decision-making is a new field. The first studies were conducted in 1985 by Klein (1998), who examined decision-making by urban firefighters. This work was part of a new program initiated by the Army Research Institute because of the Army's dissatisfaction with decision aids that had been developed on the basis of traditional decision theories. The dominant decision theories at that point grew out of economic models and emphasized rational choice to select the *optimal* decision option. Decision aids based on these models were laborious, requiring military

commanders to make judgments of probability and value associated with a set of options. This process was incompatible with the thought processes typically used by experienced commanders and so was rejected. The Army decided that there must be a better way.

The 'better way' was to examine what experts do naturally when they make effective decisions under challenging conditions and to determine the basis for the quality of their decisions. Traditional research has sought to determine why human decision makers typically fall short of optimality and fail to use fully rational strategies. In contrast, NDM researchers recognized that experts in many fields, such as nurses, pilots, and military commanders, usually make decisions that achieve their goals, even if they are not optimal from a traditional perspective. The focus of NDM research is on understanding how experts make good decisions under difficult conditions, an understanding that can then serve as the basis for training and aiding novices.

1. *How is Naturalistic Decision-making Research Conducted?*

Because of the NDM investigators' interest in experts' performance in real settings, the nature of the research settings and methods typically differ from those used in traditional decision research.

1.1 *Research Settings*

Harking back to its origins in military concerns, NDM research has been conducted in environments that share some common features that are quite distinct from the laboratory environment. They include:

1.1.1 Ambiguous cues. The need to make a decision is prompted by cues that signal that a problem exists, such as a fire, a malfunction in an aircraft system, or a deterioration of a patient's medical condition. These cues are sometimes ambiguous or subtle, or conflict with other cues, suggesting opposing courses of action. Thus, the nature of the problem may be difficult to determine, and expertise is needed to 'read' the cues and 'size up' the situation.

1.1.2 Dynamic conditions. Conditions faced by decision makers in natural environments often change over time, and the human operator must update his or her understanding of the situation in order to respond appropriately. As conditions shift, goals also may shift, sometimes from maintaining the status quo to coping with an emergency. For example, when an urban fire commander arrives at a fire, his initial goal may be to extinguish the fire. However, when it appears that the roof is about to collapse, his goal shifts to evacuating all the firefighters.

1.1.3 High risk. In most domains of concern to NDM researchers, the consequences of making a poor decision involve high costs, including possible loss of life or property. If an emergency room doctor misdiagnoses the presenting symptoms of an unconscious patient, the patient may die. Pilots' misjudgments about the severity of weather in the vicinity of their destination airport can result in a crash. Firefighters' failure to assess correctly the source and nature of a fire can result in application of the wrong fire suppressor, exacerbating rather than quelling a fire.

1.1.4 Time pressure. Many decisions in NDM settings must be made quickly before a negative consequence occurs. Fires rage, patient conditions deteriorate, enemy aircraft or missiles approach swiftly. From the initial appearance of cues that signal a problem to the onset of serious consequences may be a matter of minutes. Often there is no time to conduct a full rational analysis of all possible response options, their probabilities, and their outcomes, which can take considerable time and computational power.

1.1.5 Team and organizational contexts. Teams, rather than solo decision makers, are frequently the rule in NDM settings. While a single individual may have primary responsibility for the decision, other players provide critical information, alternative perspectives, and critiques of the decision. Teams usually function within an organizational context that establishes goals, norms, and procedures for operations, sets constraints on what is possible, and determines what counts as a good decision.

Because NDM researchers are concerned with real-world settings that embody many of the above features, the methods they use also differ considerably from those employed by traditional decision researchers working in the lab.

1.2 *Methods*

Naturalistic decision-making research tends to be conducted in the field rather than in the laboratory. Thus, the predominant methods involve observations

and interviews. Models of decision processes are built from the ground up, based on rich descriptions derived from multiple observations in field settings. Participants are interviewed about what they did and why. Laboratory experiments, on the other hand, typically involve top-down testing of hypotheses derived from theories. NDM research is young and has not yet been formalized to the point at which laboratory studies are common. However, there have been a number of studies to test predictions of NDM models.

A technique that has come to be associated with the NDM approach is called *cognitive task analysis*. This technique involves interviewing experts about critical decisions to find out what cues signaled the problem, what information was actually used, why particular options were considered and perhaps rejected, and why others were preferred. Highly structured interview protocols have been developed to assure reliability in procedures and responses. Several analyses of data collected using this method have shown it to be sound and reliable. Other approaches involve process tracing, which seeks to make explicit the knowledge used as experts work on a task and make decisions. In a team context, participants' communication can provide insight into how they shape the problem, what they think is important to attend to, their situation awareness, their plans and strategies, and often their rationales for choosing a course of action. These techniques may be applied to videotapes of individuals performing in real or highly realistic simulated situations, such as in high-fidelity aircraft simulators.

2. *The Recognition-primed Decision Model*

Perhaps the most significant accomplishment within the NDM approach has been the development of a new decision process model. Based on his extensive investigations of fire fighters in both urban and wildfire situations, of neonatal nurses, and of military personnel, Klein (1998) proposed a model known as the Recognition-Primed Decision model (RPD). This model emphasizes the importance of recognizing cues in a situation that signal a particular type of problem. This recognition triggers retrieval of a response that has been associated in the past with a similar cue pattern and has led to a successful resolution.

In contrast, traditional analytic decision theories would require the decision maker to generate all possible options in that situation and then to evaluate each option in a concurrent manner, selecting the best option among them. In the recognition-primed model, the decision maker retrieves only one response option at a time and evaluates how well it satisfies the current goals. If the option is inadequate, then another option is retrieved and evaluated. Thus, options are considered in a serial rather than a concurrent manner. Note that many possible options are ignored in this strategy. It reflects what Herbert Simon called 'satisficing,' or choosing the first option that satisfies one's goals and existing constraints, rather than searching for the best of all possible options.

The RPD model highlights several other findings that distinguish the naturalistic approach.

2.1 *Importance of Situation Assessment*

The initial process involved in the RPD model is cue recognition and interpretation. A major distinction between naturalistic and traditional analytic decision approaches is that the NDM approach includes both a situation assessment process and choice of a response option, whereas traditional analytic approaches focus exclusively on the second component. In real-world situations, it is critical to recognize and understand the cues that signal a problem before choosing a response. If a problem has been assessed incorrectly, it is unlikely that an appropriate decision will be made. For example, pilots with an engine malfunction mistakenly thought the right engine was failing and shut it down. In fact, it was the left engine that had failed, and the plane crashed. In traditional laboratory studies, the situation assessment component of the process typically is minimal: the participant simply responds to the problem as designed and presented by the experimenter. A fixed set of options is presented from which the participant makes a choice.

2.2 *Basis for Evaluating Options*

Once the situation is understood and a response option has been retrieved, the option needs to be evaluated. In traditional analytic models, mathematical computation is used to combine preferences and probabilities associated with each option to choose the option that is mathematically optimal. For example, if you are buying a car, you may choose from many models. A variety of factors may influence your choice, e.g., cost, size, make, fuel consumption, and convenience features such as a sunroof. You need to decide how important each feature is to you and then evaluate how each car stacks up on each feature. The car you select presumably maximizes the combined values across all of the features. In naturalistic situations, experts typically use a different and less cumbersome process. The retrieved option is evaluated to determine if it will satisfy the decision maker's current goal. If it does, it is chosen. If it does not, another option is retrieved and evaluated.

The basis for option evaluation in the NDM approach is mental simulation–the decision maker projects forward what is likely to happen if the candidate option is adopted. This includes identifying difficulties that may be encountered, likely results, and

future decisions that may be required. If no significant impediments are foreseen, then the option is accepted. If limitations are found, a new option is retrieved or the original one is modified to get around the obstacle.

2.3 Role of Knowledge

The findings just described reflect the importance of the decision maker's knowledge to the decision-making process. In traditional laboratory studies of decision-making and other cognitive processes such as memory, knowledge has been treated as an unwanted source of variability. As such, efforts were made to design pared-down tasks that bypassed whatever knowledge the participants might have, thus eliminating the possibility that knowledge could give one participant an advantage over another. Hence, early studies of memory involved nonsense syllables or words such as *ang* or *bwap*. In naturalistic decision studies, knowledge is seen as the basis for making a decision, so effort is directed toward assessing participants' knowledge and how that knowledge is used.

For example, knowledge is critical to situation assessment. Early studies have shown that performance differences between experts and novices can be traced to differences in their ability to recognize cue patterns, but not to differences in general problem solving or decision-making skills. For instance, when chess pieces on a board form a realistic pattern from a game, chess experts can remember the location of the pieces much better than novices following only a brief inspection. However, when the same pieces are randomly placed on the chessboard, the experts perform no better than novices. This illustrates that pattern recognition reflects experience with the game; it provides the expert with a basis for making more effective decisions about the next moves.

Likewise, knowledge plays a critical role in retrieval of appropriate options. One might question the serial option-evaluation strategy described above if the decision maker were randomly retrieving and evaluating all possible options. In fact, studies have shown that experts typically retrieve highly appropriate options first, based on past success in similar situations. For example, the quality of chess moves selected by both chess masters and intermediate players during a game was assessed by grandmasters. The players were asked to indicate the moves they thought of first, as well as subsequent moves they considered. More experienced players consistently thought of good moves as their first ones; subsequent moves were typically worse. This was not the case for novices, whose order of retrieval was less systematic.

Knowledge also serves as the basis for experts' evaluation of options. Without knowledge of outcomes based on prior experience, one cannot know what outcomes are likely. Studies have documented that decision strategies used by experts in a field are quite different from those used by novices. Klein found that relatively inexperienced tank commanders frequently used analytic concurrent option-evaluation strategies, whereas more experienced commanders more often used a recognition-primed sequential option-analysis strategy. There is one exception to this finding, however: experts may revert to more general-purpose strategies if a situation is unfamiliar and they lack specific knowledge relevant to the decision.

3. Value of the Naturalistic Approach

One may ask whether the recognition-primed decision model is appropriate to all circumstances or is limited to special cases. Basically, it is appropriate in any domain in which the decision maker has considerable experience, when time is limited and conditions are changing dynamically, and when problems are ill defined and goals are shifting, conditions that make an analytic approach difficult or impossible. An RPD approach represents an efficient use of knowledge and experience. It is less effortful and time consuming than most analytic approaches.

Analytic approaches are useful under certain conditions. These include situations in which the decision maker has little knowledge pertaining to the decision domain. Adequate time must be available in order to do a thorough evaluation of many options, when selecting the optimal solution is important. Analytic approaches are appropriate when conditions are stable, the parameters of the problem are clear, and all options are known. Analytic approaches yield a reliable, thorough outcome that can be justified to participants who may have competing goals and interests in the problem. For example, analytic approaches have been used to make decisions about where to site nuclear power plants. Analytic approaches are general-purpose tools that anyone can use when conditions permit.

4. Relations to Other Research Disciplines

Naturalistic decision researchers have borrowed techniques from several other disciplines to conduct their studies. They are closely aligned with much European research on work analysis, process tracing, and ecological psychology. Observational techniques have been drawn from ethnography, along with interview techniques for understanding the meaning of actions in context. Efforts to understand the role of expertise are grounded in cognitive psychology studies of experts, which involve verbal protocol analysis and process tracing.

In some cases the goals are similar but the approaches are different across related disciplines. For

example, researchers from both the NDM and the judgment and decision-making (JDM) communities are interested in determining what cues are used to make decisions and their relative importance. While JDM researchers seek to determine cue weights, NDM researchers seek to know how the cues support situation assessment.

5. Methodological Issues

Because they deviate from traditional laboratory methods of science, NDM efforts have been challenged on several grounds. Most notable has been a challenge to the scientific rigor of field-based methods, namely, observations and interviews. NDM researchers maintain that a thorough description of the phenomena *in situ* is required in order to understand the role of contextual factors in decision processes and how knowledge is used. Field studies support the discovery phase of science in which new phenomena are identified and documented. Laboratory experiments may be suitable at a later point when specific hypotheses or model tests are desired.

Second, NDM research has not yet yielded formal models. Investigations are continuing in many domains and local models have been developed, but a formal general process model has not yet emerged. In part this reflects the newness of the field; in part it reflects the goals and interests of the investigators. Formal models typically are developed so that studies can be done to disconfirm the models and advance the theory. At the present stage, NDM researchers are still trying to understand the nature of phenomena of interest.

Third, one might question the use of expert models as the basis for prescribing training and decision aids. Experts do not always agree and experts are fallible, so how can models based on experts be used as a basis for training novices? First, the expert models are generalized, not based on a single expert. Second, NDM researchers emphasize the importance of building thorough domain knowledge in order to make better decisions, rather than training specific expert strategies. Training of novices is most often done via context-based scenario training, which emphasizes that (a) good decisions cannot be made on the basis of incomplete or incorrect situation assessment, and (b) option evaluation must take into account future projections, present constraints, and potential pitfalls, both of which depend on domain knowledge.

6. Future Directions in Theory and Research

At the beginning of the twenty-first century, efforts in the NDM community are moving in two directions. One is to formalize the theory so that predictions may be made and tested. The other is to expand the scope to explore issues related to adaptive decision-making and critical thinking. These include study of problem identification and structuring of decision problems, especially in dynamic conditions when goals shift and conflict. Ill-structured and unfamiliar problems may require analogical reasoning or creative problem solving, processes that go beyond the RPD approach. Finally, the roles of organizational and other contextual features on decision processes need to be better understood.

7. Relevant Readings

To achieve a fuller understanding of the origins and development of the field of naturalistic decision-making, the reader is directed to the volumes resulting from a series of workshops that have been held since NDM research began. The first workshop was held in 1989 and yielded the first book on naturalistic decision-making (Klein et al. 1993). Since then, four more workshops have been held. Each proceedings volume includes a critique by a researcher representing a traditional decision-making approach. Klein (1998) is a popular book that provides a deeper understanding of NDM and its practical applications, and Flin (1996) describes decision-making challenges to incident managers in high-risk industries like offshore oil production.

Decision Making: Nonrational Theories

The term 'nonrational' denotes a heterogeneous class of theories of decision making designed to overcome problems with traditional 'rational' theories. Nonrational theories have been denoted by various terms,

including models of bounded rationality, procedural rationality, and satisficing. Although there is as yet no agreed-upon definition of 'nonrational,' rational and nonrational theories typically differ on several dimensions, discussed below. The term 'decision making' is used broadly here to include preference, inference, classification, and judgment, whether conscious or unconscious.

Nonrational theories of decision making should not be confused with theories of irrational decision making. The label 'nonrational' signifies a type of theory, not a type of outcome. In other words, the fact that nonrational theories postulate agents with emotions, limited knowledge, and little time—rather than postulating omniscient 'rational' beings—need not imply that such agents fare badly in the real world.

1. *Historical Background*

A few historical remarks on rational theories help to set the stage for nonrational theories. In the mid-seventeenth century, the calculus of probability replaced the ideals of certain knowledge and demonstrative proof (as in mathematics and religion) with a more modest vision of reasonableness. What may be called the first rational theory of decision making, the maximization of expected value, emerged at this time. According to the theory, an option's expected value is the sum of the product of the probability and the value of each of its consequences; a rational decision maker chooses the option with the highest expected value.

The notion of defining an option's reasonableness in terms of its expected value soon ran into problems, because in some situations (e.g., the St. Petersburg problem), its prescriptions conflicted with educated intuition. Mathematician Daniel Bernoulli therefore proposed to replace the concept of expected value with that of expected utility. For instance, the utility of a monetary gain (say, of $1,000) can be defined as a logarithmic function of its dollar value and the agent's current wealth, assuming that the utility of an additional dollar diminishes as the value of the gain and current wealth increase.

The fact that rational decision making can be defined in more than one way—for example, as maximization of expected value or expected utility—has been interpreted both as the weakness and the strength of the program. This ambiguity was one of the reasons why, by 1840, most mathematicians had given up attempting to define a calculus of reasonableness (Daston 1988). With a few exceptions, rational theories of decision making largely disappeared until their revival in the 1950s and 1960s. Only then did the major species of rational theories, the maximization of subjective expected utility and Bayesianism, become influential in the social and behavioral sciences. At about the same time, some psychologists and economists—most notably Nobel laureates Herbert Simon and Reinhard Selten—criticized the assumptions about the human decision maker in modern rational theories as empirically unfounded and psychologically unrealistic, and called for alternative theories.

2. *Optimizing vs. Nonoptimizing Theories*

Rational theories rest on the ideal of optimization; nonrational theories do not. Optimization means the calculation of the maximum (or minimum) of some variable across a number of alternatives or values. For instance, according to a rational theory known as subjective expected utility (SEU) theory, an agent should choose between alternatives (e.g., houses, spouses) by determining all possible consequences of selecting each alternative, estimating the subjective probability and the utility of each consequence, multiplying the probability by the utility, and summing the resulting terms to obtain that alternative's subjective expected utility. Once this computation has been performed for each alternative, the agent chooses the alternative with the highest expected utility. This 'subjective' interpretation of SEU has been used to instruct people in making rational choices, but was criticized by decision theorists who argue that preferences are not derived from utilities, but utilities from preferences. In this 'behavioristic' interpretation, no claims are made about the existence of utilities in human minds; SEU is only an attempt to describe the choice. People choose *as if* they are maximizing SEU (see Sect. 3).

Nonrational theories dispense with the ideal of optimization. For instance, Simon (e.g., 1956, 1982) proposed a nonrational theory known as *satisficing*, in which an agent is characterized by an aspiration level and chooses the first alternative that meets or exceeds this aspiration level. The aspiration level (e.g., characterization of what would constitute a 'good-enough' house) allows the agent to make a decision without evaluating all the alternatives.

There are several motives for abandoning the ideal of optimization. First, in many real-world situations, no optimizing strategy is known. Even in a game such as chess, which has only a few stable, well-defined rules, no optimal strategy exists that can be computed by a human or a machine. Second, even when an optimizing strategy exists, it may demand unrealistic amounts of knowledge about alternatives and consequences, particularly when the problem is novel and time is scarce. Acquiring the requisite knowledge can conflict with goals such as making a decision quickly; in situations of immediate danger, attempting to optimize can even be deadly. In social and political situations, making a decision can be more important than searching for the best option. Third, strategies

that do not involve optimization can sometimes outperform strategies that attempt to optimize. In other words, the concept of an optimizing strategy needs to be distinguished from the concept of an optimal outcome. In the real world, there is no guarantee that optimization will result in the optimal outcome. One reason is that optimization models are built on simplifying assumptions that may or may not actually hold. An example of a nonoptimizing strategy that performs well in the repeated prisoner's dilemma is 'tit for tat,' a simple heuristic that cooperates on the first move and thereafter relies on imitation, cooperating if the partner cooperated and defecting if the partner defected on the previous move. In the finitely repeated prisoner's dilemma, two tit-for-tat players can make more money than two rational players (who reason by 'backward induction' and therefore always defect), although tit for tat only requires remembering the partner's last move and does not involve optimization.

3. *Normative vs. Descriptive Theories*

Nonrational theories are descriptive, whereas rational theories are normative—this common distinction is half-true. Indeed, nonrational theories are concerned with psychological plausibility, that is, the capacities and limitations of actual humans, whereas rational theories have little concern for descriptive validity and tend to assume omniscience. But nonrational theories have sometimes been interpreted as normative as well. For instance, if an optimization strategy is nonexistent, unknown, or dangerous to perform because it would slow decision making, a simple heuristic— such as copying the behavior of others—can be the best decision-making strategy.

Rational theories typically do not assume that agents actually perform optimization or have the knowledge needed to do so. Their purpose is not to describe the reasoning process, but to answer a normative question: what would be the best strategy for an omniscient being to adopt? In economics, psychology, and animal behavior, however, the answer to this question is sometimes used to predict actual behavior. In this way, a rational theory can be descriptive of behavioral outcomes yet mute about underlying processes. For instance, optimal foraging theory assumes that animals select and shift between food patches *as if* they had perfect knowledge about the distribution of food, competitors, and other relevant information, without claiming that real animals have this knowledge or perform optimizing computations. Instead, it is assumed that animal behavior has evolved to be close to optimal in specific environments. The question of what proximal mechanisms produce this behavior is a different one. These mechanisms may be heuristics, habits, or forms of social imitation that are the topic of theories of nonrational decision making.

To summarize, nonrational theories aim to describe both the process and the outcome of decision making. In certain situations, they can be seen as characterizing the best an organism with limited time and knowledge can do. Rational theories are primarily normative, although often for omniscient rather than real beings. They are often seen as descriptive in the sense of predicting behavior, but not as models of underlying processes.

4. *Search vs. Omniscience*

Search is a central part of nonrational theories. In many rational theories, in contrast, search plays no role; it is instead assumed that all relevant information is already available to the agent (hence the agent's omniscience). Actual humans, however, have to search for information, either in memory or in outside sources, such as on the Internet or in encyclopedias. Information search can cost time and money.

One class of rational theories, known as 'optimization under constraints,' models limited search but retains the ideal of optimization. These theories posit an optimal stopping rule that requires the organism to stop search when the costs of further search exceed its benefits. This rule has been criticized because it can lead to infinite regress: To compute the optimal trade-off between the costs and benefits of search itself carries costs, which must be factored in to a 'meta' analysis of the costs and benefits of computing the costs and benefits of search, and so on. A second point of criticism is that accurate estimates of benefits and costs—such as opportunity costs, incurred by foregoing the benefits of activities other than continuing search—can be troublesome to obtain and may even demand knowledge close to omniscience. Therefore, optimization under constraints can lead to models that are descriptively even more unrealistic than rational theories that ignore search.

Nonrational theories model search with simple stopping rules rather than optimal stopping rules. Search can concern either of two kinds of information, *alternatives* (such as houses and spouses) or *cues* (such as reasons to choose a given house). Two different classes of nonrational theories deal with these types of search: aspiration level theories with the search for alternatives and fast and frugal heuristics with the search for cues.

4.1 *Aspiration Level Theories*

Aspiration level theories assume that an agent has an aspiration level, which is either a value on a goal variable (e.g., profit or market share) or, in the case of

multiple goals, a vector of goal values that is satisfactory to the agent. When choosing among a large (possibly even infinite) set of alternatives, agents search until they find the first alternative that meets or surpasses their aspiration level, at which point search stops and that alternative is chosen. For instance, agents might set a lower limit on the price at which they would be willing to sell their shares in a company (the aspiration level). In this satisficing model, the agent makes no attempt to calculate an optimal stopping point, in this case, the best day on which to sell. The aspiration level need not be fixed, but can be dynamically adjusted to feedback. For instance, if the investor observes that the share price is monotonically increasing rather than fluctuating over time, they might conclude that there is some stable trend and adjust the limit upward. Thus, aspiration level theories model decision making as a dynamic process in which alternatives are encountered sequentially and aspiration levels stop search. The challenge is to understand where aspiration levels come from in the first place (Simon 1982, Selten 1998).

4.2 *Fast and Frugal Heuristics*

In a different class of problems, the set of alternatives is given (i.e., need not be searched for), and the agent needs to search for cues that indicate which alternative to choose. For instance, an employer might want to decide which of three job applicants to hire or a bettor to predict which of two soccer teams will win a game. *Fast and frugal heuristics* employ simple stopping rules to make such inferences with little computation ('fast') and information ('frugally'). For instance, the 'take the best' heuristic bases its inference solely on the best cue on which the alternatives differ and ignores the rest. Such 'one-reason' decision making allows agents to make decisions quickly and, counterintuitively, often as or more accurately than the 'optimal' linear model (multiple regression), which looks up and integrates all available cues. Other types of fast and frugal heuristics include ignorance-based decision making (see below) and elimination heuristics. Thus, fast and frugal heuristics model decision making as a dynamic process in which cues or reasons are sequentially searched for—in memory or in the outside world—and simple stopping and decision rules determine inferences. The challenge here is to understand what the class of heuristics is, how a heuristic is selected, and in which environments it is successful (Gigerenzer et al. 1999).

5. *Ecological Rationality vs. Internal Consistency*

A classical criterion for rational choice is internal consistency or coherence. Numerous rules of consistency have been formulated, for instance, transitivity and additivity of probabilities. These rules, which are the building blocks of rational theories, have been used to test the limits of human rationality, beginning with the work of Jean Piaget and Bärbel Inhelder. Nonrational theories, in contrast, place less weight on internal consistency; for instance, some fast and frugal heuristics can violate transitivity. Instead, nonrational theories emphasize performance in the external world, both physical and social. Measures of external performance include the accuracy, speed, frugality, cost, transparency, and justifiability of decision making. Note that internal consistency does not guarantee that any of these external criteria are met. For instance, the statement 'there is a 0.01 probability that cigarette smoking causes lung cancer and a 0.99 probability that it does not' is internally consistent in that the probabilities add up to 1, but according to relevant research, it is not accurate.

How can heuristics be simple and accurate at the same time? Two major answers have been proposed: They can exploit the structure of environments, and simplicity can entail robustness.

5.1 *Structure of Environments*

The term 'ecological rationality' refers to the match between a heuristic and the structure of the information in a particular environment. The more closely a heuristic reflects important aspects of this structure, the more likely it is to succeed in that environment. Simple heuristics can succeed by exploiting the structure of information in an environment. In other words, the environment can do part of the work for the heuristic. For instance, consider the problem of predicting which of two soccer teams will win a game, which of two cities is larger, or which of two colleges provides the better education. Assume a fairly ignorant agent who has heard of only one of the two teams, cities, or colleges. He can use the 'recognition' heuristic, which infers that the recognized object will win the game, have the larger population, or provide the better education (Gigerenzer et al. 1999). Such ignorance-based decision making works well in environments where ignorance (e.g., lack of name recognition) is not random but systematic, as in competitive environments where the sequence in which the names of objects are first encountered is correlated with their performance, power, or size. The structure of such environments does part of the work in the sense that it allows the recognition heuristic to glean information from ignorance. If the correlation between recognition and the criterion is sufficiently large, a counterintuitive result is observed: Less knowledge leads to more accurate predictions than more knowledge, because people who recognize both alternatives cannot use the recognition heuristic.

Cricket, baseball, and other sports in which players need to catch a ball provide a second illustration of how heuristics can exploit the structure of environments. Suppose that we want to build a robot that can

catch a ball—a thought experiment because none exists so far. One approach to building robots in artificial intelligence is to endow them with a complete representation of the environment and a supercomputer that can draw inferences from this information. Taking this approach, which is consistent with rational theories, one would feed the robot parabolic functions describing all the trajectories that the ball might follow, and equip it with instruments for measuring the ball's initial velocity and angle to select the right parabola. Further instruments would be needed to measure the speed and direction of the wind at each point of the ball's flight, as well as myriad other factors, such as spin, in order to calculate the ball's deviation from the parabolic course. These measurements would be analyzed by a computer that would then compute where the ball will land. Professional athletes, in contrast to this hypothetical robot, seem to use a simple heuristic for catching (McLeod and Dienes 1996). They start running with their eyes fixed on the ball and adjust their speed to keep their angle of gaze constant (or within a certain range). Using this heuristic, a robot can intercept the ball without searching for the information that a 'rational' robot requires. It pays attention to only one variable—the angle of gaze, which does all the work. The 'heuristic' robot does not calculate where the ball will land, but it will be there when it does.

These examples illustrate how heuristics can succeed by exploiting structures of environments. These heuristics are 'domain-specific' rather than 'domain-general,' that is, they work in a class of environments in which they are ecologically rational. Heuristics do not provide a universal rational calculus, but a set of domain-specific mechanisms similar to the parts of a Swiss army knife, and have been referred to collectively as the 'adaptive toolbox' (Gigerenzer and Selten 2001).

5.2 Robustness

A second reason why a simple heuristic can make accurate predictions is robustness. To understand this point, it is necessary to distinguish between data fitting (i.e., determining the best-fitting parameter values for a model given a specific body of data) and prediction (i.e., using these parameter values to predict new data). For data fitting, it generally holds that the more parameters one uses in a model, the better the fit; for prediction; however, there can be a point where less is more (Foster and Sober 1994). For instance, if one records the air temperature on all 365 days in a year, one can fit the resulting jagged curve increasingly well as one adds more free parameters to the model. However, if one wants to predict air temperature during the coming year, the model that best fits the past data may result in less accurate predictions than a simpler model with fewer parameters and a worse fit. Similarly, one can fit one ball's trajectory through the air to arbitrary degrees of precision, but this may be of little help in predicting the next ball's trajectory.

More generally, in noisy environments only part of the available information generalizes to the future. The art of building a good model is to find this part and to ignore the rest. The more noise in the environment, the more that models with many free parameters tend to 'overfit,' that is, to reflect the noise. Overfitting can become a problem when overly powerful mathematical models, such as neural networks with numerous hidden units and multiple regression with many predictors, are used to fit and then predict behavioral data (Geman et al. 1992). Simplicity can reduce overfitting and thereby produce robust decision strategies. An alternative route to robustness is to use the computational power of modern computers to search through large numbers of models to find one that is robust by a given criteria. But one often does not have the time and knowledge to proceed this way.

Heuristics can be fast, frugal, and accurate by exploiting the structure of information in environments and by being robust. But these are not the only reasons why strategies that work with limited knowledge and time can be successful. For instance, there is evidence that language learning fails to occur in fully formed neural networks, but successfully develops in networks that begin with limited working memory and gradually mature. This finding has been interpreted to mean that young children's memory limitations may be an important precondition for rapid language acquisition (Elman 1993). Thus, cognitive limitations might not always be regrettable deficits, but actually enable learning by starting small.

6. Emotions, Imitation, and Social Norms

Like rational theories, most nonrational theories rely on cognitive building blocks, such as aspiration levels, search heuristics, and stopping rules. However, *Homo sapiens* is not only the most intelligent, but also the most emotional and social species—one of the very few in which unrelated members of the same species cooperate. Theories of decision making have often neglected emotions, and sometimes even cast them as the very opposite of rationality. However, emotions can aid decisions making just as fast and frugal cognitive heuristics do. For instance, falling in love can be seen as a powerful stopping rule that ends search for a partner and strengthens commitment to the loved one. This emotion guarantees commitment more effectively than would a nonemotional mind that tried to optimize partner quality and dropped the current partner each time a more promising one came along. Similarly, feelings of parental love, triggered by the presence or smile of one's infant, can prevent cost–benefit computations, so that the question of whether it is worthwhile to endure all the sleepless nights and other challenges of baby care simply never arises. Instead, love keeps parents focused on the

adaptive task of protecting and providing for their offspring. To take another emotion as an example, disgust can limit the choice set of potential foods and help one to avoid becoming ill from spoiled food. Finally, emotions such as fear and anger can speed decision making to the point that there is no decision to be made.

Like emotions, social norms and social imitation can function as decision-making guidelines that keep individual learning and information search to a minimum (Gigerenzer and Selten 2001). Social heuristics such as 'eat what other conspecifics eat' or 'prefer mates preferred by others' can guide behavior without much information gathering and bring benefits such as a reduced likelihood of food poisoning and social disapproval. These forms of social rationality can be found throughout the animal world. For instance, female guppies prefer the mates that other females prefer, and such social imitation can even reverse their prior preferences for one male over another. In humans, media-fueled mate preferences, and occasionally even academic hiring, follow similar heuristics, such as 'If they want him, then we want him!' Custom, not optimization, governs much of life, even in the economic and intellectual worlds.

Social systems foster not only individual but distributed intelligence. That is, by cooperating with one another, myopic individuals can exhibit collective rationality. Communities of social insects are one example of such intelligent 'superorganisms,' as is division of labor in human industry and politics. The intelligence of a superorganism can be seen as the emergent property of a few adaptive heuristics of its members. Honey bees, for instance, make intelligent collective decisions about where to build a new hive that seem to emerge from individual bees' application of a few simple, well-adapted heuristics. Complex phenomena need not to be modeled in terms of complex knowledge and computation.

7. *Summary*

Nonrational theories take account of what we know about humans' and other species' capacities rather than assuming unlimited knowledge, memory, time, and other resources. They model heuristics—cognitive, emotional, and social—that exploit the structure of information in real environments. Nonrational theories conflict with the ideal of *Homo economicus* and other visions of humans developed in the image of an omniscient God, but provide us with a more realistic picture of decision making when knowledge is scarce, deadlines are rapidly approaching, and the future is hard to predict.

Decision Making, Psychology of

Human decision making has been studied by a variety of disciplines including economics, philosophy, psychology and statistics. Behavioral decision making, as the field is generally known in psychology, is being

studied in all branches of psychology. The starting point of much work on human judgment and decision making is rational choice theory. The most influential explanatory concept in the analysis of decisions under uncertainty is the subjective expected utility (SEU) of available alternatives. SEU theory is a normative theory and is often compared to actual decisions. Deviations that violate the rational principles underlying SEU-theory systematically are termed anomalies. Anomalies of decision making will be briefly discussed in this section, followed by descriptive theories of decision making, and a brief discussion on how to improve the quality of decision making.

1. Normative Theories of Decision Making

Traditionally choices are assumed to be consequential, and options are evaluated using prior assessments of beliefs and values. Generally, tasks in this field of research therefore have a probability component or a value component, or both.

Edwards (1954) provided the first major review of research on human judgment and decision making. He argued that normative and prescriptive models based on economic and statistical theory should also be relevant to psychologists interested in human judgment and decision making. Edwards introduced SEU theory, which decomposes decisions or choices in probabilities and preferences, and provides a set of rules for combining beliefs (probabilities) and preferences ('values' or 'utilities'). SEU maximization is considered an appropriate normative rule for decision making under risk or uncertainty. The theory is normative or prescriptive because it specifies how decisions should be made. If one accepts the axioms upon which it is based, then the most rational choice or decision is the one specified by the theory as having the highest subjectively expected utility.

The axioms of SEU theory are all based on the work of Von Neumann and Morgenstern (1944). Their work showed that if a person's choices follow certain rules or axioms, it is possible to derive utilities in such a way that a preference for a specific alternative implies that its expected utility is greater than that of the other alternative(s). Their approach assumes that it is possible to associate a real number with each possible consequence of the relevant alternatives. This number (e.g., a number between one and 10) represents the utility of that consequence for the individual. The expected utility of a specific alternative is then the sum of the numbers associated with each possible consequence weighted by the probability that each consequence will occur. Thus a positive or negative outcome will be weighted by the probability of its occurrence; for example a certain outcome will be multiplied by 1.0, an outcome with a probability of 0.5 will be multiplied by 0.5, etc.

To illustrate this let us compare the two jobs in terms of three possible outcomes or consequences. These are initial salary, career opportunities and atmosphere. Initial salary is higher at firm A than at firm B, and receives ratings of eight and seven respectively on a scale ranging from one to 10. Career opportunities seem better at firm B but this element cannot be assessed with certainty. Let us assume that career opportunities get ratings of eight (firm A) and nine (firm B), but that you are less certain of your assessment of firm A (subjective probability of 0.7), than of firm B (subjective probability of 0.9). Finally, the atmosphere at firm B seemed to be better than at firm A; your scores are eight and seven, respectively. You spent quite some time at firm B and are certain about your judgment of the atmosphere (it seemed a great team of colleagues). You are less certain about your verdict of the atmosphere at firm A because you spent less time there (probabilities of 1.0 (B) vs. 0.9 (A)). This leads to the following scores: Firm A $(1.0*8+0.7*8+0.8*7=20.0)$, Firm B $(1.0*7+0.9*9+1.0*8)=23.2$. Thus, according to this analysis, the job offer of firm B is more attractive than that of firm A.

As argued by Dawes (1988) the central idea of the Von Neumann and Morgenstern theory is that it provides an important tool to reach a rational decision. SEU theory and related theories have dominated research on decision making since the mid-1940s, and especially the validity of theories such as SEU-theory as adequate descriptions of human choice and decision making has been a dominant theme in this research area. This is partly based on the idea that the study of human decision making should focus on the perceptual and cognitive factors that cause human judgment and decision making to *deviate* from the predictions of normative models such as SEU theory.

2. Violations and Anomalies

Research in the past decades has resulted in a wide variety of illustrations of systematic violations of principles of rationality. A clear example concerns the violation of the sure thing principle: If one prefers one option to another no matter what happens—or has happened—one should prefer that option without knowing what happens, or has happened. Tversky and Shafir (1992) gave an example of violating this principle. Their respondents were asked to consider a gamble with a 50/50 chance of winning $200 or loosing $100. Generally, a minority of about one third of respondents offered that gamble accept it. This preference pattern changes dramatically if respondents are asked to imagine they had already played the gamble and were now being offered the opportunity to play it a second time. In case they were asked to imagine they had won the first time, nearly 70 percent

wanted to play again. If they had been asked to imagine they had lost the first time nearly 60 percent wished to play it a second time.

Another violation is related to so-called sunk costs. It is Saturday afternoon and you are on the brink of leaving for the railway station in order to get to the stadium. You bought your ticket for the match some time ago. It is pouring with rain, you do not feel that well and standing in the rain for 2 hours is not going to help. In sum, you prefer to spend the afternoon at home. Nevertheless, if you decide not to go, you will have 'wasted' the money you paid for the ticket. The nonrefundable money already paid for the ticket is termed a sunk cost. Strictly speaking there appears to be no rational argument to do things you would prefer not to do in the interest of honoring the sunk cost. However, people often honor sunk costs. Examples include trivial anecdotes such as the one described above, but also large-scale enterprises such as the development of the Concorde passenger aircraft and the Gulf War.

Other violations concern principles such as transitivity. If people prefer option A over option B and also option B over option C, they should also prefer option A over option C. Violations of transitivity may arise from evaluating alternative options in terms of different dimensions. On some dimensions 'A' might be preferred over 'B' and 'C' while on others 'C' might be preferred over 'A.' If the salience of the dimensions varies, preferences could differ and one could violate transitivity. Another way in which transitivity may occur is through regret (see below).

The way in which alternative options are presented can also lead to anomalies. It turns out that people often make different choices as a function of the way alternatives are presented or framed, even though the alternatives remain unchanged. One example of framing is to present actions in terms of positive as opposed to negative consequences or vice versa. For example, a 50 percent chance of a successful outcome of surgery may appear to someone to be a more desirable outcome than a 50 percent chance of failure. Several studies provide support for this framing effect. Framing effects have been extensively investigated in decision problems in which the consequences of options are compared to psychologically salient reference points (e.g., a zero point, the status quo). Kahneman and Tversky (1979) found that when asked to choose between \$15,000 for sure or a 50/50 chance of \$10,000 or \$20,000 most people choose the certain option. If one has received the \$20,000 and was asked a second choice between returning \$5000 or a 50/50 chance of giving back nothing or \$10,000 most people choose the latter option. This pair of choices is contradictory. Similarly, when presented with a choice between a sure loss of \$100 or a 50/50 chance of a loss of \$200 and a 50/50 chance of no loss at all, most people will prefer the uncertain, risky alternative. This risk-seeking preference is in sharp contrast with preferences when the choice is between a sure gain of \$100 or a 50 percent chance of a gain of \$200 and a 50 percent choice of no gain at all. In this case most people will prefer the certain, risk-avoiding alternative. According to SEU-theory the two options in each problem are equally (un)attractive. Thus, inducing people to adopt a gain frame when choosing between a gamble and a sure thing tends to result in a risk-avoiding preference (the certain alternative). Inducing people to adopt a loss frame, on the other hand, tends to result in a risk-seeking preference (the risky alternative).

A final anomaly concerns violations of response invariance. Choice can also be influenced by the method by which preferences and choices are expressed. For instance, valuing something with money versus making a choice is frequently associated with preference reversals. Another example concerns the effect of choosing versus rejection of alternatives that have both bad and good characteristics. Shafir (1993) argues that a 'choose' orientation leads decision makers to search for good qualities of each option, while a 'reject' orientation makes them focus on bad qualities. Thus, if one alternative has more clear-cut positive and negative characteristics, and another alternative is relatively bland, the former could both be chosen and rejected depending on the question. Shafir (1993) demonstrated this in the context of awarding custody in which the question was either which parent to award custody or which parent to deny sole custody of the child.

3. *Heuristics*

The study of heuristics tends to focus on systematic errors in human decision making and these heuristics often help to understand anomalies of inferring expectations from evidence (see *Heuristics in Social Cognition*).

Three heuristics that deal with probabilistic thinking have received considerable attention: (a) availability, (b) representativeness, and (c) anchoring and adjustment. The availability heuristic refers to the tendency to assess the probability of an event based on the ease with which instances of that event come to mind. This heuristic has been investigated in a variety of domains and relates probability estimates to memory access. Generally people overestimate the probability of an event if concrete instances of that event are easily accessible in memory. Generally, ease of recall and frequency of occurrence are correlated. A number of factors that affect memory are, however, unrelated to probability. For example, vivid images are easier to recall than pallid ones. Thus, having been involved in a serious car accident is likely to be better remembered than annual statistics about the frequency of (types of) traffic accidents. The former is likely to have more impact on probability estimates than the latter. Dawes (1994) argued that the salience of negative and

relatively extreme exemplars of drug addicts can bias policy-makers' perceptions of the entire group and result in negative attitudes toward programs such as the provision of clean needles to prevent a further spread of the AIDS virus.

The representativeness heuristic refers to the tendency to assess the probability that a stimulus belongs to a particular class by judging the degree to which that event corresponds to an appropriate mental model. Kahneman and Tversky (1973) reported a well-known example of how ignoring prior probabilities can affect judgment. In their study, respondents were provided with brief personality sketches, supposedly of engineers and lawyers. They were asked to assess the probability that each sketch described a member of one profession or the other. Half the respondents were told the population from which the sketches were drawn consisted of 30 engineers and 70 lawyers, the remaining respondents were told that there were 70 engineers and 30 lawyers. Findings showed that the prior probabilities were essentially ignored, and that respondents estimated the probability of class membership by judging how similar each personality sketch was to their mental model of an engineer or a lawyer.

Anchoring and adjustment refers to a general judgment process in which an initially given or generated response serves as an anchor, and other information is insufficiently used to adjust that response. The anchoring and adjustment heuristic is based on the assumption that people often start their judgmental process by focusing on some initial value that serves as an anchor. The biases related to this heuristic stem from two distinct aspects. First, one could use irrelevant anchors, second one could insufficiently adjust up or down from an original starting value or anchor.

4. Descriptive Approaches to Decision Making

People often tend to solve problems in a way that satisfices (Simon 1955) in terms of avoiding computational complexity and/or in terms of having good reasons for one's decision. Descriptive theories of human judgment and decision making attempt to explain why people violate rational choice theory. These descriptive frameworks also view decisions as more reasonable and adaptive than previously thought. In this section a number of these frameworks will be briefly discussed.

4.1 Prospect Theory

Kahnemann and Tversky (1979) developed prospect theory to remedy the descriptive failures of SEU theories of decision making. Prospect theory attempts

Figure 1
Prospect theory: hypothetical value function

to describe and explain decisions under uncertainty. Like SEU theories prospect theory assumes that the value of an option or alternative is calculated as the summed products over specified outcomes. Each product consists of a utility and a weight attached to the objective probability. Both the value function and the probability weighting function are nonlinear. The two functions are not given in closed mathematical form but have a number of important features. The most important feature of the probability weighting function is that small probabilities are overweighted, and large probabilities are underweighted. The probability weighting function is generally not well behaved near the end-points. Extremely low probability outcomes can be exaggerated or ignored entirely. Similarly, small differences between high probability and certainty are sometimes neglected, sometimes accentuated. According to Kahneman and Tversky this is so because people find it difficult to comprehend and evaluate extreme probabilities.

The value function is defined in terms of gains and losses relative to a psychologically neutral reference point. The value function is S-shaped; concave in the region of gains above the reference point, convex in the region of losses (see Fig. 1). Thus, each unit increase in gain (loss) has decreasing value as gain (loss) increases. In other words, the subjective difference between gaining nothing and gaining $100 is greater than the difference between gaining $100 and gaining $200. Finally, the value function is steeper for losses than for gains. This implies that losing $100 is more unpleasant than gaining $100 is pleasant.

Prospect theory can help to explain both the violation of the sure thing principle and some of the

framing effects discussed above. Thus, for respondents who won the first gamble in the Tversky and Shafir (1992) study, the average of the value of \$100 and \$400 may well be greater than the value of the \$200 they already won. After losing, the negative value for $-\$100$ is less than the average of $-\$200$ and $+\$100$. When people do not know whether they won or lost they will compare the possible outcomes with the zero-point, and in that case the gamble is not very attractive. Prospect theory can also help to explain the framing effects discussed above. The probability function and the value function will confirm the higher attractiveness of the risky option (in case of losses) and the risk-avoiding option (in case of gains).

Most other descriptive approaches assume that people rely on a variety of strategies or heuristics for solving decision problems. Experience will affect the availability of these strategies, and strategy choice will also be affected by the expected advantages (benefits) and disadvantages (costs) of the chosen strategy. For many decisions an exhaustive analysis such as prescribed by SEU-theory simply is not worth the trouble. Thus, for many problems people aim for an acceptable solution and not necessarily the optimal solution due to the costs (time, effort) of 'calculating' the best possible option.

4.2 Other Descriptive Approaches

Beach (1990) proposed 'image theory' which stresses the intuitive and automatic aspects of decision making. In this theory the decision-maker's goals or values (images) play a crucial role and much attention is paid to simplified strategies. The theory emphasizes that individuals make judgments about the compatibility of an alternative with one's image. This assessment is assumed to be rapid and intuitive. More analytical and elaborate decision-making processes such as these assumed by SEU theory are expected to be evoked only in specific circumstances (e.g., decisions with possible severe consequences). Beach refers to so-called noncompensatory strategies that are often used in real-life decision making. Since cognitive overload provokes a need for simplification, especially when one has to combine substantial amounts of relevant information about probabilities and values, it can be expected that people use decision rules that require less cognitive effort than normative theories such as SEU-theory.

Examples of simplifying decision-rules mentioned in the literature are: *The dominance rule* (alternative A should be chosen over B if A is better on at least one attribute and not worse than B on all remaining attributes), *the conjunctive decision rule* (any alternative that does not meet a minimally required value on one or more attributes is dropped from the list of remaining possible alternatives), and *the lexicographic decision rule* (choose alternative which is most attractive on the most important attribute. If two alternatives are equally attractive in terms of the most important attribute move to the next attribute). Finally, *the elimination by aspects rule* is often interpreted as a combination of the lexicographic rule and the conjunctive rule. First, the most important attribute is selected. All alternatives that fail to meet the criterion on this attribute are eliminated. This procedure is repeated for each of the remaining attributes.

These decision rules require considerably less cognitive effort than the decision rule required by SEU models (a compensatory decision rule which allows negative scores on one attribute to be compensated by positive scores on another attribute). These simplifying rules can provide adequate short cuts in complex decision environments. Payne et al. (1992) use the term contingent decision making in which the cognitive costs and benefits of the various strategies people might use determine their choice of strategy. Basic questions in this choice concern the balance between cognitive effort and accuracy, but also factors such as decisional avoidance and accountability influence strategy selection.

4.2.1 *Rule following*

Many decisions are based on rules that convey information about who we are and how we interact with others. They may convey a personal or moral identity, but also a social or group identity. They may also express habits such as routine purchases at the grocery. Generally, rules minimize effort and saves time. For instance, Prelec and Herrnstein (1991) discuss cases in which people avoid cost-benefit analyses and rely on prudential rules such as moral considerations and self-control (see also Mellers et al. 1998). Adopting a rule is especially useful for controlling behavioral practices with adverse consequences that are felt only with repetition or with a delay between benefits and costs. Examples are dietery behavior and alcohol consumption.

4.2.2 *Reason-based choice*

Sometimes rules do not apply and fail to single out the best action. In such cases decision makers may search for reasons to guide their choices. Reasons may be lists of pros and cons, but they can also take the form of stories. Pennington and Hastie (1992) investigated this in the context of jury decision making and presented evidence to respondents either as stories or issues and found that story organization resulted in stronger and more confident decisions. People often wish to have 'good reasons' for what they do. Reasons can also help to explain the violation of the sure thing principle discussed above. Tversky and Shafir (1992) argued that in the case of accepting the gamble for a second play the simple fact that having won the first time and hence having 'nothing to lose' would be a good reason to play a second time.

Other descriptive approaches introduced added elements that play a role in judgment and decision making. One of these approaches is *Regret Theory* (Bell 1982, Looms and Sugden 1987). The basic idea underlying this approach is that the value placed on the outcome of a specific choice or gamble also depends on the outcome that would have been received if one had chosen an alternative choice or gamble. Thus winning $100 is likely to be affected by the knowledge that one could have won $500 (vs., e.g., $10) if one had selected another alternative. Basically regret theory posits that people anticipate the possibility of regret and that this anticipation affects their decision making. People not only want to maximize utility, they also want to minimize the possibility of regret.

5. *Formulas vs. Intuitive Decision Making*

One of the aims of decision-making research is to improve our understanding of how decision makers search for information and of how this information is combined or processed. These processes of information integration are often called clinical judgment, and compared with the use of a formula or model. The latter can be based on experts' decision rules, or empirically assessed relationships between predictors (e.g., the presence of symptoms, scores on tests) and outcomes (e.g., having a specific disease or the ability of a job candidate). A substantial amount of research has shown that judgments are generally better if they are made using a formula (Dawes 1988). This applies especially to diagnostic judgments in which a limited number of indicators can lead to adequate prediction.

Payne et al. (1992) note that two issues are of importance in this context. First, what factors influence the use of a statistical, automated, decision procedure? Second, how can we reach a situation in which clinical and automated decision making complement one another, rather than compete? The still modest use of automated decision procedures could be related to limited knowledge about their benefits, experienced difficulties in applying the rules to individual decisions, and overly optimistic beliefs in the accuracy of clinical judgment.

6. *Conclusions*

Nearly five decades after the seminal work of Edwards (1954), decision making research is becoming more prominent in psychology textbooks and a clear and separate research area has emerged, generally referred to as Behavioral Decision Research. An important characteristic of this field of inquiry is that it relies on concepts, models and methods from a variety of disciplines including economics, statistics, and social and cognitive psychology. Research on decision making pays considerable attention to the discrepancies between normative models and actual behavior, although this is an issue that requires more conceptual and empirical work. Most of the research attempting to account for these discrepancies has focused on the information processing strategies, or heuristics, that people use when making judgments or decisions. A variety of descriptive approaches to human decision making has improved our insight into the cognitive processes underlying decisions, and should also help to improve the quality of decision making. Tasks for the future include determining when various heuristics are most likely to be used and the role of emotion in the decision-making process.

J. van der Pligt

Decision-making Systems: Personal and Collective

The two best-known models for systematic personal decision-making are the maximization of utility and satisficing. The first was invented by Jevons and paradigmatically formulated by Wicksteed, with many formal refinements by succeeding authors; the second, which exemplifies a 'bounded rationality' approach, has been advocated by Herbert A. Simon. Neither translates easily into a model for systematic collective decision-making. Even as a personal model, maximization strictly conceived makes impossible demands for information. One would not expect it to fare any better collectively. Indeed it is hard to find a collective analogy even for its personal use in adjusting expenditures in any two categories so as to get the same marginal utility in each. It offers at best an idealized hypothetical basis for criticizing omissions in deliberation. But the ideal survives on the collective level in the confusion between being able to point out painfully omitted considerations after the event and being inclined to demand that all considerations be attended to beforehand, which is impossible.

Satisficing does not make this demand on either level; it asks only that a few threshold criteria (say, location, price, floor space) be laid down and that the first option that meets the criteria be chosen, though if this requires only a brief search through options, the next time the aspiration level of the decision-maker will rise, the thresholds will be set higher, and more criteria may be added. Unfortunately, at the collective level, unless an autocrat or a perfect bureaucracy (with a hierarchy that divides up all the issues that come up and assigns responsibility for deciding each of them under a coordinated plan) is authorized to act for the collectivity, a problem arises about different criteria with different thresholds being invoked at the same time by different people. Which are to guide the decisions of the collectivity?

This is a problem for social choice, and if the orderings of personal preferences for social criteria vary every whichway, aggregating the orderings runs into the Arrow theorem, before orderings for policy options themselves are considered. The theorem also applies to any attempt to decide directly on the options themselves. No system of aggregating personal orderings into social choices will meet at once all of Arrow's apparently very weak conditions about having the choices reflect the orderings. One of Arrow's conditions, typical in its weakness, is that if an option rises in one or more personal orderings without falling in any, then the option should not fall in the aggregated social ordering. The aggregated orderings can meet this condition and some others only at the cost of always being liable to fail because some three alternatives exhibit a cycle rather than a true ordering: for example, a majority prefer A to B, and a majority prefer B to C, but a majority prefer C to A. (An analogue of the theorem appears at the personal level, if the criteria in the set of criteria give very different orderings for the options [Thomas Schwartz 1970].)

One way of dealing with the Arrow theorem is to rely on the enterprise of politicians to invent a further option when attempts to aggregate personal orderings break down in cyclical voting. However, social choice theory raises an even worse problem (laid out in papers by R. D. McKelvey (1976) and Norman Schofield (1978), respectively) that a majority can be contrived for any option whatsoever if options are paired for decision, one pair after another, across the whole field of options. One way of dealing with this is to rely on the inertia of political institutions and on their divided jurisdictions to make it difficult to force immediate reconsideration of policies once chosen. Another way is to hope for widespread political agreement on criteria, taken together with a very limited scope for politics. A society of like-minded subsistence farmers (which was perhaps approximated in parts of New England in the eighteenth century) might get along very well without transacting much political business. The business need not be more than plausible departures from the status quo, satisficing departures that are also incremental, in important features of institutions no more than small changes; and the departures might fall into recurrent patterns answering to variations in the environment. This

arrangement could combine with a limited use of the market, either a perfectly competitive market or a market with a robust place for bargaining, allowing for trade in the products of crafts and small industry, operating with only a negligible draft on nonrenewable resources. It could even combine with a market in which modest technological innovations continually arise.

In either case, the market could serve, as Hayek (1948 following Adam Smith) maintained, to elicit details of information too multifarious to be easily dealt with by a deliberated plan, and give effects to these details in subtly coordinated features of the outcomes of economic activities. The market could serve in the same way in much more complex societies, and in many connections unobjectionably. It is thus itself a collective decision-making device furnishing from moment to moment a great variety of instructive information for producers and consumers. A purely competitive market does this without offering any room for bargaining; but a market in which bargaining is widespread can serve, too, and may likewise reach acceptable economic results that could not easily have been reached by any program for deliberate planning. The market with bargaining, moreover, is a device whose virtues can be carried over to some extent to political bargaining, in which contending interest groups reach one way or another, not always in ways that involve threats and counterthreats, what Lindblom has called 'partisan mutual adjustment,' in respect, say, to a presence of religion in the schools or on abortion policies. Bargaining will often, of course, reflect inequalities of power. The inequalities may be unjustified, and exploited in unconscionable ways. But Lindblom is supposing that partisan mutual adjustment, including hard bargaining, takes place in a context in which other systems or processes of decision, among them polyarchy, control through at least minimally democratic procedures, will operate to check oppression. Indeed, for him and Dahl, systems of decision-making come in variable combinations of four processes: the market; bargaining; polyarchy; and hierarchy (as in bureaucracies). Each does some things well that the others cannot, and all have a substantial presence in current democratic societies.

That is no ground for complacency. The present position of collective decision-making in the advanced industrial countries is one in which those taking part are compelled to make incremental decisions both because of inertia (institutional resistance to change) and because the risks of going wrong are so high. Incremental decisions, since they put only so much in present institutions at risk as can be repaired, are appropriate ones for agencies with very imperfect information, and that is the situation for all agencies during rapid social change. Prudence would not license doing more. Nevertheless, it may be suggested, things are going wrong in a very big way. Technological advances that combine with ever-increasing population to use up nonrenewable resources by leaps and bounds may be outracing attempts to combine limited scope for politics with the operation of the market. Think of deforestation; global warming; the collapse of commercial fisheries; the proliferation of the automobile; the marketing in the United States of firearms. In all these cases, collective decision-making seems to many knowledgable people to have faltered because of inattention in the market, inherently, with its shortrun preoccupations; and in politics, because attention there has been intermittent and inconclusive. (This is not to say that government can be counted on to choose better).

Moreover, with powerful political forces arrayed against taking due account of the troubles (which would mean, among other things, big interferences with the market, private profits, and personal incomes), it is difficult to see how the circumstances of decision-making can be made safe for satisficing and incrementalism. Things would not necessarily be better if corruption and special interests miraculously vanished from the system. The quickly multiplying evils cited are all public evils, and remedies for them would be public goods, from which no one could be excluded with respect to benefits and to which no one (taken by himself?) would make an indispensable contribution. So, as Mancur Olson showed in a basic application of rational choice theory (the utility-maximization theory of consumer behavior generalized to personal political choices), everyone would have a motive to escape making a contribution and to free-ride on the contributions of other people. Everyone could see as much by considering just what benefit he would get from the public good in question and how that benefit would not depend on his making a contribution.

This difficulty arises before any policy is adopted to produce the specific public goods that would remedy the evils in question. It arises about taking one's part in the system of collective decision-making. Why should a rational agent vote? There is a public good in having a polyarchal system in which the votes of the multitude exert some control over the politicians and thus check their greed and their hunger for power. It is desirable that the control extends to correcting for inequitable or shortsighted results from political bargaining and the operation of the market. Indeed a polyarchal system of decision-making will work as intended by its advocates only if this control in all its aspects is effective (an empirical condition) and a large proportion of the population participates (a definitional condition, often linked with an empirical hypothesis about the characterological benefits of participating). But no system for decision-making will work unless the people who have parts to play in the system actually take part; and polyarchy is peculiarly vulnerable on this point. Here, besides a troubling question about whether people will play their parts well, there is an equally troubling question about

whether people will play their parts at all. Every voter has a motive to avoid the bother of voting herself, since her contribution to maintaining the system will be effort thrown away either if a sufficient number of other people vote (which would make her vote redundant) or a sufficient number do not vote (which would make her vote quixotic). The same thing is true of voting for a specific policy or candidate.

Nevertheless, people do vote. In spite of complaints about turnout, they vote in large numbers even when there are no ward-heelers acting for political machines to turn them out. A common explanation is that they get entertainment value from voting. But 'entertainment' as invoked in this connection must, awkwardly, stretch to embrace an unexpected assortment of things, including the conscientious performance of duty, something like rooting for a horse to win, and perhaps something like prayer. Here the media, much berated for treating election campaigns as horse races, play a vital part. Even when they trivialize the issues, they make politics entertaining. At their best they induce people to take sides on important topics and consequently become anxious about the outcome. Voting is a ritual that discharges the anxiety and brings about closure for weeks, maybe months, of obsession with campaigns. Perhaps it is paradoxical that the maintenance of a system of decision-making should depend on such considerations, extraneous, it would seem, to the mechanics of recording and aggregating votes, and outside the program of narrow self-interest that rational choice theory starts with. But maybe the paradox lies with being attached to that program regardless of the wayward complications of human motivations.

It is true, rational choice theory can accommodate almost any considerations by accepting the considerations as having utility, even decisive utility, for the agents in question. If it keeps doing this, adding considerations after the event, it falls into tautology as an explanation of human decisions: humans decide on the basis of greater utility; but what has greater utility is to be inferred from what they decide. The tautology is easily escaped, however, even with the most diluted notions of utility: at one stage, consulting the agent and presenting her with experimental choices, drawing up the agent's utility map in advance. Then predicting her decision on the basis of the map is an empirical hypothesis, true or false as the facts turn out.

Moreover, the case of voting gives at least as much comfort to the theorists of narrow self-interest as disappointment. Large numbers of people eligible to vote do vote; but then large numbers do not, in spite of having the same stake in keeping up a democratic system and polyarchal control. In other connections, the free-riders form an even greater proportion of the public, sometimes enough to jeopardize the public good's being produced at all. Only something under 10 percent of its listeners make even small contributions to keeping the classical music radio station in Austin, Texas, on the air. Some of them are enticed (as Olson would expect) by private goods offered by the station as premiums to those who pay members' dues. Are the rest of those who decide to contribute just dupes? They may belong to that minority of the human race 'too rarely found to be presumed on' who out of 'generosity' act conscientiously and disdain to act otherwise (*Leviathan*, Chapter XIV, at the end).

In special respect to voting, turn outs in the millions, even if that is only half, maybe only a third, of the people eligible, suggest that Hobbes underestimated the proportion of conscientious people in the multitude. But even if they number enough to keep a democratic (or polyarchical) system going, will they be able to induce the system to make good decisions? However conscientious they may be, can they know enough about the complex issues of modern politics to tell good decisions from bad ones? There is a style of theorizing about decisions that throws great doubt upon the voters' capacities in this respect. It is just the style that treats social decisions as maximizing or satisficing and in either case having to strike a subtle balance between many different considerations. Doubt that the run of voters can join to do anything of the sort is reinforced by repeated empirical findings that most voters lack even what seems the most elementary political information (like which party is most eager to curtail welfare expenditures).

Yet some issues, even important ones, may lend themselves to forms of presentation that make the choices for voters easy. Among these may figure the grand absurdities of US politics, including the lack of gun control and the soaring rate of imprisonment; here a stark contrast between the status quo and a status quo ante where the problem did not exist, could elicit widespread agreement on the criterion of restoring the status quo ante so far as possible. A similarly stark and useful contrast may be drawn on occasion between the status quo in one's own country and the status quo in another, more successful in dealing with crimes or drugs or health insurance. In both sorts of cases sometimes the contrast can be brought before the public with the question, 'Shall we move to the better status quo?'; and if a simple remedy (which costs less and clearly promises to reduce or eliminate the trouble) is available, the public might reasonably be expected to make the appropriate decision in a referendum on the remedy.

In the absence of a referendum, the public might keep up pressure on suitably representative institutions for the decision that a referendum would lead to; but such pressure is difficult to sustain, and cross-purposes among the institutions, aggravated by corruption, may dissipate the impulse to reform. Tom Paine thought that it was desirable to have arrangements that made it possible to appeal from the people drunk to the people sober, and this may be applied as a caution about the unhappiness that may come from resorting to a referendum; but there may be occasion

for equal unhappiness with the decisions emerging from a complex of representative institutions. In any case, omitting to present the easy cases in the forms that make them easy, omitting to make them salient, and omitting to keep them salient until they have been resolved is not an argument against the capacities of voters or the use of polyarchy as a system of decision-making.

Decision Research: Behavioral

Rational choice theory has been, and continues to be, the dominant theoretical framework in the social sciences. The theory is enormously influential. Yet despite its popularity, the theory is based on untenable assumptions about human nature. Decision makers, or omniscient agents with stable and well-defined tastes, satisfy internal consistency and coherence by making choices that maximize their expected utilities.

Behavioral decision researchers have taken a descriptive approach to human decision making by exploring the actual judgments and decisions that people make as individuals, groups, and organizations. Researchers have identified numerous ways in which people violate the assumptions of rationality. The field has provided psychological insights about utilities and beliefs and has offered descriptive accounts of judgment and choice. This article discusses some of the empirical violations of rational choice theory, as well as alternative descriptive accounts of actual choices. Finally, it concludes with some comments about future directions.

1. Utility-Based Violations of Rational Choice

Behavioral decision researchers have identified a number of factors that influence utilities, but are either not addressed in rational choice theory or are inconsistent with it. A few of these factors are presented below.

1.1 Loss Aversion

In rational choice theory, decision makers are assumed to consider the utility of monetary outcomes as final states. They are sensitive to total wealth, not changes in wealth. In descriptive theories such as prospect theory (Kahneman and Tversky 1979), utilities (referred to as values) apply to gains and losses relative to the status quo. Furthermore, losses have greater impact than gains of equivalent magnitude. This assumption is known as loss aversion.

Loss aversion has been offered as an explanation for a well-known finding called the endowment effect, a result that cannot be predicted by rational choice theory. In a typical experiment on endowment effects, half of the participants are randomly assigned a gift, such as a university coffee mug. These participants are sellers, and the others are buyers. Sellers state their minimum selling prices for the mugs, and buyers give their maximum buying prices. Then an experimental market is conducted. Since buyers and sellers are determined randomly, rational choice theory predicts that approximately half of the mugs should be bought and sold. However, very few mugs are ever exchanged. Furthermore, selling prices are typically larger than buying prices by a factor of two or more. The psychological explanation for this effect is loss aversion; the pain of losing the object is greater in magnitude than the pleasure of gaining that object.

The way in which an object is endowed can also influence the value that people attach to it. People who

are rewarded with an object due to exemplary performance tend to value the object more highly than people who obtain the same object based on either chance or poor performance. These results tie in nicely with other findings that show that windfall gains, such as unexpected tax rebates, lottery winnings, or inheritances, are spent more readily than other assets, presumably because they are valued less.

1.2 Framing Effects

Endowment effects demonstrate how shifts in the status quo can influence the value attached to an object. Framing effects demonstrate how shifts in the *perception* of the status quo can influence choices between otherwise identical options. Framing effects were initially demonstrated by Tversky and Kahneman (1981). A now classic example of framing effects is the 'Asian disease' problem. Participants are told, 'Imagine that the US is preparing for the outbreak of an unusual Asian disease which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the programs are as follows: With Program A, 200 people will be saved. With Program B, there is a 1/3 chance that 600 people will be saved, otherwise no one will be saved.' Participants are asked to select a program, and the majority pick Program A.

Another group of participants is told the same story, except the descriptions of the programs are changed from lives saved to lives lost. They read, 'With Program A, 400 people will die. With Program B, there is a 1/3 chance that no one will die, otherwise 600 people will die.' The majority select program B. Although Program A and B are identical in the two problems, preferences between programs reverse depending on the framing of options. Preferences are risk averse in the gain domain and risk seeking in the loss domain.

Framing effects go far beyond laboratory demonstrations. Johnson et al. (1993) found that preferences for automobile insurance in New Jersey and Pennsylvania varied greatly with shifts in the status quo. Both states offered coverage at similar costs, and both states offered reductions in cost if drivers would give up the right to sue other drivers if they were involved in a collision. In New Jersey, the default coverage had no right to sue, although a driver could purchase that right at additional cost. In Pennsylvania, the default coverage included this right, although drivers could decline it to reduce costs. Different 'status quos' led to large differences in choice; only 20 percent of New Jersey drivers, but as many as 75 percent of Pennsylvania drivers, purchased the right to sue. Johnson et al. estimated that if limited tort had been the status quo in Pennsylvania, drivers would have saved approximately $200 million in annual insurance costs.

1.3 Contextual Effects

Another psychological variable that influences choices but is not addressed in rational choice theory is the surrounding context or the set of options under consideration. Effects of the surrounding options can be distinguished in terms of the local context and the global context. The local context refers to one particular choice set, and the global context refers to the context that is built up after evaluating multiple choice sets. The power of both contexts to influence choice is remarkable.

The most well-known local contextual effect was demonstrated by Huber et al. (1982). They asked decision makers to choose between options A and B, each described by two attributes. Then they calculated the preference for B relative to A. At a later point, decision makers were offered a choice among options A, B, and C, where C was selected to be worse than B on both attributes, and worse than A on only one attribute. B looked better in the presence of C, and preferences for B relative to A increased with C in the choice set. This result was a violation of a normative principle known as regularity. The preference for an option should never increase with the addition of other options to the choice set. This effect is robust across choice options, order of choices, and types of experimental designs (i.e., within-subject designs, where the same subject makes both choices, and between-subject designs, where different subjects make each choice).

Global contextual effects refer to the implicit comparisons that participants make across choice sets. One example is the overall range of attribute levels. Several researchers have found that a fixed change in an attribute has greater impact when it appears in a narrow attribute range than in a wide attribute range. For example, suppose students judge the attractiveness of a set of apartments based on information about monthly rent and distance to campus. A $50 change in rent has greater impact on attractiveness ratings when the overall range of rents is narrow (e.g., $200 to $400) than when the overall range of rents is wide (e.g., $100 to $1,000). Some researchers have argued that range effects influence the relative importance of an attribute, whereas others claim that range effects stretch or shrink the utilities of the attribute levels. Evidence favors the utility interpretation.

1.4 Uneven Effects of Time on Utilities

Behavioral decision researchers are also interested in the psychological effects of time. In the normative framework, delayed outcomes are assumed to be discounted at a constant rate over time. However, numerous studies suggest that discounting varies with the decision domain, the reference point, the riskiness of the outcomes, and the sequence of outcomes. When investigating the effects of outcome sequences,

Loewenstein and Prelec showed that, when people are offered choices between sequences of dinners at restaurants, they prefer to save the nicer and more expensive dinner until last. Presumably they derive pleasure from anticipating the nicer dinner, as well as the experience of that dinner. Despite this seemingly reasonable desire, the preference pattern is inconsistent with rational choice theory. Rational choice implies that, when all else is held constant, better outcomes should be preferred sooner rather than later.

1.5 Inaccurate Forecasts of Future Preferences

Kahneman (1994) has recently pointed out yet another problem with rational choice theory. He claims that people are not always able to accurately forecast their own future preferences. To make his argument, Kahneman distinguishes among different types of utilities that he refers to as decision utilities, predicted utilities, experienced utilities, and retrospective utilities. Decision utilities reflect the satisfaction gained from outcomes in a choice context. Predicted utilities are the anticipated hedonic experiences of the outcomes, and experienced utilities are the actual hedonic experiences. Finally, retrospective utilities are the remembered experiences.

Kahneman claims that remembered utilities can systematically differ from experienced utilities because retrospective utilities are surprisingly insensitive to the duration of an experience. For example, Redelmeier and Kahneman examined moment-to-moment and retrospective evaluations of the pain experienced by patients undergoing diagnostic colonoscopy. Patients rated their discomfort every 60 seconds and then made an overall evaluation of the painfulness of the entire experience. The duration of the procedure, which ranged from four minutes to 69 minutes, did not predict retrospective evaluations. Instead, a peak-end rule, representing the average of the worst moments and the final moments of the experience, gave a reasonable description of evaluations.

If people base their choices on predicted utilities, and predicted utilities are guided by inaccurate retrospective utilities, forecasts of preferences will surely be inaccurate and choices could be suboptimal. To illustrate, Kahneman and his colleagues exposed participants to two painful experiences that involved immersing their hand in cold water. In the short experience, people immersed their hand in water that was 14 degrees Celsius for 1 minute. In the long experience, they put their hand in the same 14 degree water for 1 minute and kept it immersed for an additional minute as the temperature gradually rose to 15 degrees. People evaluated the longer experience as less painful, consistent with a peak-end rule, despite the fact that the duration of pain was longer. When later faced with a choice between the same two experiences, people preferred the longer experience over the shorter one. Results of these studies, though quite controversial, suggest enormous possibilities for decision engineering.

2. Belief-based Violations of Rational Choice

In rational choice theory, agents are assumed to weight the utilities of the outcomes by their beliefs in different states of the world. Subjective probabilities or beliefs should obey the rules of probability. Numerous studies suggest otherwise.

2.1 Posterior Probabilities

Edwards was one of the first to investigate whether people updated their beliefs according to Bayes Theorem. (See also *Bayesian Theory: History of Applications*.) He found that participants shifted their judged probabilities in the appropriate direction, but not to the right extent, a result that he called conservatism. Tversky and Kahneman (1982) later challenged his claim on the basis of the results of studies that used stories such as the 'cab problem.' Participants are told the following story.

> A cab was involved in a hit-and-run accident at night. Two cab companies, the green and the blue, operate in the city. Eighty-five percent of the cabs in the city are green and 15 percent are blue. A witness identified the cab as blue. The court tested the reliability of the witness under the same circumstances that existed on the night of the accident and concluded that the witness correctly identified each one of the two colors 80 percent of the time and failed 20 percent of the time. What is the probability that the cab involved in the accident was blue rather than green?

Although some have argued that the cab problem is not adequately specified to determine a normative solution (Birnbaum 1983), many say the Bayesian solution to it is 41 percent. The majority of participants report that there is an 80 percent chance of the cab being blue. This value is sensitive to the 80 percent accuracy of the witness, but not the 15 percent base rate for blue cabs. This result and others like it led Tversky and Kahneman to argue that people often neglect base rate information and are not Bayesians at all. Hundreds of base-rate studies followed, and these studies have identified numerous boundary conditions on base rate neglect.

In a recent review, Koehler (1996) points out that, in fact, people frequently use base rates, depending on task structure and task representation. Within-subject designs, direct experience, frequency representations, unambiguous sample spaces, and random sampling are all factors that increase the degree to which people are sensitive to base rates when judging posterior

probabilities. People are not necessarily Bayesians, but there are many situations in which they are sensitive to base rate information.

2.2 Conjunctive Probabilities

Systematic errors in subjective probabilities of conjunctive events have also been identified by behavioral decision researchers (Tversky and Kahneman 1983). In another story, Tversky and Kahneman told participants about a woman named Linda who was described as 31 years old, single, outspoken, and very bright. She majored in philosophy and cared deeply about issues of discrimination and social justice. She also participated in anti-nuclear demonstrations. Then participants were asked to rank the likelihood of various statements, including 'Linda is a bank teller' and 'Linda is a bank teller and a feminist.' Participants report that the statement, 'Linda is a bank teller and a feminist' is more probable than 'Linda is a bank teller.' Tversky and Kahneman argued that these responses were violations of the conjunction rule, according to which the judged probability of the intersection of two events cannot exceed the judged probability of either single event. They claimed that people base their beliefs on the similarity of the target description to the category prototype, a strategy known as representativeness.

Gigerenzer and his collaborators have challenged this claim and have further explored the use of frequency representations to reduce, and even eliminate, conjunction effects. (Gigerenzer and Hoffrage 1995). They have had remarkable success at reducing base rate neglect and conjunction errors with frequency formats. This topic is yet another area of considerable controversy within the field.

2.3 Disjunctive Probabilities

Behavioral decision researchers have argued that judged probabilities are often inconsistent with the disjunctive rule, according to which the judged probability of the union of two events cannot be less than the judged probability of either single event. Tversky and Koehler (1994) recently showed that people systematically estimate disjunctive probabilities as less than the component event probabilities. For example, when one group of participants estimates the number of seven-letter words that end with 'n,' and another group estimates the number of seven-letter words ending in 'ing,' the latter group generates more examples than the former group, even though the latter group's task was a subset of the former group's task. Why? It is easier to think of seven-letter words ending in 'ing' than seven-letter words ending in 'n.'

Tversky and Koehler offered a theoretical account of these effects called support theory. People assign subjective probabilities to hypotheses about the world. These probabilities can psychologically stretch or increase as the hypotheses are 'unpacked' into more explicit disjunctions. The theory explains conjunction fallacies, hypothesis generation, decisions under uncertainty, fault-tree errors, as well as choice under uncertainty, by appealing to perceptual changes in likelihood with elaboration of plausible details.

Tetlock and Belkin (1996) have examined the effects of 'unpacking' past events, as well as future events. By imagining the likelihood of retrospective events that become increasing specific and detailed, people often judge the probabilities of those events as smaller. Tetlock and Belkin suggest the 'unpacking' of past events as a remedy for the hindsight bias, or the tendency to shift one's beliefs in the direction of an outcome once it is known.

3. Psychological Frameworks

Actual decisions depend on the individual, the context, and the environment. The combined effects of these factors are often described in terms of metaphors. Early metaphors focused on the ability of decision makers to cope with uncertainty, draw inferences, and test hypotheses about the world. Decision makers were treated as intuitive scientists, statisticians, and economists. Their judgments and choices were compared to optimal methods, and deviations were studied carefully. More recently, Tetlock (1992) has suggested some alternative metaphors. People also act as intuitive politicians balancing social pressures from competing sources, intuitive prosecutors who want accountability, retribution, and justice, and even intuitive theologians who protect sacred values from contamination. 'Mistakes' and 'errors' from one perspective may be perfectly reasonable from another.

3.1 Following Social and Cultural Rules

March (1994) offered a social and cultural metaphor for decision making called rule following. Rule following may have been based on tradeoffs initially, but eventually, these decisions become 'generic' applications of norms or conventions. Rule following conveys personal information about who we are, what we eat, and when we wake up in the morning. This strategy for decision making might also reflect a desire for self-control. Rule following is especially useful for controlling one's behavior when the impact of the act requires repetition (e.g., smoking a cigarette), has prolonged delays between costs and benefits (e.g., dieting), or has long-term benefits that are harder to imagine than short-term benefits (e.g., spending versus saving). This decision strategy can often minimize effort and permit the decision maker to avoid difficult or painful tradeoffs.

Fiske (1992) maintains that all social decisions boil down to four basic rules—communal sharing, authority ranking, equality matching, and market pricing. Communal sharing stresses common bonds

among group members, as found with families, lovers, and nations. Authority ranking focuses on inherent asymmetries in relationships; some people have higher rank, privilege, or prestige than others. Equality matching stresses reciprocity. Examples include babysitting cooperatives or car pooling, where one ought to give back whatever one takes. In market pricing, decisions are governed by supply and demand, expected utilities, or tradeoffs between costs and benefits.

What happens when a 'rule-following' decision maker applies the wrong rule to a social situation? Tetlock and his colleagues call these cases 'taboo tradeoffs.' Proposals to place monetary values on things usually thought of as priceless, such as children, body organs, or votes, do not just trigger cognitive confusion—they activate moral outrage, contempt, and a desire for retribution. The strength of people's reactions underscores the fact that taboo tradeoffs can threaten personal identities, community ties, and even social orders.

3.2 Reason-based Decisions

When rules conflict, people look for reasons to make choices (Shafir et al. 1993). Reasons may be lists of pros and cons, or they may take the form of stories. Pennington and Hastie (1993) argue that jurors construct stories to explain the facts. They present evidence to subjects either as stories or issues and find that story organizations result in stronger and more confident jury decisions than issue organizations. Reasons allow us to justify decisions to ourselves. Shafir et al. (1993) noted some interesting decision problems that arise when people have reasons to choose an act X if an event A occurs and different reasons to choose X if A does *not* occur. But if the outcome of event A is unknown, there are no reasons *of either type* to choose X, so X is rejected.

3.3 Emotion-based Decisions

How do emotions influence choices? Is the pleasure associated with an outcome well described by the utility of that outcome? Affective evaluations of outcomes are always relative, and different emotional experiences have been described in terms of different counterfactual comparisons. Some researchers have focused on the consequences of anticipated regret. Regret occurs when the obtained outcome is worse than it would have been under another choice. Other studies have focused on anticipated disappointment. Disappointment occurs when the obtained outcome is worse than an outcome under another state of the world. Both counterfactual comparisons have important influences on hedonic experiences.

There are interesting similarities between counterfactual reference points and the status quo, a critical reference point in the assessment of value. Like value shifts around the status quo, hedonic shifts around counterfactual reference points have asymmetric effects. Imagined losses have greater emotional intensity than imagined gains. Imagined losses can be quite general. Even gains can be imagined losses if one was expecting an even larger gain. The hedonic effects of these counterfactual anchors and others may be even more ubiquitous than the powerful effects of the status quo.

Mellers et al. (1999) proposed a theory of anticipated pleasure called decision affect theory. In decision affect theory, anticipated pleasure depends on obtained outcomes, counterfactual outcomes, and expectations. The theory implies that the anticipated pleasure associated with an outcome can differ from the utility of that outcome. For example, the utility of a larger win is always greater than that of a smaller win. But a smaller win can produce greater pleasure if it was completely unexpected or if a large loss was avoided in the process.

Mellers et al. also offered a link between anticipated pleasure and choice. They proposed that, when making choices, people anticipate the pleasure they might experience with all possible outcomes as described by decision affect theory, weigh those feelings by their subjective probabilities, and select the option with greater subjective expected pleasure. This theory differs from subjective expected utility theory because anticipated pleasure can differ from utility. Maximizing anticipated pleasure does not necessarily imply an egoistic variant of hedonism. It can arise from the senses, from acts of virtue, and from the relief of pain. Likewise, pain can arise from the cessation of pleasure, injustice, or the frustration from not achieving a goal.

4. Future Directions

Behavioral decision researchers have demonstrated important limitations on judgment and choice and have conveyed the message that people violate rationality. Furthermore, they have become much more circumspect about labeling behavior as 'irrational.' Although behavioral decision researchers disagree sharply among themselves about the extent and the implications of the violations, the general message that people systematically violate the assumptions of rational choice theory has had widespread effects in the social sciences. Behavioral assumptions are now being recognized in game theory, finance and legal decision making.

Demonstrations of human errors and foibles have also raised the level of debate about what constitutes rational behavior. If people repeatedly violate normative principles, at what point should the normative principles lose their elevated status? Irrational decisions can only occur when correct decisions are clearly defined. In the real world, this condition is often violated. More than one normative solution may apply. Problems may lack sufficient detail. Further-

more, decision makers may have other things in mind, especially when tasks have flat maxima or accuracy is more important than internal consistency. People may also want to avoid regret or conform to social and institutional norms. The integration of these goals with theories of behavioral decision making will provide fertile ground for future research.

For additional reading, see Kahneman and Tversky (2000) for theory and applications of behavioral decision theory, Kagel and Roth (1995) for experimental economics, Dawes (1998) for coverage of errors and biases, and Wright and Ayton (1994) for recent research on beliefs and subjective probabilities. For reading about decision technology, see Shafer (1997) for introductory material and Pearl (1988) for more advanced material.

Decision Support Systems

1. Introduction

A decision is a choice made by some agent between competing beliefs about the world or between alternative courses of action to achieve the agent's goals. The ability to reason flexibly about problems and make good choices are fundamental to any kind of intelligence and the need to do them well is highly valued in society. Consequently, there is a growing demand for *decision support systems* which can assist human decision makers make important choices more effectively. This demand has stimulated research in many

fields, including the behavioural and cognitive sciences (notably psychology, artificial intelligence, and management science) as well as various mathematical disciplines (such as computer science, statistics, and operations research).

Behavioral scientists have traditionally drawn a distinction between two kinds of theory that address problems in decision making. *Prescriptive* theories set out formal methods for reasoning and decision making, and criteria for 'rational' inference. *Descriptive* theories typically seek to explain how people make decisions and account for the errors they make that may result in violations of rational norms. Countless empirical studies of human judgement, in the laboratory and in real-world settings, have demonstrated that human decision making is subject to a variety of systematic errors and biases compared with prescriptive decision models (see *Decision Research: Behavioral*).

There are many reasons for this. Mistakes are clearly more likely when someone is tired or overloaded with information, or if a decision maker lacks the specialist knowledge required to make the best choice. Even under ideal conditions however, with full information, people still make 'unforced errors.' One of the major reasons for this is that we do not seem to be very good at managing uncertainty and complexity.

In the 1970s and 1980s cognitive scientists came to the view that people are not only rather poor at reasoning under uncertainty, but that they also revise their beliefs by processes that bear little resemblance to formal mathematical calculation, and it is these processes that seem to give rise to the characteristic failures in decision making. Kahneman and Tversky developed a celebrated explanation that people use various heuristics in making decisions under uncertainty, as when they judge things to be highly likely when they come *easily to mind* or are *typical* of a class rather than by means of a proper calculation of the relative probabilities. Such heuristic methods are often reasonable approximations but they can also lead to systematic errors (see also *Heuristics for Decision and Choice* and *Subjective Probability Judgments*).

Psychological research on 'deductive reasoning,' has looked at categorical rather than uncertain inferences, as in syllogistic reasoning but with similar questions in mind, namely: how do people carry out logical tasks? And how well do they do them by comparison with prescriptive logical models? (see also *Problem Solving and Reasoning: Case-based*). Systematic forms of error and failures to recognize and avoid logic fallacies have also been found, and this is probably because people do not arrive at a conclusion by applying inference rules the way a logician might, but they appear to construct a concrete 'mental model' of the situation, and manipulate it in order to determine whether a proposition is supported in the model (see also *Mental Models, Psychology of*).

In summary, many behavioral scientists now take the view that human cognition is fundamentally flawed (e.g., Sutherland 1992). Good reviews of different aspects of research on human reasoning and decision making can be found in Kahneman et al. (1982), Evans and Over (1996), Wright and Ayton (1994), Gigerenzer and Todd (1999) and Stanovich and West (2000).

2. *Mathematical Methods and Decision Support Systems*

If people demonstrate imperfect reasoning or decision making then it would presumably be desirable to support them with techniques that avoid errors and comply with rational rules. There is a vast amount of research on *decision support systems* that are designed to help people overcome their biases and limitations, and make decisions more knowledgeably and effectively. If we are to engineer computer systems to take decisions, it would seem clear that we should build those systems around theories that give us some appropriate guarantees of rationality. In a standard text on rational decision making, Lindley summarizes the 'correct' way to take decisions as follows:

> … there is essentially only one way to reach a decision sensibly. First, the uncertainties present in the situation must be quantified in terms of values called probabilities. Second, the consequences of the courses of actions must be similarly described in terms of utilities. Third, that decision must be taken which is expected on the basis of the calculated probabilities to give the greatest utility. The force of 'must' used in three places is simply that any deviation from the precepts is liable to lead the decision maker to procedures which are demonstrably absurd. (Lindley 1985, p. vii)

The above viewpoint leads naturally to Expected Utility Theory (EUT) which is well established and very well understood mathematically. If its assumptions are satisfied and the expected utilities of alternative options are properly calculated, it can be argued that the procedure will reliably select the best decision. If people made more use of EUT in their work, it is said, this would result in more effective decision making. Doctors, for example, would make more accurate diagnoses, choose better treatments, and make better use of resources. Similar claims are made about the decision making of managers, politicians, and even juries in courts of law.

3. *Limits to Theory*

> As living and moving beings, we are forced to act … [even when] our existing knowledge does not provide a sufficient basis for a calculated mathematical expectation. (John Maynard Keynes, quoted by Bernstein 1996).

Many people think that the practical value of mathematical methods of decision making like SEU

and the 'irrationality' of human decision makers are overstated. First of all, an expected-utility decision procedure requires that we know, or can estimate reasonably accurately, all the required probability and utility parameters. This is frequently difficult in real-world situations since a decision may still be urgently required even if precise quantitative data are not available. Even when it is possible to establish the necessary parameters, the cost of obtaining good estimates may outweigh the expected benefits.

Furthermore, in many situations a decision is needed before the decision options, or the relevant information sources, are fully known. The complete set of options may only emerge as the decision making process evolves. Neither logic nor decision theory provide any guidance on this evolutionary process. Lindley acknowledges this difficulty:

> The first task in any decision problem is to draw up a list of the possible actions that are available. Considerable attention should be paid to the compilation of this list [though] we can provide no scientific advice as to how this should be done.

In short, the potential value of mathematical decision theory is limited by the frequent lack of objective quantitative data on which to base the calculations, the limited range of functions that it can be used to support, and the problem that the underlying numerical representation of the decision is very different from the intuitive understanding of human decision makers.

There are also many who doubt that people are as 'irrational' as the prescriptive theories appear to suggest (see also *Decision Research: Behavioral*; *Utility and Subjective Probability: Contemporary Theories*). Skilled professionals may find it difficult to accept that that they do not make decisions under uncertainty as well as they 'should' and that under some circumstances their thinking can actually be profoundly flawed. Most of us have no difficulty accepting that our knowledge may be incomplete, that we are subject to tiredness and lapses of attention, and even that our abilities to recall and bear in mind all relevant factors are imperfect. But we are less willing to acknowledge an irremediable irrationality in our thought processes ('people complain about their memories but never about their judgement').

A more optimistic school of thought argues that many apparent biases and shortcomings are actually artefacts of the artificial situations that researchers create in order to study reasoning and judgement in controlled conditions. When we look at real-world decision making we see that human reasoning and decision making is in fact far more impressive than the research suggests. Herbert A. Simon observes that 'humans, whose computational abilities are puny compared with those of modern super-computers or even PCs, are sometimes able to solve, with very little computation, problems that are very difficult even by computer standards—problems having ill-defined goals, poorly characterized and bounded problem spaces, or which lack a strong and regular mathematical structure.' (Simon 1995)

Shanteau (1987) has investigated 'factors that lead to competence in experts, as opposed to the usual emphasis on incompetence,' and he identifies a number of important positive characteristics of expert decision makers: they know what is relevant to specific decisions, what to attend to in a busy environment, and they know when to make exceptions to general rules. Second, experts know a lot about what they know, and can make decisions about their own decision processes: they know which decisions to make and when, and which to skip, for example. They can adapt to changing task conditions, and are frequently able to find novel solutions to problems. Classical deduction and probabilistic reasoning do not capture these metacognitive skills. Consider medical decision making as an example. Most of the research in this area has viewed clinical decision making primarily in terms of deciding what is wrong with a patient (determining the diagnosis) and what to do based on the diagnosis (selecting the best treatment) (see *Problem Solving and Reasoning, Psychology of*; *Bounded and Costly Rationality*).

In practice a doctor's activities and responsibilities are extremely diverse. They include:

(a) recognizing the possibility of a significant clinical problem
(b) identifying information that is relevant to understanding the problem
(c) selecting appropriate investigations and other procedures
(d) deciding on the causes of clinical abnormalities and test results
(e) interpreting time-dependent data and trends (e.g., blood pressure)
(f) setting out clinical goals
(g) formulating treatment plans over time
(h) anticipating hazards
(i) creating contingency plans
(j) assessing the effectiveness of treatment

Each of these tasks involves different types of patient information and requires many different types of knowledge in order to interpret the information and act upon it appropriately. (For related issues in other areas see *Bounded and Costly Rationality*.) We must understand this complexity if we are to develop theories that are sufficiently sophisticated to capture the diversity or to build decision support systems which can emulate and improve upon human capabilities.

It has also been strongly argued that people are actually well adapted for making decisions under the adverse conditions caused by time pressure, lack of detailed information, and knowledge, etc. Gigerenzer, for instance, has suggested that human cognition is

rational in the sense that it is optimized for speed at the cost of occasional and usually inconsequential errors (Gigerenzer and Todd 1999).

4. *Effects of Tradeoffs on Effectiveness of Decision Making*

> … cognitive mechanisms capable of successful performance in a real world environment do not need to satisfy the classical norms of rational inference: the classical norms may be sufficient, but are not necessary, for a mind capable of sound reasoning. (Gigerenzer and Goldstein, 'Reasoning the fast and frugal way,' *Psychological Review*, 1996)

Tradeoffs simplify decision making and in practice may entail only modest costs in the decision maker's accuracy and effectiveness. This possibility has been studied quite extensively in the field of medical decision making. In the prediction of sudden infant death, for example, Carpenter et al. (1977) attempted to predict death from a simple linear combination of eight variables. They found that weights can be varied across a broad range without decreasing predictive accuracy.

In diagnosing patients suffering from dyspepsia, Fox et al. (1980) found that giving all pieces of evidence equal weights produced the same accuracy as a more precise statistical method (and also much the same pattern of errors). Fox et al. (1985) developed a system for the interpretation of blood data in leukemia diagnosis, using the EMYCIN expert system software. EMYCIN provided facilities to attach numerical 'certainty factors' to inference rules. Initially a system was developed using the full range of available values (-1 to $+1$) though later these values were replaced with just two: if the rule made a purely categorical inference the certainty factor was set to be 1.0 while if there was *any* uncertainty associated with the rule the certainty factor was set to 0.5. The effect was to *increase* diagnostic accuracy by 5 percent.

In a study of whether or not to admit patients with suspected heart attacks to hospital, O'Neil and Glowinski (1990) found no advantage of a precise decision procedure over simply 'adding up the pros and cons.' Pradhan et al. (1996) carried out a similar comparison in a diagnosis task and showed a slight increase in accuracy of diagnosis with precise statistical reasoning, but the effect was so small that it would have no practical clinical value.

In a recent study of genetic risk assessment for 50 families the leading probabilistic risk assessment software was compared with a simple procedure made up of *if … then …* rules (e.g., *if* the client has more than two first-degree relatives with breast cancer under the age of 50 *then* this is a risk factor). Despite the use of a simple weighting scheme for each rule, the rule-based system produced exactly the same risk classification for all cases as the probabilistic system (Emery et al. 2000).

While the available evidence is not conclusive a provisional hypothesis is that, at least for certain kinds of decision such as clinical diagnosis and patient management decisions, the strict use of quantitatively precise decision-making methods may not add much practical value to the design of decision support and artificial intelligence systems.

5. *Nonclassical Methods for Decision Making*

In artificial intelligence (AI) the desire to develop versatile automata has stimulated a great deal of research in new methods of decision making under uncertainty, ranging from sophisticated refinements of probabilistic methods such as 'Bayesian networks,' and nonprobabilistic methods such as fuzzy logic and possibility theory. Good overviews of the different approaches and their applications are Krause and Clark (1993) and Hunter and Parsons (1998). (See also *Artificial Intelligence: Uncertainty*.) These approaches are similar to probability methods in that they treat uncertainty as a matter of *degree*. However, quantitative approaches in general have also been questioned in AI because they require much data and do not capture varied human intuitions about the nature of 'belief,' 'doubt,' and natural justifications for decision making.

Consequently, interest has grown in the use of nonnumerical methods for reasoning under uncertainty that seem to have some 'common sense' validity. Attempts have been made to develop qualitative approximations to quantitative methods, such as *qualitative probability* (Wellman 1990). In addition new kinds of logic have been proposed, including:

(a) nonmonotonic logics which express the everyday idea of changing one's mind, as though the probability of some proposition being true is 1.0 at one point but at some later point the probability becomes zero;

(b) default logic, a form of nonmonotonic logic which formalises the idea of assuming that something is true until there is reason to belief otherwise;

(c) defeasible reasoning in which one line of reasoning can 'rebut' or 'undermine' another line of reasoning

Cognitive approaches, sometimes called 'reason-based' decision making, are gaining ground, including the idea of using informal 'endorsements' for alternative decision options and logical formalizations of everyday strategies of reasoning about competing beliefs and actions based on 'argumentation.' Models of argumentation are reviewed by Krause and Clark (1993) and the role of argumentation techniques in decision support systems is surveyed by Girle et al. (2001) (see also *Problem Solving and Reasoning: Case-based* and *Linear Algebra for Neural Networks*).

Some advocate an eclectic approach to the formalization of uncertainty that sanctions the use of different representations under different circumstances. Fox

and Das (2000, Chap. 4) discuss the possibility that many techniques for reasoning under uncertainty, from quantitative and qualitative probability to default logic and representation of uncertainty in natural language, capture different intuitions about 'belief' and decision making but can all be viewed as different technical specializations of the informal notion of argumentation.

Finally, as noted above, human decision makers often demonstrate 'metacognitive' capabilities, showing some ability to reason about the nature of the decision, the relevant information sources, and applicable forms of argument, and so forth. Metacognition may be at the heart of what we call 'intelligence.' Designers of decision support systems now have available a range of formalisms based on mathematical logic which can emulate such 'meta-level reasoning' (Fox and Das 2000) while conventional algorithmic decision procedures seem to be confined to reasoning about the input data, not the decision problem itself.

It appears from the foregoing that the claim that decision support systems should not be modeled on 'irrational' human cognitive processes is less compelling than it first appeared. This offers greater flexibility for the designers of decision support systems; they can adopt different decision theoretic frameworks for different applications. Indeed, they may also be able to apply various metacognitive strategies, as people appear to do, to select the most effective representations and reasoning methods in light of the demands and constraints of the current task.

Decision Theory: Bayesian

1. Overview and History

Decision theory studies the logic and the mathematical properties of decision making under uncertainty, and is applied to a broad spectrum of human activities. Much of it makes use of ideas, approaches, and formalisms that can be categorized as Bayesian. This discussion focuses on a specific, statistically oriented, definition of decision theory: the investigation of decision making when the state of the world is uncertain, yet further information about it can be obtained through experimentation. We discuss the

approach that stems from the theory of Savage (1954), and was developed in depth in the seminal texts of Raiffa and Schleifer (1961) and DeGroot (1970).

At the core of Bayesian decision theory is the principle of maximization of expected utility. A Bayesian decision maker proceeds by assigning a numerical utility to each of the possible consequences of an action, and a probability to each of the uncertain events that may affect that utility. The weighted average of the utility with respect to the probability is then used as the criterion of choice. In statistical decision theory, this plan can be applied to actions that represent inferences, predictions, or conclusions to be drawn from experimental evidence. Decision theory enables statisticians to bring basic principles of rationality to bear on both the development and the evaluation of statistical methodologies.

Decision making using probability, utility, and the expected utility principle has deep roots. The idea that mathematical expectation should guide rational choice under uncertainty was formulated and discussed as early as the seventeenth century. During that time, an important problem was finding the fixed amount of money that would be fair to exchange for an uncertain payoff, as when paying an insurance premium. Initially, the prevailing thought was that the fair fixed amount would be the expected payoff. The St. Petersburg game (Jorland 1987) revealed an example where the expected payoff is infinite but where, in the words of Bernoulli (1738), 'no reasonable man would be willing to pay 20 ducats as equivalent.' Bernoulli's view was that 'in their theory, mathematicians evaluate money in proportion to its quantity while, in practice, people with common sense evaluate money in proportion to the utility they can obtain from it.' Using this notion of utility, Bernoulli offered an alternative approach: he suggested that the fair sum to pay for a game of chance is the moral expectation, which effectively is an example of expected utility.

Another important element of Bayesian decision theory that can be traced to the Age of Enlightment is the notion that, when weighing evidence provided by data, one should often take explicitly into account the consequences of the actions that are to be taken using the data. Condorcet (1785), for example, reasoned that 'The probability that a convicted person is guilty should be in proportion to the probability that an acquitted person is innocent, as is the inconvenience of convicting an innocent in proportion to that of acquitting a culprit.' Later, the use of optimality principles in the evaluation of inferential procedures was present in some of the key developments in mathematical statistics, such as estimation efficiency (Fisher 1925), and power of statistical tests (Neyman and Pearson 1933), an approach that explicitly recognized the link between decision making and hypothesis testing. The broader connection between rational decision making and statistical inference was eventually formalized in great generality by Wald (1949), who is considered the founder of statistical decision theory.

The use of probability to quantify a decision maker's knowledge about uncertain events originates from the work of Ramsey (1931) and de Finetti (1937) on subjective probability. The subjectivist approach provides a coherent foundation to probability statements about a broad typology of events, and can be integrated in a natural way into individual decision making. A strength of the subjectivist view in statistical decision theory is in the use of a single measure of uncertainty for both experimental variation and uncertainty about the state of the world. This provides a simple, general, and self-consistent formal mechanism for modeling the effects of accruing experimental evidence on knowledge. See also *Probability: Interpretations*.

Justifications for taking the principle of maximization of expected utility as a general guide to rational statistical inference have also been the subject of extensive investigation. A fruitful approach has been to translate this principle into a set of intuitive axioms in terms of preferences among actions that are satisfied if and only if one's behavior is consistent with expected utility. The critical contribution in this regard is that of von Neumann and Morgenstern (1944), who developed the first and fundamental axiom system. Savage (1954) used the subjectivist approach, together with some of the technical advances provided by von Neumann and Morgenstern and Wald, to develop a general and powerful theory of individual decision making under uncertainty, which provides the logical foundation of current Bayesian decision theory. A sketch of what would become Savage's development is outlined by Ramsey (1931).

2. *The Principle of Maximization of Expected Utility*

In the prototypical formulation of decision making under uncertainty, an individual decision maker (DM) must choose one among a set of actions, whose consequences depend on some unknown state of the world. The set of actions will be denoted here by $\mathscr{A}$, with generic action a; the set of consequences by $\mathscr{Z}$, with generic consequences z, and the set of states of the world by Θ, with generic element θ. Objects in Θ and $\mathscr{Z}$ can be arbitrary. The basis for choosing among actions is a quantitative evaluation of the utility of the consequences. An action's consequences depend on the unknown state of the world, however, and each action yields a certain consequence corresponding to each state of the world. This correspondence defines an action, that is an actions is a function a from Θ to $\mathscr{Z}$.

Utilities of consequences are measured by a real valued function u and probabilities of states of the world are represented by a probability distribution π.

The expected utility $\mathscr{U}_\pi$ of action a is then the weighted average of the utilities of the possible consequences of the action, weighted by the probability of the corresponding state of nature. Formally,

$$\mathscr{U}_\pi(a) = \int_\Theta u(a(\theta))\pi(\theta)\,\mathrm{d}\theta \tag{1}$$

An optimal action, or 'Bayes' action a_{B}, is one that maximizes the expected utility, that is,

$$a_{\mathrm{B}} = \operatorname{argmax} \mathscr{U}_\pi(a) \tag{2}$$

Careful specification of the functions u and π is critical to sound decision making. Techniques are studied in decision analysis. See also *Elicitation of Probabilities and Probability Distributions*.

Following Wald (1949), the statistical literature often formulates decision problems in terms of the opportunity loss (or 'regret') associated with each pair (θ, a) by defining a loss function

$$L(\theta, a) = -u(a(\theta)) + \sup_{a(\theta)} u(a(\theta)) \tag{3}$$

where the sup is taken over the consequences of every possible action for fixed θ. The loss $L(\theta, a)$ is the difference between the utility of the consequence of the action for state θ, and the utility of the consequences of the best action for that state (or the lowest upper bound if the best action cannot be achieved). The expected loss is

$$\mathscr{L}_\pi(a) = -\mathscr{U}_\pi(a) + S_\pi \tag{4}$$

where $S_\pi = \int_\Theta \sup_{a(\theta)} u(a(\theta))\pi(\theta)\,\mathrm{d}\theta$ is independent of a. Therefore, the action minimizing the expected loss is again the Bayes action, and the two formulations are equivalent from this standpoint. In statistical analyses, loss functions are often stated directly, without reference to underlying consequences or utility functions.

In statistical decision theory the main alternative criterion to choosing a Bayes action is to choose a minimax action a_{M}, defined as

$$a_{\mathrm{M}} = \operatorname{argmin} \max_\theta L(\theta, a) \tag{5}$$

In words, to find the minimax action the DM considers each action in turn and computes the largest loss under any possible state of the world, for that action. The DM then chooses the actions with the smallest maximum loss. This approach does not requires specifying a probability distribution π over the states of the world. For this reason it is favored by the Frequentist school and was adopted in Wald's original formulation of decision theory. The Minimax action is not necessarily the same under the utility and loss formulation. Berger (1985) discusses the relationships between the Bayes and Minimax approaches, and provides conditions on the distribution π such that the two approaches lead to the same action. See also *Decision Theory: Classical* and *Game Theory and its Relation to Bayesian Theory*.

3. *Axiomatic Foundations*

Axiomatic expected utility theory has been concerned with identifying axioms in terms of preferences among actions, that are satisfied if and only if one's behavior is consistent with expected utility, thus providing a foundation to the use of the Bayes action. The fundamental axiom system is that of Savage (1954). A similar and relatively simple formulation, that provides insights into the most important assumptions of expected utility for statistical purposes, was proposed by Anscombe and Aumann (1963). Critical discussions and analytical details are found in Kreps (1988), whose formulation is followed here, and Schervish (1995).

For simplicity, assume that Θ and $\mathscr{Z}$ are finite: n_Θ is the number of elements in Θ. A simple action is a function a from Θ to $\mathscr{Z}$. Although interest is often in simple actions, Anscombe and Aumann build their theory in terms of more general objects that allow for a state of the world θ to determine the consequence of an action only up to a known probability distribution. In their theory an action is a function $\boldsymbol{a}$, such that a $(\theta, \cdot)$ is a known probability distribution on $\mathscr{Z}$. The boldface type distinguishes these general actions from simple action $a(\theta) = z$, corresponding to the special case in which, for every θ, there is a z such that $\boldsymbol{a}(\theta, z) = 1$.

The theory requires a rich set of possible actions. Specifically, for any two $\boldsymbol{a}$ and $\boldsymbol{a}'$ from $\mathscr{A}$, the composite action $\alpha\boldsymbol{a} + (1-\alpha)\boldsymbol{a}'$, given pointwise by the convex combinations $\alpha\boldsymbol{a}(\theta, z) + (1-\alpha)\boldsymbol{a}'(\theta, z)$, with $\alpha \in [0, 1]$ is also in $\mathscr{A}$. Also, the state θ is said to be null if the DM is indifferent between any two actions that differ only in what happens if θ occurs.

Choosing actions according to the principle of expected utility is equivalent to holding preferences among actions that satisfy the five axioms of Table 1.

The weak-ordering axiom requires that any two actions can be compared and in a transitive way. It effectively permits representation of the preferences as one-dimensional. The Archimedean axiom bars the DM from preferring one action to another so strongly that no reversal of preference by creating a composite action that includes one of the two is possible. This axiom carries most of the weight in representing the preference dimension as the real line. The Independence axiom requires that two composite lotteries should be compared solely based on the component that is different. It carries most of the weight in guaranteeing the 'expected' in the expected utility

Table 1
Axioms of the Anscombe–Aumann expected utility theory

1. Weak order	$\succ$ on $\mathscr{A}$ is a preference relation
2. Independence	If $\boldsymbol{a} \succ \boldsymbol{a}'$ and $\alpha \in (0, 1)$, then for every $\boldsymbol{a}'' \in \mathscr{A}$ $\alpha\boldsymbol{a} + (1-\alpha)\boldsymbol{a}'' \succ \alpha\boldsymbol{a}' + (1-\alpha)\boldsymbol{a}''$
3. Archimedean	If $\boldsymbol{a} \succ \boldsymbol{a}' \succ \boldsymbol{a}''$, then there are $\alpha, \beta \in (0, 1)$ such that $\alpha\boldsymbol{a} + (1-\alpha)\boldsymbol{a}'' \succ \boldsymbol{a}' \succ \beta\boldsymbol{a} + (1-\beta)\boldsymbol{a}''$
4.	There exist $\boldsymbol{a}$ and $\boldsymbol{a}'$ in $\mathscr{A}$ such that $\boldsymbol{a}' \succ \boldsymbol{a}$
5. State Independence	For all $\boldsymbol{a} \in \mathscr{A}$ and any two distribution $\boldsymbol{p}$ and $\boldsymbol{q}$ on Z If $(\boldsymbol{a}(1, \cdot),\ldots, \boldsymbol{a}(\theta-1, \cdot), \boldsymbol{q}, \boldsymbol{a}(\theta+1, \cdot),\ldots, \boldsymbol{a}(n_\Theta, \cdot)) \succ (\boldsymbol{a}(1, \cdot),\ldots, \boldsymbol{a}(\theta-1, \cdot), \boldsymbol{q}, \boldsymbol{a}(\theta+1, \cdot),\ldots, \boldsymbol{\alpha}(n_\Theta, \cdot))$ for some state θ, then for all non-null θ' $(\boldsymbol{a}(1, \cdot),\ldots, \boldsymbol{a}(\theta'-1, \cdot), \boldsymbol{q}, \boldsymbol{a}(\theta'+1, \cdot),\ldots, \boldsymbol{a}(n_\Theta, \cdot)) \succ (\boldsymbol{a}(1, \cdot),\ldots, \boldsymbol{a}(\theta'-1, \cdot), \boldsymbol{q}, \boldsymbol{a}(\theta'+1, \cdot),\ldots, \boldsymbol{a}(n_\Theta, \cdot))$

principle. Axiom 4 is a structural condition requiring that not all states be null.

The first three axioms guarantee that there is a linear function $f: \mathscr{A} \to \mathscr{R}$ that represents the preference relation $\succ$. It also follows that the first three axioms are necessary and sufficient for the existence of real valued functions $u_1,\ldots, u_k$, such that:

$$\boldsymbol{a} \succ \boldsymbol{a}' \Leftrightarrow \sum_\theta \sum_z u_\theta(z)\boldsymbol{a}(\theta, z) > \sum_\theta \sum_z u_\theta(z)\boldsymbol{a}'(\theta, z). \quad (6)$$

In this representation, the utility of consequences is specific to the state of the world. Also, each utility is defined up to a state-specific change of scale. This representation is consistent with expected utility maximization, but does not provide a unique decomposition of preferences into probability of states of the world and utility of consequences. Such decomposition is achieved by the State Independence axiom, which asks the DM to consider two comparisons: in the first the two actions are identical except that in state θ one has probability distribution over consequences $\boldsymbol{p}$ and the other $\boldsymbol{q}$. In the second the two actions are again identical, except that now in state θ' one has probability distribution $\boldsymbol{p}$ and the other $\boldsymbol{q}$. If the DM prefers the action with probability distribution $\boldsymbol{p}$ in the first comparison, this preference will have to hold in the second comparison as well. So the preference for $\boldsymbol{p}$ over $\boldsymbol{q}$ is independent of the state. This axiom guarantees separation of utility and probability. The main theorem about representation of preferences via utilities and probabilities is then:

Axioms 1–5 are necessary and sufficient for the existence of a nonconstant function $u: Z \to \mathscr{R}$ and a probability distribution π on Θ such that

$$\boldsymbol{a} \succ \boldsymbol{a}' \Leftrightarrow \sum_\theta \pi(\theta) \sum_z u(z)\boldsymbol{a}(\theta, z) > \sum_\theta \pi(\theta) \sum_z u(z)\boldsymbol{a}'(\theta, z) \quad (7)$$

Moreover, the probability distribution π is unique, and u is unique up to a positive linear transformation.

In particular, for simple actions the summation over z drops out and the expectations above correspond to $\mathscr{U}_\pi(a)$ and $\mathscr{U}_\pi(a')$.

Axiomatic systems such as Savage's or Anscombe and Aumann's provide the logical foundation for decision making using expected utility in both decision analysis and statistical decision theory. The appropriateness and generality of these axiom systems are at the center of a debate which is critical for statistical practice. Kadane et al. (1999) investigate the implications and limitations of various axiomatizations, and suggest possible generalizations.

4. *Bayesian Statistical Decision Theory*

Statistical decision theory studies applications in which there is the possibility of observing the outcome x of an experiment that has probability distribution $p(x \mid \theta)$, conditional on state of the world θ. Observing x can give information about θ, and therefore assist in decision making. Bayesian decision theory offers (a) approaches for making efficient use of the information provided by x in choosing an action and (b) approaches for measuring the value of an experiment and for deciding whether or not to perform it when it comes at a cost. All decision theoretic Bayesian approaches can be characterized by specifying $\pi(\theta)$, $p(x \mid \theta)$, $L(\theta, a)$, and possibly the cost of experimentation.

Approaches to (a) are based on the notion that the distribution used in computing $\mathscr{U}$ at any stage in the decision process should make use of all knowledge available at the time of the decision, and that knowledge is incorporated by conditioning, that is using Bayes rule. Specifically, after observing data x, the

prior distribution $\pi(\theta)$ is updated to obtain a posterior distribution,

$$\pi(\theta \mid x) = \frac{\pi(\theta)p(x \mid \theta)}{\int_\Theta \pi(\theta)p(x \mid \theta)\,\mathrm{d}\theta}. \tag{8}$$

Then, as in definition (2), the Bayes action is found by maximizing expected utility. The difference now is that the relevant distribution for computing the expectation will not be $\pi(\theta)$ but $\pi(\theta \mid x)$. Formally, the data-dependent Bayes rule is

$$a_{\mathrm{B}}(x) = \operatorname{argmax} \mathscr{U}_{\pi_x}(a) = \int_\Theta u(a(\theta))\pi(\theta \mid x)\,\mathrm{d}\theta \tag{9}$$

where π_x is shorthand for the posterior distribution. The action that minimizes this expression will depend on x. So this procedure implicitly defines a decision function, that is a mapping from data to actions.

This approach has profound implications on statistical practice (Berger 1985, Bernardo and Smith 1994). Here we review some of the salient points.

Generality. Bayesian decision theory can be used to address statistical inference problems irrespective of data type, context, likelihood function, and current knowledge. Guidance is based on basic principles that are simple to state, understand, and refute if deemed inappropriate. Obstacles to implementation can occur, and simplifying assumptions are almost always needed in practice. However, in statistical applications, difficulties seldom arise because the conceptual framework is not sufficiently powerful.

Openness. All elements needed to define a statistical approach are explicitly and quantitatively described as prior, likelihood, loss, and cost of experimentation. This description is explicit, and common to all applications.

Likelihood principle. In a Bayesian decision theoretic approach, observed experimental evidence affects decision making only to the extent to which it is captured in the posterior $\pi(\theta \mid x)$, or equivalent by the likelihood $p(x \mid \theta)$. If there exist sufficient statistics, they alone need to be recorded for decision making purposes. Berger and Wolpert (1988) elaborate on this principle, often called the likelihood principle, or the sufficiency principle. A controversial example of experimental evidence that does not affect the likelihood, but does affect frequentist inference, is provided by stopping rules that depend on the data but are independent of the state of nature (Berger 1985, Bernardo and Smith 1994). See also *Likelihood in Statistics* and *Statistical Sufficiency*.

Nuisance parameters. In statistical inference nuisance parameters, that is parameters that are required to specify a realistic population model, but are not the primary object of inquiry, have created substantial controversy and have hampered the development of general frequentist approaches (for example the so-called most powerful tests are not generally applicable with nuisance parameters). From a decision theoretic standpoint, a nuisance parameter is a parameter that appears in the sampling distribution but not in the loss function. For example, let $\theta = (\gamma, \eta)$, where η is the nuisance parameter, and γ the parameter entering the loss function, that is $L(\theta, a) = L(\gamma, a)$ for every θ. The expected loss can be rewritten as

$$\begin{aligned}\mathscr{L}_{\pi_x}(a) &= \int_\Gamma L(\gamma, a(x)) \int_{\mathrm{H}} \pi(\gamma, \eta \mid x)\,\mathrm{d}\eta\,\mathrm{d}\gamma \\ &= \int_\Gamma L(\gamma, a(x))\pi(\gamma \mid x)\,\mathrm{d}\gamma. \end{aligned} \tag{10}$$

The nuisance parameter η is handled by marginalization of the posterior distribution. While this is a trivial corollary of the expected utility principle, it provides a completely general and unified approach to statistical analyses in presence of nuisance parameters.

Sequential decisions. In multistage decision problems, successive updating of beliefs using Bayes' rule permits modeling of accruing evidence, and also prediction of future states of knowledge. This, in conjunction with backwards-induction algorithms, has constituted the basis for developing complex decision-making strategies that adapt to new evidence as it accrues (DeGroot 1970). See also *Sequential Statistical Methods*.

5. *Standard Statistical Problems as Decision Problems*

5.1 *Hypothesis Testing*

Hypothesis testing problems have traditionally been among the earliest to be approached as decision problems (Neyman and Pearson 1933). The action space usually includes endorsing the null hypothesis, specified as a subset of Θ, endorsing an alternative hypothesis, and possibly no endorsement or the requirement that more experimentation be carried out.

In the simplest formulation, Θ consists of only two points: θ_0 (the null hypothesis), and θ_1 (the alternative hypothesis), with prior probability $\pi(\theta_0) = \pi_0 = 1 - \pi(\theta_1)$. The action space includes action a_0: 'endorse the null hypothesis' and a_1: 'endorse the alternative hypothesis.' This formulation, in both Bayesian and frequentist decision theory, is in contrast with Fisher's significance testing, which is concerned with measuring the extent to which data support a null hypothesis, separate from the consequences of rejecting that hypothesis.

Table 2
Loss function for testing a simple hypothesis against a simple alternative

	a_0	a_1
θ_0	0	L_0
θ_1	L_1	0

All loss functions in this case can be described by two-way tables as in Table 2. The zeroes on the diagonal are because loss functions are constructed so that there is at least one action with zero loss for every state of the world.

The expected losses of the two actions are:

$$\mathscr{L}_\pi(a_0) = L_1\pi(\theta_1 \mid x)$$
$$\mathscr{L}_\pi(a_1) = L_0\pi(\theta_0 \mid x)$$

and the Bayes rule is a_0 whenever

$$L_1\pi(\theta_1 \mid x) < L_0\pi(\theta_0 \mid x) \tag{11}$$

and a_1 otherwise, a formal restatement of Condorcet's opinion, discussed in Sect. 1.

Rewriting the inequality above via Bayes' rule gives

$$\frac{p(x \mid \theta_0)}{p(x \mid \theta_1)} > \frac{L_1}{L_0}\frac{\pi_1}{\pi_0}. \tag{12}$$

The left-hand-side is the so-called Bayes factor in favor of the null hypothesis. It measures the strength with which the experimental evidence supports the null hypothesis as compared to the alternative, and it summarizes the data for the purpose of this decision. The Bayes rule is to accept the null hypothesis when the Bayes factor is sufficiently large. The cutoff is determined based on the prior probability of the null hypothesis and the relative disutilities of the two possible incorrect decisions.

In this simple formulation, there is a close analogy between the decision function induced by the Bayes rule and the most powerful tests (Neyman and Pearson 1933), which are in fact of the form (12). In frequentist formulations, however, the cutoff is chosen by controlling the significance level, that is the probability of incorrectly endorsing the hypothesis in repeated experiments. In practice, this is all too frequently set to 0.05 without consideration of the consequences of incorrect calls; however, original formulations of the theory demanded this consideration.

More pronounced differences between Bayesian and frequentist hypothesis testing emerge in less stylized formulations. For example, if θ is a real valued parameter and the null hypothesis is $\theta \in \Theta_0$, say $\Theta_0 = (\theta_0 - \varepsilon, \theta_0 + \varepsilon)$, the Bayes rule becomes

$$L_1(1 - \pi(\Theta_0 \mid x) < L_0\pi(\Theta_0 \mid x) \tag{13}$$

or

$$\frac{\int_{\Theta_0} \pi(\theta)p(x \mid \theta)\,\mathrm{d}\theta}{\int_{\Theta\setminus\Theta_0} \pi(\theta)p(x \mid \theta)\,\mathrm{d}\theta} > \frac{L_1}{L_0} \tag{14}$$

which preserves the general flavor of Condorcet's view, but is not consistent with typical frequentist approaches, except in very special cases.

5.2 Binary Classification

Binary classification problems (Duda et al. 2001) consider assigning an individual to one of two categories, by measuring a series of attributes. An example is medical diagnosis for a single medical condition (say disease vs. no disease) based on a battery of tests. Again the action space has two elements: (say a_1: 'diagnosis of disease' and a_0: 'diagnosis of no disease'), and the structure of the loss function is analogous to Table 2.

A typical situation occurs when the DM observes data on the attributes x and correct disease classification y of a sample of individuals, and wishes to classify an additional individual, randomly drawn from the same population. If x^* are the observed features of the new individual to be classified, and y^* is its unknown disease state, then the Bayes rule is to choose a diagnosis of no disease if

$$L_1\pi(y^* = 1 \mid y, x, x^*) < L_0\pi(y^* = 0 \mid y, x, x^*) \tag{15}$$

or

$$\frac{\int_\Theta p(y^* = 0 \mid x^*, \theta)\pi(\theta)p(y, x \mid \theta)\,\mathrm{d}\theta}{\int_\Theta p(y^* = 1 \mid x^*, \theta)\pi(\theta)p(y, x \mid \theta)\,\mathrm{d}\theta} > \frac{L_1}{L_0}. \tag{16}$$

This classification rule incorporates inference on the population model, uncertainty about population parameters, and relative disutilities of misclassification errors.

5.3 Point Estimation

Statistical point estimation assigns a single best guess to an unknown parameter θ. This assignment can be

viewed as a decision problem in which the space of actions is $\mathscr{A} = \Theta$. The loss function quantifies the consequences of estimation errors. The most commonly used, primarily for its mathematical convenience, is the squared error loss $L(\theta, a) = (\theta - a)^2$. The expected loss is of an action a is

$$\int_{\Theta} (\theta - a)^2 \pi(\theta \mid x)\, \mathrm{d}\theta = \mathrm{Var}(\theta \mid x) + (a - E(\theta \mid x))^2 \tag{17}$$

so that the Bayes rule is $a_{\mathrm{B}} = E(\theta \mid x)$, that is the mean of the posterior distribution. The expected loss associated with it is the variance of the posterior distribution.

Other commonly used loss functions include the absolute error loss $L(\theta, a) = |\theta - a|$, leading to the median of $p(\theta \mid x)$, and, for discrete Θ, the loss $L(\theta, a) = I_{\theta = a}$, assigning the same loss to all errors, and leading to the mode of the posterior distribution.

6. *The Value of Information*

One of the strengths of the expected utility approach is the simple answer provided to the problem of assessing the value of prospective information. From the point of view of decision making, information is anything that may enable a better decision, that is a decision with a higher expected utility. The expected change in utility resulting from experimentation can therefore be used as a quantitative measure of the worth of an experiment (Ramsey 1990, Raiffa and Schleifer 1961, DeGroot 1984). See also *Experimental Design: Bayesian Designs*.

In its simplest formulation, experimentation can be modeled as a two-stage decision process: in the first stage the DM decides whether to perform the candidate experiment or not; in the second the DM chooses an action a, possibly making use of the experimental outcome. This decision problem is most effectively solved in reversed order, or by backwards induction (DeGroot 1970), by first determining the Bayes action $a_{\mathrm{B}}(x)$ and its expected utility $\mathscr{U}_{\pi_x}(a_{\mathrm{B}}(x))$ as a function of the data, for every possible outcome, and then stepping back and comparing the two options: 'experiment' and 'no experiment.'

Specifically, under 'no experiment,' the DM would choose action a_{B} immediately, with expected utility

$$V(\pi) = \sup_a \mathscr{U}_{\pi}(a) \tag{18}$$

Under 'experiment,' if $a_{\mathrm{B}}(x) = a_{\mathrm{B}}$ for every outcome x, the experiment does not contribute to the solution of the decision problem at hand. An experiment has value only if it may affect subsequent decisions. How large this value is depends on the utilities assigned to the consequences, and the frequency with which the observations lead to a change of decision. Formally, under 'experiment' the expected utility, averaged with respect to the states of the world and the yet unobserved experimental outcomes, is

$$\int_{\mathscr{X}} \sup_a \mathscr{U}_{\pi_x}(a)\, \mathrm{d}x = \int_{\mathscr{X}} V(\pi_x)\, \mathrm{d}x. \tag{19}$$

The difference

$$V = \int_{\mathscr{X}} V(\pi_x)\, \mathrm{d}x - V(\pi) \tag{20}$$

is the amount of utility the DM expects to gain from the experiment. V provides a pragmatic, decision-based way of measuring the value of information and subsumes a variety of specific statistical approaches as special cases. If the experiments comes at a cost, measured by c in the utility scale, it is optimal to perform it whenever $V > c$. This logic can be extended to an arbitrary number of experimental stages (DeGroot 1970), although computational obstacles arise rapidly as the number of stages increases. See also *Sequential Statistical Methods*. The function V is convex, that is

$$V(\pi) = V\left(\int_{\mathscr{X}} \pi_x\, \mathrm{d}x\right) \leqslant \int_{\mathscr{X}} V(\pi_x)\, \mathrm{d}x. \tag{21}$$

This insures that, in expectation, experimentation can never decrease expected utility.

7. *Risk and Admissibility*

Statistical decision theory following frequentist approaches focuses on the performance of decision functions over repeated experiments, for a fixed state of the world, as measured by the risk function

$$R(\theta, a) = \int_{\mathscr{X}} L(\theta, a(x) p(x \mid \theta)\, \mathrm{d}x. \tag{22}$$

For example in point estimation using squared error loss, the risk is the so-called mean squared error, decomposable as the sum of the variance of the decision rule and the square of the bias. See also *Decision Theory: Classical*. The expectation of R with respect to a prior π is often termed Bayes risk. Minimization of the Bayes risk, under very general conditions, leads again to the Bayes rule (Berger 1985).

A critical rationality condition for the evaluation of decision rules from a frequentist standpoint is admissibility. The basis of admissibility is a dominance relation among decision rules. Specifically, decision

rule a is R-better than a' if $R(\theta, a) \leqslant R(\theta, a')$, for every θ, and $R(\theta, a) < R(\theta, a')$ for at least some θ. A decision rule a is admissible if there is no R-better rule. Restricting to admissible rules is critical, although it will often leave many rules to choose from, and the DM will need to commit to a more stringent principle to reach a decision.

Extensive statistical investigation has focused on exploring the admissibility properties of various statistical strategies. Several commonly used approaches, such as maximum likelihood and minimax decision rules, can lead to inadmissible estimates in some circumstances (Stein 1955, Berger 1985). From the point of view of Bayesian decision theory, the interesting connection is that, under relatively general conditions, Bayes rules are admissible. For example, any unique Bayes estimator is admissible (Schervish 1955). Also, in some specific applications, all admissible rules are Bayes rules with respect to some prior distribution (as in the case of finite Θ), or limiting cases of families of Bayes rules.

8. Conclusions

Bayesian statistical decision theory studies the optimal use of experimental information in decision making. It can be applied to specific decision problems as well as statistical methodology as a field, as most statistical analyses can be viewed as decision problems. In this discussion we have reviewed history, axiomatic foundations, and statistical implications of Bayesian decision theory. For further readings, Lindley (1985) presents the key concepts without complex mathematical formalisms, while Berger (1985), Robert (1994), and Bernardo and Smith (1994) provide more recent overviews and comparisons with alternative approaches.

Decision Theory: Classical

The term 'statistical decision theory' is a condensation of Abraham Wald's phrase, 'the theory of statistical decision functions' which occurs, for example, in the preface to his monograph, Wald (1950). Wald viewed his 'theory' as a codification and generalization of problems of estimation of the theory of tests and confidence intervals already developed by Neyman, often in collaboration with E. Pearson. For clear statements of Wald's view see the last two paragraphs of the introduction to Wald's pivotal paper, Wald (1939), and Sect. 1.7 of his monograph, cited above.

Because of this history the term 'statistical decision theory' can be understood as referring to an important group of specific theorems due to Wald and later extended and refined by others, as discussed below; or it can be understood in a much broader sense as a description of the frequentist outlook inherent in the work of Neyman, Pearson, and Wald, among others.

This article focuses on the former point of view, which is undoubtedly the more widely held interpretation. For a discussion of the latter point of view see Brown (2000).

1. Key Elements

1.1 Basic Concepts

The key elements that set formal decision theory apart from the remainder of statistical theory are the notions of 'loss' and 'risk' and the consequent concepts of 'admissibility' and 'minimaxity.' Consider a statistical problem with a sample space, Ξ and a family of possible distributions, $\{F\colon F \in \Phi\}$. These elements should be part of any carefully specified statistics problem. Often Φ is parametrized so that it can be written as $\Phi = \{F_\theta\colon \theta \in \Theta\}$. Θ is then called the 'parameter space,' problems in which Φ cannot be nicely parametrized by a subset of Euclidean space are often referred to as nonparametric.

In addition, Decision Theory requires specification of a set of possible decisions or actions, Δ, to be taken after observation of the data. Possible types of decisions include estimates of the parameter, hypothesis tests related to subsets of parameters, confidence intervals, or predictions about potential future observations. A 'loss function' describes the loss—or negative advantage—of taking a particular action, $d \in \Delta$, when $F \in \Phi$ is the true distribution. The resulting function can be written as $L(F, d)$, or as $L(\theta, d)$ when the 'states of nature' in Δ have been given a parametric representation. Usually, $L \geqslant 0$. A nonrandomized procedure is a map $\delta\colon \Xi \to \Delta$. (Randomized procedures can also be defined. They are useful for developing parts of the theory, even if they are almost never used in practice.) The 'risk,' R, is the expected loss of δ under F

$$R(F, \delta) = E_F(L(F, \delta(X)) \tag{1}$$

These basic notions lead naturally to a comparison of potential decision procedures that defines δ_1 as 'better than' δ_2 if

$$R(F, \delta_1) \leqslant R(F, \delta_2) \quad \textit{for all } F \in \mathscr{F}, \quad \textit{with strict inequality for some } F \tag{2}$$

The admissible procedures are those that are minimal in the sense of this partial ordering; thus, δ is admissible if there is no other procedure that is better.

1.2 Example: Inference about a Binomial Proportion

Inference about a binomial proportion is an important problem, in terms of both basic theory and statistical practice. We only discuss here the most basic version of this problem. In this the statistician observes the value of a binomial variable reflecting an unknown proportion, p.

One common objective involves estimation of p. (In terms of the preceding formal definitions, $\Xi = \{0, 1, \ldots, n\}$ and $\Delta = \{d\colon 0 \leqslant d \leqslant 1\}$ and $\Phi = \{F_p\colon 0 \leqslant p \leqslant 1\}$ with F_p indicating the binomial distribution with sample size n and proportion p.) For this objective a conventional loss function is squared error loss, defined by $L(p, d) = (d-p)^2$. See Sect. 3.2 for some further discussion of this example.

Another common objective involves testing a null hypothesis about p. The null hypothesis may be, for example, that $p = p_0$ for some fixed, pre-specified value p_0. Then the two possible decisions correspond to the statements 'do not reject H_0' and 'reject H_0.' The conventional loss function here ascribes loss 0 to a correct decision and 1 to an incorrect one. (See *Longitudinal Data*.) A related problem concerns the construction of confidence intervals for p. There is an intimate relation between this and the testing problem. See, for example, Lehmann (1986) or Robert (1994 Chap. 5).

1.3 Example: Estimation of Normal Means

Another important paradigm in both theory and practice involves the estimation of one or more normal means. In the simplest version of this problem the statistician observes the sample mean, $\bar{X}$ of a normal sample. In variants of the problem the standard deviation of the population may either be known or unknown. The first variant is easier to treat mathematically but the second is more common in applications. If the objective is to estimate the unknown population mean, say, μ, then a conventional loss function is squared error loss given by $L(d, \mu) = (d-\mu)^2$, for an estimate d being any real number. Testing and confidence interval problems are also of interest for such a family of distributions.

Many generalizations of this formulation are of practical importance, and their theory has been extensively researched. The most prominent situation includes the normal linear model. This setting includes such common statistical topics as the Analysis of Variance. In Sect. 3.1 of this article we discuss in more detail the situation that arises when one looks at several independent normal means simultaneously.

1.4 Discussion

For some authors, the law of large numbers interpretation of the expectation in (1) has suggested that the statistician contemplates a situation in which the identical experiment will be independently repeated an arbitrarily large number of times. Moreover, for the law of large numbers to apply one needs formally also that the same value of F appears in each of these repetitions. Such an interpretation has been on occasion criticized as impractical, and as invalidating the

premises of decision theory. However this interpretation is not required as a logical basis for the theory. It was also apparently not contemplated in the work of Neyman and Pearson that motivated Wald's development.

One can instead consider a collection of independent experiments, each having its own structure. A statistician who uses a collection of procedures many of which are inadmissible will not fare well in the long run by comparison to a statistician who uses a better procedure for each individual problem. One may find early reflections of this attitude in Clopper and Pearson (1934) or in Neyman and Pearson (1933). (It can be argued further that it would be still better to adopt a coherent collection of admissible procedures in such a situation. See for example, Savage (1972 [1954]), who proposes subjective Bayesian methods as the means toward this end.) (See *Bayesian Statistics*.)

Typically, in applications much care is given to realistic specification of the family of distributions in this formulation. When this cannot be done with satisfactory precision then robust methods are often recommended. Such methods can be placed directly within the above framework by considering a suitably large set for Φ. Huber (1981) has a careful treatment of this nature and proposes an often-used robust procedure with important decision theoretic properties.

The action space, Δ, is also generally subject to careful and realistic specification. The loss function, on the other hand, is not so often specified with the same degree of precision and attention to the practical situation at hand. It is common to adopt certain conventional loss functions, most prominently squared error or normalized squared error in real valued estimation problems or squared Euclidean distance in vector valued ones. In hypothesis testing problems a zero-one loss is similarly conventional and predominantly used. It has sometimes been argued that statisticians should expend more care on realistic specification of the loss or on a robust treatment of families of losses. See Robert (1994, Sect. 2.6) for more discussion of this issue.

2. Classical Themes

2.1 Characterization Theorems

A major objective of classical decision theory is to characterize the admissible procedures, or special subsets of them, in a mathematically tractable fashion. Many of these characterizations involve the notion of a Bayes procedure. Corresponding to any 'prior' probability measure, G, on the parameter space a Bayes procedure can be defined either as a procedure that minimizes the average risk with respect to G or, equivalently, as one that minimizes the conditional risk given the observation, for almost every possible observation.

A basic result in Wald's work, later developed further by others, is that a Bayes procedure is automatically admissible if it is essentially uniquely determined. It is also admissible under mild additional conditions guaranteeing continuity of risks if the prior is supported on the entire parameter set. Wald also proved a fundamental converse result: if the parameter space is finite then every admissible procedure is Bayes. He, and others, also extended this result to classes of settings where the parameter space is bounded. See Robert (1994, Sect. 6.3) for a general discussion of such results.

Here, as elsewhere, Wald acknowledged his debt to earlier work on hypothesis testing by noting that these facts about Bayes procedures could provide an alternate interpretation and an alternate proof for the Neyman–Pearson Lemma, and for various generalizations to multiple classification problems. As Wald also frequently noted, these estimators are Bayes only in a formal mathematical sense in that the decision theoretic motivation for their use is frequentist in nature (via the risk function) rather than fundamentally Bayesian (via the conditional expected loss given the data).

If the parameter space is not compact then one cannot expect that all admissible procedures will be Bayes for some prior. However there are a variety of characterizations in such settings of admissible procedures as types of limits of Bayes procedures. In some cases—usually involving exponential families—these characterizations can be extended to prove that all (or most) admissible procedures can be represented as generalized Bayes procedures. That is to say, they can be represented as formally calculated posterior conditional expectations with respect to non-negative measures that are not necessarily finite.

In some special problems more can be proven. The most notable case is the problem of estimating under squared error loss the mean of a multivariate normal distribution having known covariance matrix. There it is also possible to give an explicit characterization of the generalized priors that correspond to admissible procedures. Such a result relies in part on a method for proving admissibility due to Blyth and developed further by Stein. Lehmann and Casella (1998, Chap. 5) discuss many of these results and provide additional references.

2.2 Minimaxity

Minimaxity is another fundamental decision theoretic property defined and treated in Wald's seminal work. A procedure δ^* is minimax if

$$\sup_{F \in \mathbf{F}} R(F, \delta^*) = \inf_{\delta} \sup_{F \in \mathbf{F}} R(F, \delta).$$

Examination of this formal definition shows that minimaxity is a very cautious, conservative criterion.

Figure 1
Comparative risks for $n = 1{,}000$ of usual and minimax estimators of a binomial proportion. (The constant line is the risk of the minimax estimator)

A minimax procedure is the one that does best *if* the true $F \in \Phi$ turns out to be the worst possible from the statistician's perspective. In some special problems the minimax procedure provides a broadly satisfactory choice for a decision rule. In others it turns out that minimax rules are not admissible, or are not satisfactory because other rules have more appealing risk functions. A simple classical example may make clear how this can happen. Consider the binomial estimation problem described in Sect. 2.2. The 'usual' estimate of p is the sample proportion $\hat{p} = X/n$. It can be shown that this is not minimax under squared error loss. Instead, the minimax estimator has the somewhat more complicated formula $p^* = (X + \sqrt{n}/2)/(n + \sqrt{n})$. The respective risks of these estimators can be plotted. See Fig. 1, which plots these risks for the moderately large value, $n = 1{,}000$. Examination of these plots makes clear that $\hat{p}$ would generally be preferable to p^* in this setting, since its risk is usually smaller and often much smaller. (The exceptions would be situations where the statistician was nearly convinced that p was quite near 0.5.)

Even in cases where the minimax procedure itself may not be satisfactory, comparison with the minimax risk can provide a useful starting point for judging the worth of proposed procedures. The essays in Brown (1994) and Strawderman (2000) comment on the role of minimaxity as a benchmark for evaluating and developing alternate procedures.

2.3 Sequential Decision Theory

At the same time as he was developing statistical decision theory, Wald was also building a theory of sequential decision procedures. Wald (1947), his monograph on the topic, appeared three years before his monograph on statistical decision functions. It can be argued that there is nothing intrinsically decision theoretic in the idea of sequential stopping that is the basis for this theory. However the structure that Wald created was so thoroughly imbued with the spirit of decision theory that it has since usually been viewed as a part of it. Sequential procedures allow the experimenter to conduct the experiment in stages with a decision to stop the experiment or to continue made after each stage. In a decision theoretic version the size of the stopped sample is included as part of the overall loss function.

The most dramatic result of Wald's research here is the optimal property of the Sequential Probability Ratio Test (SPRT) in Wald and Wolfowitz (1948). The proof of this optimality property relies on a representation of the SPRT as a Bayes procedure, and uses much of the decision theoretic machinery elsewhere developed by Wald. The most prominent modern embodiment of this sequential idea undoubtedly lies in the area of sequential clinical trials. Here the spirit of Wald's work remains as an important foundation, even if the subject has mostly gone in more numerical and pragmatic directions. See Siegmund (1994) for a contemporary overview of sequential decision theory and Jennison and Turnbull (1999) for a recent comprehensive treatment of clinical trials. (See also *Sequential Statistical Methods*.)

2.4 Hypothesis Testing

The basic theory of hypothesis testing was largely developed by Fisher and by Neyman and Pearson in the decades before Wald began his codification of decision theory. It can be argued that Fisher's view of testing was not fundamentally decision theoretic. Fisher's formulation requires a specification of the distributions in the null hypothesis and of a test statistic, but it does not require specification of the possible distributions in the alternative. Neyman and Pearson proceeded further to require these to be specified, and this enabled them to study the competing requirements of high power under the alternative and low power under the distributions in the null hypothesis. (This power should be bounded by the significance level, α.) The Neyman–Pearson theory is clearly decision theoretic and, as noted above, can be cast exactly into the mold created by Wald. Subsequent work of Lehmann, Stein and others has more fully developed the theory. Lehmann (1986) contains a definitive high-level treatment of the theory and selected applications.

2.5 Invariance

Statistical invariance is the embodiment of an intuitive demand. The invariance principle applies when the decision theoretic elements of the problem are in-

variant under the action of a group of one-to-one transformations. (Some authors use the term 'equivariant' for parts of this specification.) In that case the principle demands that the decision procedure adopted also be invariant (or equivariant) under the action of this group. Although the principle seems reasonable, and the resulting procedures often have intuitive appeal, it turns out that they need not be admissible. See below for a brief discussion of the Stein phenomenon, a situation where appealing invariant procedures are inadmissible.

There are structural conditions on the group that can guarantee that there do exist invariant procedures that are minimax. The first such theorem of this type is contained in an unpublished manuscript by Hunt and Stein. In the ideal case where there is a best invariant procedure these conditions then guarantee that this best invariant procedure is minimax. See Kiefer (1957) and Brown (1986a) for more information about invariance and the Hunt–Stein theorem. (See *Invariance in Statistics*; *Analysis of Variance and Generalized Linear Models*.)

2.6 Asymptotics

The basic concepts and tools of decision theory have also been carried into the domain of asymptotic statistical theory. Le Cam was the leader in this activity by formulating and developing such concepts as asymptotic sufficiency, contiguity, local asymptotic normality, and local asymptotic minimaxity. In Le Cam (1953) the seminal paper beginning his development, he included a careful treatment of the concept of asymptotic superefficiency, and a proof in parametric problems that it was limited to sets of Lebesgue measure zero. See Le Cam and Yang (2000) for a presentation of many of these topics, and for further references.

3. Contemporary Developments

3.1 Bayesian Decision Theory

Stein (1956) described the inadmissibility of the usual estimator of a three or more dimensional multivariate normal mean. This initially surprising discovery spurred activity in decision theory, changed many statistical attitudes and preconceptions, and continues to influence current statistical methodology. For estimating the vector of means from a multivariate normal sample under squared-error loss the usual procedure, $\bar{\mathbf{X}}$, is intuitive and has various nice theoretical properties, such as those of being best invariant and minimax. It is also the formal Bayes procedure corresponding to the uniform, Lebesgue measure as the formal prior. Note that Lebesgue measure is also Jeffreys prior for this problem, and hence corresponds to a standard 'noninformative' Bayesian prescription. See Jeffreys (1939) or Robert (1994, Sect. 3.4). This usual estimator is surprisingly not admissible when there are three or more normal means involved.

James and Stein (1961) intensified Stein's earlier discovery by describing an estimator that dominates the usual one by a significant amount. Brown (1971) later demonstrated that all admissible procedures in this problem are either Bayes or formal Bayes, and also characterized which of these priors leads to admissible estimators. Strawderman (1971) subsequently used a hierarchical Bayes construction to derive formal Bayes estimators for this problem that are both minimax and admissible. When the dimension is at least 5 then some of these are actually proper Bayes. Efron and Morris (1973) explained how Stein's estimator could be derived via an empirical Bayes approach. A combined effect of these developments is to demonstrate the importance of a careful choice of prior or formal prior for such multivariate problems and to provide some guidelines for the form of such priors. Ensuing research has led in the directions of empirical Bayes methods, of robust Bayes methods, and also of methods involving careful specification of hierarchical priors. The influence of Stein's decision-theoretic discovery on contemporary Bayesian analysis is discussed at length in such monographs as Berger (1985) and Robert (1994, especially Chaps. 6 and 8).

3.2 Unbiased Estimates of Risk

Stein's discovery has also led to other methodological and substantive advances in decision theory. The most important of these undoubtedly revolve around Stein's (1981) unbiased estimate of the risk. For generalizations and other related results see Brown (1986b, Chap. 4). Where it applies, as it does in the preceding multivariate normal problem, the unbiased estimate of the risk provides a powerful tool for finding procedures that dominate previous proposals and for suggesting new, satisfactory estimates.

3.3 Nonparametric Function Estimation

Much current research in nonparametric function estimation involves a synthesis of several aspects of statistical decision theory, including asymptotic decision theory, minimax theory, and results and methods related to the James–Stein phenomenon described above. A typical problem involves the observation of a nonparametric regression. Suppose for example that $\{x_i : i = 1, \ldots, n\}$ is a given subset of predictors, e.g., $x_i = i/n$, and $Y_i \approx N(m(x_i), \sigma^2)$ are independent normal variables with mean $m(x_i)$. The goal is to estimate the unknown function, m, under a loss function such as $\sum_i (\hat{m}(x_i) - m(x_i))^2$. The problem is nonparametric in that minimal assumptions are made about the form of m. For example, one might assume only that these

functions are in a given ball in a Sobolev space or a Besov space. Using a variation of Le Cam's asymptotic decision theory various papers have recently shown that several apparently distinct problems of this character are actually asymptotically isomorphic in a decision-theoretic sense. Consult Johnstone (2000) for references.

As a sort of culmination of much research in this area, Donoho et al. (1990) proved a minimax theorem for linear estimators in such a problem. These results, and later extensions, relate the minimax risk under a restriction to linear procedures to the usual, unrestricted minimax risk for the problem. In turn, this result can be used to describe the asymptotic behavior of the unrestricted minimax value. One consequence is a determination of the minimax asymptotic rate of convergence for the risk of estimators in this problem. Imbedded in the proofs is also a practical methodology, essentially due to earlier work of Ibragimov and Hasminskii, for deriving the minimax linear procedure.

3.4 Adaptive Estimation

A new variation of the minimax concept has come forward here in order to try to overcome the inherently conservative and global nature of minimaxity. This is the notion of adaptive minimaxity. Adaptive minimaxity is defined relative to a collection, X, of subsets of the possible distributions, Φ. A procedure is adaptively minimax to within a factor K if

$$\sup_{C \in \mathrm{F}} \frac{\sup_{F \in C} R(F, \delta^*)}{\inf_{\delta} \sup_{F \in C} R(F, \delta)} \leqslant K. \tag{3}$$

Procedures built from wavelet bases have been shown by Donoho, Johnstone and others to possess desirable asymptotic adaptive minimax properties. It should also be noted that both James–Stein estimation and Stein's unbiased estimate of risk play a key role here, and in further refinements in this area. Johnstone (2000) discusses many of these issues and provides additional references. Donoho and Johnstone have also developed a new form of decision-theoretic tool, the 'oracle inequality,' that has been instrumental in papers written in the early twenty-first century such as these.

Declarative Memory, Neural Basis of

Memory is a broad topic that has its roots in both biology and psychology. Many important aspects of the problem of memory involve systems-level questions that must be addressed at a relatively global, neuropsychological level of analysis. Two long-standing and inter-related questions have been of central interest since the 1960s. The first is whether there is more than one kind of memory. The second concerns what brain structures and pathways are involved in memory. Scientific work on these issues has introduced the term declarative memory to neuroscience and identified a number of parallels between the neural organization of memory in humans and animals.

It has turned out that the brain is organized such that memory is a distinct and separate cognitive function, which can be studied in isolation from perception and other intellectual abilities. Significant information about how memory is organized has come from two experimental approaches. First, the study of patients with memory disorders (amnesia) has been enormously useful. Second, information about the anatomy of memory has come mainly from the kind of systematic and cumulative work that is possible only in experimental animals.

Figure 1
Schematic view of the medial temporal lobe memory system. The perirhinal and parahippocampal cortices receive projections from unimodal and polymodal areas in the frontal, temporal, and parietal lobes. In turn, the perirhinal and parahippocampal cortices account for nearly two-thirds of the cortical input to the entorhinal cortex, the primary source of cortical input to the hippocampal region (i.e., the cell fields of the hippocampus proper, the dentate gyrus, and the subicular complex). The hippocampal region together with the entorhinal cortex make up the hippocampal formation. The entorhinal cortex also receives other direct inputs from orbital frontal cortex, cingulate cortex, insular cortex, and superior temporal gyrus. All these projections are reciprocal

1. Amnesia and the Medial Temporal Lobe Memory System

Amnesia refers to difficulty in learning new information or in remembering the past. Amnesia can occur as a strikingly circumscribed memory impairment in the absence of other cognitive deficits (Scoville and Milner 1957). Patients with this disorder can have intact intelligence test scores, intact language and social skills, and an intact memory for a great deal of information from the remote past, especially childhood. In addition, immediate memory is intact. Indeed, patients can hold information in mind for several minutes, provided there is no distraction and the material can be rehearsed. Their intact immediate memory explains why amnesic patients can carry on a conversation and can appear quite normal to casual observation. The difficulty for individuals with amnesia arises when information must be recalled after a distraction-filled interval, or when recall is attempted directly after the presentation of an amount of information that exceeds immediate memory capacity (e.g., a list of eight or more items). In this situation, normal individuals will usually recall more items than amnesic patients.

An animal model of human amnesia was established in the monkey in the early 1980s (Mishkin 1982, Squire and Zola-Morgan 1983). Systematic and cumulative work during the next 10 years, using the animal model, succeeded in identifying the system of structures in the medial temporal lobe essential for memory (Squire and Zola-Morgan 1991) (Fig. 1). This system includes the hippocampal region (i.e., the hippocampus proper, the dentate gyrus, the subicular complex), the entor-

hinal cortex, and the adjacent perirhinal and parahippocampal cortices. A number of studies in monkeys have been carried out, comparing performance on memory tasks for monkeys with damage to different components of the medial temporal lobe. This work has shown that the severity of memory impairment depends on the locus and extent of damage within the medial temporal lobe memory system. Damage limited to the hippocampal region causes significant memory impairment, but damage to the adjacent cortex increases the severity of memory impairment. It is important to note that the discovery that larger medial temporal lobe lesions produce more severe amnesia than smaller lesions is compatible with the idea that structures within the medial temporal lobe might make qualitatively different contributions to memory function. This is because anatomical projections carrying information from different parts of the neocortex enter the medial temporal lobe memory system at different points (Suzuki and Amaral 1994).

Another important brain area for memory is the diencephalon, However, the critical regions in the diencephalon that when damaged produce amnesia have not at the time of writing been identified with certainty. The important structures appear to include the mediodorsal thalamic nucleus, the anterior nucleus, the internal medullary lamina, the mammillothalamic tract, and the mammillary nuclei. Because diencephalic amnesia resembles medial temporal lobe amnesia in many ways, these two regions together probably form an anatomically linked, functional system.

At about the same time that an animal model of amnesia was established, detailed case studies of human amnesia provided extensive neuropsychological information about memory impairment, as well as detailed neuropathological information about the locus and extent of damage in each patient's brain. New techniques for imaging brains have also made it possible to detect some kinds of neuropathology in living patients. The available neuroanatomical information from humans is consistent with the findings from monkeys. These lines of work have greatly clarified the description of memory impairment and its anatomical basis, and have made it possible to pursue parallel work in simpler animals such as rats and mice. As a result, one can now study memory in rodents and have some confidence that what one learns can be relevant to the human condition.

2. Declarative Memory

An important finding of neuropsychological studies of memory is that memory is not a single entity but is composed of several separate systems (Squire 1992, Schacter and Tulving 1994). Figure 2 illustrates how long-term memory can be divided into several parallel memory systems. The major distinction is between conscious knowledge of facts and events, referred to as declarative or explicit memory, and other nonconscious knowledge systems that provide for the capacity of skill learning, habit formation, the phenomenon of priming, and certain other ways of interacting with the world, collectively referred to as nondeclarative or implicit memory. Nondeclarative memory is not itself a brain-systems construct. Rather, this term encompasses several different kinds of memory. Nondeclarative forms of memory have in common the feature that memory is nonconscious. Memory is expressed through performance and does not require reflection on the past or even the knowledge that memory is being influenced by past events.

Declarative memory (explicit memory, relational memory) is a brain-systems construct, referring to the capacity for conscious recollections about facts and events that is dependent on the integrity of the hippocampus and anatomically related structures in the medial temporal lobe and diencephalon. It seems to be especially good at associating the various aspects of a context that are present at a particular time and place, thereby creating a memory of an episode. Declarative memory is also well suited for connecting the pieces of information needed to acquire a new fact (e.g., the capital of North Dakota is Bismarck). It is sometimes pointed out that declarative memory allows one to model the external world, and it is either true or false; nondeclarative memory is about performance, and it is neither true nor false.

Declarative memory is the kind of memory impaired in amnesia. However, the concept of declarative memory is not defined solely in terms of what amnesic patients can and cannot learn. Other characteristics of declarative memory have also been identified. For example, work with amnesic patients has emphasized the notion of conscious recollection, though this description is unhelpful when considering learning and memory in animals. Other characteristics have emerged from the studies of experimental animals. Declarative memory is fast, it is not always reliable (i.e., forgetting and retrieval failure can occur), and it is flexible in the sense that it is accessible to multiple response systems. It is especially suited for one-trial learning, and forming and maintaining an association between two arbitrarily different pieces of material.

2.1 Recognition Memory

A particularly good example of declarative memory involves the capacity to identify a recently encountered item as familiar, a capacity termed recognition memory. Recognition memory is impaired in amnesic patients, and it is impaired in monkeys and rats following damage to the hippocampal region. In the monkey, the assessment of recognition memory has

Figure 2
A taxonomy of long-term memory systems together with specific brain structures especially important for each system (reprinted, with permission, from Squire and Knowlton 1994)

depended mainly on two tasks. In delayed nonmatching to sample, two objects are presented, a new one and one that was presented earlier. The monkey must choose the new object. In the visual paired-comparison task, as adapted for the monkey, a new picture and a recently presented picture are presented side by side, and the monkey's spontaneous tendency to look at the new picture is measured. When the monkey shows a preference for viewing the new object, the monkey is demonstrating that it remembers the old object.

At the time of writing (2000), a total of six studies from different laboratories have been carried out on the effects of lesions of the hippocampal region on memory in monkeys. The lesions were made by an ischemic procedure, by radiofrequency, or ibotenic acid. Postmortem neurohistological analysis of the lesions is available in all six studies. Five of the studies have found impaired recognition memory. The sixth study, which differed from the others in potentially important ways, found no impairment (see Zola et al. 2000 for a review of these studies).

The evidence that the hippocampal region is essential for normal recognition memory is entirely consistent with current ideas about the role of the hippocampus in declarative memory and with the view that the hippocampus is essential for acquiring information about relationships, combinations, and conjunctions among and between stimuli (Eichenbaum 1997). The recognition test asks whether an item that had been presented recently now appears familiar. A recognition (or familiarity) decision requires that the stimulus presented in the retention test be identified as what was presented during learning. At the time of learning a link must therefore be made between the to-be-remembered stimulus and its context or between the stimulus and the animal's interaction with it. It is this associating and the ability to retain relational information across time that many have supposed is at the heart of declarative memory and in turn is the function of the hippocampal region in both humans and nonhuman animals.

2.2 *Episodic and Semantic Memory*

Episodic memory refers to the capacity for recollecting an autobiographical memory of events that occurred in a particular spatial and temporal context. Semantic memory refers to the capacity for recollecting general knowledge and facts about the world. Both types of memory are declarative in the sense that subjects are retrieving information explicitly, and they are aware that stored information is being retrieved. There is good agreement that episodic memory is impaired in amnesia following damage to the medial temporal lobe memory system. However, there is less agreement about semantic memory and its relationship to the memory system. By some accounts, amnesic patients are proportionately impaired in both episodic and semantic memory. By other accounts, the capacity for semantic memory is spared, or partially spared in amnesia relative to episodic memory ability, especially if the damage is limited to the hippocampal region.

Evidence for the second view comes especially from two kinds of data. First, there has been interest in cases where amnesia occurred in early childhood, before much of an individual's semantic knowledge has been acquired (Vargha-Khadem et al. 1997). Second, there have been studies of amnesic patients where the ability to accomplish fact learning and event learning has been directly compared. Taken together, the data tend to favor the view that episodic and semantic memory are similarly impaired in amnesia (Squire and Zola 1998). Other work suggests that episodic memory

additionally depends on the frontal lobes, which provide a source of autobiographical involvement with the recollected material. This orientation allows for a fundamental distinction between episodic and semantic memory, but without depending on differences in how the two kinds of memory depend on medial temporal lobe structures.

3. Overview

Work with amnesic patients and experimental animals has converged to characterize the organization of declarative memory. Declarative memory depends on the integrity of the medial temporal lobe, which works in concert with the neocortex. Declarative memory may develop gradually from early in life. Human infants six months of age successfully perform the visual paired-comparison task, and performance on this task is impaired by hippocampal lesions in humans and monkeys. The view that some declarative memory is available early in life is also consistent with demonstrations of long-term, recall-like memory abilities in human infants.

Other work with amnesic patients has suggested that declarative memory is equivalently involved in the two fundamental processes of recall and recognition. Work in humans and animals has shown that the medial temporal lobe memory system is required at the time of learning if an enduring and retrievable long-term declarative memory is to be established. Studies of retrograde amnesia in amnesic patients and in experimental animals suggest that the brain system supporting declarative memory has a time-limited function. Medial temporal lobe lesions spare very remote memories. Thus, as time passes after learning, a process of consolidation and reorganization occurs such that permanent storage does not require the medial temporal lobe. Permanent memory is thought to be stored in the neocortex where information is received and processed. Information is still accumulating about how memory is organized, what structures and connections are involved, and what functions they support. The disciplines of both psychology and neuroscience continue to contribute to this enterprise.

Deconstruction: Cultural Concerns

Deconstruction is a mode of philosophical and literary analysis, derived from the work of the French philosopher Jacques Derrida, which questions the most basic philosophical categories or concepts. In the 1970s the term was applied to analyses, by Derrida and others, of philosophical and literary writings. In the 1980s it came to designate more loosely a range of radical theoretical enterprises in diverse areas of the humanities and social sciences, including law, psychoanalysis, architecture, theology, feminism, gay and lesbian studies, political theory, historiography, and film theory. What these enterprises shared was a critical dismantling of the conceptual oppositions that had previously been regarded as fundamental to the

disciplines in question. In popular usage (e.g., Woody Allen's film *Deconstructing Harry*), the term has come to designate a critical dismantling or undoing; and in polemics about late twentieth-century thought, deconstruction is sometimes used as a pejorative synonym for 'poststructuralism' or 'postmodernism'—one which suggests nihilism or frivolous skepticism.

1. Deconstruction and Philosophy

Deconstruction undertakes a radical critique of fundamental categories of Western thought by exploring how these categories have been constructed in and by the discourses that rely on them. It is a mode of analysis that examines not only the arguments of philosophical texts but also the rhetorical procedures and devices they employ and the tensions or contradictions between what is claimed or assumed and what the texts themselves must do in order to support such claims. A major focus of deconstruction has been the traditional binary oppositions that have structured Western thought since the time of the Greeks: for example, the oppositions between inside and outside, mind and body, literal and metaphorical, speech and writing, presence and absence, nature and culture, intelligible and sensible, form and meaning. Each of these oppositions is hierarchical, in the sense that one of its terms has been taken to be primary and fundamental, and the other secondary and derivative (Derrida 1981). Thus, nature is logically prior to culture; writing is seen as merely a way of representing speech, which is taken to be the basic form of language; meaning is what comes first and is then given expression by form.

A deconstruction of these oppositions asks how the philosophical enterprise and thought in general have relied upon the privileging of one term and invites us to consider whether in fact such hierarchies should not be revised. In particular, a deconstruction questions these hierarchical oppositions by showing how they have been constructed and, in the process, undoing that construction and establishing a new relation between the terms. It can be shown, for example, that the idea of 'nature' is a product of culture: conceiving something as prior to culture is a specific cultural operation whose import and function needs to be assessed. In the opposition between nature and culture, the primacy of nature cannot, therefore, be taken for granted. What we have, rather, is an opposition elaborated within culture; what counts as nature in any historical moment will be a fact about that culture. To argue in this way is to invert and restructure the opposition (to 'displace' it) in a way characteristic of deconstruction. Instead of a primary nature and a secondary culture, we discover a variable distinction between nature and culture within culture.

For Derrida, the most telling and pervasive opposition has been the one that treats writing as secondary or derivative with respect to speech. According to this opposition, in speech the ideas and intentions of the speaker are immediately present; it is a direct and authentic form of language, whereas writing is merely a graphic representation of the spoken word (a sign of a sign) and hence marked by absence and possibilities of discrepancies between form and meaning. (Derrida 1976). By setting aside writing as a secondary and derivative, a mere representation open to misunderstanding, accounts of language have taken as their object an idealized form of speech, where the linguistic form is a direct expression of what the speaker, as we say, 'has in mind.' But Derrida argues that linguistic forms can function as signs only to the extent that they can be repeated in different contexts, in the absence of any particular speaker's presence or intention (Derrida 1988). Speech is only possible, in other words, to the extent that it has the qualities assigned to writing, such as absence, difference, and the possibility of misunderstanding. One mark of this, Derrida has shown, is the frequent recourse, in attempts to describe speech, of examples and metaphors drawn from writing. In effect, speech has been described as a form of writing, even when the claim has been that writing is derivative from speech (Derrida 1976). This deconstruction of the traditional hierarchical opposition between speech and writing argues not that there are no differences between speech and writing but that the traditional opposition is untenable and that both speech and writing are forms of a general writing (*archi-écriture*), which is the condition of possibility for any system of representation whatsoever.

Derrida argues that treating writing as secondary to speech is part of what he calls the 'logocentrism' of Western culture: the presumption of an order of truth or thought prior to its representation by signs (Derrida 1976). Logocentrism tries to treat representation as inessential rather inextricably involved in the structure of phenomena, but an attentive reading of the texts of the philosophical tradition shows that they tell a different story. Derrida's work attempts to demonstrate that discourses that treat writing as secondary in fact must make use of notions linked to writing when they characterize speech and that thus speech can be seen as a version of a generalized writing, which is the condition of language and thought in general. This is an instance of the deconstruction of concepts seen as fundamental, such as 'presence,' 'truth,' 'origin,' and 'identity.'

Deconstruction may be conceived in the first instance as a critique of Western philosophy. Philosophy, Derrida argues, has been founded on a theory of 'presence,' in which such notions as truth, being, and reality are determined in relation to an ontological center, essence, or origin, based on the repression of absence and difference. But since deconstruction works not by erecting an alternative theory but by exploring how philosophical discourses have produced their concepts through rhetorical stratagems, decon-

struction was welcomed by some students and teachers of literature as a powerful practice of reading which would illuminate how texts—whether philosophical or literary—implicitly put in question what they explicitly maintain or what they appear to assume. Barbara Johnson, a leading US practitioner, calls deconstruction 'a careful teasing out of warring forces of signification within a text' (Johnson 1980, p.5).

2. *Deconstruction and Literary Studies*

In the 1970s and 1980s deconstruction played a major role in the animation and transformation of literary studies by what was called simply 'theory,' for short. Briefly stated, 'theory' is concerned with questions about the nature of language, the production of meaning, or the relations between literature and the numerous discourses that structure human experience and its histories. In the USA, deconstruction was associated in particular with a group of scholars at Yale University, where Derrida taught regularly as a visiting professor. In the hands of Paul de Man, J. Hillis Miller, and Barbara Johnson, for instance, deconstruction became a powerful practice of rhetorical reading, attentive to what is at stake in texts of all sorts and to how texts engage those stakes.

Deconstructive literary criticism was often compared, especially by its critics, to an earlier Anglo-American New Criticism, which sought to explicate and appreciate verbal works of art as complex constructions and emphasized the role of paradox and irony in these complex artifacts. However, deconstructive readings, by critics such as those mentioned above, differ in several ways (Culler 1982). They treat works of art not as the harmonious fusion of form and content but as instances of the intractable conflicts between modes of meaning. They generally examine the individual work not as a self-contained artifact but a product of relations with other texts or discourses, literary and nonliterary. Finally, they are especially interested in the ways in which the works may offer implicit critiques of the categories critics use to analyze them.

3. *Deconstruction Beyond Philosophy and Literature*

Critics of deconstruction have tended to attack it either as obscurantist wordplay, excessively invested in supposedly minor or marginal rhetorical features of texts and cast in language that obfuscates rather than illuminates, or as a nihilistic denial of authority, certainty, and foundations, for which 'anything goes' (Ellis 1989). But despite attacks, the impact of deconstruction on modern thought, not just literary studies, has been extensive. Most generally, it has encouraged the questioning of the hierarchical oppositions that structure any field of inquiry and an interest in whether and how these fundamental oppositions are subverted by the phenomena that they are used to describe. Deconstruction is thus a powerful version of the general critique of supposedly scientific metalanguages—sets of terms or concepts used to analyze a domain and which are regarded as external to the phenomena they purport to analyze. Deconstructive analyses explore the ways in which the supposedly neutral or purportedly scientific metalanguage is deeply affected by the phenomena it is supposed to analyze. Thus, it might show, for instance, that the terms deployed by theory of metaphor or figurative language generally are themselves scarcely free of metaphor or explore how a psychoanalytic theory is itself affected by the mechanisms of repression and wish-fulfillment it purports to analyze. Since within literary and cultural studies it was above all structuralism (see *Structuralism*) which sought to elaborate metalanguages for analyzing cultural phenomena as a series of languages or signifying systems, the deconstructive critique of the possibility of a neutral metalanguage was seen as a step beyond structuralism and hence as a case of 'poststructuralism.'

There are two main aspects to the influence of deconstruction outside of literary and philosophical studies. On the one hand, granting primacy not to what a text 'says' but, rather, to how what it 'does' relates to what it says, deconstruction emphasizes that rhetorical structures are centrally at work in language of all sorts and that discourse has an important 'performative' dimension, structuring experience in particular ways. It thus seconds and invigorates the constructivist tendencies of numerous disciplines: the attempt to show how that the phenomena studied by a discipline are not simply given to experience but are produced by conceptual frameworks and discursive practices. On the other hand, as a critical exploration of fundamental oppositions and an attempt to intervene and alter the value attributed to particular terms, deconstructive thinking has affected not just how texts are read but the sense of what a discipline's goal might be. In psychoanalysis, for instance, deconstructive readings of texts by Sigmund Freud and such successors as Jacques Lacan, have done several things:

(a) focused on the structuring role of language in the formation of the psyche;

(b) shown how psychoanalytic case studies are themselves structured by the kinds of psychic mechanisms that they purport to analyze (so Freud's or Lacan's writings are themselves organized by the processes of repression, condensation, and displacement that they theorize); and

(c) questioned the complicity of psychoanalysis with a logocentrism which believes in originary principles or an ultimate reality (Derrida 1987).

Deconstructive thinking in psychoanalysis may seek not the origin of a trauma but the stakes of a belief in origin.

Some strands of feminist thinking espouse a deconstruction of the opposition between men and women and a critique of essentialist notions of identity. Judith Butler's (1990) *Gender Trouble: Feminism and the Subversion of Identity*, for instance, not only challenges the claim that a feminist politics requires an identity for woman (for Butler, identity is the product or result rather than the source of action); it develops a 'performative' concept of gender and sexual identity, modeled on the way in which linguistic acts (such as promising) work to bring into being the entities (the promise) to which they refer. This perspective has been influential in the realm of gay and lesbian studies or 'queer theory,' as the academic avant-garde linked to movements of gay liberation has styled itself.

In the field of law there has been considerable deconstructive analysis within the movement known as 'critical legal studies,' which has focused on conflicts between principles and counterprinciples within the system of legal doctrine. There are critiques of the oppositions such as public vs. private, essence vs. accident, substance vs. form, which are fundamental to the realm of law, and demonstrations that legal doctrine and argument are attempts to paper over contradictions which nonetheless reassert themselves (Kelman 1987). Attacks on critical legal studies, like attacks on deconstruction in philosophy, often accuse it of undermining confidence in a system without offering an alternative model.

Finally, the impact of deconstruction has spread beyond the humanities and social sciences to the field of architecture, where deconstructive architecture has come to mean design that flaunts, often in a parodic way, the elements from which it is constructed.

In its diffusion in the humanities and social sciences, following its greatest moment of fame in the 1970s and 1980s, deconstruction in the broadest sense has become a critique of categories taken as natural and a drive to pursue the analysis of the logic of signification in a given area as far as one can, even if the result is disquieting—an exacerbation of questions or problems rather than their resolution. It has thus joined with other strands of postmodern and post-structuralist thinking to inspire suspicion of established categories and canons and skepticism about objectivity. Although opponents of deconstruction have often sought to link its critique of established values to an amoral nihilism, as a critique scientistic pretensions in the humanities and social sciences (among other things) deconstruction has included a strong element of ethical reflection, particularly about the conditions of possibility of ethics or justice (Critchley 1992, Cornell et al. 1992).

Deductive Reasoning Systems

Reasoning is one of the fundamental capabilities associated with intelligence as manifested in humans. It is a mental activity by which we generate (propositional) knowledge not available prior to the act of generation. Experience shows that knowledge generated by reasoning on the basis of already available knowledge enables humans

(a) to predict states of the world not experienced before and to act accordingly; and

(b) to explain phenomena experienced in the world so that we can understand the reasons why they happened, and make them happen again if they are desirable, or otherwise avoid them in the future.

The combination of prediction and explanation is a fundamental and characteristic ingredient of the human way of life, which demonstrates the importance of reasoning.

Experience also shows that humans have a sense for the correctness of reasoning chains. In other words, we are not predicting arbitrary knowledge nor giving arbitrary explanations. Rather, there is an experienced correlation between the correctness of reasoning and its usefulness for predictions and explanations in the

real world. On the other hand, humans are prone to mistakes in their reasoning. In coping with this and other weaknesses lies the motivation for the mechanization of reasoning in the form of *reasoning systems*.

This article describes the technical basis for reasoning systems, points out a number of issues of particular importance for the design of such systems, and briefly surveys their numerous applications.

1. Abstractions

In order to model the complex phenomena involved in reasoning various abstractions are needed, which are now discussed.

1.1 Formal Languages

Humans express their knowledge in natural language which, however, is too complex to be useful as a starting point for the mechanization of reasoning. A first important abstraction is therefore the representation of human knowledge in some formal language. It should be rich enough to be able to express all of our (propositional) knowledge, but simple enough to be useful for the manipulations needed in modeling reasoning, and concise enough to avoid ambiguities and redundancies. There are a number of formal languages meeting these criteria. They differ in the level of abstraction taken for the representation of knowledge, and in the comparative emphasis given to the various concepts involved.

The language of *propositional logic* takes the highest level of abstraction by formalizing knowledge at the level of entire propositions. The language of *first-order logic* is less abstract and much more expressive. It is probably the most popular formal language for knowledge representation, especially in the context of reasoning systems. Many knowledge representation formalisms (like the one used in Aristotelean syllogisms, semantic nets, description languages, etc.) are first-order formalisms in disguise, but lay the emphasis, for instance, on the concept of sets (as in the Aristotelean language) rather than on the functional (or Fregean) relationships among objects emphasized in first-order logic. Modal, transitional, and higher-order languages including the lambda calculus extend the expressiveness of first-order languages even further. For the purpose of this article, we restrict our discussion to the case of first-order logic. Most of our considerations generalize in some way to the other, more general, languages.

1.2 The Inferential Relationship

Reasoning takes place with a given body of knowledge, say K, already available. In the predictive mode of reasoning we want to determine what facts, say P, could be true in the future. Correct reasoning distinguishes between facts possible on the basis of K, and those which are impossible. In other words, there is a relation which associates K and P in the positive case. Following Frege, this relation is formally denoted by $\models$. That is, $K \models P$ is short for expressing that P is a correct reasoning prediction on the basis of K. In the *predictive mode* of reasoning we thus want to determine P such that $K \models P$ holds, or test for a given P whether it holds.

Human reasoning is mostly done in time, and to a significant extent also concerns knowledge about actions and changes taking place in time. On the other hand, a large part of the inferential relation $\models$ is, so to speak, 'timeless.' To simplify further, most logical studies have abstracted from the issues concerning time and change. Only in the last few decades of the twentieth century did those issues become of great interest within Intellectics, the field covering both Artificial Intelligence and Cognitive Science. The result of those recent studies is that the timeless part of $\models$ is already expressive enough to model also the part involving time, and thus the entire relation $\models$. Insofar this abstraction from time is without restriction of generality. Under this abstraction, the predictive mode of reasoning is called the *deductive mode* of reasoning. Because of what was stated above, deductive reasoning at the surface is timeless reasoning, but may as well be regarded as predictive reasoning in general.

In the explanatory mode of reasoning based on K, we start with some observation O and basically look for some explanation E so that $K, E \models O$. This mode of reasoning is called abductive or inductive depending on the circumstances concerning O and E. Since $\models$ is a relation, the difference with deductive reasoning is minor; instead of the second argument here just (part of) the first one is to be determined. The relationship is even closer. In inductive reasoning we employ additional meta-knowledge, say M, which guides the process of generalizing from given observations. Taking this into account, inductive reasoning actually boils down exactly to deductive reasoning, namely in the form $K, M, O \models E$.

In summary, all prevailing modes of human reasoning may actually be regarded as deductive reasoning. This explains why deductive reasoning systems have such a great importance for modeling inference in all its generality.

1.3 Syntactic Inference

The fundamental observation already made more than 2000 years ago by Aristotle and his predecessors is that reasoning (for the most part) is a matter of form rather than of content. This became apparent once knowledge was represented in a *form*alized way. The knowledge 'apes are mammals'—in the sense of 'whenever the property of being an ape holds then also the mammal property holds,' or $A \rightarrow M$, and 'mammals

have hair,' $M \rightarrow H$, allows us to conclude that 'apes have hair,' $A \rightarrow H$. The inference is valid independently of the meaning of the words apes, mammals, and hair, or of the symbols A, M, H, for that matter. Rather, it is exclusively the form of the knowledge which sanctions the validity of such an inference. This fundamental property of reasoning enables machines, which are ignorant of the meaning of words or symbols, to perform correct inferences.

The example demonstrates a fundamental rule of inference: $A \rightarrow M$ and $M \rightarrow H$ implies $A \rightarrow H$. It is called (a restricted form of) resolution or (a slightly generalized form of) *modus ponens*. As we see, it produces new knowledge by eliminating the intermediate atom M; the rule may also be seen as implementing a form of transitive closure.

In order to program computers to search for chains of inferences we first need rules of inference such as the one just discussed, in addition to the formal languages mentioned earlier. The combination of a formal language, along with a set of rules is called a (formal or logical) calculus. If F is some formula i.e., a propositional expression in the formal language under consideration, viz. first-order logic according to our convention, and G is a formula obtained from F by application of the rules of the calculus, then we write $F \vdash G$. Since $\vdash$ is dependent on the calculus c—which, as in the case of formal languages, can be chosen from a great variety of alternatives—we should rather write $\vdash_c$, but omit the index whenever the calculus is clear from the context. We want to design calculi in such a way that $F \vdash G$ holds if, and only if, (iff) $F \models G$, in which case we speak of *correct* (if) and *complete* (only if) calculi. From now on we assume that the rules are chosen such that the resulting calculi are always correct and complete.

We go one step further in the abstraction process described in this entire section. According to the well-known deduction theorem, it holds that $F \vdash G$ iff $\vdash F \rightarrow G$. By applying this theorem iteratively we can always achieve that there are no formulas to the left of $\vdash$. Most deductive systems in use are therefore systems which test whether, for some given calculus and some given formula F, it holds that $\vdash F$ (affirmative proof), or dually, that $\vdash \neg F \equiv \mathit{false}$ (proof by contradiction).

The field in which such systems are developed, studied and applied is called automated deduction (AD). It has applications in any field where reasoning of any kind is relevant, which actually is most of science. AD's first application was to Mathematics, for which historical reason the field is also known as automated theorem proving (ATP).

2. *Issues in AD*

Deductive systems have been developed for numerous different calculi with different formal languages and different rule sets. A very popular language is a version of first-order logic, called *clausal logic*. It uses sets of clauses like the three clauses in our apes example (which actually form four clauses, since presenting the set in the form $\neg F$ logically splits the last clause into the assumption $\rightarrow A$ with an empty premise and the denial of the conclusion, i.e., $\neg H$ or, equivalently, $H \rightarrow$ with an empty conclusion). In general, a clause may contain a conjunction of atoms in the premise and a disjunction of atoms in the conclusion. A correct and complete calculus based on clause sets is given by (essentially) the single rule of resolution in its general form. Resolution allows the elimination of intermediate literals even if they are not exactly identical but can be made identical by replacing variables in the atoms by functional terms, a process known as unification.

A deductive system based on resolution works as a saturation process. It takes the given clause set, and iteratively applies resolution until the so-called empty clause $\rightarrow$ (no premise, no conclusion, representing *false*) is obtained which forms the criterion for the validity of the inference represented by the input. The advantage of this type of system is the simplicity of the data-structures involved (clause sets) and the operations performed at each iteration (resolution). The problem is that, without additional constraints, the system produces relevant and irrelevant intermediate results alike, and for hard problems is often drowned in up to billions of generated clauses. An irrelevant intermediate result in our earlier example might be that 'apes have eyes,' on the basis of the additional knowledge that 'mammals have eyes,' when our only interest is in the question about hair. Strategies (like the so-called set-of-support strategy) to some extent help to reduce the amount of irrelevant clauses generated.

Alternatives to this saturation-based approach are the goal-oriented tableaux-based deductive systems. Human proofs, i.e., chains of inferences, may be regarded as tree-like structures, or (closed) tableaux, which in each branch start out from an obviously valid fact. The basic data-structure of tableaux-based systems is a (not necessarily closed) tableau. Starting with the tableau consisting of the (denial of the) given formula, the tableau is extended at each iteration with the goal of closing it. The data-structure (tableau) and the operations (extension of tableau) are more complicated than those in the saturation-based systems, which complicates the system development. But the approach allows a more goal-oriented fine-tuning of the search for the final proof and therefore is able to avoid some of the redundancy involved in resolution systems. At the time of writing, both approaches have reached about the same performance levels.

Systems based on the connection method may be regarded as a compactly coded form of tableaux systems. In this method, all information coded by a tableau is attached to the parts of the given formula in an extremely condensed form as structural information. Starting with an initial structure of this kind, only

the structure is modified at each iteration until a certain final structure is reached signaling validity of the formula; the latter itself is not changed at all in the process.

Research in AD pursues all three kinds of approach, with the focus in each case being on eliminating redundancy. This can be achieved in various ways. One way consists in refined calculi in terms of the rule sets used. For instance, the application of resolution may be restricted in many ways without sacrificing completeness (e.g., linear resolution). Another way to reduce redundancy consists in applying various strategies which guide the rule application. A third consists in performing several small steps as a single global step (e.g., hyperresolution) which again narrows the search space. A fourth involves global steps sanctioned by theories involved (such as equality theory). Finally, ever-improved software engineering techniques and faster machines contribute to a continuous enhancement of system performance.

3. *Applications and References*

Mathematics is a primary field of application for AD. Deductive systems have been applied to virtually all subdisciplines in Mathematics, and tens of thousands of theorems have been proved automatically. New proofs have been found automatically for known theorems as well as for conjectures never proved before by any human. For instance, a system called Otter/EQP in 1996 settled an important mathematical problem which had been open for sixty years.

AD techniques are further used in programming. For instance, the programming language PROLOG basically works as a deductive system. Systems which synthesize programs from descriptive specifications, like the system KIDS, involve strong deductive components. Another important application of AD techniques to programming consists in the verification of software or hardware. Entire chips as well as compilers have been proved correct this way.

AD techniques have spread out into all fields of science by way of so-called knowledge-based systems which encode knowledge of specific disciplines and allow the manipulation of such knowledge in a deductive way. In the CYC system, an entire encyclopedia of knowledge is encoded in this way.

Bibel (1993) is a special textbook on all aspects of deductive methods and systems. Bibel and Schmitt (1998) is a reader covering all modern deductive techniques, a number of very successful systems, and several important applications. Gabbay et al. (1991) is a handbook which includes deductive reasoning systems and other topics. Robinson and Voronkov (2000) is a handbook covering only deductive methods, techniques and systems. Ongoing research is reported in the *Journal of Automated Reasoning* (Kluwer Academic Publishers) and in the proceedings volumes (published by Springer Verlag) of the International Conferences on Automated Deduction, as well as in other journals and conferences.

Defense, Economics of

This entry treats the nature of defense economics in applying economics to warfare. It first discusses the role of the state in providing the resources to wage war. Second, it presents the Richardson model of arms races. Third, it considers how nuclear proliferation affects the probability of nuclear war. Fourth, it treats the economics of guerrilla warfare. Finally, it reflects on the changing nature of warfare in the twenty-first century.

1. *The Political Economy of War*

Logistics has long been important to warfare. As railroads became more important in the latter part of the nineteenth century, moving men and materials became more complicated and it became necessary to create schools to train officers to formulate and to implement elaborate plans that depended on railroads. These plans may have reached their most refined level in the mobilization plans of the French, German, and Russian armies prior to World War I. These plans were so delicate that any delay in implementation would lead to defeat since the first army to complete its

mobilization was expected to have a decisive advantage. These plans and the strategic environment they created are an example of what later became known as 'crisis instability' during the Cold War. Many historians believe that this requirement to mobilize without delay led to a war that could have been avoided. The plans and the strategic environment they created exemplify a case where maximizing behavior on the part of agents and technology can lead to unexpected or undesirable consequences. In the 1970s and 1980s such cases became a matter of concern among economists working on defense issues.

It can be argued that waging war is one of the more important reasons why states exist. The preamble of the United States Constitution states this explicitly: 'We the people of the United States in order to form a more perfect Union, establish justice, insure domestic tranquility, *provide for the common defense* … do ordain and establish this Constitution for the United States.' (Emphasis added)

Historically, an important function of the state has been to provide the resources to wage war and this became an important issue in political economy. The organization of the state reflects, in part, its need to raise resources for military purposes. A very good example of such a phenomenon and its evolution is the organization of the military in England. William the Conqueror, Duke of Normandy, defeated King Harold at the Battle of Hastings in 1066 and became King of England. He did not invade England in his capacity as Duke of Normandy, however, but rather as the head of a mercenary army motivated primarily by the possibility of enrichment. The barons of Normandy had refused to follow William to England in their corporate capacity and, as a result, the army of William was composed of individuals who were following him for 'land or for pence.' William was the warlord of an army that is estimated to have been about 10 to 12,000 mounted men and about 12 to 20,000 foot soldiers.

After William conquered England, he divided the land among his followers. These followers were expected to provide military service in return for their land. This manner of landholding was known as 'military tenure' and was based on a personal relationship between a man and his lord. Approximately 4500 knights were due this distribution of land. What William and his followers developed created an instrument by which a few thousand men could control a population of approximately one and half million people. The granting of land to tenants-in-chief and subinfeudation by military tenure was an effective mechanism for both supporting an army of occupation and providing a local political presence to control the country. A knight with a smallholding could support himself while not in service and also provide stability to the countryside.

By the early reign of Henry II (1154–89) England's military needs had changed and were no longer primarily internal. Henry's interests were primarily in France, and they required the services of mercenaries rather than the feudal levy of knights. The service of the English feudal levy was not very useful for these purposes. The term of service was such that it would have ended before the force could be employed. Further, feudal hosts were untrained for siege warfare. The mercenaries, on the other hand, were trained professional soldiers who would serve as long as they were regularly paid.

The other historical force that helped to end military tenure was the period that has come to be known as the Great Anarchy. At the death Henry I, in 1135, William the Conqueror's grandson, Stephen of Blois was crowned king of England rather than Henry's daughter, the Empress Matilda, who had been recognized as his successor by his barons. Stephen's coronation was followed by a long period of warfare between his supporters and those of the Empress Matilda. This long war ended with the treaty of Winchester in 1154. A key element of the treaty was that tenure in land became a right guaranteed by the king, based on legitimate possession in 1135. The holding of land was no longer a relationship between a man and his lord. Money replaced military service as a means of payment. Holding of land in what is now known as 'fee simple' replaced military tenure, and land could be bought and sold.

One of the consequences of land being held in fee simple is that it created a class of small landholders who were free men, yeoman, who were able to acquire skill with a longbow. Since this class did not exist in France, the English armies were able to deploy a weapon that was not available to French armies. The value of these weapons was dramatically demonstrated at Agincourt and Crecy when the ratio of casualties between the French and English were on the order of 1000 to 1.

England became primarily a seapower after the sixteenth century. The middle class was the source of officers for the Navy. English naval officers went to sea as young boys, acquired technical skills and were promoted mostly on merit. This approach contrasted with those of the French and Spanish navies where there was a sharp distinction between the aristocrats who commanded the ships and the sailing masters who had the technical skills. As a result, 'Britannia ruled the waves', and seapower became the keystone of the British Empire.

The lesson that can be inferred from this example of England is that institutions can be created and can evolve to meet military needs, but these institutions themselves create both opportunities and constraints for military technology and tactics.

The importance of the relationship between technology, military needs, and political institutions must be kept in mind as we face three military problems of the twenty-first century. First is the question of weapons of mass destruction. Second is the need to use

force to maintain civil order under circumstances where there is weak external political support. Third is the support of guerrilla warfare by nonstate actors. These are all problems that will require creative solutions with respect to military technology and institutions.

2. *Richardson's Equations and the Arms Race*

In the period from the end of World War II in 1945 to the breakup of the Soviet Union in 1991, the most important issue that demanded the attention of economists and political scientists working on defense issues was the arms race between the USA and the Soviet Union. The main goal was to develop models that could be used to address two very important questions: Were arms races stable? Did they lead to war?

The Richardson arms race model was the starting point for most of this research. It was the first formal model of an arms race and one of the most influential formal models in all of the international relations literature. (Richardson (1960), Isard (1988), Brito and Intriligator (1995).) The Richardson model is summarized by two differential equations that describe the rate of change over time of weapon stocks in each of two countries. According to the Richardson model, arms increases can be described as the sum of three separate influences. First is the 'defense term', where the accumulation of weapons is influenced positively by the stock of weapons of the opponent, representing the need to defend oneself against the opponent. Second is the 'fatigue term', where the accumulation of weapons is influenced negatively by one's own stock of weapons, representing the economic and administrative burden of the arms race. Third is the 'grievance term' representing all other factors influencing the arms race, whether historical, institutional, cultural, or derived from some other source. In the Richardson model, these terms are independent, additive, and linear, resulting in two coupled linear differential equations and linear reaction functions that determine the equilibrium levels of weapons.

In the early 1960s stock adjustment models, such as those of Boulding (1962) and Intriligator (1964) were developed. Each country determines a desired stock of weapons, and the rate of change of weapon stocks is assumed to be proportional to the discrepancy between desired and actual weapon stocks. Thus, each side acquires additional stockpiles in order to offset and overcome a perceived deficiency in its stockpiles of weapons, the deficiency given by the gap between the desired and actual levels of weapons.

In general, the desired stocks of weapons depend on the levels of weapons in both countries. If, as one example, each country desires a certain base level of weapons and, beyond that, to match increments of the other side's levels according to a fixed ratio, then the desired stocks are linear functions of the levels of weapons held by the other side. This results in two coupled differential equations as in the Richardson model. Conversely, the Richardson model can be interpreted as a stock adjustment model, with desired stocks a linear function of the weapons held by the opponent.

The problem with these models is that they are mechanical and there is no maximizing behavior. Brito (1972) formulated a model in which the arms race was a result of optimizing behavior. Countries were assumed to choose between investment in weapons or consumption (guns or butter). Weapons were assumed to be inputs into a public good, 'defense', that produces a positive externality for the country that produces them and a negative externality for the other country. The result of this process was a differential game and the equations that described the investment in weapons resulting from this differential game formed a nonlinear version of the Richardson model.

Brito was able to show that there exists an equilibrium level of armaments and to derive sufficient conditions for the equilibrium to be stable. Finally, he showed that in a dynamic economic model total disarmament is unstable except under very special circumstances and that behavior very similar to 'Prisoner's Dilemma' would be observed.

A criticism that can be lodged against the Brito model is that it ignores strategic considerations, in particular, the roles of weapons in both deterring and conducting a war. Intriligator (1975) developed a model that took such factors into account, connecting the acquisition of weapons to their use in both peace (deterrence) and war (war fighting). The political authorities will generally require the military authorities to justify their proposed budgets, in particular, any request for increases in the level of weapons. They may also question the existing levels of weapons in term of their danger and/or expense. The military authorities would typically seek to justify both their budgetary request for weapon acquisitions and their current inventories of weapons in terms of national security considerations by showing their deterrence or war fighting. Intriligator showed that there were combinations of weapons stocks that would make it advantageous for one or both parties to launch a first strike and result in crisis instability. At the same time, there were combinations of weapons stocks that eliminated the advantage of a first strike for both parties and thus were stable in a crisis. Low levels of weapons stocks on both sides were associated with crisis instability.

3. *Nuclear Proliferation and the Probability of War*

An important question that has been the subject of controversy is the influence of additional nuclear weapons states on the probability of nuclear war.

While the usual argument is that proliferation will increase the probability of nuclear war, some have argued that proliferation may reduce rather than increase this probability, as in Gallois (1961), Wentz (1968), and Waltz (1981). Gallois argued that additional nuclear weapon states, such as France at the time he was writing, would so raise the stakes of a potential conflict that such proliferation would make nations more cautious and thus reduce the probability of nuclear war. Wentz argued that it might be in US interest to promote selective nuclear proliferation. Waltz argued that proliferation was, in general, stabilizing.

Intriligator and Brito (1981) showed that there generally are qualitatively different effects of the acquisition by an additional nation of nuclear weapons on the probability of nuclear war, depending on the existing number of nuclear nations. In that paper we introduced the possibility of a nuclear war as a result of an accident or other inadvertent behavior to show that eventually more nuclear powers increase the probability of nuclear war. As additional nations acquire nuclear weapons, it becomes more likely that there will be other nuclear powers prepared to exploit any postwar weakness of the initiating power, further reinforcing general deterrence and thus enhancing stability against war outbreak. The probability of a deliberate initiation of a war thus decreases as the acquisition of nuclear weapons restrains the existing nuclear nations.

Increasing the number of nuclear nations implies that a nation that initiates a war would be relatively worse off in the post-war environment, both in the case where the other nuclear nations are belligerents and in the case where they remain neutral. Increasing the number of nuclear nations also increases the uncertainty as to how other nuclear powers will react during and after a war. As the number of nuclear nations increases, however, there is a rapid increase in the number of potential nations or counter coalitions with which any initiating nuclear power would have to contend both during and after a war. As a result, the probability of a calculated attack may fall. A related treatment is that of Bueno de Mesquita and Riker (1982) that uses an expected utility model to show that the probability of a nuclear war declines as the number of nuclear nations increases.

Brito and Intriligator (1996) demonstrated, however, that a formal proof of this proposition is beyond the scope of existing models since they cannot satisfy the necessary conditions. Formal propositions about the effects of additional nuclear powers on the probability of a deliberate nuclear war require more than just qualitative assertions about the change in the probability that an individual nation will initiate a nuclear war as the number of nuclear powers increases. To make such predictions it is necessary that the model makes quantitative predictions about the magnitude in the change in these probabilities that are beyond the capability of most models in economics and political science, so the formal debate on this issue should be viewed with caution.

An implication of this analysis, however, is that of reorienting policy away from nonproliferation *per se* and toward control over accidental or inadvertent war. While proliferation of nuclear weapons may either increase or decrease the probability of war, control over accidental or irrational war must reduce the chance of nuclear war. In fact, policies and actions, both technical and political, which would reduce the chance of accidental or inadvertent war, could overcome many of the problems associated with nuclear proliferation. The nuclear nations as a group should probably be as concerned about accidental or inadvertent war as about nuclear proliferation. This policy conclusion is further strengthened when considering the relative numbers of weapons involved. There can be considerably more value in controlling the accidental or inadvertent detonation of even a few of the thousands of warheads in the current nuclear nations than in preventing the acquisition of a small number of weapons in a new nuclear nation. There may be, for example, merit in sharing technology to control nuclear weapons with the other nuclear nations or even with all potential nuclear weapons nations. Such policies, which would have the effect of lowering the probability of accidental war, can significantly offset the potentially destabilizing effects of nuclear proliferation.

4. *The Economics of Guerrilla Warfare*

Guerrilla wars are usually considered to be driven by political issues. The mention of guerrillas can conjure up images such as Spanish peasants fighting Napoleon, Lawrence of Arabia leading the Arabs in the desert against the Turks, Fidel Castro fighting in the Sierra Madre against Batista, Vietnamese peasants fighting the forces of the USA, and the Mujahedeen fighting the Afghan government. Whether or not one agrees with the political motivation of these guerrillas, it is hard to dispute the contention that their motivation was primarily political. This political motivation of the guerrillas may, however, be in the process of changing. The motivation for nations to sponsor guerrilla wars has declined dramatically since the breakup of the Soviet Union and the end of the Warsaw Pact.

As guerrilla movements lose the possibility of finding an external sponsor between antagonists in the old bipolar world, a new symbiosis may be developing between guerrilla movements and narco-traffickers. Guerrilla wars appear to be evolving from ones based on political and ideological movements to ones based on political–economic forces that appear to be supported by the international traffic in drugs. Such an

evolution is occurring in Colombia, for example, as guerrillas have become active in protecting the drug trade. At the same time, the drug lords also corrupt government forces. The result is a three-person game in which the drug lords can influence the outcome of the conflict between the government and the guerrillas by transferring resources to one side or another.

Che Guevara divided guerrilla wars into two types (Guevara 1987). He suggested that the first type is an armed group against an established government. Examples of such wars include the Mexican Revolution, the wars in Indochina and Algeria against the French, the Communist insurgencies in Greece and Malaya, and the Cuban Revolution. The second type consists of actions in support of conventional forces in the field. Examples include the Peninsular Campaign against Napoleon, the Arab revolt in World War I, and partisan actions against German and Japanese forces in World War II. Unlike the first type, the motivation of these forces is not unambiguous.

Mao Tse-tung had characterized a guerrilla war as having three stages (Mao 1954). In the first stage, the primary task of the guerrillas is to establish a force. The second stage is then one of stalemate in which the guerrillas slowly accumulate resources and establish a geographical base. The third stage, finally, is marked by the metamorphosis of the guerilla forces into conventional forces and the possible subsequent collapse of the government. Mao's observation was that '… the people are the sea and the guerrillas are the fish.' To extend his metaphor, the government forces are the sharks.

Brito and Intriligator (1989) developed an economic model of guerrilla warfare which combined two classic models from economics, the Solow growth model and the Ricardian model of economic rents, with two classic studies of guerrilla warfare, T. E. Lawrence's *Seven Pillars of Wisdom* (1936) and Mao's *On the Protracted War* (1954). The result was a model of the transition of a guerrilla war from Mao's first stage to his second. The successful transition of a guerrilla force from the first to the second stage would depend on several economic characteristics of the terrain, such as the economic resources available to the guerrillas and the government forces and the 'porosity' of the country, defined as the guerrilla's ability to obtain aid from abroad.

This transition was characterized by a stable equilibrium. A crucial element in determining whether or not a guerrilla force can make such a successful transition, however, is the existence of an outside sponsor. This characteristic of the model is supported by the history of guerrilla warfare. Most successful guerrilla wars, including the Peninsular Campaign, the revolt in the desert, and the Vietnamese war, were characterized by an external sponsoring power that supported the insurgent forces. The one possible exception in recent history is Cuba, where, according to Chapelle (1960), some 85 percent of Castro's arms and ammunition were obtained from Batista's forces in one way or another.

The primary difference is that the problem should now be treated as a three-person game. The players are the guerrillas, the government, and the drug lords. As Stackelberg leaders, the drug lords want to construct a reward schedule that will induce the government and the guerrillas to react according to their desires.

The guerrillas start, as in Mao's first stage, by holding the economically marginal sections of the country, such as mountains and jungle, which are easier to defend. As they gain ground, as in Mao's second stage, they capture increasingly developed and more open parts of the country with a transportation infrastructure that gives the advantage to the offense.

The guerrilla's goal is to maximize the present discounted value of its future consumption subject to its constraints. The government's goal is to maximize the present discounted value of its future consumption subject to its constraints. These goals reflect the assumption that, regardless of political goals, a fundamental objective of the government is that of controlling resources, whether for redistribution, for the provision of public goods, or for other possible less altruistic goals, e.g., in the case of an autocratic government.

Brito and Intriligator (1992) treated the subject of narco-terrorism, where the production of narcotics is assumed to take place in three stages. First, the raw material, poppies or coca plants, are grown on land that is not under the control of the government. Second, the raw material is gathered and processed. Third, the drug is transported to foreign markets. The first stage depends on the degree of control exercised by the guerrillas. The second stage depends on support from the guerrillas and the 'protection' they furnish, permitting the drug lords to purchase the coca leaves or poppies from the peasants and to operate the processing laboratories. The third stage depends on the support from the government in permitting access to airfields and other means of transportation. The government and the guerrillas both furnish generalized support in not attacking the crops. Clearly, the output of the raw material would be maximized if the most productive lands were to be devoted to the cultivation of coca leaves or poppies. Given that the government can be corrupted, an explanation is needed as to why these crops can only be grown in areas which the government does not control. This is equivalent to the question of why a country cannot legalize drugs and export them. This would, other things being equal, be a profitable enterprise. After all, the UK exported Scotch whisky to the USA during prohibition. A possible explanation is that, unlike alcohol, there is an international consensus about the dangers of cocaine and heroin, so that a country openly sponsoring traffic in these drugs would face severe international sanctions. Alternatively, the targeted importing countries such as the USA, would not face severe international

sanctions if they would intervene unilaterally in a country that openly sponsors the drug traffic. Thus, the drug trade can exist only under the apparent inability of the government to control the drug producing areas.

The drug lords will maximize the present value of profits subject to the dynamics that describe the evolution of the guerrilla war. The choice of strategy on the part of the drug lords, which is reflected in the transfer functions, must satisfy the incentive compatibility constraint that requires that the maximization by the guerillas and by the government yield precisely the allocation described by the drug lords. Resources can be transferred from the drug lords to either the government or the guerrillas. In fact, the drug lords currently play a role similar to that played earlier by governments, in particular, the governments of the superpowers that would try to influence the outcome of various guerrilla wars.

5. *Conclusion: The Changing Nature of War*

We now return to the three military problems of the twenty-first century. First was the question of the proliferation of weapons of mass destruction. According to the Brito–Intriligator Cardinality Theorem, however, the question of how the proliferation of nuclear weapons changes the probability of war is one that cannot be answered. Thus, any research that makes claims on this issue must be viewed with skepticism as having been designed to support a particular cause or viewpoint.

Second was the need to use force to maintain civil order under circumstances where there is weak external political support. A major problem in the twenty-first century will be the need to deploy military forces in remote areas of the world, where there are few important national interests. Such conflicts create great difficult political problems for the governments of the major powers of the USA and the European Union. The legacy of the colonial era makes direct intervention very difficult. Furthermore, there is little political support in these countries to intervene and risk lives in such a remote conflict. Armies are institutions that are very difficult to build, and they reflect the society from which they come, as the USA came to learn in Vietnam.

Third is the support of guerrilla warfare by nonstate actors. An example is the conflict in Colombia, where the raw economic motives of nonstate actors play a major role, but is not the only example of such behavior. Another example is the current conflict in various parts of Africa, where warlords are exploiting local conflict to control natural resources such as diamonds or oil. Technological progress will only make the political problems more difficult, with decreasing marginal cost technology becoming more common as computer-controlled machines are substituted for labor in most manufactured goods.

Another problem facing the developing world is the fact that raw materials are becoming less valuable. In general, technology is substituting away from metals. Silicon (sand) has replaced copper in many electronic uses and may soon replace silver in photography. Carbon fiber and similar material are replacing steel and aluminum in many structural uses. Food is in excess supply and biotechnology will continue to reduce employment in agriculture. Recent developments in thin film solar cell suggest that solar energy will be competitive with hydrocarbon fuels in the near future. If the developed world becomes economically independent of the developing world, military intervention will become politically very difficult. The end of the Cold War resulted in decreased interest in the problems of the developing world. Economic disengagement will further compound the problem.

Markets are powerful entities and will satisfy wants if these wants can be translated into demands with resources. Competent armies that fight for profit have been effective throughout history. Henry II found mercenary troops an effective solution to his problems in France in the thirteenth century, and European mercenaries were successful in Katanga until the United Nations intervened. The French Foreign Legion, although not a mercenary army, demonstrates that an effective army can be created from the dregs of humanity if it has good officers. Mercenaries supported by the major powers or multinational corporations will likely fight the wars of the twenty-first century. This process has already started. While mercenary armies seem unattractive, the alternative may be chaos and massacres, such as were witnessed recently in Africa. Clausewitz said that war was not merely a political act, but the continuation of political relations by other means, and money may be the means by which the major powers wage war in the twenty-first century. The emergence of this market may be a most interesting phenomena for economists to study.

Defense Mechanisms

Defense mechanisms are patterns of feelings, thoughts, or behaviors that are relatively involuntary. They arise in response to perceptions of psychic danger or conflict, or to unexpected change in the internal or external environment, or in response to cognitive dissonance (American Psychiatric Association 1994). They obscure or diminish stressful mental representations that if unmitigated would give rise to depression or anxiety. They can alter our perception of any or all of the following: *subject* (self?), *object* (other person), *idea*, or *emotion*. In addition, defenses dampen awareness of and response to sudden changes in reality, emotions and desires, conscience, and relationships with peoples. As in the case of physiological homeostasis, but in contrast to so-called coping strategies, defense mechanisms are usually deployed outside of awareness. Similar to hypnosis, the use of defense mechanisms compromises other facets of cognition.

General Description of Defense Mechanisms

Phenomenology and pathophysiology both play an important role in our understanding of disease. Whereas nineteenth century medical phenomenologists viewed pus, fever, pain, and coughing as evidence of disease, twentieth century pathophysiologists learned to regard such symptoms as evidence of the body's healthy efforts to cope with physical or infectious insult. In parallel fashion, much of what modern psychiatric phenomenologists classify as disorders can be reclassified by those with a more psychodynamic viewpoint as homeostatic mental mechanisms to cope with psychological stress.

The use of defense mechanisms usually alters perception of both internal and external reality. Awareness of instinctual 'wishes' is usually diminished. Alternatively, as is the case with reaction formation, antithetical wishes may be passionately adhered to. Mechanisms of defense keep affects within bearable limits during sudden changes in emotional life, such as the death of a loved one. They can deflect or deny sudden increases in biological drives, such as heightened sexual awareness and aggression during adolescence. Defenses also allow individuals a period of respite to master changes in self-image that cannot be immediately integrated. Examples of such changes might be puberty, an amputation, or even a promotion. Defenses can mitigate inevitable crises of conscience (e.g., placing a parent in a nursing home). Finally, defenses enable individuals to attenuate unresolved conflicts with important people, living or dead. In each case the individual appears to deal with a sudden stress by '*denial*' or '*repression*.' But used indiscriminately, these two terms lose their specificity. For example, the denial of the conflict laden realization 'I hate my father' might become transformed by defense to: 'My father hates me' (maladaptive projection); 'I love my father so much' (compromising reaction formation); or 'I beat my father at tennis' (adaptive sublimation).

Defense mechanisms involve far more than simple neglect or repression of reality. They reflect integrated dynamic psychological processes. Like their physiological analogues of response to tissue injury—rubor, calor, dolor, and turgor—defenses reflect healthy, often highly coordinated responses to stress rather than a deficit state or a learned voluntary defensive strategy. Thus, a defense mechanism has more in common with an opossum involuntarily but skillfully playing dead than with either the involuntary paralysis of polio or the consciously controlled evasive maneuvers of a soccer halfback.

Implicit in the concept of defense is the conviction that the patient's idiosyncratic defensive response to

stress shapes psychopathology. For example, physicians no longer classify a cough as disease, but as a coping mechanism for respiratory obstruction. There is increasing evidence that choice of defensive styles makes a major contribution to individual differences in response to stressful environments (Vaillant 1992). For example, some people respond to danger or loss in a surprisingly stoic or altruistic fashion, whereas others become phobic (displacement) or get the giggles (dissociation) or retreat into soothing reverie (autistic fantasy). These responses can be differentiated by assigning different labels to the mechanisms underlying the responses. While cross-cultural studies are still sorely needed, socioeconomic status, intelligence, and education do not seem to be causal predictors of the maturity of an individual's defenses (Vaillant 1992).

Despite problems in reliability, defenses provide a valuable diagnostic axis for conceptualizing psychopathology. By including defensive style as part of the mental status or diagnostic formulation, clinicians are better able to comprehend what is adaptive as well as maladaptive about their patients' unreasonable behavior. By reframing patients' irrational behavior in terms of defense mechanisms, clinicians learn to view qualities that initially seemed most unreasonable and unlikeable about their patients as human efforts to cope with conflict.

Taxonomy of Defense

Unfortunately, there is as much disagreement about the taxonomy of defense mechanisms as about the taxonomy of personality types, but progress is being made. First, adaptation to psychological stress can be divided into three broad classes. One class consists of voluntary cognitive or coping strategies which can be taught and rehearsed; such strategies are analogous to consciously using a tourniquet to stop one's own bleeding. The second class of coping mechanisms is seeking social support or help from others; such support seeking is analogous to seeking help from a doctor in response to bleeding. The third class of coping mechanisms are the relatively involuntary *defense mechanisms*. Such coping mechanisms are analogous to depending on one's own clotting mechanisms in order to stop bleeding.

Anna Freud (1936), Sigmund Freud's daughter, was the first investigator to introduce a formal taxonomy of defenses. By the 1970s due to the protean and ephemeral nature of defensive mental phenomena, other competing taxonomies arose (e.g., Kernberg 1975, Thomae 1987, Beutel 1988, Lazarus and Folkman 1984).

Since the 1970s, several empirical studies have suggested that it is possible to arrange defense mechanisms into a hierarchy of relative psychopathology (e.g., projection (paranoia), to displacement (phobia), to sublimation (art)), and also place them along a continuum of personality development (Vaillant 1977, Perry and Cooper 1989). With the passage of decades, a sexually abused child's defenses could mature from *acting out* (e.g., rebellious promiscuity to *reaction formation* (?joining a convent where sex is bad and celibacy is good) to altruism (as a nun in midlife counseling pregnant teenage mothers). The most recent American diagnostic manual (American Psychiatric Association 1994) provides a glossary of consensually validated definitions and arranges defense mechanisms into seven general classes of relative psychopathology (Table 1).

All classes of defenses in Table 1 are effective in 'denying' or defusing conflict and in 'repressing' or minimizing stress, but the mechanisms differ greatly in the severity of the psychiatric diagnoses assigned to their users and in their effect on long-term psychosocial adaptation. At level I, the most pathological category, are found denial and distortion of external reality. These mechanisms are common in young children, in our dreams, and in psychosis. The definition of such *denial* in Table 1 is a far more narrow but more specific use of the term than many writers who use the term *denial* interchangeably with *defense mechanisms*. Level I defenses rarely respond to simple psychological intervention. To breach them requires altering the brain by neuroleptics or waking the dreamer.

More common to everyday life are the relatively maladaptive defenses found in levels II–V. These categories are associated with adolescence, immature adults, and individuals with personality disorders. They externalize responsibility and allow individuals with personality disorders to appear to refuse help. Such defenses are negatively correlated with mental health. They profoundly distort the affective component of human relationships. Use of such defenses cause more immediate suffering to those in the environment than to the user.

Defenses in these categories rarely respond to verbal interpretation alone. They can be breached by confrontation—often by a group of supportive peers. These maladaptive defenses can also be breached by improving psychological homeostasis by rendering the individual less anxious and lonely through empathic social support, less tired and hungry through rest and food, less intoxicated through sobriety, or less adolescent through maturation.

Level VI defenses are often associated with anxiety disorders and with the psychopathology of everyday life. Level VI include mechanisms like repression (i.e., deleting the idea from a conscious emotion), intellectualization (i.e., deleting the emotion from a conscious idea), reaction formation, and displacement (i.e., transferring the emotion to a more neutral object). In contrast to the less adaptive defenses, the defenses of neurosis are manifested clinically by phobias, compulsions, obsessions, somatizations, and

Table 1
Defensive function scale

I. Level of Defensive Deregulation. This level is characterized by failure of defensive regulation to contain the individual's reaction to stressors, leading to a pronounced break with objective reality. Examples are
- delusional projection (e.g., psychotic delusions)
- psychotic denial of external reality
- psychotic distortion (e.g., hallucinations)

II. Action Level. This level is characterized by defensive functioning that deals with internal or external stressors by action or withdrawal. Examples are
- acting out apathetic withdrawal
- passive aggression
- help-rejecting complaining

III. Major Image-Distorting Level. This level is characterized by gross distortion or misattribution of the image of self or others. Examples are:
- autistic fantasy (e.g., imaginary relationships)
- splitting of self-image or image of others (e.g., making people all good or all bad)

IV. Disavowal Level. This level is characterized by keeping unpleasant or unacceptable stressors, impulses, ideas, affects, or responsibility out of awareness with or without a misattribution of these to external causes. Examples are:
- denial
- projection
- rationalization

V. Minor Image-Distorting Level. This level is characterized by distortions in the image of the self, body, or others that may be employed to regulate self-esteem. Examples are:
- devaluation
- idealization
- omnipotence

VI. Mental Inhibitions (Compromise Formation) Level. Defensive functioning at this level keeps potentially threatening ideas, feelings, memories, wishes, or fears out of awareness. Examples are
- displacement
- dissociation
- intellectualization
- isolation of affect
- reaction formation
- repression
- undoing

VII. High Adaptive Level. This level of defensive functioning results in optimal adaptation in the handling of stressors. These defenses usually maximize gratification and allow the conscious awareness of feelings, ideas, and their consequences. They also promote an optimum balance among conflicting motives. Examples of defenses at this level are
- anticipation
- altruism
- humor
- sublimation
- suppression

amnesias. Such users often seek psychological help, and such defenses respond more readily to interpretation. Such defenses cause more suffering to the user than to those in the environment.

High adaptive level (VII) defenses still distort and alter awareness of and emotional response to conscience, relationships, and reality, but they perform these tasks gracefully and flexibly—writing great tragedy (i.e., sublimation), for example, is financially rewarding, instinctually gratifying, and sometimes life saving for the author. The 'distortion' involved in stoicism (suppression), humor, and altruism seems as ethical and as mentally healthy to an observer as the immature defenses seem immoral and antisocial.

Historical Background

That emotions were significant to humans had been known since ancient times, but it was difficult to develop a concept of defense until psychology could

conceptualize the interaction and/or conflict between ideas and emotions. For example, in their influential textbooks the two greatest psychologists of the nineteenth century, Wilhelm Wundt (1894) and William James (1890) discuss a psychology that consisted almost entirely of cognition, not emotion.

Appreciation of the likelihood that it was distortion of ideas *and* emotions via unconscious mechanisms of defense that led to psychopathology originated with Sigmund Freud (1894). Late in the nineteenth century neurologists had obtained a clearer understanding of the sensory and motor distribution of the nerves. They could appreciate that it was impossible for an individual to have 'glove anesthesia,' and certain common paralyses due to neurological damage. Thus, it became possible for neurological science to appreciate that patients could experience anesthesia to pin prick based on their mind's 'defensively' or 'adaptively' to distort sensory reality. Trained in both neurology and physiology, Freud was able to appreciate the importance of the phenomena to psychopathology. He suggested that upsetting emotions and ideas could be cognitively distorted in a manner similar to pain and motor behavior. Freud (1894) observed not only that emotion could be 'dislocated or transposed' from ideas (by involuntary mechanisms like dissociation, repression, and intellectualization), but also that emotion could be 'reattached' to other ideas (by the mechanism of displacement). Later, Freud expanded his theory to suggest that no experience 'could have a have a pathogenic effect unless it appeared intolerable to the patient's ego and gave rise to efforts at defense' (Freud, 1906/1964, p. 276). In other words, much mental illness like coughing and fever might be due to psychological efforts of homeostasis.

Over a period of 40 years, Freud described most of the defense mechanisms of which we speak today and identified five of their important properties. (a) Defenses were a major means of managing impulse and affect. (b) Defenses were involuntary. (c) Defenses could be distinguished from each other. (d) Defenses reflected states, not traits. They were dynamic and reversible. (e) Finally, defenses could be adaptive as well as pathological. Freud conceived of a special class of defense mechanisms—'sublimations'—that could transmute psychic conflict not into a source of pathology, but into culture and virtue (1905/1964, pp. 238–9).

From the beginning, however, defenses posed a problem for experimental psychology. First, there is no clear line between character (enduring traits) and defenses (shorter-lived responses to environment). For example, what is the difference between paranoia and projection. There is no clear line between symptoms of brain disease and unconscious coping processes. For example, sometimes one's obsessions are due to genetic factors alleviated by serotonin reuptake inhibitors and sometimes obsessions are efforts at conflict resolution via the defenses of intellectualization, displacement, and reaction formation. Sometimes the symptoms of neuropathology are wrongly imputed to be due to conflict-driven adaptive aberrations of a normal brain. In addition, behaviors associated with level VII defense can arise from sources other than conflict. For example, altruism can result from gratitude and empathy as well as from conflict.

Thus, in the 1970s both the demands for rater reliability and advances in neuropsychiatry led to psychodynamic explanations for psychopathology falling from favor. As was true in the pre-Freudian era, phobias and paranoia were again attributed more to brain pathology than to adaptive displacement and projection of conflict. Very recently, the limitations of such a purely descriptive psychiatry has led at least American psychiatrists to return defenses to their diagnostic nomenclature (Table 1).

Since the 1970s, several empirical studies well reviewed by Cramer (1991), Vaillant (1992), and Conte and Plutchick (1995) have clarified our understanding of defenses with experimental and reliability studies. This led to a tentative hierarchy and glossary of consensually validated definitions of defense being included in *DSM-IV* (American Psychiatric Association 1994), the American psychiatric manual for diagnosis.

Future Research

A major danger in using psychodynamic formulation as an explanatory concept in psychopathology remains unwarranted inference and subjective interpretation. The hierarchy of defenses presented in Table 1 is no more than a system of metaphors, and is not readily susceptible to experimental proof. But several empirical strategies permit placing defense mechanisms on a firmer footing than say handwriting analysis, phrenology, and astrology.

In the future, psychology needs to take advantage of recent advances in neuroscience to achieve further reliability, objectivity, and validity for the study of defenses.

First, we can identify defenses much as we measure the height of mountains that we cannot climb—by triangulation. We can contrast a patient's *symptoms* (or a healthy person's *creative product*) with his own self-report or *mental content* and with someone else's *objective report*, biography, or medical record. In this way an unconsciously motivated slip of the tongue can be distinguished from a simple mistake, a true paralysis can be distinguished from paresis due to psychogenic illusion, and a paranoid delusion can be distinguished from true political persecution.

The second method is predictive validity. Phrenology and astrology fail to predict future behavior assessed by independent observers. In contrast, choice of defense mechanisms robustly predicts future behavior (Vaillant 1992). Third, the increasing use of

videotape to evaluate complex human process offers the same opportunity for reliability in assessing defense mechanisms (Perry and Cooper 1989).

In the future, there is a need to study defense choice cross-culturally and to clarify the social basis for defense choice and familial transmission. As techniques for brain imaging become perfected, functional magnetic nuclear resonance (FMNR) also offers promise. So does genetics, for there is increasing evidence that personality disorders, which are often characterized by a dominant mechanism of defense, run in families. The demonstration of genetic influences upon defense choice will offer another advance that may make defenses more tangible. Finally, integrating advances in cognitive psychology and evolutionary psychology with advances in our understanding of neural networks may offer still another potential means of studying defense mechanisms with greater scientific rigor.

Deforestation–Forestation

Deforestation is a major global concern. Despite increased attention to various facets of this issue, however, considerable uncertainty rests in estimates of the rates, the impacts, and the driving forces of deforestation. This article reviews these issues. It focuses primarily on tropical deforestation because of its greater pace and strong social and environmental implications. Three levels of causes are discussed: the agents or proximate causes, the immediate causes, and the underlying causes. The central thesis is that deforestation occurs because it is profitable to some individuals and groups.

1. Past and Present Deforestation

1.1 Rates and Definitions

About one half (47 percent) of Earth's forest cover of 8,000 years past is gone (World Resources Institute 1998), largely the impress of human activity. Yet forests continue to occupy about one quarter of the land surface, or 3.5 million hectares (ha). Fifty-five percent are located in developing countries, primarily in the tropical world. From 1980 to 1995, developing countries lost some 200 million ha (10 percent) of their forest, while developed countries gained about 20 million ha (FAO 1999).

Deforestation is defined as the permanent transition from forest to all other land categories. *Forests* in developing countries, according to the FAO, are ecosystems with a minimum of 10 percent crown cover of trees and/or bamboos covering a minimum of 0.5 ha. Estimates of global deforestation, however, are normally based on national forest inventories which use self-defined measures and data of varying quality and commonly differ from estimates derived from satellite data. Many countries use simple extrapolations or model-based estimates. The uncertainty of deforestation estimates, therefore, must be emphasized.

Deforestation is distinguished from forest degradation or a reduction in tree density and/or increased disturbance resulting in loss of forest products and

forest-derived ecological services. Selective logging—practiced properly—does not qualify as deforestation, but might lead to forest degradation. In addition, roads constructed for this purpose make forests accessible and may attract migrants, precipitating deforestation.

1.2 The Forest Transition

Deforestation in developing countries and reforestation in developed ones form part of a global pattern in land use (see *Land Use and Cover Change*) that some envision as a long-term, temporal sequence. The forest transition captures this sequence, referring to a pattern of forest use initially leading to deforestation during extractive and agrarian episodes and subsequently to reforestation as economic activity shifts to industry and services (Grainger 1995, Mather and Needle 1998, Rudel 1998). Most developed regions of the world incurred rapid deforestation in the past, closely linked to the growth in their populations. With industrialization and urbanization, however, forest land subsequently increased beginning in the nineteenth century in Europe and the twentieth century in the United States.

This decoupling of population growth and deforestation is more complex than changing sectoral composition of the economy. Improved transport networks stimulated commercial agriculture, permitting specialized production based on local conditions. Improved agricultural technologies shifted major production to areas suitable for mechanized cultivation and adjusted agriculture to land capability, permitting the abandonment of marginal lands. Industrialization pulled people off the land and shifted energy supplies from wood to coal and later to other fossil fuels. In the latter half of the twentieth century, forest plantations have contributed to the forest transition, although they contribute only 3 percent to the world's forests at the beginning of the twenty-first century. Finally, political and cultural changes played a role, primarily through state environmental management and policy. The role of forests in stabilizing water supply and runoff was recognized; forests became more than timber.

2. Impacts of Deforestation

2.1 Appropriate vs. Inappropriate Deforestation

Not all conversion of forests to agriculture or other uses is inappropriate. Kaimowitz et al. (1998) use three criteria to define inappropriate deforestation: ecological (high adverse local or downstream effects, high biodiversity and biomass), economic (high forest value to local people and low agricultural potential), and political (none or few stakeholders gain). Appropriate deforestation, therefore, involves relatively benign consequences environmentally and on current forest uses but significant gains to a significant portion of the stakeholders.

Underlying such terms as '(in)appropriate' or 'excessive' deforestation is the concept of 'optimal levels of deforestation'—balancing all relevant costs and benefits of alternative land uses. Besides the practical data and measurement problem such an analysis entails, the concept raises critical methodological and philosophical issues. How are future costs balanced against the current ones (discounting)? How is the enormous uncertainty related to the (costs of) climate change and biodiversity loss taken into account? How are costs and benefits occurring to different groups balanced? Nevertheless, there is convincing evidence for the current pace of deforestation being too high: land managers usually fail to incorporate the downstream or long-term environmental effects of forest conversion; government policies frequently stimulate forest clearing in the service of powerful interest groups, and business may ignore or attempt to circumvent indigenous forest land rights.

2.2 Climate Change

Global concern for tropical deforestation has been strongly linked to the issue of climate change and loss in biotic diversity (see *Extinction of Species*), although increasingly ecosystem services have been invoked as well. Forests are reservoirs (storage in biomass and soils), sinks (increasing area and/or growth), and sources (release through burning, biomass decay, and soil disturbance) of carbon (FAO 1999). The Intergovernmental Panel of Climate Change (IPCC) estimates that net CO_2 emissions from land-use changes, mainly tropical deforestation, contributed about 20 percent of the global anthropogenic CO_2 emissions during the 1990s (IPCC 2000). Deforestation emits two other greenhouse gases, methane (CH_4) and nitrous oxide (N_2O), but no reliable global emission estimates exist. The main emissions of these other gases related to deforestation are not from forest clearing and burning *per se*, but rather from subsequent uses of the deforested land (Houghton 1993).

Reduced deforestation, improved land management, and more agroforestry and forest plantations can reduce the net emissions from tropical forests. The IPCC estimates that over the first half of the twenty-first century such measures could—under a reasonable scenario—amount to 12–15 percent of fossil fuel carbon emissions.

2.3 Biodiversity Loss

Tropical rain forests are the biologically richest terrestrial biome on the planet, hosting 50–90 percent of all plant species. Tropical deforestation is, therefore, the single largest threat to maintaining the planet's flora and fauna diversity. Estimates of species loss—

whether 10 or 150 species/day—are at best educated guesses, but many scientists believe that the rate of extinction at the end of the twentieth century constitutes a mass extinction on the order of those driven by nature in the geological past (see *Extinction of Species*).

High biological diversity is worth preserving for several reasons (e.g., Botkin and Talbot 1992). On utilitarian grounds, forest products provide direct benefits to humans. A large proportion of agricultural plants originates in forests, and new plants with potentially high commercial value may yet be discovered. High genetic diversity also enhances plant breeding and productivity.

In the 1990s, attention has shifted to the functioning and value of ecosystems, and the value of high biodiversity within these systems (Kremen et al. 2000). Change in ecosystem sensitivity to perturbations and loss of *resilience* (the ability of an ecosystem to absorb disturbances) follows from changes in diversity and function and can have serious consequences for local communities (Perrings et al. 1995).

Forests and the biodiversity they contain also have an aesthetic value, and the threat of extinction of 'charismatic fauna' has raised public concerns over deforestation. Finally, as stated in the UN General Assembly World Charter for Nature of 1982, species have a moral right to exist.

2.4 Forest Products

Forestry contributes about 2 percent of gross domestic product globally, and 3 percent of international merchandize trade (FAO 1997). Wood production from natural forests is shrinking due to the 'mining' of precious timber (e.g., tropical hardwoods) and deforestation, but also because of conservation (i.e., parks, biospheres, reserves). Production is shifting to intensively managed forests (i.e., plantations) and other tree media outside forests (FAO 1999).

The supply of fuelwood and charcoal, the sole or dominant source of domestic energy for more than two billion people, is threatened by the loss of forest. The most alarming reports of the 1970s and the early 1980s on the extent of fuelwood crises have passed. Yet FAO (1997) estimates about one billion people face fuelwood shortages.

Non-wood forest products (NWFPs) have drawn great attention due to their role in both rural households and national economies, and due to their potential to combine income generation and forest conservation objectives. At least 150 NWFPs are significant in international trade. Among these, plants used in pharmaceuticals, nuts, ginseng roots, cork, and oils each have an annual trade value of more than US$300 million (FAO 1997).

2.5 Local Communities

Indigenous people living close to or within the forest use a wide range of forest products. Forests provide food, fiber, fuel, medicinal products, and wood for shelter and tools. Close to 50 million of the world's 300 million indigenous people live within or depend on tropical forests for these necessities. Indian tribes in the Amazon and Dayak groups in Borneo, for example, have been put at risk by large government development projects and colonization schemes that remove natural forests. Tropical deforestation therefore threatens cultural diversity.

3. Driving Forces

The process of deforestation involves at least three levels of causes: agents, immediate causes, and underlying causes (Angelsen and Kaimowitz 1999, Contreras-Hermosilla 2000). The various agents of deforestation and their actions are the proximate sources of deforestation. Their land-use decisions are based on their individual characteristics and factors external to them, such as prices, access to technology, information, services, and infrastructure. These factors determine the choice set and the incentives for different land uses, and form the immediate (direct) causes of deforestation. In turn, they are determined by broader forces—the underlying causes: for example, markets and institutions which are strongly influenced by political decisions.

3.1 Agents of Deforestation

The agents of deforestation are those that cut the trees, including smallholders, large commercial landowners, plantation companies, and infrastructure construction agencies. The key actors vary significantly by world region. Most deforestation in Latin America links to medium and large-holder actors, especially cattle ranchers. Deforestation in Africa is largely related to smallholders converting forest and woodlands to short fallow cropland. Asia, in contrast, represents a mix between small- and large-holder operations, in which agro-industrial companies play a significant role, for example, in converting large tracts of forest to oil palm plantations in Indonesia.

Shifting cultivators have been held responsible for more than half of tropical deforestation, but their share remains controversial. Part of the controversy stems from ambiguous use of the terms 'shifting cultivation' (some include any type of smallholder farming) and 'deforestation' (temporary vs. permanent clearing). Moreover, agents often interact (e.g., logging companies provide farmers with chainsaws or

access roads) or different activities can take place *sequentially* (e.g., small farmers occupying abandoned timber concessions). Often 'there are no clear guilty or innocent parties' (Kaimowitz et al. 1998, p. 303).

3.2 Immediate Causes

The farmers or companies deforest because it is the most profitable alternative and they have the necessary means to do so. Thus, the immediate causes are those that make deforestation more profitable and possible. Higher output prices and technologies that increase yield or reduce input costs make expansion more attractive. Better access to credit and lower interest rates pull in the same direction. Higher wages, reflecting the costs of hiring labor or the best alternative use of family labor, work in the opposite direction. Reduced access costs (new or better roads) also provide a great stimulus for deforestation.

These linkages are empirically founded. A survey of more than 140 economic models of deforestation finds a broad consensus on three immediate causes of deforestation: higher agricultural prices, more/better roads, and low wages and shortage of off-farm employment (Angelsen and Kaimowitz 1999). But the effect of factors such as technology, property rights, and poverty is ambiguous.

Easy and cheap access to improved technologies has contradictory effects on deforestation (Angelsen and Kaimowitz 2001). Farmers might shift to more intensive systems and reduce their total demand for land. Yield-increasing technologies will also boost supply and put downward pressure on prices, depending on the scale of adoption and the size of markets. But agricultural land expansion might also become more profitable. The history of tropical deforestation, for example, includes a long litany of situations where new crops led to massive deforestation: bananas, cocoa, coffee, oil palm, and sugar cane in various parts of the world (Barraclough and Ghimire 1995).

Insecure property rights, in principle, reduce the incentives for long-term investments. This can make farmers opt for extensive production systems and avoid investments in forest management. But forest clearing itself is an investment as it commonly gives or strengthens farmers' rights to land. In this context, more secure land rights can actually stimulate 'land races' and deforestation.

Finally, poverty is claimed to exacerbate deforestation because poor households have short time horizons and few alternatives, making the forest frontier the employer of last resort. But poor families also lack the capital to deforest large areas, and they must be present in large numbers to have a significant impact. Their lack of alternative sources of livelihood may make the poor more concerned with the local effects of deforestation and forest degradation.

3.3 Underlying Causes

The links between underlying causes and deforestation are highly complex, difficult to establish, and tend to be location-specific, making generalizations difficult. Indeed, the empirical foundation for much of the conventional wisdom of these causes is surprisingly weak (Angelsen and Kaimowitz 1999).

Excessive deforestation can—as with other environmental problems—be seen as a problem of market failure. The existence of negative externalities (alternatively, the public goods' characteristics of many ecological services from forests) creates a conflict between individual and collective rationality. The land managers have little incentive to consider the implications of their actions on, for example, global warming. Although sketchy, calculations of such non-market values indicate that by far the largest potential lies in the carbon storage service of tropical forests (in the range of US$1,000–3,600/ha), comparable to the timber value. Interestingly, existing estimates of the pharmaceutical and ecotourism potential yield very small monetary values per ha (Pearce 1996).

The term policy failure parallels market failure in reference to government action (or inaction) leading to excessive deforestation. The reasons behind policy failures are many: inadequate government capacity to enforce regulations, and policies with unintended and unforeseen effects or with known effects yet lack of concern about them. Examples include agricultural subsidies and promotion of export crops leading to agricultural encroachment of forests. Moreover, a strong political economy dimension may reside in policy failure. Policies are often designed to benefit elite interests at the expense of marginal groups and the environment. Governments have also used forest rents to buy support from powerful groups or to gain popular support.

Historically, deforestation has been closely linked to population growth. 'Men are a foe to the woods, in proportion as their numbers increase,' argued J. Robertson (1808). But as the forest transition notion shows the link is conditioned by markets, technology, institutions, and policies. Globalization of markets will make international demand rather than local needs increasingly determine the rate and scale of forest clearing.

Another line of argument relates deforestation to declining terms of trade and international debt in developing countries, and their subsequent structural adjustment policies and economic liberalization. Countries are forced to exploit their forests to service their debt or compensate for a shortfall in export income, with environmental impacts determined by the characteristics of this use. The debt crisis and economic reforms have also led to changes in government investments and expenditures (e.g., less road building), whose net effects on forests are context specific. Angelsen and Kaimowitz (1999, p. 91) con-

clude that 'any general claims about the relations among economic liberalization, structural adjustment, and deforestation is misleading.' If anything, the evidence suggests that higher agricultural output and timber prices which normally follow as part of economic liberalization will lead to more pressure on forests.

Overall, the relative emphasis of different explanations has changed over the past decade, reflecting both changing political winds and new research, but also changes on the ground. Population (and poverty) related explanations have lost ground. 'Policy failure' remains a persuasive explanation, but probably less so now compared to the (late) 1980s and early 1990s. Many of the deforestation-inducing policies (e.g., subsidies for colonialization of the Brazilian Amazon) have been weakened or removed. There has also been a tendency to blame governments for everything that went wrong, including the destruction of rainforests, failing to recognize that some government interventions—although bad for the economic performance—probably slowed down deforestation (e.g., high taxation of agriculture). In summary, market and political economy explanations appear to be the more powerful for tropical deforestation presently. Deforestation occurs because it is profitable to some agents, and some groups have the capability to influence the policies to create or enlarge the economic opportunities for themselves.

4. *Future Challenges*

The forces driving tropical deforestation seem to outweigh those favoring forest conservation, a situation unlikely to change in the near future. One strategy to reduce losses in biotic diversity would be to concentrate conservation efforts on the most valuable sites from a biodiversity perspective. Sayer et al. (2000) argue that a set of about 100 strategically located sites or 'hot spots' covering 3–5 percent of the tropical forests might save most tropical biodiversity (also Myers et al. 2000).

The failure and impracticability of land managers to include all the costs in their decisions is the fundamental reason behind excessive deforestation. Payment for one of the most important environmental services standing forests provide—carbon storage—should serve as a strong incentive for forest conservation. The Kyoto Protocol of 1997 allows for carbon trade under the Clean Development Mechanism (CDM), including changes in greenhouse gas emissions due to direct human-induced land-use change and forestry activities. But many technical and political problems remain to be sorted out (e.g., Richards and Moura Costa 1999, IPCC 2000). It remains to be seen whether carbon trading related to forests will become the mechanism that slows the destruction of tropical forests, another form of neo-colonialism where rich countries buy large areas of tropical land and exclude local communities, or whether practical and political problems and high transaction costs will prevent beneficial effects on the fate of tropical forests.

Deindividuation, Psychology of

According to deindividuation theory, the psychological state of deindividuation is aroused when individuals join crowds or large groups. The state is characterized by diminished awareness of self and individuality. This in turn reduces an individual's self-restraint and normative regulation of behavior. In social psychology, deindividuation is a major theory of group behavior: it provides an explanation of collective behavior of violent crowds, mindless hooligans, and the lynch mob. In addition, deindividuation has been associated with other social phenomena such as genocide, stereotyping, and disinhibition in other settings such as computer-mediated communication. Below, the theoretical evolution of deindividuation is sketched, followed by a brief impression of the empirical support for this theory. Finally, recent research is discussed, which argues for a reconceptualization of deindividuation: It appears deindividuation is not a loss of individual identity, but may be better construed as a transition to a social identity.

1. *Theoretical Evolution of Deindividuation*

Deindividuation theory is rooted in the earliest works of social psychology, in particular Gustave Le Bon's (1895/1995) crowd theory. In his book '*The Crowd*' Le Bon vividly describes how the individual in the crowd is psychologically transformed. He proposes that the psychological mechanisms of anonymity, suggestibility and contagion transform an assembly into a 'psychological crowd.' In the crowd the collective mind takes possession of the individual. As a consequence, a crowd member is reduced to an inferior form of evolution: irrational, fickle, and suggestible. The individual submerged in the crowd loses self-control and becomes a mindless puppet, possibly controlled by the crowd's leader, and capable of performing any act, however atrocious or heroic.

Although many have criticized Le Bon's theory and his politics—the two are closely linked— the influence of '*The Crowd*' in science and society is difficult to underestimate. The sales of this book are among the highest of scientific texts. In science, his analysis has inspired many theories of collective behavior, for example those of Freud, McDougall, Blumer, and Allport. In society, Le Bon's influence has been remarkably strong and more questionable: His theory informed figures such as Mussolini and Hitler, whose ideologies resonated with Le Bon's emphasis on racial factors (Nye 1975).

The field of social psychology revived Le Bon's ideas in the 1950s. They were couched in more scientific terms as a theory of 'deindividuation.' Initially, it was argued that deindividuation occurs when individuals in a group are not paid attention to as individuals (Festinger et al. 1952). Thus, being unaccountable in a crowd or group has the psychological consequence of reducing inner restraints, and increasing behavior that is usually inhibited. The causes of deindividuation were extended from anonymity in groups to other contextual factors, such as reductions of responsibility, arousal, sensory overload, a lack of contextual structure or predictability, and altered consciousness due to drugs or alcohol (Zimbardo 1969).

Thus, although Le Bon's ideas were the blueprint for the deindividuation concept, the situations that cause deindividuation were gradually expanded to include other settings than the crowd. Deindividuation theory differs from Le Bon's theory in one further important respect: The consequence of deindividuation is not that the loss of individuality is replaced by a collective mind that guides the individual's actions. Rather the loss of individuality leads to a total loss of control, and releases a person from internalized moral restraints to produce emotional, impulsive, irrational, regressive and intense behavior.

In the 1970s, deindividuation theory became a popular focus of scientific research, encouraged and inspired in part by the collective disorders characteristic of that period. However, the empirical support for deindividuation theory was not especially forthcoming. In particular, there was inconsistent evidence regarding the influence of anonymity in groups, and there was virtually no evidence for the psychological state of deindividuation (Diener 1980). Indeed, it appeared that this psychological state, which by all accounts appeared to be easily induced, was more elusive than initially conceived.

In order to come to terms with the empirical obstacles, deindividuation theory was gradually modified over the course of the 1980s. In particular, the psychological underpinnings of deindividuation have

been narrowed down. In the original version of the theory, deindividuation was closely bound up with the lack of accountability that accompanies submergence in the group. Hence, empirically the focus often was on anonymity in the group as the most important factor to produce deindividuation. Contemporary formulations of the theory focus on the psychological process of reduced (private) self-awareness as the defining feature of deindividuation (Diener 1980, Prentice-Dunn and Rogers 1982). Self-awareness entails a person's becoming the object of one's own attention. This attention for (private) aspects of oneself, such as one's attitudes and norms, increases the capacity for self-regulation. Classical and contemporary views agree, however, on the main thrust of the deindividuation hypothesis: The psychological state of deindividuation brings about antinormative and disinhibited behavior, see Postmes and Spears (1998) for a review.

2. *Deindividuation Research*

Several influential studies were conducted to illustrate the force of deindividuation. For example, Zimbardo (1969) reports a study that inspired much subsequent deindividuation research. In one study, participants were rendered anonymous by clothing them in oversized lab coats and hoods, compared with normal clothes and name tags in the control condition. The participants' task was to shock a confederate in a situation similar to the classic Milgram studies on obedience. In a first experiment using groups of female students, Zimbardo demonstrated that anonymous participants shocked longer (and therefore more painfully) than identifiable participants, in confirmation of his theory.

Aware of the limitations of Zimbardo's research in terms of external validity, Edward Diener and colleagues devised more naturalistic contexts in which to test the theory. In some studies, groups of participants were required to 'test' a so-called pacifist, trained to remain non-responsive, by hitting the pacifist with foam swords and so forth. The researchers claimed this provided a measure of aggression that was more ecologically valid for crowd behavior. Results were inconsistent, however. In one study, for example, isolated individuals displayed more aggression than groups did, see Postmes and Spears (1998) for a review.

In another study, Prentice-Dunn and Rogers (1982) induced deindividuation by instructing participants repeatedly to focus attention outward. In addition to attentional focus, participants were seated in a dimly lit room with loud rock music playing, verbal interaction was encouraged and the groups played exciting video games. In contrast, participants in an internal attention focus condition were told not to interact, performed individual tasks and played non-arousing games in a well-lit quiet room. Results showed that when attention was focused outward, higher levels of aggression were obtained.

3. *Support for Deindividuation Theory*

These examples illustrate that empirical investigations of deindividuation theory resorted to more and more extreme conditions in search of evidence for deindividuation. Although some studies found support for deindividuation theory's propositions, many failed to support it, and many reported contrary results. Even Zimbardo's (1969) original paper reports that a replication of the study mentioned above obtained the exact opposite results.

Thus, evidence for deindividuation theory appears to be mixed. A recent meta-analysis of the deindividuation literature confirms this impression. This study examines 60 tests of deindividuation theory and concludes that there is insufficient support for deindividuation theory (Postmes and Spears 1998). Disinhibition and anti-normative behavior are not more common in large groups and crowded anonymous settings. Moreover, there is no evidence that deindividuation is associated with reduced self-awareness, or even that reduced self-awareness increases disinhibition. Overall, then, deindividuation theory does not receive sufficient empirical support.

4. *Reconceptualizing Deindividuation*

One likely reason for the lack of support for the deindividuation concept is that the theory is based on Le Bon's analysis of the crowd, which is so oversimplified as to be fundamentally flawed. According to Le Bon, collective behavior is always irrational: The individual in the crowd loses cognitive control. Deindividuation theory accepts this notion. For example, Diener argued that crowd members are 'similar to the stimulus-response organism of early behaviorism, with reduced conscious mediation' (1980, p. 230). This negative and disorderly view of collective behavior stands in stark contrast to historical analyses of the crowd, which stress the crowd's capacity for restraint and orderly behavior (e.g., Rudé 1964). Moreover, these historical analyses accentuate that the crowd often acts on the basis of moral principles and popular consensus (see also Turner and Killian 1972). Thus, a compelling case can be made that collective behavior is not unrestrained (as argued by deindividuation theory) but rather restrained by normative processes. The implication is that collective behavior is under conscious control, and far from irrational and unrestrained.

In recent social psychological research, a normative analysis of collective behavior is supported. In deindividuation studies, for example, people are more likely

to follow local group norms if they are 'deindividuated' (Postmes and Spears 1998). The idea that behavior could be the result of local group norms was considered explicitly by Johnson and Downing (1979) who varied the manipulation of anonymity developed by Zimbardo. Participants were made anonymous by means of mask and overalls reminiscent of the Ku Klux Klan (similar to Zimbardo's uniforms) or by means of nurses' uniforms. Although compared to the control condition participants shocked somewhat more when dressed in the Ku Klux Klan uniforms, they actually shocked less when dressed as nurses. This finding illustrates that groups are sensitive to normative cues associated with the social context.

Researchers working within the framework of social identity theory have attempted to reconceptualize deindividuation in order to account for the crowd's normative regulation. They argue that deindividuating settings do not cause a loss of self, but they shift a person from an individual identity to a collective identity as a member of the group or crowd. For example, being in a demonstration will accentuate the unity of participants if they rally behind their cause—seemingly oblivious to strong divisions and disagreements that may exist between them. This common group membership may become accentuated if an opposing group (such as the police) acts upon the crowd as if it were one, for example by blocking its way or attempts to contain it. The strong adherence to this common group membership, which emerges over the course of such events, explains why normative regulation within the crowd may occur (Reicher 1987).

In sum, whereas deindividuation theory argues that the crowd causes a loss of identity, reverting the individual to irrationality, it seems more productive to reconceptualize deindividuation as a shift from a personal identity to a social identity, shared by members of the crowd. This may explain the normative restraint within the crowd as observed by historians, as well as the normative restraint observed in experimental studies of deindividuation.

Deinstitutionalization, Psychiatry of

The term 'deinstitutionalization' is a somewhat cumbersome shorthand for the process that has occurred in North America and Western Europe of shifting the locus of psychiatric care from the large dedicated psychiatric hospitals to the districts in which people live. In order to appreciate the impetus behind deinstitutionalization, it is first necessary to review the reasons for the establishment of asylums. The rundown and closure of the asylums raises fundamental questions about the attitudes of the public to the mentally ill and the nature of 'the community.'

1. The Rise of the Asylum

One of the oldest psychiatric institutions in the West is the Bethlem hospital, founded as a priory in 1247 and used to house the mentally ill from 1403 to the present day. Its name, corrupted to Bedlam, attracted the stigma that became an inescapable feature of such institutions and was used to vilify the psychiatrically ill as bedlamites. Similar hospitals were established throughout Europe and North America in the ensuing centuries but the massive expansion of psychiatric hospitals, or asylums as they became known, did not occur until the nineteenth century. In the UK this was as a result of government policy to provide each county with at least one public asylum, as legislated in the County Asylum Act of 1808. Large sums of money were made available for the asylum building program,

of which the Victorians were very proud. Considerable effort went into the design of the buildings, with particular attention to the circulation of air throughout the asylum and to the external decoration.

Asylums were usually sited some miles outside of towns or cities: far enough away to avoid disturbing the public, but near enough to facilitate the transport of patients. Friern Hospital was constructed on a rural site north of London and the nearest railway line was extended to make it accessible. The hospital was opened in 1851 by Prince Albert, the husband of Queen Victoria, and was designed to house a thousand patients. It rapidly filled up and its population continued to grow way beyond the original limit, reaching a peak of 2,400 a century after its inauguration. This rapid expansion was a general feature of asylums. Once a place of containment became available, the opportunity was seized to expel from society people with a wide variety of problems who were seen as undesirable. These included people with developmental disabilities, who were sometimes sent to segregated institutions and sometimes mixed indiscriminately with the mentally ill. There were even instances of women bearing illegitimate children who, when pregnant, were sent to such institutions where they spent the rest of their life.

As their populations grew steadily, the asylums became increasingly overcrowded, until they reached the point where the beds were so close together that patients had to climb over others' beds to reach their own. Overcrowding generated squalor, and since the staff were unable to cope with the large number of disturbed patients, it was almost inevitable that abuses occurred. The public scandals that ensued hastened the demise of the asylums, but before charting their decline it is worth considering how they functioned in their heyday.

The typical asylum was either a very large building or a collection of villas set in extensive grounds which were surrounded by a high wall with a single entrance guarded by a gate lodge. Within the walls were vegetable gardens and often a farm with cows and sometimes pigs. Some asylums had their own artesian wells and many were virtually self-sufficient or even produced a surplus. Powick hospital in the west of England during the 1920s was selling one thousand bushels of wheat and 1,800 pounds of beef per year. The patients provided the labor to work the farms, as well as helping in the hospital kitchens and the laundry. The use of unpaid patient labor was viewed by the trade unions in the West as exploitation and it ceased in most hospitals in the mid-twentieth century.

When patient labor was replaced by a paid professional workforce, activities for the patients had to be organized. These took the form of recreational activities, designated as occupational therapy, and work-like activities, often termed industrial therapy. Industrial therapy ranged from simple repetitive tasks such as assembling darts to complex procedures such as making furniture designed by the staff. The industrial therapy unit at Friern Hospital, at its peak, employed 120 people, some of whom commuted daily from their homes since nothing comparable existed in the community.

2. *The Turning Point*

In the UK the number of psychiatric beds climbed steadily for more than a century, reached a peak of 149,000 in 1954, and since then has fallen progressively. A similar pattern occurred in the USA, where the number of residents in state psychiatric hospitals declined from 186 per 100,000 in 1969 to 33 per 100,000 in 1992. Psychiatric bed occupancy has also been falling in most Western European countries since the 1970s but the rate differs by country. In Italy the number of psychiatric hospital beds rose from 36,000 at the beginning of the century to a peak of 188,000 in 1971. Since then there has been a steady decline to 7,500 in 1999, including both state and private hospitals. In Israel the number of psychiatric hospital beds has fallen from more than 11,000 to 6,000 in 1999. Four factors can be identified that prompted this change: the introduction of specific antipsychotic drugs, abuse of patients by staff that provoked public scandals, critiques of institutions by sociologists and others, and a change in the attitudes of psychiatrists.

It has been claimed that the key factor was the advent of antipsychotic drugs, but that cannot be the only answer since chlorpromazine, the first of the genre, came into general use in 1955, whereas in some pioneering psychiatric hospitals in the USA and UK the bed numbers began to fall in the late 1940s. By controlling disturbed and unacceptable behavior, the drugs certainly facilitated the process of deinstitutionalization, but they did not initiate it. Similarly, public scandals gave a high profile to the problems of institutions and helped to mobilize a search for alternative forms of care, but did not start the process.

Academic books criticizing psychiatric institutions began to appear at the end of the 1950s and certainly exerted some influence on the attitudes of psychiatrists and other staff. The first was by a psychiatrist, Russell Barton, and appeared under the title *Institutional Neurosis* in 1959. The term he invented was inappropriate since the great majority of patients adversely affected by institutional living suffered from psychotic illnesses. However he accurately described the apathy, inertia, lack of motivation and affective poverty which characterised long-stay patients in institutions. This was followed by a particularly influential book by Erving Goffman (1961) entitled *Asylums*. Goffman spent a year in the late 1950s observing interactions in a US psychiatric hospital. He described the humiliating rituals which were inflicted on new entrants and

saw their main purpose as being to sever all links with the everyday world outside the institution. He coined the term 'total institution', which he defined as 'a place of residence and work where a large number of like-situated individuals, cut off from the wider society for an appreciable period of time, together lead an enforced, formally administered round of life.' Asylums certainly provided accommodation and work, but in addition many supplied every amenity likely to be required in everyday life, including a place of worship, a patients' club, hairdressers, and shops, so that there was no need ever to leave the confines of the hospital.

These books, however seminal, appeared in print too late to explain the fall in beds in the pioneering asylums. For example, Dr. Duncan Macmillan, who occupied the unique position of Medical Officer for Mental Health for Nottingham, UK, established an outpatient clinic in the local general hospital in 1932. Later he became Physician Superintendent of the psychiatric hospital, Mapperley, and by 1957 the senior members of the hospital's medical staff were spending over 50 percent of their time in 34 clinics in the community. As a consequence of these developments, the number of inpatient beds began to fall in 1949.

World War II seems to have provided psychiatrists with experiences that led to innovative experiments in therapy. This entailed the recognition of the legitimacy of fear in the face of appalling danger, and affected soldiers were treated with psychological approaches. Military psychiatrists saw healthy young men break down with severe psychiatric syndromes under stress, and then recover when treated in group settings. In these military centers every aspect of the regime was designed to counteract the development of chronicity. At the end of the war, the army psychiatrists, imbued with optimism about the potential for recovery, took up posts in the psychiatric hospitals. They included British pioneers such as Maxwell Jones (1952) who founded the Henderson hospital as a therapeutic community for people with psychopathy, and Tom Main, who took over and transformed the Cassell hospital. As directors of psychiatric hospitals, these charismatic men had the power to make their vision a reality, unimpeded by bureaucratic inertia. However, they had to fight the resistance of other members of staff, who were often more institutionalized than the patients.

In the USA the impetus for attitude change also arose from the war, but from a surprisingly different source. Conscientious objectors were obliged to do public service in psychiatric hospitals. They brought into these institutions a humanitarian attitude which had not been dulled by the hospital regime. Furthermore, as they had no professional training, they treated the patients as equals and as valued individuals. The ferment they introduced into the system worked its effects on the professional staff.

3. *Decline and Fall of the Psychiatric Hospital*

Once the antipsychotic drug, chlorpromazine, became available, the handful of pioneering hospitals were joined by the rest in discharging patients in large numbers, and a steady decline in the number of occupied beds occurred in the USA and in England and Wales. This was not observed in Scotland, which had a separate health administration. The decline in England and Wales was so steady over a number of years that Tooth and Brooke (1961) predicted that the existing long-stay population of psychiatric hospitals would be eliminated through discharges and deaths by the year 1986. The reasons their prediction proved to be wrong are of considerable import. First, some patients admitted to acute wards remained in hospital for over a year. They were termed the 'new long-stay' in distinction to the old long-stay who were a relic of custodial care. Of course the distinction between the two is arbitrary depending on the point in time when observations are made. The significance of this group is that their problems are clearly not created by the institution but are a consequence of their psychiatric illness. Hence closure of the institutions will not abolish the 'new long-stay.' The second group of patients that confounded Tooth and Brooke's prediction are those whose behavior is so disturbed and disturbing that they cannot be moved to homes in the community. These 'difficult-to-place' patients pose a major challenge to deinstitutionalization and will be considered in more detail later.

Despite these problems, the run-down of the asylums has progressed to the point where many of them have been closed. In the USA the number of state psychiatric hospitals decreased from 277 in 1970 to 231 in 1996. There has been an even more dramatic change in England and Wales where 100 of the 130 psychiatric hospitals have closed since 1980. In Italy the closure of the institutions was achieved by revolution rather than evolution. In 1978 the Italian parliament passed Law 180 which prohibited the admission of patients to psychiatric hospitals thenceforth. This legal constraint on admissions did not directly affect the patients already resident in the asylums, and it took many years to improve their conditions of life.

Law 180 reminds us that changes in psychiatric services cannot be carried through by staff alone. They require the backing of the government of the day to provide the financial resources necessary to create and develop new services. The Italian law was pushed through parliament by the Communist party, whose support was recruited by Franco Basaglia, a charismatic psychiatrist and founder of the Democratic Psychiatry movement. In the UK there was no political polarization over deinstitutionalization. The closure of psychiatric hospitals was heralded by the Conservative Minister of Health, Enoch Powell, in a famous speech in 1961 in which he referred to the

asylums as 'isolated, majestic, imperious, brooded over by the gigantic watertower and chimney combined, rising unmistakeable and daunting out of the countryside.' Successive governments, whether of the right or the left, continued to endorse the policy, but with different agendas: the left supported patients' rights for ideological reasons, while the right hoped to save money by closing the old asylums.

4. *Alternatives to the Psychiatric Hospital*

Where were patients to live when they were discharged from an asylum? Wherever the process of discharge has been studied it has emerged that the least disabled patients were selected to move out first. Many of these patients were able to cope in independent accommodation. As the more dependent patients were considered for discharge, it became evident that they needed supervision in their community homes. For the most disabled patients, 24-hour supervision was required. The closure process for two London psychiatric hospitals, Friern and Claybury, was studied by the Team for the Assessment of Psychiatric Services (TAPS) over 13 years (Leff 1997). TAPS found that 78 percent of the long-stay patients were discharged to staffed homes. In the USA, Eileen Rothbard and her colleagues (1999) monitored the closing of Philadelphia State Hospital and found that 75 percent of the long-stay population were living in residences with 24-hour staff supervision. Intensive staffing invariably carries a high cost, since over 80 percent of the cost of care in the community is contributed by staff salaries.

The obvious choice might seem to be to resettle patients with their families, but this is rarely achieved for the long-stay patients. In the Friern and Claybury programs only 4 percent of them returned to their family home. This is partly due to loss of contact with relatives over the course of decades in an institution, which had occurred to 75 percent of the Friern and Claybury patients. The other reason is that a high proportion of patients are experiencing active delusions and hallucinations which are not controlled by medication and require specialized care.

In many of the resettlement programs, the more disabled patients live in small groups in ordinary houses, indistinguishable from neighboring buildings. This has an obvious advantage in easing reintegration into the community. However there are barriers other than distinctive architecture, which became apparent from the TAPS evaluation. Nearly 700 long-stay patients were followed up for five years after discharge to homes in the community. Although there was no amelioration of their psychiatric symptoms or problems in social behavior, they did acquire skills in caring for their homes and in using community amenities. Compared to the hospital wards, they enjoyed much greater freedom in their homes, which they greatly appreciated. When asked where they wanted to live, 84 percent preferred to stay in their current home, and almost all those who wanted to move wished to live independently. Only a handful desired to return to the hospital.

Beneficial outcomes for long-stay patients discharged from psychiatric institutions have been reported by other researchers in the UK and the USA, although few have studied a large sample of patients over a long period of time. An exception is Courtney Harding and her colleagues (1987) who conducted a 32-year follow-up of 269 patients discharged from Vermont State Hospital, USA in the 1950s as part of an experimental rehabilitation program. The findings were that over half the patients were functioning much better than expected.

One drawback to life outside the asylum that TAPS revealed was the failure of most patients to develop social relationships with their neighbors. Undoubtedly the impairment of social skills by schizophrenia was contributory, but it is not the whole story. Most of the patients were resettled in cities, where there is not a strong sense of community and even healthy neighbors have little to do with each other. Geoffrey Wolff and his colleagues (1996) mounted an experimental study of an education campaign in a street in which long-stay patients from a south London asylum were resettled. The campaign was successful in reducing neighbors' fear of the mentally ill and in increasing their social contact with the new residents.

Another problem is the lack of employment prospects for people with a long history of psychiatric hospitalization. When the national unemployment rate is high, it is almost impossible for someone with such a history to obtain a job. One solution is to establish cooperatives, or 'social firms' as they are sometimes known. These are particularly well-developed in Italy, and a comparison of people with schizophrenia between Boulder, Colorado, and Bologna, Italy (Warner et al.1998) showed that the Italian patients worked for more hours and earned more than the US patients. The development of employment opportunities for mentally ill people in the community needs far more attention than it has received to date, as it is one of the prime means of social integration.

5. *Is Community Care Affordable?*

It is not difficult to provide cheap community care. There have been several low cost schemes to house discharged patients in the USA and the UK. In the USA, 'board and care' was an inexpensive way to provide patients with accommodation, but very little else. The proprietors of these homes ran them as commercial enterprises and had little or no instruction

in the care of the patients. It is hardly surprising that patients were treated extremely badly in some cases, giving rise to public scandals. In the UK, patients were placed in seaside boarding houses, many of which are empty during the winter and would otherwise have closed until the summer season. Hence the offer of permanent residents all the year round was attractive to their owners. However, no provision was made for the patients' work and leisure needs, and television documentaries showed pathetic scenes of patients wandering along deserted windswept promenades in the driving rain. Patients placed in these seaside towns were even further from their districts of origin than when in the asylums.

The crucial question is how a *good* system of community care compares with hospital care in terms of cost. There have been very few attempts to make this comparison. The TAPS project involved a collaboration with a team of health economists who carried out a detailed costing of all services used by the long-stay patients when in Friern and Claybury hospitals and then when they had been in the community for one and five years. As this was done prospectively, the costs for specific individuals can be compared over time, adjusting for inflation. For all the discharged patients, the cost in the community after the first year was slightly less than their cost when in hospital, although the community costs rose slightly by five years (Leff 1997). However, not all the long-stay patients were discharged to community homes. A sizeable group were considered to be too disturbed to move to the community. When the hospital closed these difficult-to-place patients were transferred to highly staffed facilities, mostly on other hospital sites. The high staffing levels made their care very expensive, so that when they were added into the cost equation, community care became more expensive than care in the hospital had been.

By contrast, a costing exercise by Eileen Rothbard and her group (1999) for patients discharged from Philadelphia State Hospital showed that community care was considerably cheaper than the estimated cost of hospital care. Cost comparisons on their own are insufficient: what is needed are cost-benefit analyses across sites and countries.

6. *Critiques of Deinstitutionalization*

Criticisms have come from within the psychiatric profession and from outside, mainly from the media, from disgruntled family members, and from citizens who object to sheltered homes being established in their neighborhood. One of the most stringent professional critics has been Harold Lamb (1976) in the USA who has pointed to the large number of severely mentally ill people who are in prison. He argues that patients have been transferred from a relatively benign institution, the psychiatric hospital, to a punitive one, prison, and has dubbed this process 'transinstitutionalization.' Two related issues are raised by his critique: does community care inevitably lead to the imprisonment of the mentally ill, and are the mentally ill more dangerous than the average citizen? In the TAPS study, of the 670 patients followed up for five years after discharge only five spent time in prison, while 13 (2 percent) committed assaults on others. In the study by Eileen Rothbard and colleagues (1999), 2 percent of the 321 long-stay patients followed up for three years were involved in the criminal justice system. Thus it appears that a well-organized and funded community program does not lose many patients to prison, and furthermore that the great majority of mentally ill people are not dangerous. Unfortunately the media prefer to highlight the few tragic homicides that do occur, hence reinforcing the public stereotype of the 'mad axeman.' It is this irrational fear that fuels the 'not in my backyard' attitude of some members of the public. Geoffrey Wolff and his colleagues (1996) have shown that a localized educational campaign can reassure neighbors about ex-hospital patients coming to live in their street.

The other concern of the media and the public is that many patients discharged from long-term care end up on the streets. While the number of homeless mentally ill has undoubtedly increased, several surveys have found that very few of them have spent much time in psychiatric institutions. In support of this observation, less than 1 percent of the TAPS sample became homeless over five years and only 2 percent of the Philadelphia State Hospital ex-patients over three years. While no mentally ill person should be without a home, the problem stems from the inadequacy of aftercare for those coming out of admission units and not from the long-stay patients who are resettled in sheltered residences.

This raises the question of the balance of resources to be invested in community care programs. The asylums represent a large investment of capital, in the land and buildings, and of revenue, in staff salaries. The value of the site is often considerable since urban expansion has incorporated the once distant asylums. Various financial strategies have been used to release the capital and revenue bound up in the asylum, so that they can be reinvested in providing a good quality service for the long-stay patients. But patients with long-term disabilities continue to arise in a population and need the kind of rehabilitation facilities which used to exist in the psychiatric hospitals but have generally not been re-provided in the new services. Additionally, the care of acutely ill patients is becoming increasingly difficult with the ready availability of street drugs. It seems to be difficult for funders to invest in acute and rehabilitation services at the same time as providing for the long-stay patients coming out of the institutions. Within North America and Europe, only Finland seems to have achieved a

reasonable balance between these two sectors. Without such a balance, it is not surprising that family members are discontented with the service offered to their acutely ill relatives, and that deinstitutionalization has become the target of criticisms that should justly be directed at the failure to provide a *comprehensive* psychiatric service of a uniformly high standard.

Deixis

Deixis is a type of reference constituted by the meaning of a linguistic sign being relativized to the extralinguistic context in which the sign is used. The semiotic nature of this kind of reference, its exact communicative prerequisites and functions, its acquisition by children, and its processing have long puzzled linguists, philosophers, psychologists, and anthropologists. This article presents an introduction to some of the research that has focused on deictic signs and meanings and their phenomenology.

1. Introduction

It is one of the fundamental design features of human language that the interpretation of linguistic utterances may strongly depend both on the linguistic and the nonlinguistic context. This context dependence of linguistic reference is known as *indexicality* (cf. Silverstein 1976). It has been argued by philosophers that in fact without some such underlying indexicality in all *referring* expressions, no successful reference to the world would be possible (Putnam 1975). Take, for example, the utterance *She brought this flower for me yesterday*. The noun *flower* has a meaning that can be defined independently of context (e.g., 'the reproductive organs of a plant and their colored (nongreen) envelope'), and it can be used to refer to real or imaginary flowers that fulfill this definition. Yet, in order to refer successfully to a plant as a *flower*, more than mere knowledge of the meaning of *flower* is required: speaker and addressee have to agree on the plant being identifiable by that term (botanists, for example, use the term differently—they do not require the envelope to be colored).

However, there are expressions that point to the context in their very meaning, such that they cannot be used to refer to anything before the relevant information from the context is retrieved. In the above example, the pronoun *she* takes up a referent of feminine gender that must have been introduced in the preceding stretch of discourse (if the speaker announced in the preceding utterance that he is planning to marry his girlfriend Helen, then it will be inferred that it was Helen who brought him the flowers). This illustrates *anaphoric* reference. *Deictic* reference occurs whenever a linguistic sign receives part of its meaning from the *extra*linguistic context. For example, the pronoun *me* refers to the speaker—it has a different meaning depending on who utters it. The demonstrative *this* selects a referent in the speaker's proximity—*this flower*, as opposed to *that* one over *there* (at least in its most simple spatial use).

The verb *bring* designates transport to a deictically defined location (*here*); this could be the location at which the conversation takes place, or the speaker's home (there are in fact many possibilities). The past tense of *brought* indicates that the flower arrived at this location prior to the time of utterance, and the adverb *yesterday* restricts this time interval to the day before the day of utterance. So in order to know what exactly is meant by *She brought this flower for me yesterday*, and whether this statement is true, one first needs to know who uttered it, on what day, and where.

It can be argued that reference to most objects (including people), places, and times in the real world (to be precise, to all those that neither have a proper

name nor a unique status, such as celestial bodies) ultimately requires some form of deictic anchoring. To understand this claim, one may select an object at random from the environment and try to make a statement about it that avoids any form of deixis. If the claim is correct, it follows that language could not be used to talk about the real world (other than in generic statements) without deictic reference.

2. Deictic Expression vs. Deictic Use

The class of linguistic expressions that can be *used* deictically is much larger than the class of linguistic signs with an inherently deictic meaning. Relational expressions seem to have a particular propensity of being used deictically or anaphorically. Relational terms in the domain of spatial orientation are often used deictically, even when their 'arguments' are expressed nondeictically, because they imply a particular observer perspective. Thus, *The rock is left of the tree* means that the rock is to the left of the tree as projected from an observer, as the tree has no inherent left, and *The rock is in front of the tree* means it is between the observer and the tree, as the tree has no inherent front; the perspective will usually be understood as that of the speaker, the addressee, or both. However, the same terms refer nondeictically when used with respect to people (which do have an inherent left side) or, for instance, buildings (which do have an inherent front), respectively (Fillmore 1997).

3. Deixis and Indexicality

Definite descriptions are indexical. Thus, *the chair* refers to a chair that the speaker assumes to be uniquely identifiable to the addressee, e.g., 'the aforementioned chair.' Therefore, definite descriptions can be used deictically, provided the uniqueness condition is fulfilled in the context: *Move the chair over!* will be felicitous in a situation in which there is only one free chair in the room and the addressee is aware of that. Anaphoric expressions generally admit deictic use, while anaphoric use of inherently deictic terms is usually more restricted. True time-deictic expressions apparently cannot be used anaphorically at all, and neither can genuine first or second person pronouns. The English demonstratives *this* and *that* can both be used anaphorically, though under slightly different conditions (see Fillmore 1997), and so can the proximal and distal place adverbs *here* and *there*. In contrast, in Yukatek Maya, only the distal demonstrative forms and adverbs can be used anaphorically (Hanks 1990). The combined impact of the rather weak deictic anchoring of demonstratives in some languages and the pervasiveness of their nonspatial uses has led some researchers to propose nonspatial analyses of the underlying meanings. Similarly, Wilkins and Hill (1995) show that *go* and its equivalents in other languages only acquire a deictic reading pragmatically, through the contrast with a truly deictic *come*.

4. Transposed Deixis and Text Deixis

Textual deixis occurs when (part of) an utterance or discourse is itself the referent of a deictic expression, as in *The preceding sentence contains 27 words*. It has been suggested that some form of textual deixis is present in every anaphoric reference, to the extent that anaphors direct the addressee's attention to an earlier mention of the referent. As long as it is clearly discernible as deixis, textual deixis will always have a *metalinguistic* reference. But as soon as any part of the *meaning* of an utterance becomes the target, textual deixis becomes increasingly indistinguishable from anaphoric reference. An intermediary case is constituted by reference to propositions, facts, or events (cf. Lyons 1977).

Transposed deixis is constituted by an *imagined* situation replacing the actual speech context as the 'indexical ground' of a deictic form. When the imagined situation is itself described in discourse, this may have a quasi-anaphoric effect. Consider *He arrived in Paris in early May. Now he finally had the time to explore this great city*. The deictic forms in the second sentence refer to the time and place introduced in the first sentence. However, they are relativized to the character perspective and therefore function as true deictics. This perspectivizing effect was actually one of the primary concerns of Bühler (1934), who laid the foundations of modern research on deixis.

5. The Semiotics of Deixis

Many philosophers of language have pondered the nature of deictic expressions. Perhaps the most widely known account is within the semiotics of C. S. Peirce. Signs are classified in this framework based on the relationship between their form and the object they represent into *icons* (constituted by similarity; e.g., pictures, blueprints, maps), *indexes* (constitputed by an 'existential' relationship; e.g., a pointing arrow, or smoke as a sign of fire), and *symbols* (constituted by convention; e.g., hammer and sickle as the symbol of Communism). Like all linguistic signs, deictics are fundamentally symbolic on this account; that is, their form does not stand in any *natural* relationship with the object they designate. However, deictic expressions are then often considered 'indexical symbols' (e.g., Tanz 1980) which somehow combine symbolic meaning and indexical reference. Notice, though, that it cannot be the expression itself, as a *type*, that bears the 'existential' relation in Peirce's sense (which in the case

of deictics is always a relation of spatio-temporal contiguity), but only its *use* in a particular context, as a *token* (Silverstein 1976), as an acoustic or graphic gesture, as it were (often accompanied by a manual gesture, see below). This 'token-indexicality' evidently underlies *all* deictic reference, irrespective of whether the form used deictically is itself a deictic or a nondeictic expression. What, then, is the symbolic meaning of deictic signs?

6. *The Semantics of Deixis*

As illustrated with the example *flower* above, the conventional type meaning of a nonindexical term can be conceived of as a set of criteria that has to be fulfilled by all possible referents of the term. This is called an 'intension' in the tradition of Frege and Carnap. Indexical signs do not have such intensions. Perhaps the most striking feature of indexical *meanings* is that they cannot be completely reduced to nonindexical meanings (although the indexical components of an utterance may of course be replaced by nonindexical expressions that happen to have the same *referents*). Philosophers (notably Reichenbach) have attempted to paraphrase an utterance like *I am writing this article* as 'The person who writes the sentence that contains the reference to the person at the time of writing the sentence is writing an article that contains the sentence.' This would in fact eliminate all deictic reference, but it would also fail to identify any article or person in particular, and would therefore make little sense.

D. Kaplan has suggested that the meaning of indexical expressions is not an intension, but rather a rule that directly determines a referent in the context in which the expression is used (e.g., Kaplan 1990). For example, the rule associated with the pronoun *I* may be stated as 'The referent is the person using the pronoun.' It is not the rule that contributes to the propositional content of the utterance, but merely the referent. The rule belongs to a fundamentally different type of meaning, which Kaplan calls *character*.

It is presumably due to their lack of intensionality that no more than a few distinctions of deictic reference are made in each of a limited number of highly general semantic domains in every language. Deictic expressions single out persons as participant roles with respect to the speech act (speaker, addressee, nonparticipant, and, in some languages, nonaddressed participant); they may encode the relative social distance between these (an example are honorific pronouns such as French *vous* or German *Sie*; cf. Brown and Levinson 1987); they refer to objects in space (demonstratives), to locations (place adverbs and motion verbs; cf. Rauh 1982), and to times (tenses and time adverbials). No language has been attested to have a genuine event deictic, but many languages (including Yukatek) have manner indexicals (translating 'like this/that') that are used in reference to events.

7. *The Pragmatics of Deixis*

Indexical elements have, arguably, three functions in linguistic utterances. First, they represent the referent in the utterance, as a variable of sorts. Second, they specify what may be called a *search domain* for the referent in the context. Third, they direct the addressee's *attention* to the referent. The latter two functions constitute the 'character' of the indexical sign.

The complexity of deictic search-domain distinctions varies considerably across languages (see Anderson and Keenan 1985, Weissenborn and Klein 1982). Where the English demonstratives *this* and *that* make just a two-term distinction of distance relative to the speaker, the Bantu language ChiBemba is said to distinguish proximity to the speaker, proximity to the addressee, proximity to both, distance to both, and relative proximity to the speaker *with respect* to the addressee (other languages have been claimed to make even more fine-grained distinctions, but more recent research has failed to confirm such analyses). Whereas English demonstratives distinguish essentially *relative* distance, such that *this* and *that* may be used *contrastively* within a space close to the speaker, the Yukatek system mentioned earlier operates on an *absolute* proximal–distal distinction. Similarly, whereas English tenses merely distinguish past, present, and future with respect to the utterance time, many other languages distinguish e.g., a past of the same day from a 'yesterday' past, a 'tomorrow' future from a more distant future, and so on. ChiBemba distinguishes four such 'degrees of remoteness' in the past and four in the future (Givón 1972). For an example of a complex pronominal system, see Foley (1997, pp. 112–18) on Tagalog.

The conditions for felicitous deictic reference in space may depend on whether the addressee's attention is already on the referent or not. Some languages even have a formal contrast that matches this distinction. Thus, in Yukatek, the regular demonstrative forms translating 'this' and 'that' are expanded by deictic place adverbs ('this here,' 'that there') when the addressee's attention is not on the referent. It has been argued that what is traditionally considered the 'mid-distal' demonstrative of Turkish really has a purely attention-calling function and contrasts with the proximal and distal forms only in this domain, not in terms of distance from speaker (Özyürek 1998). Pointing gestures may support attention direction, and in addition serve to narrow down the search domain. Moreover, in case more than one potential referent of the same kind occurs in the search domain selected by the deictic form, pointing gestures may be used to disambiguate the referent. There are, however, search domains which can be referred to without any additional gesture, since they are uniquely identifiable to the addressee. This is true of *here* when used to refer to the speaker's location, and also of *there*, when used to designate the addressee's location,

e.g., during a phone conversation (Fillmore 1997). The extent to which the use of spatial deictics requires accompanying gestures seems to vary both with the context of use and with the language-particular term. The attention-directing demonstrative of Turkish cannot be used without a gesture at all. In addition to pointing gestures, iconic and conventional gestures may occur with deictic terms, such as extending the hand, open palm facing up, with presentatives (*Voila!*), or iconically indicating an extension in combination with *this big* or a manner of motion with *like this*. The relationship between such gestures and the linguistic reference act is different from the function of pointing gestures.

Directing the addressee's attention to an object in space is subject to the perceptual accessibility of the object. Many languages exclude the use of certain demonstratives in reference to objects that are not visible, or provide special forms for this purpose. Yukatek has a presentative form for referents of which there is perceptual (e.g., acoustic), but not visual, evidence (Hanks 1990). In the Wakashan language Kwakwa'la of British Columbia, every noun phrase is marked for whether its referent is visible to the speaker or not (Boas 1947).

8. The Genesis of Deixis

It has been argued that pointing gestures are a proto-form of reference, and that accordingly deixis should be the earliest form of verbal reference both in the phylogenetic rise of language in human prehistory (Rolfe 1989) and ontogenetically in child language acquisition (Clark 1978). Despite their plausibility, both proposals meet with a major difficulty: the perspectivizing effect of deixis requires highly non-trivial cognitive skills. Thus, there is no conclusive evidence that free-ranging primates use pointing communicatively, and it has been shown that chimpanzees in captivity produce what are commonly considered pointing gestures irrespective of whether they are seen by the addressee or not; in other words, they seem to lack awareness of the interlocutor's mental state of attention (Povinelli et al. 1997). Likewise, it is not the case that the first referring expressions acquired by children are deictics. The first deictic forms acquired by English-learning children are personal pronouns, and the adult-like use of these does not occur before the third year of life. Perspectivizing expressions such as *in front of* are consistently used nondeictically at first, and deictic usage does not come in until the fifth year (cf. Tanz 1980).

9. Conclusions

Deictic reference plays a particularly important role in language: it serves to 'hook up' linguistic representations to the world. Deictic expressions directly point the addressee's attention to a referent given in the situation in which the utterance is made, often in combination with gestures. By relativizing the utterance to the particular context in which a particular speaker uses them, they relativize the utterance to this speaker's perspective. The cognitive demands imposed on language processing by this perspectivizing effect are in sharp contrast with the apparent semiotic primitiveness of deictic reference and with its pervasiveness in verbal communication.

Delegation of Power: Agency Theory

1. The Role of Delegation

Delegation occurs when some people ask others to perform tasks on their behalf. For most of us, delegation is an important part of daily life. We delegate to grocers the task of acquiring various foods, we delegate to doctors the task of repairing broken bones, and we delegate to news agencies the task of informing us about local and world events. Delegation is beneficial because we can use it to overcome personal shortcomings. This benefit is important because each of us has limited time, energy, and talents. When the people to whom we delegate devote their time, energy, and talents to our needs, delegation increases the number of tasks that we can accomplish.

In addition to being an important part of daily life, delegation is a central concept in the conduct and the study of politics. Governments great and small use delegation to increase the range of services that they can provide. The governments of large nations, for example, delegate to defense ministries the task of maintaining national security and they delegate to finance ministries the task of managing their nation's economy. Indeed, the modern nation-state could not exist without delegation—for without delegation, lawmakers would be forced to implement and enforce every single law that they pass. With delegation, by contrast, national governments can address a wide range of social issues simultaneously.

In most polities, the most prominent form of delegation is from lawmakers (e.g., parliaments) to government agencies (e.g., economic, security, and public welfare agencies). Such agencies house the persons responsible for enforcing laws and tend to employ the nation's leading experts in the agency's policy area (e.g., economic agencies employ leading economists). In many places, these agencies are known collectively as the bureaucracy. In some places, people who work within these agencies are called bureaucrats or civil servants.

While delegation allows lawmakers to benefit from the expertise and abilities of others, it can also be hazardous. The hazards arise from the fact that delegation entails a transfer of power. For example, every time lawmakers delegate to bureaucrats, they give away a portion of their authority to govern.

The great danger of delegation is that the people to whom power is delegated will abuse the power they receive. This possibility is why some people equate delegation to abdication (e.g., a presidential resignation or a king giving up his throne). If this fear is realized, then those entrusted with the responsibility of governing lose control of what is done in the government's name and anarchy can ensue.

2. The Study of Delegation

The scholarly study of delegation occurs primarily in the fields of Political Science and Economics. This research examines when delegation confers the benefits of expertise to social decision-makers and when it leads to anarchy. It also helps scholars and practitioners around the world answer one of the most fundamental questions in politics, 'Why do governments do what they do?' For this reason, delegation has been a central focus for social scientists throughout the twentieth century.

2.1 Early Studies

In the first half of the twentieth century, scholars sounded a pessimistic tone about the consequences of delegation. Weber's (1946 p. 232) warning is among the best-known:

> Under normal conditions, the power position of a fully developed bureaucracy is always overtowering. The 'political master' finds himself in the position of the 'dilettante' who stands opposite the 'expert,' facing the trained official who stands within the management of administration. This holds whether the 'master' whom the bureaucracy serves is a 'people,' equipped with the weapons of 'legislative initiative,' the 'referendum,' and the right to remove officials, or a parliament, elected on a more aristocratic or more 'democratic' basis and equipped with the right to vote a lack of confidence …

Michels (1915) was also skeptical of delegation. In his iron law of oligarchy, he asserts that democratic organization inevitably becomes subordinated to the interest of their leaders and that the leadership becomes an entrenched oligarchy. Like most of his contemporaries and many of the scholars who followed him, Michels believed in the tendency of people to whom governing power is delegated to use their power against the interests of those who delegated such powers.

2.2 Recent Work: The Rise of Agency Theory

Modern scholarship has produced more precise insights about when delegation benefits those who delegate. Many scholars now adopt the language of

principal–agent models (i.e., agency theory) to describe the logic of delegation.

The *principal* in principal–agent theories represents someone who delegates. The *agent* represents someone to whom authority is delegated. When a lawmaker delegates authority to an agency, for example, the lawmaker is the *principal* and the agency is the *agent*.

Scholars use principal–agent models to determine when agents do (and do not) act in their principals' interests. *Agency loss* provides a common metric for their distinctions. Agency loss is the difference between the consequences of delegation for the principal and the best possible consequence. Agency loss is zero when the agent takes actions that are entirely consistent with the principal's interests. As the agent's actions diverge from the principal's interests, agency loss increases. When the agent does things that are bad for the principal, agency loss is high.

Research on delegation (see, e.g., Lupia and McCubbins 1998) shows that agency loss is minimized when two statements are true. The first statement is that the principal and agent *share common interests* (Niskanen 1971, Romer and Rosenthal 1978). In other words, the principal and agent desire the same outcomes. The second statement is that the *principal is knowledgeable* about the consequences of the agent's activities. In other words, principals know enough about their agents' actions to determine whether or not these actions serve their interests.

If either of these two statements is false, then agency loss is likely to arise. Agency loss arises when the agent and principal do not have common interests because the agent gains an incentive to act against the principal's interests. If a liberal lawmaker delegates to conservative civil servants, for example, then the agents have less of an incentive to pursue the lawmaker's favored policies than they would if they were also liberals. Agency loss arises when the principal lacks knowledge about an agent's activities because the agent can act against the principal's interests without the principal being aware of the indiscretion. If, for example, lawmakers asks the police to enforce a restriction on public drunkenness, but lack information about agency activities, then the police may not fear retribution if they choose not to enforce the restriction (see Gerber et al. 2001 for examples).

Agency loss is even more likely if neither of the two statements is true. In other words, when principals have conflicting interests with agents whose activities they cannot know, delegation is likely to be abdication. The threats are greatest in these situations because agents have both an incentive and an opportunity to act against the principal's interests without fear of retribution.

When comparing the main themes of modern and early work on delegation, we see that many early scholars reached their dour conclusions because they presumed that the two statements described above were false. More recent work disputes this presumption, uncovering the many ways in which principals can induce their agents to have common interests and learn about their agents' activities. While the new work does not totally contradict the idea that delegation can become abdication, it is more precise about when this negative outcome occurs.

A central theme in recent literature shows how principals design political institutions to affect the incentives and future actions of their agents. McCubbins et al. (1987), for example, examine how legislative decisions about the structure of political institutions affect the extent of agency loss. Drawing on a wide array of actual administrative procedures, they show that lawmakers can and do set rules for agents that reduce agency loss by ensuring that people who share their policy interests are able to influence what agents do. For example, lawmakers often not only require agents to file extensive reports on their activities, but also invite interested parties from outside the agency to do the same. These interested parties are chosen because they are known to share the lawmakers' policy preferences—including them in the process makes agents more attentive to the lawmakers' policy desires. Many studies also show how lawmakers attempt to reduce agency loss by choosing agents who share their interests (i.e., by making civil service appointments on a strictly political basis: see Epstein and O'Halloran 1999 and Laffont and Tirole 1993 for reviews of such findings).

3. *Future Trends*

Emerging trends in world politics make understanding delegation more important than ever. Many nations delegate increased responsibility to international organizations such as the European Union and the World Trade Organization. While such actions can produce lower trade barriers and increase social prosperity, they also require national governments to transfer power to others. Many people fear that such transfers will leave nations too weak to combat critical problems. As a result, the future value of research on delegation will be tied to how well it provides political leaders with the theory and evidence they need to make wise choices when delegating to others. Fortunately, today's scholars are responding to this challenge in creative and influential ways.

An emerging trend in delegation research clarifies which ways of delegating are most effective and efficient for political principals. Lupia and McCubbins (1998), for example, use principal–agent models and laboratory experiments to distinguish the types of institutional designs that are most effective in helping principals overcome problems associated with their lack of information about their agents' activities. Their results show when a wide range of political principals (i.e., voters, legislators, and jurors) can (and cannot) learn what they need to know about their agents.

Elsewhere, Epstein and O'Halloran (1999) use substantial theoretical and empirical research to distinguish when legislatures can (and cannot) benefit from narrowly constraining the agencies to which they delegate (see Huber and Shipan (2000) for a review of recent studies that adopt this perspective).

Works such as these will likely increase the extent to which real-world politicians learn the most effective and efficient ways to delegate. If they do, then delegation research will continue to give governments large and small the ability to cure broader ranges of social ills—a product of great value in an increasingly complex world.

Deliberation: Political Aspects

In its political signification 'deliberation' refers to a process of reasoning about political choices. Such choices may include, among others, the selection of political leaders; the development of the laws, public policies, or regulations that govern a state; or the formation of alliances or agreements with other nations. Political deliberation may occur both within governing institutions and among the citizenry more generally. Despite an ancient lineage, the concept of political deliberation was largely ignored by political scientists for much of the twentieth century. This inattention was dramatically reversed in the last decades of the century as political theorists and experts on governmental institutions focused increasingly on the processes of deliberative decision making and on 'deliberative democracy.'

1. Origins

The first systematic treatment of political deliberation is found in Aristotle's ethical and political works from the fourth century BC. In the *Nicomachean Ethics* Aristotle defined deliberation as the reasoned consideration and investigation of 'things that are in our control and are attainable by action' (Aristotle 1934, p. 135). In political life such deliberation is a necessary element of prudence, or practical wisdom, the preeminent virtue of the statesman. Political deliberation, which draws heavily on experience (Aristotle 1934, p. 351), concerns itself with 'things that are good and bad for human beings' (Aristotle 1934, p. 337). Unlike 'execution [of laws and policies, which] should be swift,' 'deliberating takes a long time' (Aristotle 1934, p. 353).

In his *Politics* Aristotle argued that all regimes have three basic parts: one which 'deliberate[s] about common matters,' one which administers the government through various offices, and one which adjudicates disputes among citizens, and between citizens and the state (Aristotle 1984, p. 139). He called the deliberative part—which is responsible for matters of war and peace, foreign alliances, laws, the choice of public officials, and judicial cases that carry the most severe penalties (Aristotle 1984, p. 139)—the 'authoritative element of the regime' (Aristotle 1984, p. 182). In ancient democracies there were various modes for public participation in political deliberation; most popular was the assembly in which the citizens of the city-state (the free adult males) came together periodically to deliberate on and decide the great issues that faced the polity.

2. The Rise of Modern Democracies

In modern representative democracies the people in their collective capacity choose their lawmakers but normally do not otherwise engage in authoritative deliberation and decision making on matters of war and peace, laws, and foreign alliances. Many of the founders of modern democracies shared the belief, as

stated by Montesquieu, that 'the great advantage of representatives is, their capacity of discussing public affairs. For this the people collectively are extremely unfit, which is one of the chief inconveniences of a democracy' (Montesquieu 1949, p. 154). This preference for political deliberation by the people's representatives rather than by the people themselves was shared by the framers of the US Constitution. As Alexander Hamilton wrote in one of his essays defending the proposed Constitution of 1787, '[i]n the ancient republics, where the whole body of the people assembled in person, a single orator, or an artful statesman, was generally seen to rule with as complete a sway as if a scepter had been placed in his single hand.' In such assemblies (as well as in very large legislative bodies) '[i]gnorance will be dupe of cunning, and passion the slave of sophistry and declamation' (*Federalist* 58 in Hamilton et al. 1999, p. 328).

The desire to promote deliberative lawmaking also explains, in part, the development of bicameral (two-house) legislatures as a common feature in representative democracies. Those who designed the US Congress, for example, believed that one relatively large branch, whose members served short terms so as to keep them close to public opinion, should be balanced by a smaller branch with longer terms, which would function, as James Madison said about the US Senate, 'with more coolness, with more system, and with more wisdom, than the popular branch' (Farrand 1966, Vol. 1, p. 151).

As democratic institutions spread in the eighteenth century, many came to believe that elected representatives should defer to the desires of their constituents on policy matters. The issue was whose deliberations should rule: those of the lawmakers, as formed by their participation in legislative debates, or those of the people themselves? British statesman Edmund Burke gave classic expression to the case for the independent judgment and deliberation of legislators in his famous 'Speech to the Electors of Bristol' (1774). Delivered to the voters who had just elected him to parliament, Burke's speech attacked the growing sentiment that the people had a right to instruct their representatives authoritatively on legislative matters. A legislator, Burke argued, was duty bound to exercise 'his unbiased opinion, his mature judgment, [and] his enlightened conscience' even if these led to conclusions inconsistent with public desires. 'Government and legislation,' he maintained, 'are matters of reason and judgment'; and that judgment must be formed by the debate and discussion that occur within lawmaking bodies. 'Parliament is a *deliberative* assembly of *one* nation, with *one* interest, that of the whole; where … the general good, resulting from the general reason of the whole [ought to guide]' (Burke 1949, pp. 115–16). Although Burke's view was not universally accepted at the time, it became the dominant understanding of theorists and statesmen for many decades hence.

3. *Twentieth Century Developments*

In the twentieth century two powerful alternative interpretations of decision making within governing institutions pushed deliberation to the background. One was the development of the group theory, or pluralist interpretation, of democratic politics that gained prominence in the 1950s and 1960s. This view identified bargaining among group interests, rather than collective deliberation about a common good, as the decisive characteristic of governmental, and especially of legislative, decision making. The second development was the rise of rational-choice theories that posited that legislative decision making could be best understood as a process of aggregating the personal goals and ambitions of political actors. Rational-choice theorists maintained that legislators do not argue and reason together about what constitutes, or how to achieve, the public good but rather find ways through the legislative process to achieve their personal preferences.

Interest in political deliberation was rekindled in the 1980s as a result of (a) the empirical limitations of the alternative paradigms (they could not account for much of what happens in legislatures); (b) a renewed appreciation of the normative consideration that if democracies are to function well they need the capacity to engage in sound deliberation about matters of common concern (both within the governing institutions and among the populace more generally); and (c) a revival of interest in participatory politics, especially among democratic theorists.

4. *Characteristics of Deliberation*

In a process of political deliberation the actors reason together about some matter requiring a political or governmental decision. In so doing they must be open to the facts, arguments, and proposals that come to their attention, and must share a willingness to learn from their colleagues and others. Although such processes may take a variety of forms, deliberative decision making by its nature involves three essential elements: information, arguments, and persuasion. Information here refers to the substantive facts pertinent to some policy issue; arguments connect facts with desirable goals; and persuasion refers to the change or development in the minds of deliberators that results from the reasoned consideration of facts and arguments. As commonly, if not universally, understood, political deliberation is centrally concerned with the merits of public policy. It is, then, distinct from political strategizing, from reasoning about purely self-interested considerations, and from political bargaining—none of which necessarily involve a reasoned consideration of the merits of policy (Bessette 1994, pp. 46–55).

5. Deliberation and Governing Institutions

Within the governing institutions of liberal democracies deliberation is the particular, although not the exclusive, province of the legislative branch (especially in separation of powers regimes). One reason that legislatures in liberal democracies typically are relatively large collegial institutions is to promote the serious consideration of a variety of opinions on policy issues. Moreover, the internal structure (especially committee systems) and the formal rules that govern legislative procedures are designed, at least in part, to promote the careful and (generally) unhurried review of policy options. By contrast, hierarchical and centrally organized executive branches are structured less to promote deliberation than quick, decisive, and sometimes secret, decision making and action (see especially *Federalist* 70 in Hamilton et al. 1999, pp. 391–9). Members of executive branches must, nonetheless, deliberate about such matters as appointments, legislative proposals, the use of military force, and the conduct of foreign policy. The problem is that hierarchy, secrecy, and the need for quick decisions may inhibit sound deliberation.

6. Democratic Deliberation

Despite the renewed interest in the deliberative capacities and functions of governmental institutions, more scholarly attention has focused on deliberation among a democratic citizenry than among its elected representatives. Although the term 'deliberative democracy' is the one most widely used by scholars to characterize 'the idea that legitimate lawmaking issues form the public deliberation of citizens' (Bohman and Rehg 1997, p. ix), some scholars use instead such terms as 'communicative democracy,' 'discursive democracy,' and 'unitary democracy.'

Proponents of deliberative democracy tend to share the belief that policy deliberations by an energized populace will both make for better citizens and help to ensure that national policy will conform to reasonable public desires. Scholars disagree, however, as to whether and how intelligent public deliberation can occur within the large nation-state. Some look to smaller political subunits as the more likely locus of such deliberation (Mansbridge 1983). Others raise concerns about the power of government officials to manipulate public deliberations (by, for example, withholding vital information) or about the ability of the media to shape debates and outcomes (Page and Shapiro 1992, pp. 355–82, Page 1996). Another proposes, as a surrogate for national public deliberation, choosing a random sample of the populace to come together to deliberate (Fishkin 1991). Yet other scholars remain confident that new institutions and procedures (such as neighborhood assemblies, televised town meetings, office-holding by lot, and a multistage national initiative and referendum process) can promote sound public deliberation on national issues (Barber 1984). The spread of the Internet has raised new possibilities for informing and educating the citizenry, and for assessing public reaction and opinion (so-called 'electronic democracy' or 'teledemocracy').

The key issue surrounding political deliberation in liberal democracies remains, as was the case in the time of Edmund Burke, the extent to which national policy should be decided by the independent deliberations of elected officials or whether the formal decision makers should defer to, or at least take direction from, the direct deliberations of the citizenry.

Delinquency, Sociology of

1. Sociology of Delinquency

The purpose of this article is to elucidate the major ideas and questions that have animated sociological theories of delinquency over the course of the twentieth century. Current trends and the direction that future research is likely to take in the twenty-first century are also examined. First, the study of delinquency is placed in its definitional, historical, and intellectual context.

2. What is Delinquency?

Delinquency is generally thought to mean criminal behavior committed by juveniles under the legal age of adulthood. A widely used definition was proposed by Hirschi (1969, p. 47), '[D]elinquency is defined by acts, the detection of which is thought to result in punishment of the person committing them by agents of the larger society.' Although the notion of juvenile delinquency is now ubiquitous, prior to the late nineteenth century few legal distinctions were made between juveniles and adults. Even childhood itself is a relatively modern concept.

Breaking from the tradition of treating children as 'miniature adults,' the start of the twentieth century witnessed a group of reformers in Chicago create the first juvenile court. The motivating idea was that children had special needs, and that to treat them like adults violated American ideals of fairness. The juvenile court was to act as a 'parent' for troubled youth whose own families could not, or did not, control them. The doctrine of '*parens patriae*' led to profound changes in how juveniles were treated, not only for the commission of crimes, but also for a range of so-called 'status' offenses (truancy, use of profanity, sexual precocity, tobacco use, running away, and curfew violations). Although most theories of delinquency focus on criminal rather than status offenses, versatility is the hallmark of adolescent misbehavior.

3. Multifactor Correlates of Delinquency

In the early part of the twentieth century, disciplines such as biology, psychiatry, and psychology were major players in delinquency research, along with sociology. In what was then known as a 'multifactor' approach, research proceeded in a purely empirical fashion by identifying all possible correlates of delinquency. Many factors were identified, such as poverty, being male, lack of parental discipline and supervision, poor school performance, peer delinquency, large family size, parental criminality, and immigrant status. Scholars also established a sturdy array of individual characteristics associated with delinquency, including hyperactivity, early conduct disorder, impulsiveness, and low measured intelligence. Moreover, research showed that a small group of juvenile delinquents became repeat offenders and adult 'career criminals,' reinforcing the belief that the State needed to identify and treat troubled youth at an early age. The basic correlates of delinquency have held remarkably consistent over time, as has the belief in a small group of chronic offenders that commits the majority of delinquent acts (Laub 2001).

4. Classic Sociological Theories of Delinquency

Beginning in the 1920s, the sociological study of delinquency began to take a different tack than other disciplines. Against the multifactor approach emerged a shift in attention away from the individual offender and toward the social milieu thought to produce the delinquent. Indeed, as Matza (1964) has argued, the two major contributions of sociology to the understanding of delinquency are that deviance has a history in particular locales and that delinquency best flourishes when it has group support. The 'Chicago School' provided the intellectual breakthrough that spawned this twofold contribution.

4.1 Social Disorganization

Steeped in the tradition of urban sociology pioneered by Park and Burgess at the University of Chicago, Shaw and McKay (1942) proposed a community-level approach to explaining delinquency. In their classic work, *Juvenile Delinquency and Urban Areas*, Shaw and McKay argued that three structural factors—low economic status, ethnic heterogeneity and residential instability—led to community social disorganization. In turn, delinquent gangs and the age-graded transmission of delinquent traditions ensued, accounting for the ecological concentration of delinquency. Delinquent traditions and high crime rates persisted in the same communities over time, Shaw and McKay maintained, regardless of the racial or ethnic groups passing through. Social disorganization was later reconceptualized by Kornhauser (1978) as the inability of a community to realize the common values of its residents and maintain effective social controls. The social-disorganization approach is noted for its focus

on the explanation of rates of delinquency rather than on factors that distinguish offenders from nonoffenders.

4.2 Differential Association

A related intellectual development was linked to one of the most dominant theories of the twentieth century—differential association. In 1934, Sutherland's *Principles of Criminology* was published (Sutherland 1934). As described by a leading student of the theory, 'The balance of learned criminal and anticriminal definitions determines whether one will be conforming or deviant with respect to a given legal code. If the balance of definitions is favorable to abiding by the law, the outcome is conformity; if violative definitions are in excess criminal behavior is the result' (Akers 1998, p. 27). Burgess and Akers (1966) revised the theory to argue that an individual is more likely to commit a violation when he/she differentially associates with others who commit, model, and support law violation; the violation is differentially reinforced; he/she is exposed to more deviant than conforming behavior; and his/her own learned definitions are favorable to committing deviance (Akers 1998, p. 51). Differential association theory thus turns on the idea that delinquency is learned, and that exposure to delinquent definitions (the ratio of definitions favorable to law violation over definitions unfavorable) is the key to explanation.

4.3 Anomie and Subculture

Merton's seminal article, *Social Structure and Anomie*, (1938) set the stage for another dominant strand of sociological inquiry. Merton claimed that there was a disjuncture in American society between the materialist goals to which all aspired (the 'American Dream') and the opportunities to reach them. In a stratified or unequal society coupled with a common value system that stresses material gain, strain, or 'anomie,' is inevitable. Merton developed a typology of adaptations to structurally induced strain; crime, he reasoned, was the innovative response to blocked opportunities. Merton took it for granted that anomie and crime were greatest in the lower socioeconomic strata of American society.

It fell to Cloward and Ohlin (1960) to carry Merton's theory to its logical conclusion for youth, especially adolescent males in lower-class areas of American cities. Finding routes to conventional success blocked, Cloward and Ohlin argued that deprived adolescents formed delinquent subcultures. But the opportunities for crime also varied, with some youth joining criminal subcultures, others conflict (fighting) subcultures, and still others found themselves in retreatist subcultures characterized by drugs and alcohol. Another class-based subcultural theory was proposed by Miller (1958), whereby the focal concerns of lower-class culture—especially an emphasis on 'toughness'—were argued to spawn a generating milieu of juvenile delinquency.

Cohen (1955) also wrote an influential treatise on delinquent subcultures, but his focus was on the status frustration of lower-class boys in an educational system dominated by middle-class standards. The motivation to join delinquent subcultures was not economic in origin, according to Cohen, but frustration borne of educational inadequacy and humiliation in school. The result was 'negativistic' delinquency (e.g., vandalism).

4.4 Control Theory

Rather than looking at 'push' factors to delinquency, such as blocked opportunities and subculture, control theory reverses course and sees delinquency as a lack of restraint. At the heart of control theory is the assumption that delinquent acts result when an individual's bond to society is weak or broken. Delinquency is viewed as a natural outcome of unrestrained human motives, and hence a 'pull' factor. Although there are several versions of control theory that share this basic viewpoint, by far the most influential has been that of Hirschi in *Causes of Delinquency* (1969). Hirschi posed the now-classic question about delinquency, 'Why don't we do it?' His answer is that most juveniles are bonded to society through attachment, involvement, commitment, and belief. Hirschi (1969) showed, however, that these elements of social control varied widely across adolescents and were strongly related to lower delinquency regardless of social status or class background.

4.5 Labeling and Societal Reaction

Unlike theories that explain the origin of delinquency, the innovation of labeling theory was to focus on official reactions to delinquent acts. In Becker's famous dictum, deviance is not a quality of the act a person commits, but rather a consequence of the application by others of rules and sanctions. 'The deviant is one to whom that label has successfully been applied; deviant behavior is behavior that people so label' (Becker 1963, p. 9). The insights of labeling theory led to two strands of research, one on the sources of juvenile justice sanctions, and the other on the consequences of labeling. The latter is most relevant for understanding delinquency causation in the traditional sense. Lemert (1951) maintained that

stigmatizing reactions to primary (or original) deviance created what he termed secondary deviance. In other words, whereas primary deviance arises for a wide variety of reasons, Lemert argued that secondary deviation is an adaptation to problems of adjustment created by official societal reactions. The original causes of deviation thus give way to the disapproving, degradational, and isolating reactions of society, leading to exclusion from conventional opportunities and increased contact with deviant subgroups, and finally to secondary patterns of delinquency. According to Becker (1963 pp. 24–39), delinquent careers are sustained by official labeling and sanctioning processes.

5. *Recent Currents in Delinquency Research*

Social disorganization, differential association, anomie, subcultural, control, and labeling theories have generated a plethora of empirical studies that are beyond the scope of this review. It is fair to state that in some form or another, all these theories remain viable competitors in the current explanation of variations in delinquency. However, a number of developments have taken place to complicate the theoretical story laid down by the classic perspectives.

5.1 *Measuring Delinquency*

Debates have raged for the last few decades on the proper way to measure delinquency and test the classical theoretical perspectives. There are three major sources of data that have been used, self-reports of delinquent behavior, victimization surveys, and official accounts (e.g., arrests, court records). Unfortunately, these sources of data do not always agree. In general, survey-reports of delinquency show weaker associations between social status (e.g., poverty, race, gender) and delinquency than official records. Whether or not the differential correlations of social factors with official records and self-reports reflect bias by the State or methodological weaknesses in survey research is still subject to debate. There has emerged a consensus, however, that the two sources of data yield reasonably similar patterns when the object of inquiry is serious and persistent delinquency (Hindelang et al. 1981).

5.2 *Peer Influence*

One of the sharpest disagreements in the sociology of delinquency centers on the fundamental insight (Matza 1964) that (a) most delinquency is group behavior, and (b) most delinquents have delinquent friends. Differential association theory claims, of course, that peers influence delinquency. But the hypothesis that 'birds of a feather flock together' (Glueck and Glueck 1950) was offered as a direct challenge to this interpretation, and there has been dispute ever since. It is not an exaggeration to say that after decades of research on the matter, we do not know for sure whether peers cause delinquency or delinquent adolescents choose delinquent friends. Although peers remain one of the strongest correlates of delinquency, empirical attempts to identify the causal mechanism thus continue to be paramount. One of the ways in which the mechanism is likely to be identified is through social network analysis, whereby the delinquency patterns of peer groups are independently assessed through sociometric methods.

5.3 *Routine Activities*

The 'routine activities' perspective (Cohen and Felson 1979) was built on the insight that predatory crime involves the intersection in time and space of motivated offenders, suitable targets, and the absence of capable guardians. Because illegal activities feed on the spatial and temporal structure of routine legal activities such as transportation, work, and shopping, delinquency cannot be understood apart from the ecology of everyday life. For example, the increased availability of lightweight, durable goods (radios, cell phones) and the location of stores, entertainment, subway stops, and unsupervised play spaces near schools are opportunities hypothesized to induce delinquency independent of the pool of motivated offenders. Routine activity theory represents a major shift in thinking that shapes current research.

5.4 *Age Invariance and Self-control*

With much controversy, Gottfredson and Hirschi (1990) introduced the concept of 'self control' and argued that the age–crime curve (with delinquency peaking in late adolescence) is invariant across social conditions. They proposed that low self-control causes crime at all ages; self-control differs between individuals but remains constant over the lifetime of a person. In this view, delinquent behavior is generated by heterogeneity across individuals in an underlying propensity to pursue immediate self-gratification. Because differences in self-control are alleged to emerge early in adolescence and remain stable thereafter, Gottfredson and Hirschi (1990) argue that the distinction between delinquency and adult crime is not meaningful theoretically. Attempts to test age-invariance and low self-control represent a major stream of research.

5.5 *Life-course Approaches*

Sociologists have typically addressed the problem of delinquency by studying why some adolescents commit crimes and not others, leading to between-individual analyses and attribute-based correlates

(e.g., sex, family background, personality). The life-course framework proposes a different strategy. Taking a developmental view on changes within persons, life-course criminology is motivated by an apparent paradox: although adult criminality is nearly always preceded by antisocial behavior in childhood, most antisocial children do not become criminals as adults. There is marked variability in adult outcomes even among serious and persistent juvenile delinquents. For example, Sampson and Laub (1993) found that none of the static variables measuring family background, such as poverty, parental criminality, and child supervision, predicted trajectories of adult offending among formerly incarcerated delinquents. Measures of childhood extroversion, egocentricity, aggressiveness, and difficult temperament also failed to distinguish persistent offenders from desisters. Looking forward from youth thus reveals troubled adolescents who desist, yet, apropos the paradox noted above, looking back over the careers of adult criminals exaggerates the picture of stability.

In short, background variables are surprisingly weak in the prospective explanation of trajectories of delinquency over the life course. Sampson and Laub's (1993) life-course theory argues that the reason is because within-individual changes in delinquency are mediated by proximate and time-varying social processes grounded in life transitions, situational interactions, routine activities, and turning points. They propose an age-graded theory of informal social control, where the manifestations of social bonds vary by developmental phases of aging. According to this perspective, theories limited to time-stable factors are incapable of unpacking the temporally variable pattern of individual trajectories of delinquency. Efforts to explain stability and change in delinquency over the life course, along with controversy over whether a small group of persistent offenders comprises the heart of the delinquency problem, dominate recent research and policy debates in delinquency (Laub 2001).

5.6 *Community Variations and Social Process*

A final move concerns the social mechanisms that account for the association of community-level background characteristics with rates of delinquency. A renewed tradition of ecological research has focused on the increasing concentration of poverty in cities worldwide and its implication for delinquency. If 'neighborhood effects' of concentrated poverty on delinquency exist, as hypothesized by Shaw and McKay (1942), presumably they are constituted from processes that involve collective aspects of community life (e.g., social disorganization, reduced collective efficacy). Yet studying these processes has proven difficult for a host of reasons, such as reciprocal causation (crime can cause concentrated poverty) and the differential migration of individuals into and out of communities. Moreover, neighborhood-level research has been dominated by the cross-sectional study of poverty and other demographic characteristics drawn from government statistics that do not provide information on explanatory mechanisms and dynamic processes. A growing body of research in criminology has thus committed to analyzing both structure and process at the community level (Sampson et al. 1997).

6. *Whither Sociological Delinquency?*

There is good reason to believe that the multilevel study of dynamic social processes will be at the forefront of future sociological inquiry in delinquency. Harnessed to the rich tradition of sociological theory on structured inequality, the prospects appear bright for better understanding of social processes of stability and change, within both individuals and communities.

Demand for Labor

Demand for labor denotes the number of workers and the intensity of effort sought by employers—companies, governments, and others that hire workers. It is derived from employers' desires to profit or otherwise to satisfy customers or clients by selling or providing products or services whose creation requires human inputs in some form. The study of labor demand focuses on the determinants of these inputs into production, how they are affected by other economic variables, and how government policies alter them. The demand for labor helps to generate and partly determines the monetary payments that provide about three-quarters of national income in most industrialized economies.

1. *Static Theory*

We can imagine an employer using technology, described by a production function, that links output Y to inputs such as labor, capital, materials, etc., all represented by L and a vector of other inputs X:

$$Y = F(L, X) \tag{1}$$

If we assume that the employer minimizes the cost of production, the demand for each input is determined by its own price (in the case of labor, the wage, w), other inputs' prices, p_x, the product's price, p, and the scale of the enterprise Y:

$$L = L(w, p_x, p, Y) \tag{2}$$

Throughout this article I subsume in w all costs of employment, including wages, nonwage monetary benefits paid to workers, and also nonmoney benefits. In studying the demand for inputs we typically set the product price equal to 1 , so that the input prices are adjusted for inflation. This labor-demand function then focuses on changes in employers' labor inputs in response to changes in the wage rate (the own-price effect), prices of other inputs (cross-price effects), and total output (the scale effect). All of these responses are determined solely by the underlying technology summarized in the production function. In the end the demand for labor is a technological relationship, but one that is generated by cost-minimizing and often profit-maximizing behavior. Its derivation from underlying economic motivations is similar to that of the consumer's choice of goods and services (see *Consumer Economics*).

A major focus since Marshall (1920) has been on the own-wage elasticity of labor demand—the percentage change in labor demanded in response to a 1 percent increase in the wage rate. Marshall offered four ' laws ' describing the determinants of this elasticity. It is higher: (a) the more readily substitutable other inputs are for labor; (b) the easier it is for customers to switch away from the product when its price rises after an increase in labor cost; (c) the greater share that labor cost represents in the enterprise's total cost; and (d) the more readily the supply of other inputs adjusts when a higher wage leads employers to attempt to switch away from labor and toward other inputs.

Measuring the wage elasticity of labor demand and the underlying technology that generates it has been the central empirical focus of the study of labor demand. The measurements answer the crucial question: if the cost of labor is raised, do employers cut the amount of labor they use, and by how much? The representation of technology that we use to infer the magnitude of this elasticity has become increasingly general over the years. The Cobb–Douglas function (Cobb and Douglas 1928) imposed the requirement that the own-wage elasticity equals $(1–s)$ at each constant output level, where s is the share of labor in total cost. The Constant Elasticity of Substitution function (Arrow et al. 1961) allowed this elasticity to assume any constant value, but it required the cross-price elasticities of labor with respect to each other input to stand in the same ratio as the other inputs' shares in costs. When we attempt to infer this elasticity today we either estimate it directly from labor-demand functions like Eqn. (2) or use generalized representations of technology, such second-order approximations as the translog function (see, e.g., Berndt and Christensen 1974). These approaches allow estimates of the own-wage and cross-price elasticities to take on any value indicated by available data on input quantities, their prices, and the scale of production.

The discussion thus far treats labor as if it were homogeneous, which is obviously wrong. One could expand Eqn. (1) to include labor disaggregated by any set of criteria of interest, for example, sex, race/ethnicity, age, educational attainment, occupation, immigrant status, and others. In each of these cases Eqn. (2) expands into a system of equations, one for each group of workers, each containing the wage rates of each type of worker, other input prices, and scale Y. These expanded representations of technology allow researchers to examine how em-

ployers substitute among workers of different types. They generate estimates of cross-wage elasticities that indicate how the demand for one type of worker changes when the wage costs of others rise or when the prices of nonlabor inputs, particularly the cost of capital services, change. These may be positive, indicating that the two types of workers are p-substitutes, or negative, indicating that they are p-complements.

Equations (1) and (2) and the expanded versions that include several types of workers assume technology is unchanging. The existence of technical progress means that the demand for workers of different types may change even without changes in wage costs. Technical progress may, as seems to have been true in industrialized countries in the 1980s and 1990s, enhance the productivity of skilled relative to less-skilled workers and thus increase the relative demand for skill (see *Innovation and Technological Change, Economics of*). With a limited supply of skilled workers this in turn raises their relative pay, partly choking off employers' desires to employ more of them (see *Wage Differentials and Structure*). The rate and nature of technical progress mean that the underlying technological parameters that determine own- and cross-wage elasticities are changing, so that the parameters themselves are not constant over time.

2. *Inferring the Structure of Labor Demand*

Moving from the theory to inferring the sizes of the responses requires ensuring that we measure employers' reactions rather than other behavior, particularly changes in the supply of labor (see *Labor Supply*). The issue is one of identification—inferring from simultaneous changes in such outcomes as wages and employment (either of all labor, or of particular groups of workers) which ones reflect employers' responses. Consider Fig. 1, which shows two data points, A and B, describing combinations of wage rates and labor employed in a market observed at two different times, or in two different labor markets. Empirical economists might connect these two points, assume that they are traced out by changes in the supply of labor from S0 to S1, and infer that they lie along the demand curve for labor D. The percentage change in L relative to the percentage change in w between these points could then be used to measure the own-wage elasticity along this demand curve.

Figure 1
The labor market, illustrating the difficulty of identifying the labor-demand elasticity from combinations of wages (w) and labor (L)

Making this inference might be wrong and misleading. Points A and B could have been generated by a shift in supply from S0 to S1 that was simultaneous with a shift in demand from D0 to D1. Labor demand might have shifted because product demand increased, because technology became more labor-using, or because the price of some p-complementary input to labor fell or that of some p-substitute rose. In that case the true demand elasticity (along D0 or D1) is smaller than the estimate one would obtain by ignoring the possibility that demand shifted. One must adjust for those factors that we believe shift demand (p_x and Y in Eqn. (2)). Most importantly, one needs to find an exogenous source of variation in supply, so that we can be sure that the variations we observe in the combinations (w, L) are generated by shifts that are beyond employers' control. After substantial concern until the 1960s about properly identifying labor-demand responses, it is only since the early 1990s that research on labor demand has refocused researchers' attention on identifying changes in (w, L) combinations as reflecting movements along a demand curve.

3. *Estimates of Wage Elasticities*

3.1 *Sizes of Responses*

An immense body of empirical research has been devoted to measuring the own-wage elasticity of demand for homogeneous labor. Using data on employment, wages, and scale (output) of entire countries, major industries or small industries examined over time, or on individual employers at a point in time, researchers have attempted to pin down this central parameter in the theory of labor demand. Others have used similar data for other research purposes, with estimates of this parameter being a by-product of their investigations. Estimates have been produced for most industrialized countries and for many developing countries.

The central conclusion of the empirical literature on the demand for labor validates the principle of substitution. At a given scale of output, a rise in labor costs leads employers to substitute away from labor and toward other inputs whose cost has not risen. This is true in nearly all the over 100 studies summarized by Hamermesh (1993, Chap. 3) that were unconcerned

about problems of identification. It is also true in the newer literature that pays special attention to ensuring that the slope of the demand curve is identified (e.g., Angrist 1996). With the many different sets of data and methods, the estimates of elasticity vary widely. Nonetheless, the bulk of estimates cluster in the range -0.15 to -0.75, with a ' best-guess ' meta-analytic estimate being -0.30. At a given level of output, a rise in labor cost of 10 percent will eventually reduce employment by 3 percent as employers substitute toward technologies that use less of the now more-expensive labor and more of the now relatively cheaper other productive inputs.

The constant-output own-wage elasticity tells us the degree of substitution between labor and other inputs. That knowledge is useful, for example, for inferring how much extra employment is generated at a given level of output when employment is subsidized, or how much might be lost when payroll tax rates are raised. In order to infer the full effect on employment of labor taxes or subsidies, or of changes in other input prices, in an economy with some available labor (one that is not at full employment) we also need to add the scale effect of changes in labor costs. The evidence suggests that the scale effect is fairly substantial, probably larger than the substitution effect, so that the total elasticity of labor demand for the average employer may be as large as -1.0. Interestingly, this estimate, based on a very large body of empirical studies, is exactly what is implied by the simplest representation of technology, the Cobb–Douglas production function.

When Eqn. (2) is expanded into a system of demand equations describing several types of labor, our ability to draw fairly tight inferences about the sizes of the own- and cross-wage elasticities is diminished by the sheer number of possible disaggregations. The current literature says nothing definite about the absolute sizes of particular own- and cross-wage elasticities, and making progress on this front is high on the agenda for research in the next decade. Nonetheless, the literature does offer some secure conclusions about such parameters for skills defined generally. There is very strong empirical support for the notion of capital-skill complementarity (Griliches 1969)—cuts in the cost of capital services not only lead to more capital being used, but also lead employers to use relatively more skilled and fewer unskilled employees at each output level.

One might array workers by their level of skill and also use the empirical literature to infer the relative sizes of the own-wage demand elasticities for skill. Examples include rankings from most to least formal education, from longest to shortest tenure with their employer, or from technical/professional worker to laborer. Arraying workers by skill yields the inference that own-wage demand elasticities are more negative—larger responses of labor demand to the same percentage change in labor costs—the less skill is embodied in the group of workers. This conclusion is supported by a wide variety of studies within individual economies, but it also seems valid in comparing own-wage demand elasticities for homogeneous labor across economies at different stages of economic development.

3.2 *Usefulness for Policy*

Estimates of own- and cross-wage elasticities are central to debates over a large variety of social and economic policies. If, for example, we wish to determine how imposing a higher payroll tax to finance national health insurance might affect employment, knowledge of the own-wage demand elasticity for labor is central to predicting employers' responses. Many governments encourage employers to add particular types of workers (typically low-skilled workers) by subsidizing their employment cost using targeted wage subsidies. The success of such policies depends on the own-wage demand elasticity for the targeted group. Many payroll taxes have ceilings on the employee's earnings on which the employer must pay the tax. Others exempt some initial amount of earnings from the tax. A rise in the payroll tax ceiling implicitly raises the relative cost of higher-wage workers, leading employers to substitute toward lower-wage workers, with the extent of substitution determined by the cross-wage elasticity of demand between high- and low-wage workers. A rise in the level of initial earnings exempt from payroll taxes induces a similar substitution toward low-wage workers.

Many countries attempt to stimulate job creation by offering employers tax credits to add new equipment and buildings. These policies are often targeted toward geographic areas with high unemployment or unusually high rates of poverty. They may increase employment through a scale effect, as the cut in capital costs leads firms to expand their demand for both capital and labor. But capital-skill complementarity suggests that most of the employment gains will be by more skilled workers. If there are few skilled workers in the area, Marshall's Fourth Law suggests that even the scale effect is unlikely to generate much increase in employment.

Other labor-market policies impose restrictions on the price at which labor can be sold. Minimum wages are the most well-known example and have been extensively studied in numerous countries. The central labor-market issue is the extent to which higher minimum wages alter employment (although the central policy issue may be whether and to what extent they raise total earnings of low-skilled workers). Their effect on employment depends on the own-wage elasticity of demand for the low-skilled workers whose employment opportunities are likely to be affected when the minimum is raised, an elasticity that is quite large. It also depends on the number of workers whose

wages are so low that they might be affected by a higher minimum. Even with a high own-wage demand elasticity, raising the minimum has very small employment effects if there are few such workers. Thus job losses when minimum wages are raised are higher in countries that have maintained a high minimum wage relative to the average wage (historically, for example, France) than in those where the minimum wage has been relatively low (historically, for example, the United States).

4. *Demand for Workers and Hours*

Labor inputs consist of workers (E) and the intensity at which they work. One measure of intensity is hours worked (H) per time period (typically per week in the data we use to examine this issue). The term L in Eqn. (1) can be written as the function:

$$L = L(E, H) \tag{3}$$

A pair of demand equations expanding on Eqn. (2) for workers and hours can be derived from this expansion of Eqn. (1) and includes the prices of each. The difficulty lies in specifying the components of the prices of an extra worker and an extra hour of labor. A higher hourly wage rate raises the prices of both an extra worker and an extra hour. An increase in the payroll tax rate per hour worked, for example, also raise the prices of both. A mandate that employers provide health insurance coverage for all workers, regardless of how many hours they work, raises the price of an extra employee with no impact on the price of an additional hour per employee. These latter two examples demonstrate that determining how a particular increase in labor costs affects the relative prices of workers and hours depends on institutional specifics—changes in nonwage costs can affect both prices and do so differently depending on institutional structures (Hart 1987).

That an increase in the price of an employee, for example, an increase in hiring costs, induces firms to use fewer workers and lengthen workweeks is strongly supported by nearly all empirical research on the issue. Consensus estimates of the magnitudes of the own- and cross-price elasticities for these two facets of labor are not available. Within the range of weekly hours observed in industrialized economies (where issues of worker fatigue are typically unlikely to be crucial), however, employers appear able to substitute fairly readily between workers and hours as their relative costs change.

The major interest in the demand for workers and hours has been for evaluating policies that penalize overtime work. For many years in the United States employers have been required to pay a 50 percent overtime penalty for weekly hours beyond standard hours of 40; many Western European countries impose standard hours below 40, although often at fairly low penalty rates. Overtime penalties are imposed in the hope of generating additional jobs by shifting employers from more intensive use (longer hours) of a few workers to shorter hours for more workers. Early evidence that ignored identification (summarized in Hamermesh 1993, Table 3.11) suggests that this substitution does occur when the penalty is raised, a finding confirmed by research which ensures that the relative cost changes are exogenous to employers (Hamermesh and Trejo 2000). However, when one factors in the scale effect that arises as employers cut back labor demand generally because the higher penalty raises labor costs, the ability of higher overtime penalties to generate additional jobs appears quite small.

Reduced standard hours have been introduced in many countries as a way of spreading work. This policy change has subtle effects. Some hours of work that previously did not require overtime penalties suddenly become liable for penalties, thus reducing employers' demands for hours and leading them to substitute toward more workers. It also increases the cost of employees generally, leading to a decline in the demand for labor and substitution toward nonlabor inputs. The evidence, including (Hunt 1999) who accounts for the identification problem, suggests that mandated cuts in standard hours lead to cuts in actual hours, but not quite on a one-for-one basis. Total employment rises, but by a smaller percentage than hours fall, so that total labor input and presumably total production drop.

5. *New Employers, New Jobs*

Labor-demand functions like Eqn. (2) are based on the behavior of a firm that lasts forever; but most companies do not survive even 10 years. A line of research that accelerated in the late 1980s pointed out the need to abandon the notion that all labor demand is by existing firms. That research has focused on accounting for gross flows of jobs. It has demonstrated that about one-third of new jobs that are added in developed economies each year are in new firms, and about one-third of jobs that end disappear when firms close down (Hamermesh 1993, Davis and Haltiwanger 1992).

Research has hardly begun to study how job creation is affected by wages and changes in product demand as they lead new firms to open and existing companies to close. Evidence on these issues is important for analyzing the impact on employment of such policies as tax holidays that local governments offer to firms. The ideal would be estimates of opening- and closing-wage elasticities of labor demand that indicate how drops (rises) in labor costs move potential (existing) companies across the margin of opening (closing) to generate changes in employment.

6. Hiring, Firing, and Employment Dynamics

The majority of theoretical, empirical, and policy research on labor demand has focused on the level of labor input demanded, not its time path. Understanding the dynamics of employment and hours, and of the flows of hires (h) and separations (s) that are linked to net employment change (ΔE) by the identity $\Delta E \equiv h - s$ is important for understanding cyclical behavior in labor productivity (Y/L) since changes in labor demand may lag behind changes in production. It is also important for evaluating the impacts of policies that alter hiring and firing costs, such as training subsidies, mandated advanced notice of layoffs, and mandated severance pay.

We view employers as maximizing the expected present discounted value of their future profits (or minimizing the expected present discounted value of their future costs) by choosing at each time a plan for the future paths of their inputs, including labor and its components. As in the static case of Sect. 1, the path is lower when product demand and the prices of substitutes for labor are expected to be lower, and when wages are expected to be higher. It is also affected by costs of adjusting labor inputs, including internal disruptions to production that occur when new workers enter or experienced workers leave, and such external costs as advertising for new workers or offering severance pay and unemployment benefits to laid-off or fired workers (Oi 1962).

The size and structure of these adjustment costs alter the path of employment by changing the incentives that employers face when labor demand is shocked by changes in product demand, wages, or other input costs. With larger adjustment costs per worker, a shock to product demand that is viewed as temporary will be met by changing hours rather than altering employment, since employers will seek to avoid incurring hiring or layoff costs. Larger adjustment costs cause changes in employment and perhaps even hours per worker to lag behind those in output, thus generating procyclical changes in labor productivity. The path of employment demand may be smooth if adjustment costs are structured so that it pays employers to spread hiring or firing over several time periods. Hiring and firing may be bunched (lumpy) if adjustment costs are structured so that the marginal cost of an extra hire or fire in a particular period of time is decreasing in the size of the adjustment.

The costs of hiring workers affect both hires and layoffs: employers who know that laying off someone in bad times will create a vacancy that must be filled in good times by incurring hiring costs will be more hesitant to lay off workers. Conversely, imposing restrictions (costs) on layoffs reduces hiring, since employers know that hiring a worker when demand is high will generate additional costs in the future when reduced demand leads to that worker's layoff. One might imagine an extreme employment protection policy in which any layoff is punishable by the employer's death. No layoffs will occur; but employers will be sure to hire only those workers whose jobs might be justified even in slack times. This *reductio ad absurdum* illustrates the general point that higher adjustment costs reduce the overall demand for labor. Like any other increase in labor costs, higher adjustment costs lead employers to substitute away from labor.

Empirical research on dynamic labor demand has lacked the explicit links to the underlying theory and the credible identification of employers' responses that characterize empirical research on own-wage demand elasticities and input substitution. Linking empirical work more closely to theory is high on the research agenda. A number of results are strongly supported by fairly large bodies of literature, however, and are probably reliable. Hours of work adjust more rapidly in response to shocks to labor costs and product demand than does employment. Most important, the more skill–human capital in a group of workers, the slower employers are to hire or fire them when demand conditions change (Rosen 1968). This result has the important implication that employment of less-skilled workers and production workers generally is more highly cyclical than that of skilled and nonproduction workers.

Policies that alter hiring and firing costs have been blamed for causing slow employment growth in Europe in the 1980s and 1990s, and this concern has generated a substantial amount of empirical research trying to gauge their impacts. Much of this research has consisted of broad-brush cross-country comparisons that suffer from problems of identification like those discussed in Sect. 2. The one certain conclusion from this literature is that employment adjustment is faster in North America than in Europe; but whether this is because of differences in the extent of employment protection is unclear. Some researchers have tried to examine how the detailed characteristics of policies that alter adjustment costs have affected the path and level of employment. In some cases, where the policy changes are both unexpected and large (as in the example of Peru studied by Saavedra and Torero 1998), the research has generated evidence that is not confounded by suppliers' behavior (see discussion in Sect. 2). These studies show that higher adjustment costs (severance pay in particular) reduce both the speed of employment adjustment and levels of employment.

Dementia: Overview

Dementia is a medical condition which is characterized by a generalized mental deterioration. The word has Latin roots, 'de' meaning separation, cessation or contraction, and 'meme' meaning 'mind.' Therefore, in dementia there is a cessation or contraction of the mind.

The usage of the term dementia can be traced back to the Roman writer and encyclopedist, Aulus Cornelius Celsus in the first century AD. Celsus distinguished dementia, a chronic 'contraction of the mind,' from acute conditions such as delirium. The first medical identification of aging with dementia can be traced to Aretaeus of Cappadocia in the second century AD. He distinguished a condition which began in old age and continued until death, characterized by 'a torpor of the senses, and a stupefaction of the gnostic and intellectual faculties' (Adams 1861). Galen, perhaps the most influential physician of all time, also identified old age as a cause of dementia in the second century AD. He defined 'morosis' as a condition in which 'the knowledge of letters and other acts are totally obliterated, indeed they can't even remember their own names' (Galen 1821–33 translation). One condition associated with morosis was old age.

No further advances in the clinical description of dementia appear to have been made for more than 1500 years. In 1793, the eminent American physician, Benjamin Rush, a signer of the United States Declaration of Independence and author of the first American textbook of psychiatry, a man who is credited by the American Psychiatric Association with being the father of American psychiatry, added to the clinical description of dementia. He noted that:

> it would be sufficiently humbling to human nature if our bodies exhibited in old age the marks only of a second childhood, but human weakness descends even lower. I met with an instance of a woman between 80 and 90 who exhibited the marks of a second infancy, by such a total loss of her mental faculties as to lose all consciousness in discharging her alvine and urinary excretions. In this state of the body, a disposition to sleep succeeds the wakefulness of the first stages of old age' (Rush 1793).

The accuracy of Benjamin Rush's description has become increasingly apparent over the past two centuries.

The modern term, 'senile dementia,' is derived from Esquirol (1838), who described this condition in a French textbook of psychiatry. He noted that this is a condition in which there occurs a weakening of the memory for recent experience and a loss of drive and will power. He noted that senile dementia (in French, *démence senile*), appears gradually and may be accompanied by emotional disturbances.

In modern usage, the term dementia refers to either: (a) any condition associated with a generalized mental deterioration, or (b) a progressive generalized mental deterioration, frequently occurring in later life. Both usages are commonly applied.

1. *Progressive Dementia*

The most important progressive dementia is Alzheimer's disease, which plays a role in a majority of cases (Tomlinson et al. 1970). Other progressive dementias include cerebrovascular dementia, Lewy body dementia, and the frontotemporal dementias. With the exception of the frontotemporal dementias, these conditions increase in occurrence with increasing age. Consequently, the modern increase in lifespan in most regions throughout the world has been accompanied by a dramatic increase in the occurrence of these conditions (Henderson and Jorm 2000).

1.1 *Alzheimer's Disease*

Alzheimer's disease (AD) is one of the most devastating medical conditions of contemporary times.

Table I
Global Deterioration Scale (GDS) for age-associated cognitive decline and Alzheimer's disease[1]

GDS stage	Clinical characteristics	Diagnosis and prognosis[2,3]
1	**No Subjective complaints of memory deficit.** No memory deficit evident on clinical interview.	Normal Adult
2	**Subjective complaints of memory deficit,** most frequently in following areas: (a) Forgetting where one has placed familiar objects; (b) Forgetting names one formerly knew well. No objective evidence of memory deficit on clinical interview. No objective deficit in employment or social situations. Appropriate concern with respect to symptomatology.	Age associated memory impaired (sometimes termed normal aged forgetfulness or aged-associated cognitive decline) 15% develop dementia within 4 years[2]
3	**Earliest clear-cut deficits.** Manifestations in more than one of the following areas: (a) Patient may have gotten lost when traveling to an unfamiliar location. (b) Co-workers become aware of patient's relatively poor performance. (c) Word and/or name finding deficit become evident to intimates. (d) Patient may read a passage or book and retain relatively little material. (e) Patient may demonstrate decreased facility remembering names upon introduction to new people. (f) Patient may have lost or misplaced an object of value. (g) Concentration deficit may be evident on clinical testing. Objective evidence of memory deficit obtained **only with an intensive interview.** Decreased performance in demanding employment and social settings. Denial begins to become manifest in patient. Mild to moderate anxiety frequently accompanies symptoms.	Mild cognitive impairment Two-thirds develop dementia within 4 years[2]
4	**Clear-cut deficit on careful clinical interview.** Deficit manifest in following areas: [a]Decreased knowledge of current and recent events. [b]May exhibit some deficits in memory of one's personal history. [c]Concentration deficit elicited on serial subtractions. [d]Decreased ability to travel, **handle finances,** etc. Frequently no deficit in following areas: (a) Orientation to time and place. (b) Recognition of familiar persons and faces. (c) Ability to travel to familiar locations. Inability to perform complex tasks. Denial is dominant defense mechanism. Flattening of affect and withdrawal from challenging situations.	Mild Alzheimer's disease Mean duration: 2 years
5	**Patient can no longer survive without some assistance.** **Patient is unable during interview to recall a major relevant aspect of their current life,** e.g.: [a]Their address or telephone number of many years. [b]The names of close members of their family (such as grandchildren). [c]The name of the high school or college from which they graduated.	Moderate Alzheimer's disease Mean duration: 1.5 years

Table 1 Continued

GDS stage	Clinical characteristics	Diagnosis and prognosis[2,3]
	Frequently some disorientation to time (date, day of the week, season, etc.) or to place. An educated person may have difficulty counting back from 40 by 4s or from 20 by 2s. Persons at this stage retain knowledge of many major facts regarding themselves and others. They invariably know their own names and generally know their spouse's and children's names. They require no assistance with toileting or eating, but may have difficulty choosing the proper clothing to wear.	
6	May occasionally forget the name of the spouse upon whom they are entirely dependent for survival. Will be **largely unaware of all recent events and experiences in their lives.** Retain some knowledge of their surroundings; the year, the season, etc. May have difficulty counting by 1s from 10, both backward and sometimes forward. **Will require some assistance with activities of daily living:** (a) May become incontinent. (b) Will require travel assistance but occasionally will be able to travel to familiar locations. Diurnal rhythm frequently disturbed. Almost always recall their own name. Frequently continue to be able to distinguish familiar from unfamiliar persons in their environment. Personality and emotional changes occur. These are quite variable and include: [a]delusional behavior, e.g., patients may accuse their spouse of being an imposter; may talk to imaginary figures in the environment, or to their own reflection in the mirror. [b]obsessive symptoms, e.g., person may continually repeat simple cleaning activities. [c]anxiety symptoms, agitation, and even previously non-existent violent behavior may occur. [d]cognitive abulia, e.g., loss of willpower because an individual cannot carry a thought long enough to determine a purposeful course of action.	Moderately severe Alzheimer's disease Mean duration: 2.5 years
7	All **verbal abilities are lost over the course of this stage.** Early in this stage words and phrases are spoken but speech is very circumscribed. Later there is no speech at all—only unintelligible vocalizations. **Incontinent; requires assistance toileting and feeding.** **Basic psychomotor skills** (e.g., ability to walk) **are lost with the progression of this stage.** The brain appears no longer to be able to tell the body what to do. Generalized and cortical neurologic signs and symptoms are frequently present.	Severe Alzheimer's disease Mean time to demise: 2–3 years Potential for survival: 7 or more years

For example, in the United States, the number of persons in nursing homes and related institutions with AD exceeds the total number of persons in all hospitals and related institutions. Consequently, the institutional burden of AD in the United States is approximately the same as the institutional burden of all other illnesses combined. Worldwide, AD is estimated to afflict more than 15 million persons, and the prevalence continues to increase with increasing life expectancy of the world's people.

The precise mechanism of the cause of AD is unknown. However, particular genotypes which predispose to early onset AD have been identified. These genetic 'defects' are β-amyloid precursor protein mutations located on chromosome 21, presenilin 1 mutations located on chromosome 14, and presenilin 2 mutations which are located on chromosome 1. Some investigators point out that each of these mutations is associated with increased production of β-amyloid protein, one of the neuropathologic hallmarks of AD (Selkoe 1997). However, the presenilin mutations in particular, have been related to a variety of other pathologies apart from increased β-amyloid protein. Further evidence for the role of β-amyloid in the etiopathogenesis of AD is the observation that persons with Down's syndrome develop Alzheimer's pathology early in life and carry an extra copy of the β-amyloid precursor protein gene resulting in excess β-amyloid production.

The occurrence of the common late-life form of AD has also been associated with particular genotypes. The most clearly identified gene which influences the occurrence of late life, also known as 'sporadic' Alzheimer's disease, is the apolipoprotein E (apoE) gene (National Institute on Aging /Alzheimer's Association Working Group 1996). Caucasians who carry the apoE4 allele are at increased risk for AD in later life. Caucasians who are homogenous for apoE4 have as much as eight times the risk of AD as similarly aged persons who do not carry the apoE4 allele. Other genes and gene interactions which influence the occurrence of the common, late-life form of AD have not yet been fully elucidated.

Although the mechanism by which AD occurs is not known, a characteristic clinical course of AD has been described (Reisberg et al. 1982, 2000). This characteristic clinical course is accompanied by characteristic neuropathologic manifestations and a characteristic neuropathologic progression.

Clinically, AD can be described on a continuum with the changes in what is now termed normal aging, progressing to mild cognitive impairment (MCI) and subsequently to AD. This clinical continuum is illustrated in terms of the cognitive, functional and emotional progression of aging and AD in Table 1. Functionally, the progression of brain aging, MCI and AD can be described in even greater detail, in terms which are universally clear to both lay persons and professionals. This characteristic functional progression is familiar to many observers because it reverses the sequence of functional acquisition in human development, a phenomenon which has been termed 'retrogenesis' (Table 2) (Reisberg et al. 1999, 2000)

The hallmark neuropathologic manifestations of AD are extracellular senile plaques which contain the β-amyloid protein, and intracellular neurofibrillary tangles which contain the protein tau (see *Alzheimer's Disease, Neural Basis of*). Very strong relationships have been found between the clinical progression of AD and the progression of pathology in the hippocampus, a brain region which has been notably associated with memory. Progressive pathologic manifestations in the hippocampus include neurofibrillary pathology, volume loss, and neuronal cellular loss. Although the hippocampus is a brain region which manifests early and progressive AD pathology, AD is a generalized brain disease with, for example, progressive decrements in brain glucose utilization (energy metabolism) and progressive slowing of brain wave electrical activity on the electroencephalogram, as well as neuropathologic manifestations in numerous brain regions, which become particularly evident as AD progresses.

Neuropathologic stages of AD have been described (Braak and Braak 1991). These are transentorhinal stages I and II, limbic stages III and IV, and neocortical stages V and VI. Each of these stages of Braak and Braak are based upon the evolution and spread of neurofibrillary pathology in the brain of the AD patient.

Braak and Braak (1996) and Reisberg et al. (1992, 1999) have described a common basis for the neuropathologic and clinical manifestations of AD. This is the progressive involvement of the most recently, and therefore the most thinly, myelinated brain regions, followed by progressively more thickly myelinated, and therefore, better protected, brain regions. The most thickly myelinated brain regions subsume the functions and associated cognitive skills, which are the first to be acquired in the course of human development. Conversely, the most thinly myelinated brain regions subsume the most recently acquired functions and associated cognition. These recently myelinated regions are the most vulnerable to AD pathology. Consequently, cognitive and functional skills which are the most recently acquired are the most vulnerable to AD pathology, and those cognitive and functional skills which are the first to be acquired in normal human development are the last to be lost with the progression of AD. In brief, last in, first out. This retrogenesis phenomenon, which is illustrated for functional skills in Table 2, also applies to cognition and many aspects of brain physiology, including neurologic reflexes and apparently, to at least some extent, brain electrophysiology and metabolism.

Very recently it has been demonstrated that the β-amyloid, the major putative toxic pathology in AD is destructive to the oligodendroglia, the brain cells

Table 2
Retrogenesis: functional landmarks in normal human development and Alzheimer's disease (AD)

Normal Development Approximate Total Duration: 20 years			Alzheimer's Degeneration Approximate Total Duration: 20 years			
Approximate age	Approximate duration in development	Acquired abilities	Lost abilities	Alzheimer stage	Approximate duration in AD	Developmental age of AD
Adolescence

which produce the myelin (Xu et al. 2001). ApoE, the AD risk-determining factor, is a molecule associated with cholesterol transport. ApoE has been shown to affect neuronal repair mechanisms and the apoE3 allele appears to have a greater neuroprotective effect than the apoE4 allele (Poirier et al. 1993; Buttini et al. 1999). Therefore, a common basis for the molecular, pathologic, and clinical manifestations of AD can be postulated although many elements of the precise pathogenic mechanism remain unknown.

1.2 Vascular Dementia

Formerly, this entity was designated multi-infarct dementia because of its strong relationship to strokes, both large and small (Hachinski et al. 1974). Although originally considered by Hachinski to be a stroke-like entity with an abrupt onset and stepwise pattern of deterioration, this deterioration pattern is rarely observed. Vascular dementia is now thought to be a condition marked by progressive decline in cognition and functioning in which cerebrovascular, i.e., stroke risk factors, play a major role. These risk factors include hypertension and cardiovascular disease, as well as more overt evidence of cerebrovascular disease such as transientischemic attacks and focal neurologic signs and symptoms. In most cases, vascular dementia occurs in association with Alzheimer's brain pathology, a condition which is sometimes termed 'mixed dementia.' Much less frequently, vascular dementia appears to occur without evidence of concurrent AD. Consequently, many investigators view vascular dementia as on a continuum with AD. This continuum concept has become particularly compelling in recent years, since virtually all of the elements associated with vascular dementia have been shown to be risk factors for so-called 'pure AD.'

In accordance with the concept of an additive morbidity of vascular dementia and AD, the course of vascular dementia has been found to be generally more rapid than AD. Vascular dementia is generally considered to be the most common dementia entity after AD.

1.3 Lewy Body Dementia

Lewy bodies are spherical inclusions located in the cytoplasm of neurons which characteristically contain a protein known as α-synuclein. Originally Lewy bodies were considered to be a prominent feature of Parkinson's disease and were not associated with late life dementia. However, new staining techniques in the 1990s indicated that Lewy bodies in the brain stem and the cortex commonly occur in dementia patients studied postmortem. Estimates indicate that as many as 15 to 25 percent of dementia patients manifest Lewy bodies at the time of demise (McKeith et al. 1996). However, in the great majority of these cases, Lewy bodies exist together with neuropathologic manifestations of AD and/or vascular dementia. When this mixed neuropathology occurs, the clinical manifestations of the dementia are those of AD and/or vascular dementia, and there is no distinctive Lewy body dementia clinical syndrome.

In approximately 4 percent of all dementia cases coming to autopsy, Lewy bodies occur in the brain in the absence of other dementia disorders. In these cases, a classical Lewy body dementia (LBD) clinical syndrome occurs. This syndrome is marked by three core features, any/or all of which may be present: (a) a relatively fluctuating clinical course, with variability in cognition; (b) the presence of vivid, well formed, visual hallucinations; and (c) the presence of Parkinsonian features. Another important aspect of LBD is sensitivity to neuroleptic (antipsychotic) medications, particularly those known to be associated with Parkinsonian side effects (Ballard et al. 1998). In general, the onset of LBD is more acute than the onset of AD, and the course of LBD appears to be shorter than that of AD.

1.4 Frontotemporal Dementias

These are a diverse group of disorders for which various classification schemata have been developed. For example, biomolecular categorizations have been developed recently which are extremely useful in categorizing one subgroup of frontotemporal dementias, those with frontotemporal dementia with Parkinsonism linked to chromosome 17 (FTDP-17) (Foster et al. 1997). The FTDP-17 dementias are characterized by mutations which alter tau, the protein responsible for neurofibrillary changes such as those found in AD. Another frontotemporal dementia type marked by abnormal tau accumulation is Pick's disease. In Pick's disease there is an intracellular inclusion known as the Pick body which contains tau accumulations as well as other substances. Other forms of frontotemporal dementia are classified mainly on the basis of their clinical presentation. They include semantic dementia (see *Dementia, Semantic*), progressive aphasia, and motor neuron disease dementia.

The core clinical features of the frontotemporal dementias have been described in part as disinhibition, decreased insight, apathy, disorganization, lack of personal hygiene, mental rigidity, and hyperorality (Brun et al. 1994, Kertesz 2000). In addition, aphasia and other language disturbances are frequently present. Like the basic pathologic disturbances, these behavioral manifestations are very heterogenous and occur on a clinical spectrum.

In general, the frontotemporal dementias occur in adults at a younger age than AD. Some believe that

these conditions are very common in patients who are institutionalized for mental illness.

1.5 Other Progressive Dementias

Various other diverse conditions produce progressive dementia. In general, these other conditions are believed to be considerably less common than the dementias which have been reviewed more specifically in the preceding sections.

Perhaps the most notable of these other dementias are the prion dementias, of which the most frequent is Creutzfeldt-Jakob disease (CJD). Prion dementias are believed to result from a self-propagating conformational change in a protein, known as the prion protein. This prion, a proteinaceous infective agent, can be acquired either spontaneously or through transmission of biologic materials containing the prion, including brain, pituitary glandular substance, and corneal lens transplants. Spontaneous CJD occurs in approximately one person per million population worldwide. Recently, a form of transmissible CJD arose in Britain as a result of transmission of a prion disease in cattle to humans. This 'epidemic' which has affected dozens of persons in Britain and, more recently, several persons on the European continent, has resulted in the destruction of the entire British cattle herd and a change in dietary habits of tens of millions of persons in Europe and elsewhere. Consequently, although the prion dementias remain rare conditions in humans, the threat of the spread of these proteinaceous infections, has caused somewhat justified alarm, in particular in Europe, but also throughout the world.

Other relatively uncommon progressive dementias include progressive supranuclear palsy, and corticobasilar degeneration. These conditions, like some of the frontotemporal dementias, are marked by abnormal tau protein and resultant neurofibrillary accumulations.

There are also many progressive dementias associated with broader pathologic spectra, of which dementia is only one element. Among these are the dementia of Down's syndrome, the dementia of normal pressure hydrocephalus (NPH), and the dementia of Huntington's disease. Some of these dementias are very closely related to AD dementia. For example, persons with Down's syndrome universally develop an Alzheimer's type neuropathologic and clinical picture at a relatively early age in comparison with persons with classical AD. Similarly, brain biopsy studies have recently demonstrated that many elderly persons with NPH who manifest a dementia component to the clinical syndrome, show Alzheimer's-type pathology, specifically neuritic plaques, upon brain tissue examination (Golomb et al. 2000). As is the case for AD, the percentage of NPH dementia patients with biopsies demonstrating neuritic plaques increases with dementia severity, rising from about 20 percent of patients with MCI to about 75 percent of patients in stage 6 and 7 of the global deterioration scale (see Table 1). These studies indicate that the gait disturbance which is characteristic of NPH appears to be associated with dilated cerebral ventricles (i.e., expansion of the fluid filled cavities in the brain), whereas the dementia component of NPH is probably related to concomitant AD.

2. Dementias with Variable Prognoses

Numerous diverse physiologic disturbances can produce dementias which may be acute or chronic, reversible or permanent. These diverse conditions include infectious conditions, toxins, tumors, brain trauma, endocrine and metabolic disturbances, nutritional disturbances, and medications. For example, infectious conditions which produce encephalitis may cause dementia of viral or bacterial origin. A relatively common example is herpetic encephalitis. Syphilis and acquired immune deficiency syndrome (AIDS), have been associated with dementia. Heavy metal toxicity, such as aluminum toxicity from dialysis, can cause dementia. A space-occupying brain lesion may produce dementia, such as brain metastases resulting from neoplasms. Brain trauma resulting in diffuse brain injury is a source of dementia. Thyroid disturbances, hyponatremia, and other endocrine disorders are known to cause dementia. Vitamin B_{12} (cobalamin) deficiency, which is associated with demyelination, is a cause of dementia, as is folate deficiency. Numerous medications can produce dementia or exacerbate a preexisting dementia. Some of the conditions which can produce dementia independently are now believed to be risk factors for AD as well. Examples of the latter include major depression and depression dysphoric disorder, and Vitamin B_{12} deficiency.

Dementia: Psychiatric Aspects

Dementia has many aspects, and neurobiological, clinical, and family related or socioeconomic factors have been investigated. Here neuropsychiatric aspects are presented i.e., the signs and symptoms of dementia diseases which cause the disturbance in behavior, cognitive functions, and subjective experience of the patients, which are classified as emotional problems or personality change.

1. *Definition of Dementia*

In history, the term dementia has been subject to several changes in meaning. Today, it is defined as acquired, severe loss of mental functions due to structural brain diseases.

In dementia, the information processing capacity has deteriorated to a critical degree. Deficits are found predominantly in cognitive, but also in emotional and intentional domains. By definition, these deficits severely compromise the social and cultural activities of a person. There must be a loss of mental functions which had been acquired before (i.e., the long-standing cognitive deficiencies in mental retardation are excluded). The underlying pathology is a destruction or degeneration of brain structures, therefore dementia may not be caused by functional organic disorders such as psychoses or transient brain dysfunction like in delirium. Psychiatry is concerned primarily with the detection and diagnosis of dementia syndromes, and concerned secondly with the identification and treatment of certain dementia diseases. Dementia syndromes and dementia diseases have to be differentiated (Wells and Whitehouse 1996).

1.1 *Dementia Syndromes*

Characteristic clinical profiles emerge, patterns of cognitive, affective, and intentional disturbances because in dementia diseases, the destruction or degen-

eration takes place with a predominance of certain brain regions or brain systems; the disease does not impair all brain structures to the same extent.

1.1.1 Dementia syndrome of Alzheimer type. What is the clinical presentation, the pattern of deficits which characterize the syndrome of a dementia patient who suffers from Alzheimer's disease? This issue has been clarified in large longitudinal studies (e.g., Berg et al. 1990). A second question addresses the reasons for failures in activities of daily living and the need for care. The syndrome can be differentiated into cognitive signs and not primarily cognitive signs.

(a) *Cognitive neuropsychological signs*

(i) *Amnestic signs*. Early in the time course of the dementia syndrome, deficits in episodic memory are noticed (Brandt and Rich 1995). Recall of word lists, stories, second word of paired associates, or the reconstruction of figures-drawings, which were encoded several minutes earlier, becomes increasingly impaired. The immediate recall of digits (digit span), however, remains typically unimpaired. The patients can immediately repeat a list of words but forget the words within several minutes, e.g., after a disruption by intermittent attention to other topics.

Furthermore, errors of orientation for time and space are hallmarks of this dementia syndrome. Demented persons get lost easily—at first in unfamiliar, and then even in familiar surroundings. The forgetting of data of major impact or the forgetting of actions with dangerous consequences affects activities of daily living. These deficits are characteristics of anterograde amnesia and are a consequence of mediotemporal brain damage, including the hippocampus and entorhinal cortex. Degeneration within the basal forebrain, however, may also explain a large part of the symptoms. Later retrograde amnesia starts and the recollection of data which were well known in former times becomes impaired. In later stages of the disease, demented persons cannot remember anything but episodes from the first decades of their life.

To summarize, a dementia syndrome in persons with Alzheimer's disease presents initially with amnestic signs. Episodic memory and orientation, with respect to time and place, deteriorate, and a retrograde amnesia occurs.

(ii) *Language disturbance, aphasic signs*. Word finding is impaired early in the time course of the dementia syndrome of Alzheimer's type, but these and other signs of language impairment usually occurs later than memory impairment. Difficulties in word finding are the most important feature of this language disturbance. Word finding is clinically observed mostly in the communication situation and in fluency tests.

As demented persons become increasingly incapable of finding correct words, in later stages of the disease, not much content is communicated: a phenomenon which has been called empty speech. Phonematic paraphasias (errors in the phonematic composition of words) or disordered syntax, which characterize various forms of aphasia after cerebrovascular strokes, are, however, not considered prominent signs in this dementia syndrome.

A lowered performance in fluency tasks is often assessed in clinical diagnosis, for example, by asking the patient to name as many animals as possible. It has been argued that fluency is not only a language test, but also a test of retrieval from semantic memory, and it is known that effective retrieval depends on nonlanguage functions. Patients with frontal lobe lesions cannot retrieve words in fluency tasks, presumably because of inefficient retrieval strategies and a defective suppression of overlearned alternative word-finding routines. Furthermore, demented persons cannot retrieve semantic features of perceived objects because of a disturbance in semantic memory (Martin and Fedio 1983).

Later in the time course, language comprehension difficulties additionally impair the communication with a demented person. In summary, there are important language problems in the dementia syndrome of Alzheimer's type which are predominantly caused by deficits in word finding and language comprehension.

(iii) *Apraxia signs*. Persons with the dementia syndrome of Alzheimer's type show errors in performing purposive movements. These errors occur although there are no obvious motor problems, such as weakness of the limb or sensoric deficits in guiding movements. It is thought that the central control of movements is defective. Apraxia in the narrow sense describes errors in specific action sequences, for example, using tools. Clinically, errors in dressing properly are encountered. Tests of apraxia include the call for imitation of limb movements or gestures.

In diagnostic schedules for dementia, constructional apraxia is tested quite often. This apraxia comprises deficits not only of the execution of movement schemata, but also of the integration of visuospatial information into appropriate action (Heilman and Rothi 1997). Copying visual designs or drawings of well-known objects, such as a clock, are defective and are performed laboriously and slowly. In addition, many demented subjects show an apractic type of writing disorder, where the action sequences of writing the individual letters can no longer be carried out correctly.

To summarize, subjects with Alzheimer's dementia show errors in performing motor tasks without weakness or paresis of the limbs, resembling central motor control deficits. Later in the time course of the disease, the impairments lead to incapability to perform any practical task in the household or in self-care.

(iv) *Disorders of judgement*. Judgement errors and inadequate evaluation are especially relevant for the

every day functioning of demented persons and with respect to legal responsibility. In the narrow definition, erroneous or inadequate judgements, with full understanding and appreciation of the problem, can be related to the decision process in itself. This specificity is difficult to ascertain in clinical neuropsychological investigation. Therefore, more generally, inadequate judgements about the own person and the disease are considered for diagnostic evaluation.

Self-related judgements: demented persons often cannot correctly evaluate the cognitive deficits they suffer from. Some patients describe grossly inadequate future plans. At times, not only disorder of judgement, but also the psychopathological phenomenon of denial has to be considered in such situations.

Formal assessment of logical decisions, as part of the capacity for adequate judgment, is done usually by intelligence tests which, demand, for example, the understanding of a logical rule within the sequence of symbols, and finding incorrect items.

In summary, inadequate or wrong judgements in self-related or logical problems are found commonly in the dementia syndrome of Alzheimer Type and may lead to legal consequences or intensify the demand of care for the patient.

(v) *Other cognitive neuropsychological signs*. Demented persons with Alzheimer's diseases often show deficits in executive functions. The term 'executive functions' denotes the planning and the execution of goal directed activities, including preparations and the monitoring of already reached partial goals. Some researchers also included self-regulation and volitional processes in the domain of executive functions. Brain structures for executive functions are at least in part localized in the dorsolateral prefrontal lobe.

Mental calculations are often tested in the clinical diagnosis of a dementia syndrome. They do not, however, test calculation function only. For these tasks, the attentional demands, and additionally, in serial calculations, the demands on working memory are high. Therefore, the reason for individual test deficits is difficult to attribute precisely.

Agnosia is mentioned in some of the dementia criteria. The classical form of object agnosia, however, is very rare. In object agnosia, the patient perceives an object—and is even able to copy the form—but is not able to grasp its meaning, to name it, or describe it's attributes or functions. Demented persons often fail to identify faces of well-known friends or relatives in later stages of the disease, but memory problems contribute to this deficit. More often, however, a perceptual deficit concerning visuospatial features of figural information can be documented by neuropsychological tests. Furthermore, the appreciation of the relation of many objects within a complex pictorial scene is often disturbed in dementia.

In addition to cognitive deficits, there are other dimensions of the dementia syndrome of Alzheimer's type.

(b) *Noncognitive part of dementia syndrome of Alzheimer's type*

Patients with a dementia syndrome of Alzheimer type suffer from affective symptoms or delusions. Noncognitive signs of dementia are traditionally described by psychopathology. They are not specific for dementia. Several of these signs are commonly observed in other psychiatric diseases, for example, anxiety or restlessness. Although these signs are not as relevant for diagnosis as cognitive deficits, they present major problems for the caregivers (Cummings et al. 1996) and are often the reason for institutionalization of demented patients.

(i) *Signs in the affective domain*. Early in the development of the dementia syndrome depression is observed. Later, affect control becomes impaired. Patients may cry after minor adverse events or be aggressive or inadequately cheerful. Often the emotional state lasts often only for a short period of time. The perceived emotional experience may not be as dramatic as the affective expression suggests. This phenomenon has been termed affective lability.

Affective states like aggression may also be expressed as an increased intensity. Such behaviors may often present as behavior which cannot be tolerated and may lead to institutionalization.

(ii) *Signs in the intentional and attentional domain*. The cerebral information processing for motivation and attention is impaired in late stages of Alzheimer's dementia. A state of 'apathy' is described quite often. A person, for example, sits in a chair for most of the time and does not move, and has no intention to start any action. Many of the noncognitive signs of the dementia syndrome are traditionally described as organic personality change. A further component of this is, as a consequence of frontal lobe disturbance, a disinhibition of action tendencies, which are usually supressed because of cultural constraints. In addition, paranoid delusional thinking and hallucinations occur quite often within the time course of a dementia syndrome of Alzheimer's type. These also may induce aggressive behavior.

In summary, signs in multiple domains of brain functions are observed. The signs which characterize the dementia syndrome of Alzheimer's type are predominantely from the cognitive domain. However, disorders in the emotional and intentional domains have some impact for the resulting individual syndrome and for caregivers and relatives. The primary sensory and motor functions, however, are relatively spared. Accordingly, the spread of the Alzheimer's pathology in the brain does not include the primary sensory and motor areas.

1.1.2 Frontotemporal dementia syndrome. The dementia syndrome of frontotemporal type is less common than the dementia syndrome of Alzheimer's

type and should be described here in outline only (Brun et al. 1994). The major feature of this syndrome is a change in personality. Features of the dementia syndrome of Alzheimer's type, like predominantly amnestic and apractic signs, or a decrease in intellectual functions, are not detectable at early stages of the frontotemporal dementia syndrome.

The personality change comprises changes in the way of experiencing certain situations, in the way of reacting in certain situations, or in the way a person was used to acts spontaneously.

(a) *Lack of expected reactions or actions*. The patient is aspontaneous and does not react as they did before the onset of the dementia syndrome. At times, a lack of drive is noted. As there is no emotional symptom of depressed mood and despair, this has been named pseudodepression.

(b) *Disinhibition*. A lack of control of intentions, especially with respect to social norms or cultural restraints, is observable.

(c) *Perseveration and stereotyped behavior*. The patient reiterates actions and is inflexible in the way of reacting.

(d) *Lack of insight and disorder of judgement*, as described above (Sect. 1.1.1(a))

In addition to the psychopathological symptoms described above, formalized neuropsychological testing reveals deficits in planning, in shifting mental set, and in working memory. The frontotemporal dementia syndrome can be identified clinically only in early stages. In late stages, mostly an unspecific terminal dementia syndrome is clinically observed.

As for the dementia syndrome of Alzheimer's type, also in frontotemporal dementia there is a heterogenous etiology with mostly genetically determined underlying diseases.

1.2 Dementia Diseases

Dementia has two sides—the individual pattern of neuropsychological or psychopathological impairments on the one side, and the damage or degeneration within the brain on the other side.

A dementia disease is a class of pathophysiological processes which result in structural brain changes that are underlying the clinical signs of the dementia syndromes (Wells and Whitehouse 1996, McHugh and Slavney 1998). There are many diseases of the brain which lead to a dementia syndrome.

1.2.1 Primary dementia diseases. Alzheimer's dementia disease, Pick dementia disease, or Lewy body dementia are degenerative brain diseases which up to now inevitably lead to a progressive dementia syndrome. They cause no other symptoms except symptoms of the dementia syndromes.

1.2.2 Neurological diseases with associated dementia syndrome.

(a) In some diseases the dementia outcome is obligatory. In Huntington's chorea, for example, a movement disorder precedes the progressive dementia syndrome, which regularly develops later in the time course of the disease.

(b) In other diseases, the dementia outcome is facultative. These diseases are not dementia diseases *per se*. Vascular dementia, which is the second most frequent cause of dementia cases, is in some of its variants not associated with a dementia syndrome. Prevention of subsequent strokes, furthermore, may stop the cerebrovascular disease and prevent the development of vascular dementia.

The brain behavior relationship is interindividually variable and even the distribution of pathological changes within one disease is varying. Because in many cases the dementia disease cannot be identified reliably before neuropathological post mortem examination, the clinical dementia syndrome guides the medical decisions about treatment and secondary prevention.

1.2.3 Dementia disease etiology. Alzheimer's disease is genetically heterogenous. Many different mutations on several genes are known to cause a presenile Alzheimer's dementia. The same is true for frontotemporal dementia. Additionally, multiple causal factors are identified in senile dementia of Alzheimer's type, and it is not known whether an interaction of several factors is responsible for senile dementia cases. In some dementia cases, etiologically distinct causes are known, like in dementia following traumatic brain lesion, or in a dementia patient with a series of strokes within strategic regions of the brain.

2. Diagnosis of Alzheimer's Dementia

The diagnosis of a dementia disease will be described for the most frequent dementia, Alzheimer's.

(a) The confirmation of the disease can only be given by a neuropathological investigation of the brain after death. The microscopic analysis will reveal the amount and distribution of neuropathological features like neuritic plaques and neurofibrillary tangles.

(b) There is some uncertainty as to the clinical diagnosis of Alzheimer's dementia. There are several lists of criteria proposed, e.g., by diagnostic systems, such as International Classification of Diseases (ICD) and by consensus committees (e.g., the classification of probable or possible Alzheimer's dementia according to clinical criteria). However, the criterium lists differ considerably, and the criterium variance results in major differences in the estimated prevalence rates of population-based studies (Erkinjunnti et al. 1997).

Prospective studies of dementia syndromes improved the specificity of clinical diagnostic methods. However, at present technicians cannot distinguish between dementia diseases such as Lewy body dementia and Alzheimer's dementia with sufficient reliability.

2.1 Problems of Diagnosis of Mild Dementia in Old Age

The factors mentioned add to the diagnostic uncertainty with respect to differential diagnosis. Most dementia cases are seen in old age. The differentiation from normal aging and organic psychiatric disorders, like mild cognitive impairment or amnestic syndrome, is for many cases not easy or, especially in early stages, not possible at all.

The early detection of dementia is difficult in old age, because age in itself is associated with some cognitive decline (Reischies 1998). Furthermore, mild cognitive deficits have to be differentiated from low talent domains of a person, and personality changes have to be diagnosed considering the premorbid personality.

2.2 Dementia Case

If the severity of the cognitive impairments of the dementia syndrome of Alzheimer's type is sufficiently high, and the severity of impairment in everyday functioning is high as well, a dementia case can be diagnosed. For these decisions, cut-off values of assessment instruments have been applied (e.g., the Mini Mental State Examination and the Global Assessment of Functioning scale).

The diagnosis of a dementia case without specification of the kind of probable dementia disease is often a clinical reality. With the advent of better diagnostic methods, however, the diagnosis of the dementia disease may be made before a clinical dementia syndrome has developed.

3. Time Course of Alzheimer's Dementia

There is a characteristic time course of Alzheimer's dementia over about 10 years. Interindividual variation of the time course with plateaus and progression phases are common.

Within a preclinical stage of Alzheimer's disease, cognitive decline takes place which can be assessed by serial neuropsychological testing. Especially memory decline can be found. With memory deficits as the only clinical sign, no formal diagnosis of dementia can be made. The early phase of Alzheimer dementia thus represents an amnestic stage.

In the second stage, a clinical dementia syndrome of Alzheimer's type is detectable, which exhibits more or less the complete features of the dementia syndrome, as described above. In this stage, there are disturbances in activities of daily living, but they may still be minor.

In the stage of a severe dementia syndrome, memory loss, aphasia, apraxia, and the noncognitive symptoms have increased, and global functioning is deteriorated such that normal activities of daily living are critically compromised or no longer possible. Additionally, the noncognitive disorder disturbs the relation between the patient and the environment. Institutionalization is common.

The last stage is a terminal or vegetative stage, where no communication is possible, the patient is mostly bedridden, and has to be cared for completely.

4. Treatment, Professional Care, and Prevention

An increasing number of new drug treatments for Alzheimer's dementia are being investigated. However, at present only limited relief can be provided. At best, the time course can be stopped or retarded for a short time only. Training of activities of daily living, with the goal of adaption to the specific environment, can be quite successful in order to aid care of subjects with an advanced dementia syndrome.

Major efforts must be directed to prevention, detection of risk factors, and early detection of dementia syndromes. A certain success of prophylaxis by controlling risk factors for artherosclerosis has been documented in the field of vascular dementia.

Dementia, Semantic

1. Introduction

Semantic dementia, which results from a degenerative brain disease, is a cognitive syndrome whose hallmark is a progressive deterioration of semantic memory. Semantic memory is the label given to the component of human memory that encompasses knowledge about concepts, objects, people, facts, and the meanings of words. It was once a matter of considerable controversy whether something so wide-ranging in form and content as semantic memory could constitute a separable cognitive subsystem, in the sense that damage to a specific brain region would disrupt this aspect of cognition and no other (Fodor 1983). However, the debate seems largely to have been resolved with a positive answer.

Semantic dementia (SD), given its current syndrome label by Snowden et al. (1989), was first described around 1900 in some individual case reports by neurologists intrigued by the fact that degenerative diseases could yield such striking and selective cognitive impairments (Girling and Berrios 1997: translation of Pick 1904). The modern history of SD began in the 1970s, with two papers cataloguing the cognitive syndrome in impressive detail (Warrington 1975, Schwartz et al. 1979). Further substantial interest in SD and related conditions has been stimulated in part by the recent dramatic increase in both availability and sophistication of structural brain imaging (particularly Magnetic Resonance Imaging, MRI) and techniques for analyzing and quantifying the brain abnormalities in individual MRI scans.

A specific cognitive impairment combined with a clearly identified locus of neuroanatomical lesion, documented across a large-ish number of patients, has traditionally been considered to licence the assignment of that cognitive function to that brain region. On this logic, the *sine qua non* of semantic memory is the anterior, inferior, lateral region of the temporal lobe, because this is consistently the location of the earliest and most severe atrophy in patients with the syndrome of SD (Mummery et al. 2000). Initially, this atrophy may be measurable just on one side, or at least is often very asymmetrical, but invariably there is bilateral temporal involvement with disease progression. There is also the important caveat, emphasized by recent studies of functional brain imaging, that areas which do not themselves reveal significant structural abnormalities may nonetheless fail to function adequately, presumably because of reduced input from the damaged areas to which they are normally connected. The first activational PET (Positron Emission Tomography) study of SD (Mummery et al. 1999) identified such an area in the posterior left temporal lobe. The consistent locus of atrophy in the antero-lateral temporal lobe for these patients only establishes that this region is one essential component of the brain's network for semantic memory.

2. The Core Syndrome of Semantic Dementia

2.1 Memory

SD is one of the main presentations of fronto-temporal dementia (see Sect. 5) that together constitute the second commonest cause of dementing illnesses with an onset before age 65. The most prevalent cause of dementia, certainly in later life but even before 65, is Alzheimer's disease (AD) (see *Dementia: Overview*). In typical presentations of AD, semantic memory is eventually also disturbed; the earlier and more prominent cognitive consequence of AD, however, is a severe impairment of the capacity for new learning, or episodic memory. A sharp distinction between episodic and semantic memory, originally proposed by Tulving (1972), is almost certainly over-simplified; but it does seem to capture a salient difference between two types of long-term memory. One's semantic knowledge of (for example) the Egyptian pyramids, comprising some facts about their appearance and about how, when, where, for what and by whom they were built, seems to stand in sharp contrast to one's episodic or autobiographical memory of the experience of visiting the pyramids. One typically cannot retrieve much in the way of episodic or contextual details associated with learning the semantic facts about these structures, whereas such details of time, place, sights, sounds, etc., seem the very essence of

memory for the autobiographical episode. An appropriate, though approximate, summary is that a patient with SD would remember at least some aspects of a trip to Egypt to see the pyramids, but would be unable to produce almost any conceptual knowledge about them.

There are at least two ways in which the notion of preserved episodic memory in SD should be qualified. First, there is solid experimental evidence that these patients have good ability to encode new memories of experiences based on perceptually rich information. When asked to look at photographs of paintings (Warrington 1975) or of objects like telephones, bicycles and zebras (Graham et al. 2000), followed by a larger set of such photos incorporating the earlier set plus some new ones, SD patients display good recognition memory for the items seen earlier. This is true even if the objects in the photos are ones on which the patients perform poorly in tests of conceptual knowledge. However, suppose that the recognition memory test employs perceptually altered materials: in the experiment with photos of objects, for example, the picture in the test phase would be of the same object type, such as a telephone, as that seen earlier, but represented in the test by a different exemplar of a telephone. In this case, the SD patients' episodic memory is significantly impaired relative to normal control subjects. This result suggests that stimulus meaning normally supports new learning, especially when the perceptual characteristics of the material to be recognized do not, on their own, readily reinstate the earlier event. The same principle helps to explain SD patients' poor recognition memory for written words, which constitute rather perceptually impoverished stimuli.

A second qualification on this issue concerns memory age. Probed for information about world events or about significant autobiographical episodes in their own lives, SD patients have revealed good memory for events and people prominent over the last year or so, but degraded and vague knowledge of earlier events (Graham and Hodges 1997). This pattern is consonant with the neuroanatomical facts of SD. Extensive research with humans and other animals suggests that structures in the medial areas of the temporal lobe (particularly the hippocampal complex) are essential for establishing new memories and for keeping them retrievable for some period of weeks or months. This is why amnesia-inducing head injuries, which often affect hippocampal regions, tend to disrupt memory of events just preceding the accident. It also explains why patients with Alzheimer's disease, to which medial temporal structures are especially vulnerable, are so poor at remembering recent events. The process whereby memories 'consolidate' in the brain seems to involve lasting changes in the more lateral structures of the temporal lobe, with decreasing reliance on the hippocampus for memory retrieval. SD is associated with significant atrophy in these lateral regions, but less so in the medial areas, thus fitting the observed relative preservation of very recent autobiographical memory. This constitutes a qualification on a sharp semantic/episodic distinction because, while semantic memories are typically 'old,' and thus likely to be disrupted by the disease process of SD, autobiographical memories may be old or new, and their status in SD according to this account will be determined more by this factor of age than by the content/quality of the memory itself.

2.2 Other Cognitive Features

Unlike patients with AD, those with SD are well oriented in time and space and find their way around with ease in familiar or even recently encountered (e.g., hospital) environments. They have good reasoning and problem-solving skills provided that the tasks do not require knowledge of specific concepts. Within the domain of language, they speak in well-formed sentences consisting of properly articulated words. The initial deficit that brings the patient into the clinic is almost always anomia: a difficulty in naming people, places, objects, and concepts. This early word-finding difficulty is typically followed, in both disease progression and prominence, by impaired word comprehension. Deterioration in both the production and comprehension of content-word vocabulary (nouns, verbs, adjectives) is significantly modulated by word frequency or familiarity, with more common words being more resilient. In SD speech, specific content words are replaced by more general and higher-frequency catchall terms: nouns such as 'thing' and 'place,' verbs such as 'make' and 'do.' One patient could only refer to each of the significant people in her life (husband, daughter, sister, etc.) as 'my person.'

These prominent twin problems with producing and understanding the content words of speech might imply that semantic dementia is a deficit restricted to words. On the other hand, in studies where patients with SD have been rigorously assessed on semantic tests involving no verbal stimuli or responses (such as pairing up objects that are standardly found and used together, or photos of famous people that are linked, or demonstrating the conventional use of familiar objects, Hodges et al. 2000), the impairment almost invariably extends well beyond language-based tasks. This suggests that SD is a general conceptual deficit that disrupts knowledge of objects and people as well as the meanings of words. The abilities to produce and comprehend words are probably especially vulnerable even to mild degradation of underlying conceptual knowledge because of the arbitrary relationship between meaning and word form. As discussed further in Sect. 3 and Sect. 4, the robustness of knowledge seems to be governed in part by the extent of consistency or systematicity between representations at different levels of the system. Names of things suffer because

they are devoid of systematicity: nothing about the word 'tiger' gives a clue to the nature of the object that it labels, or to the similarity of that object to a lion.

3. *The Cognitive and Neuroanatomical Progression of Semantic Dementia*

The disruption to conceptual knowledge in SD is eventually profound. A patient with severe SD (Hodges et al. 1992), during a test of yes/no questions about category membership and other semantic features of various familiar objects and animals, was asked 'Is a zebra an animal?' She replied 'Is a zebra an animal? I wish I could remember what an animal was.' At earlier stages of the disease, however, this broad level of object categorization is one of the better-preserved aspects of conceptual knowledge. This is indicated by a large range of cognitive tests, including semantic judgments about pictures or names of objects at different levels of specificity. When patients are studied longitudinally, the conceptual deficit emerges earliest for specific details such as the stripes on a zebra or where it lives, while success in classifying a zebra as an animal is maintained longest. The same pattern is revealed by the patients' responses in picture naming tasks, where they fail to name the particular exemplar but often provide either the general category name 'animal' or else a very high-frequency prototypical animal name such as 'dog' or 'horse' (Hodges et al. 1995). In another revealing anecdote, a patient responded to a picture of a zebra by saying 'It's a horse, isn't it?' Then, as she pointed to the stripes, she queried 'What are these funny things for?' An influential interpretation of this pattern of conceptual deterioration in SD, with important implications for the way in which such information is structured in the normal system, is the notion of disruption to elements in a similarity-based sub-symbolic connectionist network (McClelland et al. 1995). Features that are characteristic of many similar concepts (such as four legs on an animal) are more securely supported by connection weights across the network and are therefore more robust under damage than idiosyncratic features like the stripes of a zebra.

Another notable longitudinal feature of SD concerns the severity of the patients' anomia in relation to the specific pattern of neuroanatomical progression. As noted earlier, although the infero-lateral temporal atrophy characteristic of SD seems invariably to be bilateral beyond the earliest stages of the disease, it is often highly asymmetrical. The fact that semantic memory is disrupted by a predominance of either left or right damage is most consonant with the assumption that the semantic network is distributed bilaterally across both temporal lobes. Recent research demonstrates, however, that for approximately equated degrees of semantic deficit, the anomia is more severe in patients with more prominent left temporal atrophy than for those with greater right-sided abnormality (Lambon Ralph et al. 2001). The left-hemisphere elements of the distributed semantic network may be more crucial for activating the phonological system for speech production, which is typically strongly left-lateralised in the human brain.

4. *Collateral Symptoms*

Knowledge of word meanings is clearly central to the abilities to produce and comprehend informative connected speech, and also to the ability to name objects and people; these aspects of language competence therefore progressively deteriorate in patients with SD. By contrast, there are a number of more constrained language skills, involving the transformation of a word from one modality or form to another, that seem largely independent of word meaning. Two examples of a modality transformation are reading a word aloud (a transformation from orthography to phonology) or writing a word to dictation (phonology → orthography); and an example of a simple change in word form is generating the past tense of a verb from its present-tense form. If word meaning is not significantly implicated in these language skills, then patients with SD should perform well on these tasks. Do they? The answer is yes, and no. Their level of success depends on two aspects of the stimulus word to be transformed: whether it is a common or uncommon word, and whether the relationship between the stimulus and response form is consistent or inconsistent with that for other similar words in the speaker's vocabulary. In the English language and in the domain of reading aloud, an example of an inconsistent or irregular word is PINT, because the relationship between its spelling pattern and its pronunciation deviates from other similar and more typical words like PRINT, MINT and HINT. Likewise, in English and in the domain of past-tense verb morphology, an atypical word is THINK; unlike most verbs, and even unlike the phonologically similar verb BLINK, the past-tense of THINK is not THINKED but THOUGHT.

For reasonably high-frequency words with a typical relationship between stimulus and response, patients with SD achieve excellent reading aloud, spelling to dictation and transformation of a verb from its present to past tense. Relative to normal age- and education-matched subjects, the patients show a significant but not too severe decrement for words that are either high frequency but irregular, or regular but lower frequency. On low-frequency irregular words, however, their average success is a dramatic 30–50 percent below normal on the three tasks (Patterson 2000). The patients' errors to these difficult items reflect the well-learned generalizations: the overwhelmingly typical error is to pronounce a written word like 'pint' as if it rhymed with 'mint;' to spell a spoken word like 'cough' as 'coff;' and to turn the spoken present-tense verb

'grind' (in a sentence context like 'Today I grind' the coffee; yesterday I '—— the coffee') into grinded. To the extent that parallel experiments have been performed in languages other than English, patients with SD have revealed precisely comparable phenomena. For example, the generalizations and inconsistencies of the relationship between orthography and phonology in the non-alphabetic writing systems of Japanese are quite different from those in alphabetic English; but Japanese written words do have varying degrees of consistency in this relationship, and Japanese patients with SD succeed in reading aloud the high-frequency consistent words, and fail on the low-frequency atypical words (Patterson et al. 1995).

How is this pattern of performance to be understood? One view of word processing, based on networks of parallel distributed processing, includes the premise that semantic representations of words interact with phonological and orthographic representations in all forms of lexical processing (Plaut et al. 1996). It further predicts that the interaction with semantic knowledge should have a somewhat more influential role precisely for this set of words that the patients find difficult. The prediction regarding word frequency stems from the fact that, in the networks responsible for these tasks, the strength of connections is heavily influenced by the frequency with which particular patterns are encountered and processed. The prediction regarding typicality of relationship between stimulus and response stems from the fact that the very same distributed network that is sensitive to individual word knowledge and frequency also captures similarities and generalizations about stimulus-response relationships across words in the vocabulary. In this framework, if a word benefits from neither strong connections in its own right (by virtue of being commonly encountered), nor from the strong shared connections that apply to words with typical mappings, its processing comes to depend more on additional activation from other parts of the language system, particularly word meaning. According to this theory, then, the SD patients' pattern of successes and failures in these relatively 'non-semantic' language tasks can be explained in terms of the reduced activation available from semantic representations.

5. *Semantic Dementia in the Context of other Related Syndromes*

The book by Snowden et al. (1996) entitled *Fronto-Temporal Lobar Degeneration* distinguished three major syndromes that result from neurodegenerative diseases selectively affecting the frontal and/or temporal lobes of the human brain. How does SD relate to the other two syndromes, behaviorally and neuroanatomically?

Progressive aphasia, first described in the modern era by Mesulam (1982), is a disorder restricted to the domain of language, at least until late in disease progression. SD itself has sometimes, perhaps confusingly, been called progressive aphasia, because of its profound impact on both language production and comprehension; but this alternative syndrome of progressive aphasia is very different. SD gradually obliterates content word vocabulary, leaving fluent but anomic speech with good phonology and syntax. By contrast, the hallmark of nonfluent progressive aphasia, as it is more informatively called, is disrupted phonological and syntactic processing (Hodges and Patterson 1996). Progressive aphasic patients of this type lose the ability to produce connected sentences; their speech is increasingly restricted to short phrases or even to single content words, and these often contain phonological distortions. For example, one patient named a picture of an elephant as 'feleftent:' recognizable if the referent is known but obviously very distorted from the correct phonological word form. Neuroanatomically, nonfluent progressive aphasia seems to be associated with a less focal pattern of atrophy than SD. Both *in vivo* structural imaging and post-mortem analyses reveal atrophy in the left hemisphere, including both superior temporal and posterior frontal regions around the sylvian fissure.

The third member of the triumvirate of conditions described by Snowden et al. (1996) is frontotemporal dementia, often called just frontal (or frontal lobe) dementia. Although an adequate understanding of frontal lobe function in human behavior and cognition is yet to be achieved, it seems clear that much of what can be called human problem solving, judgment, decision making, emotional and social appropriateness, etc., crucially depends on intact frontal lobes; and these are precisely the capacities that are eroded in frontal dementia. Although profound semantic disruption is characteristic of SD and not of frontal dementia, SD often does, especially with disease progression, begin to reveal some of the behavioral disturbances that are the hallmark of frontal dementia. This is perhaps not surprising in light of the fact that, after initial consistent abnormalities of the anterior temporal lobe, atrophy in SD typically spreads not only posteriorly within the temporal lobe but also anteriorly to inferior frontal regions (Mummery et al. 2000). The behavioral changes include a strong preference for fixed daily routine, often to the point where it virtually becomes a demand for ritual.

6. *The Neuropathology of Semantic Dementia*

The underlying pathological cause of many neurodegenerative conditions can only be identified by analysis of brain tissue, which typically happens (if at all) only after the patient's death. Hodges et al. (1998) summarized the findings for all 13 cases to that date which met two criteria: (a) the patient had been studied in sufficient detail in life to enable identification of a clear

pattern of SD; (b) brain tissue was available for post-mortem analysis. In this set, there were no cases with the neurofibrillary tangles and neuritic plaques that constitute the pathological features of Alzheimer's disease. All 13 cases had either the specific intraneuronal inclusions that typify Pick's disease (Hodges 1994) or nonspecific degeneration/neuronal loss (see *Dementia*: *Overview*). It is worth mentioning, however, that Alzheimer's pathology has recently been identified post-mortem in a few patients who had profound semantic disruption, even if not the most prototypical presentation of SD (Galton et al. 2000). In these cases, the brunt of the AD pathology was found in the left anterior temporal lobe—atypical for AD but exactly where atrophy is centered in semantic dementia. It seems clear that cognitive deficits are determined more by the neuroanatomical locus of pathology than by its precise nature.

Democracy

Democracy is universally understood as a form of government involving 'rule by the people,' which has essentially been its meaning since the term and practice were introduced in ancient Greece around 500 BC. At about the same time, a system of popular rule was also created in Rome in the form of the Roman Republic. Although efforts have sometimes been made to distinguish democratic from republican types of government, the only valid distinction is linguistic: democracy from Greek (*demos*, people, *kratia*, rule) and republic from Latin (*res*, thing, *publica*, public).

In any case, democracy as it came to be understood in the twentieth century was shaped not only by the ideas and practices of Greece, Rome, and the city-state

republics of medieval and Renaissance Italy, but perhaps even more importantly by the development of representative institutions in northern Europe and Britain.

No standard description of democracy exists, and the term has been used in many different and sometimes even contradictory ways. However, for an adequate account we need to describe democracy as a goal, aspiration, or ideal that a good political system would satisfy, and also as a set of actual political institutions, practices, or processes that are required in order for the criteria to be satisfied, within limits set by historical circumstances, human capacities, and other realities.

1. *Democracy as an Ideal*

To understand democracy as an ideal or goal, it is helpful to imagine an association composed of members who view one another as basically equal in their competence to participate in governing their association. In short, they consider themselves to be political equals. In order for the association to be governed in a manner consistent with this assumption, it would need to satisfy at least four criteria. Before a policy is adopted by the association, all the members should have equal and effective opportunities for making their views known to the other members as to what that policy should be. Next, when the time arrives at which the decisions about policy will finally be made, every member should have an equal and effective opportunity to vote on the final decisions of the association, and the vote of each should be counted as equal. Third, within reasonable limits as to time, each member should have equal and effective opportunities for learning about the relevant proposals under consideration, their alternatives, and their likely consequences. Finally, in order to insure that the process required by the three preceding criteria is never closed and the association's policies are always open to change by its members, they should also have the exclusive opportunity to decide how proposals are to be placed on the agenda for decisions, and, if they choose, what proposals should be on the agenda.

Each of these criteria implies the existence of a right: the rights of members to participate in decisions, to equal votes, to explore the issues, to decide on the agenda. Thus the criteria not only prescribe a process; they also prescribe a set of rights to which members of a democratic association are entitled.

Needless to say, these democratic criteria are so demanding that probably no association ever fully achieves them. Yet they are useful for judging how far and in what ways an association is undemocratic and for designing, introducing, and improving democratic governments.

Although democratic criteria can be, and often are, applied to many different kinds of association, their most important application is to the government or the state. Because a state possesses extraordinary power, exercises control over means of coercion to enforce its rules, including imprisonment and death, and has enormous capacities for achieving both harm and benefit, advocates of democracy from the Greeks onward have held that the most desirable state is one governed by democratic procedures.

1.1 *Democracy and the State*

Democracy cannot be applied to a state, however, without an answer to fundamental and often difficult question. To whom should the assumption of political equality be extended? Among all those subject to the government of a state, which persons should be entitled to all the rights and opportunities of membership described earlier? Who, in other words, should be full citizens?

That these rights and opportunities should be confined to adults, variously defined, has never been seriously in question. However, from the introduction of democratic ideas and practices in Greece and Rome until the twentieth century, the assumption that only a minority of adults was qualified for the rights of full citizenship all but universally prevailed. Thus all women were excluded, and so too were many males: slaves, the poor or propertyless, illiterates, and others. Consequently, throughout most of its long history democratic and republican government was not, in fact, government by 'the people' who were subject to it. 'Democracy' in governing a state was understood instead to mean government by a minority of adult males—sometimes, indeed, a very small minority.

During the first quarter of the twentieth century a fundamental change in democratic ideas and practices occurred in most 'democratic' countries then existing: women gained the franchise and other political rights. Democratic ideas and practices shifted away from exclusion toward inclusion. This shift was amplified in the last quarter of the century when other groups that had been denied the rights and privileges of citizenship, such as African-Americans in the southern states of the USA and long-settled immigrants in Germany, were granted those rights and privileges.

During the twentieth century, then, a fifth democratic criterion gained wide acceptance: a state could not be democratic unless all or almost all adults subject to it were full citizens entitled to all the rights and opportunities implied by basic democratic criteria. In effect, then, even if adults were unequal in other respects, it was now assumed that they should be treated as political equals in governing a state.

2. *Democratic Institutions*

The actual political institutions that might be required to achieve these democratic criteria (within the limits of the real world) can vary depending on the actual

circumstances of time and place, and historically they have varied in important ways. One aspect of the real world that greatly influences both democratic theory and practice is the size or scale of the unit to be governed by democratic processes. The two most relevant dimensions are the number of members (in a state, citizens) and area. Units consisting of a small number of members associating in a small, compact area not only tend to be more homogeneous than larger units with a great many members, but small units can also provide greater opportunities for direct participation in political life. In a very small and compact unit, such as a committee or a town, all the members can meet face-to-face, and within reasonable limits of time every member can engage in discussion and deliberation with the others. Consequently, other things being equal, smaller units are potentially more capable of meeting democratic criteria at a higher level than larger units.

It is not altogether surprising, then, that democratic practices (limited of course to males) first took root in towns and cities, as they did, for example, in ancient Greece and Rome, in some Italian city-states during the late Middle Ages and early Renaissance, in mountain villages in central Switzerland, and among small bands of Vikings during the eleventh and twelfth centuries. In these circumstances it was feasible, indeed quite natural, for the free adult males all to assemble in one place, at a site perhaps marked by traditional boundaries, and there to make their collective decisions. The most basic democratic institution was thus the citizen assembly. 'Democracy,' then, meant the direct democracy of the citizen assembly or town meeting.

Yet for many purposes small units are inadequate. For one thing, a city-state can be conquered by a larger imperial state, as Athens was in 323 BC by Macedonia, and later by Rome. Moreover, the important problems that human beings face, including the need to obtain food, water, or myriad other wants, typically require actions beyond the boundaries of a small unit. Consequently, the more interdependent human beings become, the less satisfactory small units become. At the very heart of democratic theory and practice, then, lies the dilemma of scale: the smaller a unit, the greater are the opportunities it can provide its members for participating in governing themselves; but the lower is the capacity of its government for dealing satisfactorily with all the important problems its members face. Conversely, the larger the unit the greater is the capacity of its government for dealing satisfactorily with problems that transcend the boundaries of the smaller units within it; but the more reduced are the opportunities it can provide its members for participating in its decisions.

Since the Middle Ages, city-states and other small units have been almost universally incorporated into nation-states or countries. The dilemma of scale has been met, not always satisfactorily, by granting some autonomy on some matters to smaller units within a country—towns, cities, states, provinces, regions, and so on—and maintaining some control, even exclusive control, by the national government.

To provide a satisfactory level of democracy in the larger units required a set of political institutions which, taken in their entirety, were historically novel.

2.1 The Institutions of Large-scale Democracy

Modern large-scale democracy in units the size of a country, even a small country, required the creation of new political institutions. These can be described at several levels of specificity. At the most general level one can specify the basic political institutions that are essential in order for a country to satisfy democratic criteria: to become and remain a democratic country. At a more specific level, the main varieties of constitutional arrangements that have existed in different democratic countries can also be described—for example, presidential or parliamentary systems, federal or unitary, two-party or multi-party, and so on. Finally, at the most specific level one might describe a country's concrete political institutions and practices, which are likely to form a unique pattern.

Descriptions of the second and third kind are beyond the scope of this article. At the most general level, however, the basic political institutions required in a democratic country are these:

(a) Elected officials. Control over government decisions about its laws and policies is constitutionally vested in officials elected by citizens. Thus modern, large-scale democratic governments are representative.

(b) Free, fair, and frequent elections. Elected officials are chosen in frequent and fairly conducted elections in which coercion is comparatively rare.

(c) Freedom of expression. Citizens have a right to express themselves without danger of severe punishment on political matters broadly defined, including criticism of officials, the government, the regime, the socioeconomic order, and the prevailing ideology.

(d) Access to alternative, independent sources of information. Citizens have a right to seek out alternative and independent sources of information from other citizens, experts, newspapers, magazines, books, telecommunications, and the like. Moreover, alternative sources of information should actually exist that are not under the control of the government or any other single political group attempting to influence public political beliefs and attitudes, and these alternative sources are effectively protected by law.

(e) Autonomous associations. To achieve their various rights, including those required for the effective operation of democratic political institutions, citizens also have a right to form relatively independent associations or organizations, including independent political parties and interest groups.

(f) Inclusive citizenship. No adult permanently residing in the country and subject to its laws can be denied the rights that are available to citizens and are necessary to the five political institutions listed above.

3. Beyond Polyarchal Democracy

It is not difficult to show why each of the institutions described in Sect. 2.1 is necessary in order for a country to satisfy ideal democratic criteria at a minimally acceptable level. Without freedom of expression, for example, it would be impossible for citizens to make their views known, hear the views of others, learn what they need to know about relevant proposals, or control the agenda.

Because the combination of institutions described above was developed fully only in the twentieth century, some political scientists wishing to distinguish such modern systems more clearly from other forms of democracy that exist or had existed in smaller units, such as the city-states of Athens or the town meetings of New England, referred to it as polyarchy or polyarchal democracy. In any case, during the twentieth century, political scientists and other observers tended to agree that a considerable number of countries adequately maintained the political institutions described above, and therefore should be regarded as democratic countries. Typical examples were France, India, Japan, the Scandinavian countries, the United Kingdom, the USA, and most other European and English-speaking countries.

In practice, however, the minimally acceptable levels for satisfying democratic criteria have shifted upward over time. Following his visit to the USA in 1831 Alexis de Tocqueville famously described that country as a democracy, as did his contemporaries in Europe and America. Yet an observer employing twentieth-century standards might hesitate to designate a country as a democracy as long as it excluded women from the suffrage, supported slavery, forcibly expelled its indigenous peoples from their territories, and denied them citizenship.

Because the ideal democratic criteria set extraordinarily high and perhaps unattainable standards, it is altogether possible that an increasing number of citizens in democratic countries might conclude that the institutions of polyarchal democracy are inadequately democratic. If so, the acceptable level for meeting democratic criteria might continue on the upward trajectory traced during the twentieth century.

Democracy, History of

In a democracy, political authority is based on the will of the people. From its origins in ancient Greece, democracy has been what the British philosopher W. B. Gallie called an 'essentially contested concept,' that is, a concept whose meaning is permanently open to debate. (Gallie 1955–6) The history of democracy is the history of these debates, debates between democrats and their opponents and, no less vigorously and persistently, among the advocates of different sorts of democracy. Three overlapping sets of issues have dominated disagreements about democratic theory and practice. First and most obviously is the question of whom to include in the demos. If democracy means government by the people, who are the people? Everyone? All Adults? All male adults? All male adults

with property or education? Second is the matter of democracy's prerequisites. What rules, institutions, and values are necessary for democracy to succeed? Are correct procedures sufficient to ensure democratic government or does genuine democracy require a particular kind of society or culture? Is there one road to democracy or many? And finally, there is the issue of what might be called democracy's institutional scope. Is democracy primarily a political system of self-government or is it equally important, or equally necessary, in other aspects of life, such as the family, the workplace, and the schoolroom? In order for there to be a 'true' democracy must its principles and aspirations be realized throughout the social order?

1. *Classical Models*

The openness and complexity of democracy's history were already apparent in the fifth and fourth centuries BC when a number of Greek-speaking city states scattered across the eastern Mediterranean adopted various forms of popular self-government. From the beginning, there was an ambiguity in the meaning of demos which reflected the Greeks' uneasiness about democratic government. For democracy's admirers, the people's will confirmed legitimacy: decrees passed by popular assemblies often began with the words, 'the demos has decided.' But for democracy's critics, the people were the mob, unreliable and easily swayed by passion and self-interest. This is why Plato, in his famous attack on democracy in the eighth book of The Republic, argues that the excesses of democracy will inevitably lead to tyranny.

The ancient city's distinctive blend of religion and politics, the small scale of its public life, the superiority of the spoken over the written word in its political deliberations, and its emphasis on military service and war, reflected a distinctive set of historical conditions that would never be repeated. Nevertheless, the Greek experience continued to play a role in Europe's political imagination. Pericles's eloquent defense of Athenian democracy, recorded (or perhaps composed) by Thucydides in his history of the Peloponnesian War, was persistently cited as a statement of democratic virtue, just as Plato's and Aristotle's criticisms of democracy were used to underscore its dangers. Like the elements of classical buildings, which architects adapted over and over again to serve their own purposes, Greek ideas about democracy were repeatedly borrowed by European thinkers, who often imbedded them in structures quite distant from their original meaning and purpose.

There is no institutional continuity between ancient Greece and modern politics. The democratic practices that Pericles praised and Plato decried did not survive the destruction of the polis by internal discord and foreign enemies. To be sure, the Roman state based its legitimacy on the popular will: its armies fought in the name of 'The Senate and People of Rome.' But after the fall of the republic, first the substance and then the form of popular sovereignty disappeared from European history for almost a millennium. When they reappeared in the late middle ages, republican institutions were limited to relatively small entities, usually city states, in which political power was in the hands of a narrow, exclusive elite. There were also a few self-governing rural communities in medieval and early modern Europe, but they were small and scattered. None of these polities thought of itself as a democracy. The concept, revived with the rest of the Greek legacy in the late middle ages, was a matter for political theory and scholarly debates, not the everyday conduct of public affairs.

2. *The Age of Democratic Revolution*

The history of modern democratic practice begins with a series of political revolutions in the final decades of the eighteenth century. But before erupting into the realm of practical politics, democratic ideals were nourished by three currents of enlightenment thought: first was a new concept of the individual, whose identity was defined by his (and for a few, also her) own talents and desires, rather than his place in the social order; second was a new concept of equality, which accorded to each person (definitions of which varied greatly) the same rights and responsibilities; and finally there was a new concept of social and intellectual activity, which imagined a sphere of free competition among people, commodities, and ideas. Many, perhaps most, of the thinkers who formulated these ideas did not think of themselves as democrats; some of them expressly condemned democratic institutions in terms that Plato would have recognized. Nevertheless, enlightenment notions of individualism, equality, and society helped to undermine the ideological foundations of the old regime and to open the way for democracy's long and circuitous march to political power.

Among enlightenment political theorists the most significant for the history of democracy was Jean Jacques Rousseau, whose ideas inspired the revolutionaries' assaults on the old regime and at the same time reflected democracy's deepest ambiguities. Rousseau is correctly regarded as a spokesman for individual liberty and, no less accurately, as the advocate of the individual's subordination to the 'general will.' He attempted to reconcile these two convictions with a program of education that aimed at freeing individuals from the corruptions of existing society and a program of political reform that was supposed to create institutions appropriate for the products of this education. The result would be a genuinely free society in which individuals want to choose what is best for them and for their community. Because this vision of total harmony between individual desire and social imperatives set a standard that no government could match, among Rousseau's

legacies was the temptation to force people to be free, that is, to use political power to shape their desires to match the alleged needs of the community.

The first step from democratic theory to democratic practice was taken on the far fringes of the European world, in North America, where the struggle for independence from colonial rule was carried out in the name of 'the people's' natural and inalienable right to self-government. Of course the new American democracy was qualified in a number of important ways: the demos excluded women, African-American slaves, and, in some places, men without sufficient property. Nevertheless, the creation of a republic in the new world established a regime whose institutions and legitimacy depended on the people's will.

The democratic experiment in America aroused widespread interest and some enthusiasm, but no imitators among enlightened Europeans. But when revolution engulfed France, Europe's greatest power and the recognized center of fashion and culture, its wider significance could not be ignored. In the summer of 1789, the French National Assembly solemnly proclaimed 'the rights of man and the citizen,' which promised social equality and political liberty. Sovereignty was now firmly rooted in the popular will: 'No body and no individual may exercise authority which does not emanate directly from the nation.' But who spoke for the nation? At each stage of the revolution there was a different answer to this question as power moved from the nation's elected representatives, to the mobilized people of Paris, to the Committee of Public Safety, to an elite of propertied men intent on restoring order, until it finally came to rest in the hands of an heroic young general, Napoleon Bonaparte. As the revolution moved from moderation to terror to reaction to military dictatorship to imperial monarchy, each successive regime invoked the nation, each claimed to rule in the people's name. Beyond France's borders, the revolution's friends and enemies shared one essential conviction: once the forces of democratic government had been unleashed, the world would never be the same.

For more than a century after the revolution was defeated, its historical memory lived on, a common source of inspiration and anxiety. People drew from the revolution's grand narrative the lessons appropriate for their political hopes and fears. To a democrat like Jules Michelet, the revolution was the truest expression of France's commitment to liberty, the most glorious chapter in the 'people's' struggle to realize their historical destiny. Reactionaries like Hippolyte Taine drew a different message from the revolution's course: popular sovereignty, he argued, will always lead first to anarchy, then despotism. But the revolution's most astute analyst was neither a democrat nor a reactionary: Alexis de Tocqueville saw it as part of a larger historical process through which the ideals and institutions of old-regime Europe were destroyed by the forces of social and political democracy that were deeply woven into the fabric of modern life. Like many of democracy's critics, Tocqueville feared it could easily lead to dictatorship; only in America was there a chance that democracy's true promise could be fulfilled (Tocqueville 1988).

3. *The Nineteenth Century*

In 1815, many Europeans hoped or feared that democracy had been defeated for ever. The monarchical principle seemed triumphant; republican institutions survived in Switzerland and a precarious handful of city states. Although monarchy remained the most common form of government in Europe for another century (France after 1870 was the most important exception), almost everywhere representative institutions gradually began to play an important role in public life. The right to vote, always the most obvious marker of democracy's progress, was granted to an increasing number of European males in the course of the century; political parties, interest groups, trade unions, and a variety of newspapers and other publications provided an infrastructure that supported political participation. By 1900, therefore, the distinction between monarchical and democratic governments, which conservative statesmen had struggled to maintain, was hopelessly blurred.

Every political movement had to come to terms with democratic pressures. During the first half of the century, most European liberals, who were the direct heirs of the Enlightenment's ideals of individualism, equality, and freedom, were suspicious of the masses—all the more so after the collapse of the French republic into terror and dictatorship. But in the course of the century, the left wing of the liberal movement was reconciled to democracy, supported universal suffrage (for men) and tried, with varying degrees of success, to win their share of the newly enfranchised voters. Conservatives, who had begun the century as democracy's most consistent enemies, were also unable to resist being pulled into the orbit of democratic politics. Following the example of the Emperor Napoleon III, who had consolidated his position with popular plebiscites after being elected president of France in 1848, conservative statesmen such as Bismarck in Germany and Disraeli in England, set out to use democratic means in support of conservative ends. No less remarkable than these 'Tory democrats' were the defenders of the Roman Catholic church, another of democracy's former enemies, who turned to electoral politics to defend their religious interests against the intrusions of the secular state. Here too we find evidence of the inexorable expansion of democratic ideals and institutions.

Some nineteenth century democrats insisted that political reform was not enough; authentic self-government, they believed, required social revolution. Far and away the most influential version of this belief

was formulated in the 1840s by Karl Marx and Friedrich Engels, who argued that a proletarian revolution was required to establish a truly free and equal society. To Marx, Engels, and their more orthodox disciples, democratic politics was always a means to an end: parties, unions, elections had no value beyond helping the proletariat obtain the power they needed to transform society. In this transformed society, organized political activity would become superfluous because class conflict would disappear. But as so often happens, the socialist parties' democratic means began to shape the ends for which they fought. Eventually the political organizations they built took on their own value, winning elections became an end in itself, democratic politics, a way of life. By the early twentieth century, the European labor movement, most prominently the Social Democratic Party in Germany, had become the most consistent and resolute defender of democratic reform.

In the nineteenth century, the most significant extension of democratic aspirations was not to the social order but rather to the national community. The French revolutionaries had insisted that because people did not belong to a ruler, they could not be traded back forth like pieces of property; nations, like individuals, had the sacred right to determine their own character and destiny. In the course of the century, self-determination came to mean the right of nations to have their own state, a fateful combination of democracy and sovereignty that made the national state the only legitimate way of organizing political space. In the middle decades of the century, Italians and Germans formed new nations; nationalities like the Polish and Irish struggled unsuccessfully to follow their example. In fact, nationality was an elastic and elusive quality, easy enough to invoke, but extraordinarily difficult to use as the foundation for a state. Even in the West, where strong states had had centuries to impose a kind of cultural homogeneity, ethnic minorities remained, while in the multinational empires of the East, the complexities of ethnic settlement meant that any potential nation state would have to contain substantial linguistic and religious minorities. Self-determination, the British political scientist Ivor Jennings remarked, 'seemed reasonable enough: let the people decide. It was in fact ridiculous because the people cannot decide until someone decides who are the people' (Anderson 1996, p. 40).

As difficult as the question of self-determination might be within Europe itself, its problems became even greater when applied to the rest of the world, much of which remained either directly or indirectly under European control. But if the Germans and Italians had a right to their own nation, if the Irish and the Polish could aspire to nationhood, what about the populations of India, Africa, and Asia? In the nineteenth century, even progressive Europeans would have responded that these peoples were not yet ready for independence because they were barbarous. John Stuart Mill, for instance, believed that 'independence and nationality, so essential to the due growth and development of a people further advanced in improvement, are generally impediments' to uncivilized peoples (Mill 1859, p. 252). But by the early twentieth century, advocates of national independence had challenged European influence in the ancient empires of the Manchus and Ottomans, while the ideals of democratic self-determination slowly began to attract followers throughout the colonized world. The global movement against colonization, which would be central to the history of the twentieth century, had many sources and took various forms, but its origins and eventual triumph cannot be understood without the democratic tools that had been forged within Europe itself.

4. *The Twentieth Century*

The historical period that stretched from the Congress of Vienna in 1815 to the outbreak of the First World War in 1914 began with democracy's defeat and ended with its apparently irresistible, if still notably incomplete spread throughout Europe. The period from 1914 to 1945 was characterized by a series of near fatal assaults on the integrity and viability of democratic institutions. There were moments during this dark epoch when thoughtful people could readily imagine that the ideals that had inspired Rousseau and the eighteenth-century revolutionaries, having been abandoned by their advocates and defeated by their enemies, would be consigned to history's dustbin. Who in 1940 could have predicted that, at the century's end, it would be democracy's enemies who would everywhere be in disarray?

That the years after 1914 would be so full of peril for democracy was not immediately apparent. In fact, the First World War destroyed many of democracy's most obdurate opponents, especially the Russian empire, which collapsed into revolution in 1917. Moreover, in most of Europe and America the war accelerated the extension of voting rights to women, an issue that had become increasingly contentious after the turn of the century. Finally, the war ended with the victory of the Western powers, allied since 1917 with the USA, whose president, Woodrow Wilson, proclaimed that the purpose of the war was to make 'a world safe for democracy.' Wilson's League of Nations, a keystone of the treaties signed in the spring of 1919, was designed to create a society of democratic states, in which self-government at home would nurture goodwill abroad and thus purge the world of the twin evils of tyranny and aggression.

The Wilsonian peace was supposed to be the fulfillment of the belief, held in the eighteenth century by men like Immanuel Kant and in the nineteenth by the followers of Jeremy Bentham, that democracy and peace inevitably went together. 'There are properly no

other criminals than the heads of nations,' Bentham had declared, 'the subjects are always honest' (Hinsley 1963, p. 86). Always a triumph of hope over experience, this belief was especially illusory in the years after 1919, when, having been brutalized by the war and frustrated by its outcome, the peoples of Europe were not necessarily peace-loving, while their elected leaders—including those in the USA—were not prepared to cooperate in a common defense of democratic institutions.

In retrospect, therefore, it is clear that two other events in the spring of 1919 were more significant for democracy's immediate future than Wilson's treaties. In March, Benito Mussolini formed his first fascist organization, an inchoate band of the alienated and discontented, which, within three years, was able to take advantage of Italy's postwar crisis and become the basis for a new government. In one state after another, parliamentary democracy collapsed in the twenties and thirties, and nowhere more consequently than in Germany, where Mussolini's admirer, Adolf Hitler, created a dynamic regime based on race, radical nationalism, and anticommunism. Mussolini's fascism and Hitler's National Socialism were at once the enemies and the perversions of democratic politics. Both of them blended dictatorial practice with the trappings of participatory politics—a mass party, rallies and demonstrations, and plebiscites.

A few weeks after Mussolini formed his fascist organization in Milan, Lenin established the Third International in Moscow. Lenin's hopes for world revolution, still very much alive in 1919, were soon disappointed. Contrary to Marxist theory and his own expectations, Lenin was faced with the need to build a socialist society in Russia. This required the violent repression of dissent by the revolutionary regime and then, under Lenin's successor, Joseph Stalin, the ruthless use of state power to create a new social order from above. Tens of millions died in the doomed attempt to turn the USSR into a workers' paradise. Like fascism, which claimed to rule on behalf of the nation, Soviet Communism was a perversion of nineteenth century democratic aspirations which sought to conceal a brutal tyranny behind a facade of cynical democratic rhetoric and empty participatory practice. That so many intelligent people outside of the USSR were drawn to communism in the 1920s and 1930s was a symptom of the political malaise that afflicted democratic regimes everywhere in Europe and America.

The second global war of the twentieth century ended in 1945 with the defeat of the fascist powers. The interwar political spectrum, in which democratic regimes had faced enemies from both the left and the right, was now dramatically simplified; radical right-wing parties were discredited, outlawed, and, in some places, vigorously repressed. Almost all of the regimes that emerged from the war's wreckage declared themselves to be democratic. In the East, 'people's democracies' were formed under the auspices of the USSR and, with the exception of Yugoslavia and Albania, with the assistance of Soviet armies of occupation; in the West, parliamentary regimes were allied with and, to varying degrees, influenced by the USA. This bipolar division of the continent lasted until 1989, when the creation of a reformist regime in the USSR opened the way for democratic movements throughout Eastern Europe. With remarkable speed and, except in Romania, without violence, the communist regimes were driven from power and new, authentically democratic governments were elected to take their place. With the collapse, first of the Soviet imperium and then of the USSR itself, a new era in the history of democracy—with a new set of problems and possibilities—clearly began.

Among the casualties of the Second World War was European colonialism. The principle of national self-determination, proclaimed by Wilson at the end of the First World War and reaffirmed by Franklin Roosevelt and Winston Churchill at the beginning of the second, was not applied to the non-European world without great delay and difficulty. Obviously Japan lost its overseas possessions when it lost the war. While neither Britain nor France, who were on the winning side in 1918 and 1945, wanted to abandon their colonies, they lacked both the ability and the will to maintain them in the face of indigenous resistance, the hostility of both the USA and the USSR, and the reluctance of their own peoples to support a vigorous defense of their empires. Sometimes peacefully, sometimes after violent wars of liberation, Europe's former colonies achieved independence; by the 1980s virtually no residue of direct imperial rule remained. Although the struggle against colonialism was carried out in the name of national self-determination, it proved to be extremely difficult to plant democratic institutions in the new states. With a few notable exceptions, most significantly India, the world's largest democracy, most of Europe's former colonies, especially in Africa, fell under authoritarian regimes, often based on the power of the military. For many of the world's population, therefore, the promise of democracy remained unfulfilled.

5. *Conclusion*

Despite democracy's disappointing record in much of Africa and Asia, there are more functioning democracies in the world at the beginning of the twenty first century than at any other time in history. Furthermore, alternative sources of political authority have apparently disappeared; even dictatorial regimes usually feel obliged to exercise power in the people's name. Elections, even when they are manifestly fraudulent, have become the essential rituals through which authority is legitimized.

Although the alternatives to democracy have largely disappeared, at least in theory, debates about democracy's meaning continue. Some of these debates are new versions of old contests about the composition of the demos, the procedures best suited to guarantee democratic representations, the social and cultural preconditions of popular rule, and the proper scope of democratic politics. Some of the contemporary debates over democracy's meaning reflect new sources of conflict, such as the question of how—or whether—ethnic minorities should be shielded from the impact of majority rule? Others concern the extension of democratic principles into families, schools, religious institutions, healthcare systems.

These debates, as painful and occasionally destructive as they sometimes are, reflect the continued vitality of the democratic tradition. A more serious danger to democracy is a growing skepticism about whether democratic institutions can solve the most significant problems people face in their everyday existence. To the rich, democracy sometimes seems superfluous, an unnecessary distraction from the challenges and opportunities of private life. In the USA, for instance, less half of those eligible turn out to vote in national elections. To the poor, democracy can seem irrelevant, a woefully inadequate antidote to the poisonous power of poverty, violence, and political corruption. Over the past two centuries, the democratic vision has survived defeat and outlived its historic enemies; if it is to survive and flourish in the new century, it must recapture—and in some places, attain for the first time—its hold on ordinary men and women's political imagination.

Democracy: Normative Theory

Normative democratic theory deals with the ethical foundations of democracy and democratic institutions. It is distinct from descriptive democratic theory. It does not offer in the first instance a scientific study of those societies that are called democratic. It aims to provide an account of when and why democracy is ethically desirable as well as ethical principles for guiding the design of democratic institutions. Of course, normative democratic theory is inherently interdisciplinary and must call on the results of political science, sociology, and economics in order to give this kind of concrete guidance. This brief outline of normative democratic theory focuses attention on three distinct issues in recent work. First, it outlines some different approaches to the question of why democracy is morally desirable at all. Second, it explores the problem of the rationality of participation in large democratic societies given the inevitably small impact of participants on the outcomes. It also discusses blueprints of democratic institutions for dealing with this. Third, it surveys different accounts of the proper characterization of equality in the processes of representation. The last two parts display the interdisciplinary nature of normative democratic theory.

1. Foundational Questions

To fix ideas, the term 'democracy' refers very generally to a method of group decision making characterized by a kind of equality of input among the participants. That equality may be the mere formal equality of one person, one vote in an election for representatives to an assembly, or it may be more robust, including equality in the processes of deliberation and coalition building. 'Democracy' may refer to any of these political arrangements. Normative democratic theorists attempt to determine which one of these kinds of arrangements is desirable, ethically speaking, and in

what contexts. For instance, Joseph Schumpeter (1956) argues, with some force, that the first highly formal kind of democracy is highly desirable while the second is dangerous. On the other hand, Jean-Jacques Rousseau (1967) is apt to argue that the first kind of democracy is akin to slavery while only robustly egalitarian democracies have political legitimacy. To evaluate their arguments we must decide on the merits of the different principles and conceptions of humanity and society from which they proceed.

2. *The Justification of Democracy*

We can evaluate democracy ethically along at least two different dimensions. We can evaluate a group decision-making method in terms of the outcomes of using it and compare the values of those outcomes with those of other possible methods of political decision making. We can also evaluate democracy in terms of qualities that are inherent in the method itself. We can ask whether there is something inherently fair about making democratic decisions on matters on which people disagree.

3. *Instrumental Values*

The instrumental values often attributed to democracy can be broadly classed into two categories: the quality of the resulting legislation and the impact of democracy on the characters of the participants. John Stuart Mill (1991) argued that democratic ways of deciding tend to be superior to non-democratic ways on account of the fact that they produce superior legislation in three distinct ways. Strategically, democracy is thought to produce superior outcomes to other forms of rule just because it forces decision-makers to take into account the interests, rights and opinions of most people in society. Since democracy gives some political power to each, more people are taken into account than under aristocracy or monarchy.

Epistemologically, democracy is thought to be the best decision-making method on the grounds that it is generally more reliable in helping participants discover the right decisions. Since democracy brings a lot of people into the process of decision making, it can take advantage of many sources of information and critical assessment of laws and policies. Democratic decision making tends to be more informed than other forms about the interests of citizens and the causal mechanisms necessary to advance those interests. Furthermore, the broad-based discussion typical of democracy enhances the critical assessment of the different moral ideas that guide decision makers.

Regarding its effects on character, many have noted with Mill and Rousseau that democracy tends to make people stand up for themselves more because it makes collective decisions depend on them more than monarchy or aristocracy do. Hence, in democratic societies individuals are encouraged to be more autonomous. In addition, democracy tends to get people to think carefully and rationally more than other forms of rule because it makes a difference whether they do or not. Finally, some have argued that democracy tends to enhance the moral qualities of citizens. When they participate in making decisions, they have to listen to others, they are called upon to justify themselves to others and they are forced to think in part in terms of the interests of others. Some have argued that when people find themselves in this kind of circumstance, they come genuinely to think in terms of the common good and justice. Hence some have argued that democratic processes tend to enhance the autonomy, rationality, and morality of participants. Since these beneficial effects are thought to be worthwhile in themselves, they count in favor of democracy and against other forms of rule.

Some argue in addition that the above effects on character also tend to enhance the quality of legislation. A society of rational, autonomous, and moral decision makers is more likely to produce good legislation than a society ruled by a self-centered person or small group of persons who rule over slavish and unreflective subjects.

More detailed knowledge of the effects of political institutions can be used to discriminate in favor of particular kinds of democratic institutions or modifications of them. For instance, in the United States, James Madison (1788) argued in favor of a fairly strong federal government on the grounds that local governments are more likely to be oppressive to minorities. Of course, the soundness of any of the above arguments depends on the truth or validity of the associated substantive views about justice and the common good as well as a causal theory of the consequences of different institutions.

It is also the case that many theorists argue against any kind of democracy on instrumental grounds. Hobbes (1968) argues that democratic institutions are inferior to monarchical government on the grounds that they are more likely to breed destabilizing dissension among subjects. Plato (1974) argues that democracy is inferior to various forms of monarchy, aristocracy, and even oligarchy on the grounds that democracy tends to undermine the expertise necessary to properly governed societies. Some recent thinkers have argued in favor of giving over complete control over society to the market, on the grounds that democracy tends to produce serious economic inefficiencies. More modest versions of these arguments have been used to justify modification of democratic institutions.

4. *Instrumentalism*

Instrumentalists argue that these instrumental values of the democratic process are the only bases on which to evaluate democracy or compare it with other forms

of political decision making. The standards one uses depend on one's conception of a just and good society. For example, libertarian instrumentalists such as Friedrich Hayek (1960) argue that democracy is desirable only to the extent that it protects liberty and private property.

5. *Noninstrumental Values*

Few theorists deny that political institutions must be at least in part evaluated in terms of the outcomes of having those institutions. Some argue, in addition, that some forms of decision making are morally desirable independent of the consequences of having them. A variety of different approaches have been used to show that democracy has this kind of intrinsic value. The most common of these come broadly under the rubrics of liberty and equality.

6. *Liberty*

Some argue that the basic principles of democracy are founded in the idea that each individual has a right to liberty. Democracy, it is said, extends the idea that each ought to be master of his or her life to the domain of collective decision making. First, each person's life is deeply affected by the larger social, legal, and cultural environment in which he or she lives. Second, only when each person has an equal voice and vote in the process of collective decision making will each have control over this larger environment. Thinkers such as Carol Gould (1988) conclude that only when some kind of democracy is implemented will individuals have a chance at self-government. Since individuals have a right to self-government, they have a right to democratic participation. This right is established at least partly independently of the worth of the outcomes of democratic decision making. The idea is that the right to self-government gives one a right, within limits, to do wrong. Just as an individual has a right to make some bad decisions for himself or herself, so a group of individuals have a right to make bad or unjust decisions for themselves.Here we can see the makings of an argument against instrumentalism. To the extent that an instrumentalist wishes to diminish a person's power to contribute to the democratic process for the sake of enhancing the quality of decisions, he or she is committed to thinking that there is no moral loss in the fact that our power has been diminished; but if the liberty argument is correct our right to control our lives is violated by this.

One major difficulty with this line of argument is that it appears to require that the basic rule of decision making be consensus or unanimity. If each person must freely choose the outcomes that bind him or her, then those who oppose the decision are not self-governing. They live in an environment imposed on them by others. So only when all agree to a decision are they freely adopting the decision.

The trouble is that there is rarely agreement on major issues in politics. Indeed, it appears that one of the main reasons for having political decision-making procedures is that they can settle matters despite disagreement. Hence it is hard to see how any political decision-making method can respect everyone's liberty.

7. *Democracy as Public Justification*

One distant relative of the self-government approach is the account of democracy as a process of public justification defended by, among others, Joshua Cohen (1998). The idea behind this approach is that laws and policies are legitimate to the extent that they are publicly justified to the citizens of the community. Public justification is justification to each citizen as a result of free and reasoned debate among equals. Citizens justify laws and policies to each other on the basis of mutually acceptable reasons. Democracy, properly understood, is the context in which individuals freely engage in a process of reasoned discussion and deliberation on an equal footing. The ideas of freedom and equality provide guidelines for structuring democratic institutions.

The aim of democracy as public justification is reasoned consensus among citizens. However, a serious problem arises when we ask about what happens when disagreement remains. Two possible replies have been suggested to this kind of worry. It has been urged that forms of consensus weaker than full consensus are sufficient for public justification and that the weaker varieties are achievable in many societies. For instance, there may be consensus on the list of reasons that are acceptable publicly but disagreement on the weight of the different reasons. Or there may be agreement on general reasons but disagreement about particular interpretations of those reasons. What would have to be shown here is that such weak consensus is achievable in many societies and that the disagreements that remain are not incompatible with the ideal of public justification.

8. *Equality*

Many democratic theorists have argued that democracy is a way of treating persons as equals when there is good reason to impose some kind of organization on their shared lives, but they disagree about how best to do it. On one version, defended by Peter Singer (1973), when people insist on different ways of arranging matters properly, each person in a sense claims a right to be dictator over their shared lives. However, these claims to dictatorship cannot all hold up. Democracy embodies a kind of peaceful and fair compromise

among these conflicting claims to rule. Each compromises equally on what he or she claims as long as the others do, resulting in each having an equal say over decision making. In effect, democratic decision making respects each person's point of view on matters of common concern by giving each an equal say about what to do in cases of disagreement.

One difficulty is that this view relies on agreement much as the liberty views described above. What if people disagree on the democratic method or on the particular form democracy is to take? Are we to decide these latter questions by means of a higher order procedure? And if there is disagreement on the higher order procedure, must we also democratically decide that question? The view seems to lead to an infinite regress. Another egalitarian defense democracy asserts that it embodies the equal consideration of the interests of the citizens of a society when there is disagreement about how best to organize their shared life. On this account, equal consideration of interests requires that individuals' judgments be taken into account equal when there is disagreement. Respect for each citizen's judgment is grounded in the fallibility of everyone's judgment as well as the generally recognized tendency of the moral judgments of persons to be biased towards their own interests. Each citizen would have good reason to think that his or her interests were not being given the same weight as others if he or she had less decision-making power than the others. On this account, since each person has a pre-eminent interest in being recognized as an equal member of the community, only equality in decision-making power is compatible with equal consideration of interests. The principle of equal consideration of interests also implies limits to what can be up for democratic control and so the infinite regress noted above is avoided.

9. *Democratic Citizenship*

A vexing problem of democratic theory has been to determine whether ordinary citizens are up to the task of governing a large society. There are three distinct problems here. First, Plato argued that some people are innately more intelligent than others and that those persons ought to rule. Second, others have argued that a society must have a division of labor. If everyone were engaged in the complex and difficult task of politics, little time or energy would be left for the other essential tasks of a society. Conversely, if we expect most people to engage in other difficult and complex tasks, how can we expect them to have the time and resources sufficient to devote themselves intelligently to politics?

Third, since individuals have so little impact on the outcomes of political decision making in large societies, they have little sense of responsibility for the outcomes. Some have argued that it is not rational to vote since the chances that a vote will affect the outcome of an election are nearly indistinguishable from zero. Worse still, Anthony Downs (1957) has argued that almost all of those who do vote have little reason to become informed about how best to vote. On the assumption that citizens reason and behave roughly according to the Downsian model, either the society must in fact be run by a relatively small group of people with minimal input from the rest or it will be very poorly run.

These observations pose challenges for any robustly egalitarian or deliberative conception of democracy. Without the ability to participate intelligently in politics one cannot use one's votes to advance one's aims, nor can one be said to participate in a process of reasoned deliberation among equals. So, either equality of political power implies a kind of self-defeating equal participation of citizens in politics or a reasonable division of labor seems to undermine equality of power.

Plato and Hobbes argued against democracy in any form on these grounds. Some modern theorists of democracy, called elite theorists, have argued against any robustly egalitarian forms of democracy on these grounds. They argue that high levels of citizen participation tend to produce bad legislation designed by demagogues to appeal to poorly informed and overly emotional citizens. They look upon the alleged apathy and uninformedness of citizens evidenced in many empirical studies in the 1950s and 1960s as highly desirable social phenomena. Joseph Schumpeter's assertion that the 'democratic method is that institutional arrangement for arriving at political decisions in which individuals acquire the power to decide by means of a competitive struggle for the people's vote' (Schumpeter 1956, p. 269) still stands as a concise statement of the elitist view. In this view, the emphasis is placed on responsible political leadership. Political leaders are to avoid divisive and emotionally charged issues and make policy and law with little regard for the fickle and diffuse demands made by ordinary citizens.

An approach that is in part motivated by the concerns above but that attempts to avoid elitism is the interest group pluralist account of politics. Robert Dahl's early statement of the view is very powerful.'In a rough sense, the essence of all competitive politics is bribery of the electorate by politicians… The farmer… supports a candidate committed to high price supports, the businessman…supports an advocate of low corporation taxes… the consumer…votes for candidates opposed to a sale tax' (Dahl 1959, p. 69). In this conception of the democratic process, each citizen is a member of an interest group with narrowly defined interests that are closely connected to their everyday lives. On these subjects citizens are supposed to be fairly well informed and interested in having an influence. On this account, democracy is not rule by the majority but rather rule by coalitions of minorities.

The account ensures that individuals can participate roughly as equals to the extent that it narrowly confines the issues with which each individual is concerned.

A third approach inspired by the kinds of problems above may be called the neoliberal approach to politics favored by public choice theorists such as James Buchanan and Gordon Tullock (1965). Against elite theories, they contend that elites and their allies will tend to expand the powers of government and bureaucracy for their own interests and that this expansion will occur at the expense of a largely inattentive public. They argue against the interest group pluralist theorists that the problem of participation occurs within interest groups more or less as powerfully as among the citizenry at large. Only some interest groups are likely to succeed in organizing to influence the government. Hence only some interest groups will succeed in influencing government and they will do so largely for their own benefit while spreading the costs to others.

Neoliberals argue that any way of organizing a large and powerful democratic state is likely to produce serious inefficiencies. They infer that one ought to transfer many of the current functions of the state to the economic market and limit the state to the enforcement of basic property rights and liberties. These can be more easily understood and brought under the control of ordinary citizens.

But the neoliberal account of democracy must answer to two large worries. First, citizens in modern societies have more ambitious conceptions of social justice and the common good than are realizable by the minimal state. The neoliberal account thus implies a very serious curtailment of democracy of its own. More evidence is needed to support the contention that these aspirations cannot be achieved by the modern state. Second, the neoliberal approach ignores the problem of large private concentrations of wealth and power that are capable of pushing small states around for their own benefit and imposing their wills on populations without their consent. The assumptions that lead neoliberals to be skeptical about the large modern state imply equally disturbing problems for a neoliberal society.

A considerable amount of the literature in political science and the economic theory of the state are grounded in the assumption that individuals act primarily and perhaps even exclusively in their self-interest narrowly construed. The problem of participation and the accounts of the democratic process described above are in large part dependent on this assumption. While these ideas have generated interesting results and have become ever more sophisticated, there has been a growing chorus of opponents. Against the self-interest axiom, defenders of deliberative democracy and others claim that citizens are capable of being motivated by a concern for the common good and justice. They also claim, with Mill and Rousseau, that such concerns are not merely given prior to politics but that they can evolve and improve through the process of discussion and debate in politics. They assert that much debate and discussion in politics would not be intelligible were it not for the fact that citizens are willing to engage in open-minded discussion with those who have distinct morally informed points of view. Empirical evidence suggests that individuals are motivated by moral considerations in politics in addition to their interests. Accordingly, many propose that democratic institutions be designed to support the inclination to engage in moral and open minded discussion with others.

Once we approach the idea of citizenship from a moral point of view and we recognize the importance of a division of labor, the question arises of what the appropriate role for a citizen in a democracy is. If we think that citizens are too often uninformed, we should ask two questions. What ought citizens have knowledge about in order to fulfill their role? What standards ought citizens' beliefs live up to in order to be adequately supported? Some have proposed that citizens know about their particular sectors of society and not others. We have seen that this view has a number of difficulties. Christiano (1996) proposes, along with others, that citizens must think about what ends the society ought to aim at and leave the question of how to achieve those aims to experts. This kind of view needs to answer to the problem of how to ensure that politicians, administrators, and experts actually do attempt to realize the aims set by citizens. And it must show how institutions can be designed so as to establish the division of labor while preserving equality among citizens. But if citizens genuinely do choose the aims and others faithfully pursue the means to achieving those aims, then citizens are in the driver's seat in society.

It is hard to see how citizens can satisfy any even moderate standards for beliefs about how best to achieve their political aims. Knowledge of means requires an immense amount of social science and knowledge of particular facts. For citizens to have this kind of knowledge generally would require that we abandon the division of labor in society. On the other hand, citizens do have first-hand and daily experience with thinking about the values and aims they pursue. This gives them a chance to satisfy standards of belief regarding what the best aims are. Still the view is not defensible without a compelling institutional answer to the question of how to ensure that others are genuinely pursuing the means to achieve the aims specified by citizens.

10. *Legislative Institutions*

A number of debates have centered on the question of what kinds of legislative institution are best for a democratic society. What choice we make here will

depend heavily on the kind of underlying ethical justification of democracy, our conception of citizenship, and our empirical understanding of political institutions and how they function. The most basic types of formal political representation available are single-member district representation, proportional representation, and group representation. In addition, many societies have opted for multicameral legislative institutions. In some cases, combinations of the above forms have been tried.

Single-member district representation returns single representatives of geographically defined areas containing roughly equal populations to the legislature and is present most prominently in the USA and the UK. The most common form of proportional representation is party-list proportional representation. In a simple form of such a scheme, a number of parties compete for election to a legislature that is not divided into geographical districts. Parties acquire seats in the legislature as a proportion of the total number of votes they receive in the population as a whole. Group representation occurs when the society is divided into nongeographically defined groups such as ethnic or linguistic groups or even functional groups such as workers, farmers, and capitalists and returns representatives to a legislature from each of them.

Many have argued in favor of single member district legislation on the grounds that it has appeared to them to lead to more stable government than other forms of representation. The thought is that proportional representation tends to fragment the citizenry into opposing homogeneous camps that adhere rigidly to their party lines and that are continually vying for control over the government. Since there are many parties and they are unwilling to compromise with each other, governments formed from coalitions of parties tend to fall apart rather quickly. The post-War experience of governments in Italy appears to confirm this hypothesis. Single-member district representation, in contrast, is said to enhance the stability of governments by virtue of its favoring a two-party system of government. Each election cycle then determines which party is to stay in power for some length of time.

Charles Beitz (1989) argues that single-member district representation encourages moderation in party programs offered for citizens to consider. This results from the tendency of this kind of representation towards two-party systems. In a two-party system with majority rule, it is argued, each party must appeal to the median voter in the political spectrum. Hence they must moderate their programs to appeal to the median voter. Furthermore, they encourage compromise among groups since they must try to appeal to a lot of other groups in order to become part of one of the two leading parties. These tendencies encourage moderation and compromise in citizens to the extent that political parties, and interest groups, hold these qualities up as necessary to functioning well in a democracy.

In criticism, advocates of proportional and group representation have argued that single-member district representation tends to muffle the voices and ignore the interests of minority groups in the society. Minority interests and views tend to be articulated in background negotiations and in ways that muffle their distinctiveness. Furthermore, representatives of minority interests and views often have a difficult time becoming elected at all in single-member district systems, so it has been charged that minority views and interests are often systematically underrepresented. Sometimes these problems are dealt with by redrawing the boundaries of districts in a way that ensures greater minority representation. The efforts are invariably controversial since there is considerable disagreement about the criteria for apportionment. In proportional representation, by contrast, representatives of different groups are seated in the legislature in proportion to citizens' choices. Minorities need not make their demands conform to the basic dichotomy of views and interests that characterize single-member district systems so their views are more articulated and distinctive as well as better represented.

Another criticism of single-member district representation is that it encourages parties to pursue dubious electoral campaign strategies. The need to appeal to a large, diverse, and somewhat amorphous sector of the population can very often be best met by using ambiguous, vague, and often irrelevant appeals to the citizens. Thus, instead of encouraging reasonable compromise, the scheme tends to support tendencies towards ignorance, superficiality, and fatuousness in political campaigns and in the citizenry. It encourages political leaders to take care of the real issues of politics in back rooms while they appeal to citizens by means of smoke and mirrors. Of course, those who agree in the main with the elitist-type theories will see nothing wrong in this; indeed, they may well champion this effect. Proportional representation requires that parties be relatively clear and upfront about their proposals, so those who believe that democracy is ethically grounded in the appeal to equality tend to favor proportional representation.

Advocates of group representation such as Iris Marion Young (1993) have argued that some historically disenfranchised groups may still not do very well under proportional representation. They may not be able to organize and articulate their views as easily as other groups. Also, minority groups can still be systematically defeated in the legislature and their interests may be consistently set back even if they do have some representation. For these groups, some have argued that the only way to protect their interests is legally to ensure that they have adequate and even disproportionate representation.

One worry about group representation is that it tends to freeze some aspects of the agenda that might be better left to the choice of citizens. For instance, consider a population that is divided into linguistic

groups for a long time, and suppose that only some citizens continue to think of linguistic conflict as important. In the circumstances, such schemes may tend to be biased in an arbitrary way that favors the views or interests of those who do think of linguistic conflict as important.

Democratic Party

The Democratic party in the United States claims Thomas Jefferson and Andrew Jackson as its founders. It was the first modern political party, and it remains the oldest political party in continuous existence in the world. For more than two centuries, the Democratic party and its predecessor, the Democratic-Republican party, have been the mainstays in two-party competition that has pitted them sequentially against the Federalists, the Whigs, and the Republicans.

1. Democratic-Republican Prelude

The distant origins of the Democratic party can be found in the governmental faction led by Secretary of State Jefferson at the outset of the new national government established by the 1787 Constitution. Serving under President George Washington, who persistently decried the emerging partisanship in his administration, Jefferson found himself consistently at odds with Secretary of the Treasury Alexander Hamilton.

1.1 Jeffersonians vs. Hamiltonians

Their rivalry was rooted in personal ambition, policy, region, constituency representation, and ideology. Each aspired to inherit Washington's mantle of national leadership. On behalf of his rural, agrarian, common constituents, Jefferson opposed Hamilton's policy initiatives that favored the urban, commercial, affluent interests in society. Jefferson's understanding of the proper role of the national government was much more limited than Hamilton's expansive, energetic one.

More specifically, Jefferson and his followers tended to distrust executive and judicial power, even as the Hamiltonians, or Federalists, as they called themselves, embraced it. Rather, the Jeffersonians exalted the legislature, with its clearer popular links, within the separation of power structure of the federal government, in contrast with the more elitist Federalists. As such, their pioneering partisan institution was the legislative caucus, a gathering of the congressional representatives loyal to Jefferson. The caucus plotted legislative strategy and assumed responsibility for presidential nominations.

When Washington, partisan disclaimers notwithstanding, generally embraced Hamilton's policy initiatives, Jefferson extended his partisan opposition beyond the legislative caucus to the electoral arena in an effort to assume control of the national government. His organizational vehicle was the Democratic-Republican party. Meanwhile, this initiative encouraged Hamilton similarly to organize his Federalist faction within the government into a political party.

1.2 Democratic-Republican Dominance (1800–24)

As the nineteenth century dawned, Jefferson's election to the presidency, accompanied by victories of supportive majorities in both houses of Congress, signaled

the ascendancy of the Democratic-Republican party, and the decline of its Federalist opposition. Under the Virginia Dynasty of Presidents Jefferson (1801–9), James Madison (1809–17), and James Monroe (1817–25), the Democratic-Republicans thoroughly dominated the political landscape.

1.3 Democratic-Republican Disarray (1824–8)

However, the looming presidential election of 1824 revealed serious divisions in the coalition of forces that comprised the Democratic-Republican party. The breakdown of consensus undermined the legitimacy of the legislative caucus' presidential nomination and led to a split that produced a new partisan alignment and the appearance of the Democratic party. One faction flocked to the banner of Andrew Jackson in his unsuccessful 1824 presidential campaign and the two succeeding ones in which he prevailed. This Jackson faction became known as the Democrats, distinguishing themselves from Jackson's rivals, including John Quincy Adams and Henry Clay, whose reconstituted factions became the Whig party.

2. The Jacksonian Democracy

The Democratic party, while clearly rooted in the old Democratic-Republican party, nonetheless demonstrated noteworthy shades of difference pertaining to region, class, religion, and ideology. It had strong appeal in the new southern and western states admitted to the Union. The Democrats also attracted support from urban workers whose heightened presence reflected increasing industrialization in American society. This constituency brought into the party coalition large numbers of Catholic immigrants. The Democrats more enthusiastically promoted the value of popular participation in the political arena. In 1832, they supplanted the discredited caucus with the presidential nominating convention. Following Jackson's lead, they tended to be more comfortable with the exercise of executive prerogative, linking the presidency with the public.

2.1 Democrats vs. Whigs (1828–56)

In this second distinctive era of party competition, lasting over a quarter-century, the Democrats were clearly dominant on the national scene. Their Whig opponents united around their common opposition to the person and policies of Jackson, but they were divided otherwise. In addition to Jackson (1828, 1832), the Democrats also elected Martin Van Buren (1836), James K. Polk (1844), Franklin Pierce (1852), and James Buchanan (1856) to the presidency for single terms. On two occasions in the 1840s, they lost presidential elections when the Whigs nominated military heroes: William Henry Harrison (1840), and Zachary Taylor (1848). Unfortunately for the Whigs, both standard-bearers died before completing a single term, and the Democrats reclaimed the presidency in the ensuing elections.

For the most part, Democratic control of Congress was also the norm. On only one occasion, 1841–3, did the Democrats lack majorities in both houses. Twice they lost a single chamber: the Senate, 1843–5; and the House, 1847–9. Otherwise, from the late 1820s until the mid-1850s, the Democrats were clearly in charge on Capitol Hill. However, the intensifying slavery controversy and rising sectionalism proved divisive and debilitating for both major political parties in the decade of the 1850s. Indeed, the unstable Whig coalition disintegrated, and a new party, the Republicans, arose to challenge the fragmented Democrats for national dominance, winning control of the House in 1854 and 1858.

3. Democrats vs. Republicans I: Democrats in the Minority (1860–96)

With its Northern and Southern wings competing electorally, the Democrats were trounced in the 1860 elections, which produced a Republican president, Abraham Lincoln, Republican congressional majorities, and a new, third era of party competition, in which the Democrats found themselves in an unaccustomed position as the minority party. During the Civil War, the Democrats floundered following the departure of their traditionally strong Southern wing to secession. They held on as the major party alternative to the now-dominant Republicans with their support in the urban strongholds of the Northeast. After the war, the return of the solidly Democratic Southern states to the Union revived party fortunes, but the Democrats continued to suffer nationally from the stigmas of their longtime accommodation of slavery and acquiescence to secession.

For more than three decades following the outbreak of the Civil War, the Democrats typically lost presidential elections, albeit by narrow margins. Only Grover Cleveland, in 1884 and 1892, was able to break the Republican lock on the White House. In turn, only two Congresses in these decades featured Democratic majorities in both chambers: the 46th (1879–81), and the 53rd (1893–5). The Democrats were much more competitive in the lower house, winning control on six additional occasions: 1874, 1876, 1882, 1884, 1886, and 1890.

3.1 Democratic Factions

During this era, the Democrats became even more fragmented. Reinforcing their traditional sectional

division, with its attendant urban–rural dimension, they separated into persistent dueling factions that featured Protestants vs. Catholics, protectionists vs. free traders, wets and drys, populists and progressives vs. reactionaries and states-righters, and hard money and easy money advocates.

4. *Democrats v. Republicans II: Democratic Downturn (1896–1932)*

The critical election of 1896 marked a severe downturn in Democratic party fortunes. Their presidential nominee, William Jennings Bryan, represented the ascendant Southern and Western, rural, Protestant, populist, easy money, free trade, dry factions within the party. He went down to a crushing defeat at the hands of Republican William McKinley. Renominated in 1900 and 1908, Bryan continued to lead the party to electoral disasters, as the new pattern of national electoral competition solidified. In this fourth party system, lasting until 1932, the Democrats maintained their base in the South, and did relatively well in the West, but were usually overwhelmed by the Republicans in the more populous Northeast and Midwest, despite their enduring urban strongholds there.

Their entrenched minority status was interrupted in the twentieth century's second decade. In 1910, the Democrats won a majority in the House. Two years later, division within the dominant Republican party allowed nominee Woodrow Wilson to capture the presidency, and the Democrats to control both houses of Congress for the first time in two decades. Wilson's narrow 1916 re-election was the first by an incumbent Democrat since Jackson's in 1832, but the Democrats relinquished both congressional chambers in the midterm elections of 1918. The 'return to normalcy' was completed by the loss of the White House to the resurgent Republicans in 1920. The Democrats suffered convincing electoral defeats in the remaining national elections of that decade.

5. *Democrats vs. Republicans III: Democratic Resurgence (1932–52)*

However, the onset of the Great Depression in 1929 signaled a revival in party fortunes, catapulting the Democrats back to majority status nationwide. Franklin D. Roosevelt, their successful presidential nominee in 1932, played the leading role in this electoral realignment, justifying his inclusion with Jefferson and Jackson in the top echelon of party heroes. Roosevelt assembled a formidable electoral coalition under the party umbrella. It embraced white Southerners, urban workers, farmers, racial and ethnic minorities, and ideological liberals, who united behind the activist governmental response to economic and social problems embodied in Roosevelt's New Deal. Roosevelt effectively reconciled Hamilton's energetic founding vision for the Federalists with the Democrats' traditional, antielitist identity as the party of the people.

This coalition elected Roosevelt president an unprecedented four times, and kept his successor, Harry S. Truman, in the White House for another full term, encompassing an epochal two decades that featured not only the Depression, but also World War II and the onset of the Cold War. In addition, the Democrats took control of the House of Representatives in 1930 and the Senate in 1932. They held both through 1946, and recaptured the Congress in 1948. Thus, the Roosevelt coalition, mobilized in support of his New Deal policies, dominated this fifth distinctive era of party competition,

6. *Democrats vs. Republicans IV: Fluctuating Fortunes (1952–)*

In the five decades since Truman's 1948 triumph, the national electoral fortunes of the Democrats have fluctuated dramatically and generally deteriorated. They lost the White House and Congress as well in 1952, when the Republicans nominated General Dwight D. Eisenhower, a World War II hero. However, they recaptured control of Congress in 1954. Having done so, they controlled the House for an unprecedented 40 consecutive years and the Senate for 26.

This sustained Democratic dominance of Congress masked a much more vulnerable position in presidential elections. After two terms for Eisenhower, the Democrats regained the presidency under John Kennedy in 1960 and retained it for his successor Lyndon Johnson in 1964. They surrendered the White House in 1968, when Republican Richard Nixon won his first of two terms. Scandals associated with the Nixon presidency enabled Democrat Jimmy Carter to defeat Nixon's replacement, Gerald R. Ford, in 1976. However, Carter met defeat in his 1980 reelection bid against Ronald Reagan. That election also featured the Democrats' loss of the Senate for the first time in over a quarter-century.

Throughout Reagan's two terms, the Democrats held on to their majority in the House, and they took back the Senate in 1986. Nevertheless, their weakness in presidential contests was unmistakable. In 1988, Reagan's vice president, George Bush, won the presidency, marking the first time since 1928 that the Democrats lost three consecutive presidential elections.

Uniting behind nominee Bill Clinton in 1992, the Democrats finally recaptured the White House; but two years later, they lost both houses of Congress for

the first time in four decades. In 1996, Clinton won reelection, the first Democrat since Roosevelt to do so. In turn, the Republicans have maintained their control of Congress at least through 2000, marking the longest stretch the Democrats have constituted the minority since the 1920s.

6.1 Erosion of the New Deal Coalition

The past five decades of volatility in Democratic party fortunes reveal serious erosion in the New Deal coalition. Most notably, the Democrats have lost the allegiance of the white Southerners who had been a party bulwark since the days of Jefferson and Jackson. When the national Democrats embraced the cause of civil rights in the late 1940s, they set the stage for a regional realignment that was clearly underway by the mid-1960s and has continued through the century's end.

In addition, even as their social and economic reforms became widely accepted, the Democrats suffered electorally from rising public distrust of the national government and its capacity to solve social problems. Moreover, the advent of the Cold War led to criticism of the Democrats as 'soft' on communism, undermining their voter support on foreign policy issues. Intraparty conflict over the Vietnam War and the attendant cultural divisions it spawned further weakened the Democrats. Further, both major parties struggle with the disinclination of contemporary voters to develop enduring partisan attachments.

7. Organization and Leadership

The Democratic Party is organized according to the federal principle, in keeping with the constitutional structure of government under which it developed. Thus, at every level of government, national, state, and local, there is a corresponding level of party organization. Traditionally, decentralization prevailed within the party organization, with the state and local parties maintaining noteworthy autonomy. Party reforms beginning in the late 1960s ushered in an era of unprecedented nationalization, as well as an enhancement of the role of primaries in presidential nominations. The organization of the Democratic party, at any level, typically features several distinct institutions: convention, committee, chair, and headquarters staff.

Traditionally, the party's presidential nominee is designated its titular leader. When that nominee occupies the presidency, party leadership is indisputable. Otherwise, it may also be claimed by the congressional chieftains, the national party chair, and, occasionally, incumbent governors of major states.

Democratic Theory

Democratic Theory is a body of normative and empirical claims focused on at least five related questions: (a) Whose preferences count? (b) What kinds of preferences or opinions count? (c) What decision rule is employed to aggregate those preferences? (d) Through what kinds of institutions are those results represented? (e) How can the democratic decision process avoid bad or unacceptable outcomes such as 'tyranny of the majority'?

1. Who is included?

Early democratic institutions, such as those in ancient Athens, enfranchised only a tiny portion of the population. But the 2500 year history of democracy can be viewed as one of progressive inclusion—through the gradual elimination of restrictions based

on narrow definitions of citizenship, on property and/or educational qualifications, on race and ethnicity, and on gender. Most modern developed democracies approach universal enfranchisement of adult citizens (Dahl 1989). Of course, many citizens theoretically entitled to participate do not actually do so. Except for a few countries such as Australia and Brazil that have successfully implemented compulsory voting, most democracies leave participation to individual decision with variations in terms of how much of the burden of voter registration falls on the individual. Countries such as the USA or Switzerland that are distinctive for offering many opportunities for public consultation routinely have low turnout rates. In the United States, only about one-half of the citizen adult population actually votes, even in the most important elections, such as for the US Presidency.

Much of the modern dialogue about adapting democracy to the large-scale nation-state began with the famous debate over the American Constitution between Federalists and Anti-Federalists. The American Founders did not even use the term 'democracy' to apply to the 'Republic' that they wished to establish. The term 'democracy' was reserved, for example, by James Madison (author of many of the key Federalist papers and one of the chief architects of the US Constitution) for small-scale city-states where everyone could gather together. The danger in direct democracy, Madison and the Founders thought, was that passions or interests might motivate 'factions' endangering some people's rights (Madison et al. 1788).

2. *What is Public Opinion?*

The American Founders wanted institutions that would give expression not just to any public views, but to those opinions that had been 'refined' or 'filtered' so as to produce 'the deliberative sense of the community.' Representatives, they believed, serve to 'refine and enlarge the public views by passing them through a chosen body of citizens' as Madison argued in *Federalist* No. 10. 'The public voice' pronounced by representatives under such a regulation 'will be more consonant to the public good than if pronounced by the people themselves convened for the purpose.' Small deliberative bodies, such as the US Senate or a Constitutional Convention, allow representatives to come to a better determination of the public good than one would get just by bringing the people together and asking them. There is a difference, in other words, between the deliberative or thoughtful public opinion one can find in representative institutions, at least at their best, and the uninformed and unreflective preferences commonly found in the mass public.

A central problem in democratic theory is how to reconcile the aspiration for thoughtful and informed preferences with another key aspiration—counting everyone's preferences equally. Deliberative bodies may represent highly informed and competent preferences, but those preferences are often shared only by an elite. Direct consultation of mass preferences will typically involve counting uninformed preferences, often simply reflecting the public's impressions of sound bites and headlines. Hence the hard choice between politically equal but unreflective mass preferences and politically unequal but relatively more reflective elite views.

This basic dilemma is reinforced by the tendency of ordinary citizens in the large-scale nation-state to have little incentive to become well informed. Each voter can understand that his or her individual vote or individual opinion is only one out of millions and is, as a result, unlikely to make much difference to the outcome of an election or to public policy. As a result, individual citizens have little reason to become well informed about complex political or policy issues. Anthony Downs coined the term 'rational ignorance' for this situation in which voters find themselves (Downs 1957). A host of empirical studies confirm that the mass public in most modern societies is not well informed about politics (see Delli Carpini and Keeter 1996, for an overview of both American and comparative data).

3. *The Design of Institutions*

We seem, in other words, to face a forced choice between elected elites and uninformed masses. But there are institutional experiments with deliberation among representative microcosms of the mass public. These experiments, ranging from so-called 'citizens juries' to Deliberative Opinion Polls, take random samples of the public and subject them to situations where they are effectively motivated to get good information, hear balanced accounts of competing arguments, and come to a considered judgment. These experiments show that ordinary citizens are capable of becoming informed and dealing with complex policy matters. And it is possible to get an input to policy-making that is representative of the mass public while also embodying deliberation (Fishkin 1995).

Once opinions are solicited by some democratic process, how should they be aggregated? There is a long-standing claim for majority rule as a procedure that counts everyone's views equally. Modern work in rational choice theory has shown that majority rule is the only decision rule that satisfies a number of appealing normative criteria (May 1952). But majority rule, like other decision rules, is subject to 'instability'—to cycles, violating transitivity (the requirement that if A is preferred to B and if B is preferred to C, then A should be preferred to C). This problem is part of a more general account of problems in social choice theory developed in the modern era by Kenneth Arrow in Arrow's so-called 'impossibility theorem' (Arrow 1951, 1963). For our purposes, it is worth noting that the conundrums of social choice theory,

including the violations of transitivity, presume 'universal domain'—they presume that all logically possible preference orderings may occur. One way out is to limit the range of preference orderings that occur in a given decision-making process. If preferences are, for example, organized according to some overarching dimension so that they are 'single-peaked' (Black 1958) then violations of transitivity will not occur. Some political theorists have suggested that if citizens deliberate, they will come to some shared understanding of the questions at issue and achieve a structure for their preferences that tends to satisfy single peakedness (Miller 1992). To the extent this turns out to be the case, then deliberative preferences could avoid cycles that undermine the claim to rationality for democratic decisions.

Most democratic decisions in the large-scale nation-state do not conform to the simplified situation of citizens voting directly on policy alternatives. Of course, they do fit that picture in initiatives and referendums. And citizens do elect representatives through a variety of electoral systems. However, these systems vary greatly in how well they translate majority preferences into seats in legislatures and into public policies. Robert Dahl, in a classic work (Dahl 1956), described two competing pictures of democracy—'Madisonian' and 'Populistic.' The former offers significant impediments to majority rule (in the interests of avoiding tyranny of the majority). The latter offers a high degree of correspondence between majority preferences and public politics. Most systems, however, are somewhere in between. For example, the United States, Dahl argued, was a 'hybrid' of the two that actually was best understood as operating not on 'majority rule' but on 'minorities rule'—a system in which intense minorities tend to get their way. People who feel most strongly tend to participate actively to make sure their voice is heard. People who do not care tend not to participate.

4. *Tyranny of the Majority?*

A remaining central problem of democratic theory is how to avoid 'tyranny of the majority.' A decision may count all or most people's preferences, it may be supported by the public's considered judgments, it may be aggregated by an appropriate decision rule such as majority rule, and it may, nevertheless, conflict with justice or impose unacceptable consequences on some portion of the population. In other words, the people may, democratically, decide to do bad things. For 2500 years, the image of mob rule in Ancient Athens did much to discredit democracy (Roberts 1994). The fact that the Athenians had killed Socrates worried the American Founders.

Attempts to address the problem of majority tyranny usually rely on answers to the questions addressed above: Whose preferences count? What kinds of preferences are considered? What decision rule is employed? What is the design of democratic institutions? First, the spread of the franchise to most or all adult citizens has been an important factor in making sure that the interests of those citizens are considered. The spread of voting rights across racial, ethnic, religious, gender, and class divisions has proven to be an important factor in creating institutional incentives for addressing the problems of those who were previously disenfranchised. But such a solution is imperfect. A group can have its votes counted, but outvoted, its interests considered but neglected—or even despised.

Hence, the second issue bears on majority tyranny: what kinds of preferences do people bring to the democratic process? The fear of majority tyranny has long focused on 'passions' or 'interests' that might motivate 'factions' adverse to the rights of some members of the community, to use terms that James Madison made famous in the *Federalist Papers*, especially No. 10. One of Madison's strategies for insulating democracy from factions is to 'filter' preferences through deliberation that 'refines and enlarges' the public's views. The idea is to get the 'cool and deliberate sense of the community' rather than the kinds of passions that might motivate faction. Hence democratic theory has long recognized that the kinds of preferences brought to the democratic process may influence whether majority tyranny results.

Third, some theorists have looked to the decision rule itself to limit majority tyranny. Supermajority requirements, specifying a percentage greater than 50 percent plus one, but usually less than unanimity, can make it harder to get new measures passed. Such decision rules bias decision making toward the status quo, as it becomes harder to get changes passed. Hence if there arc bad outcomes that result from inaction, from the failure to pass new measures, then those bad outcomes are made more, not less, likely by such a decision rule. Hence supermajority requirements are an imperfect protection against the system producing unacceptable outcomes.

Fourth, there are institutional designs that can protect, to some degree, against tyranny of the majority. One strategy is to specify a list of rights that are immune to majority decision, and that are protected by judicial review. However, the bad outcomes that might be considered or adopted by democratic decision making can never be fully anticipated. And the empowerment of judges through judicial review, when it is broad enough to provide protection against tyranny of the majority, also threatens democracy in another way. It seems undemocratic for the judiciary to overturn decisions of the public expressed through their representative institutions. Hence, judicial review that can set aside democratically passed legislation, or a bill of rights that takes certain issues off the democratic agenda, protects democracy from itself, by limiting the purview of democratic institutions.

Democratic theory provides us with conflicting visions rather than some uniquely authoritative answer to the questions posed here. Questions about democracy remain unsettled. But unlike any other period in its history, the authority of the basic democratic idea is virtually unchallenged in the modern era. Democracy (in some sense) triumphs even as disagreements proliferate as to what it is, or might be.

Democratic Transitions

The study of democratic transitions focuses on the critical step in the history of democracy when a country passes a threshold marked by the introduction of competitive elections with mass suffrage for the main political offices in the land. Though a concern of thinkers since the late eighteenth century, it blossomed as a distinct area of scholarly research in the context of the wave of democratic transitions that swept through every corner of the world in the last quarter of the twentieth century.

1. The Subject Matter

Research on democratic transitions is part of the broader field of democratic theory that gains its distinctiveness from a sharply defined focus on elections. Indeed, the status of democratic transitions as a distinctive field of research is given by an undeniably Schumpeterian approach to democracy, which emphasizes the procedures that regulate the access to power. This delimitation of the subject matter did little to spur interest at the time university-based research was expanding dramatically in the 1960s and 1970s. Not only did the realities of world politics appear to devalue this line of research, but the Schumpeterian conception of democracy was widely out of favor. Even though some landmark studies on democratic transitions were published as early as 1960 (Lipset 1960, Rustow 1970), interest in democratic transitions took a back seat to other, more pressing or more valued concerns.

The status of research on democratic transitions, however, changed quite considerably thereafter. First and most important, the wave of democratization beginning in 1974 made the subject matter immediately relevant. In addition, the influential writings of Robert Dahl (1971) helped foster widespread acceptance in the social sciences of the erstwhile disparaged Schumpeterian view of democracy. Finally, the seminal work of Guillermo O'Donnell and Philippe Schmitter (1986) did much to set the initial terms of the debate and give a strong impetus to research on the topic. With the boom in research on democratic transitions in the 1980s and 1990s, by the turn of the century research on democratic transitions had attained the status of an established field.

2. Research and Findings

The focus on a sharply delimited subject matter has a definite advantage, in that it has allowed research to concentrate on a fairly clear question: why have some countries had democratic transitions while others have not? Thus, an impressive basis of knowledge was generated quite rapidly through a succession of studies. Following in the wake of pioneering work on the transitions in southern Europe and Latin America in the 1970s and early 1980s (O'Donnell et al. 1986), major cross-regional analyses were conducted comparing Latin America to East and South East Asia (Haggard and Kaufman 1995), and southern Europe and Latin America to Eastern Europe and the former Soviet Union (Linz and Stepan 1996, see also Huntington 1991). Excellent region-based studies were produced, focusing on Africa (Bratton and van de Walle 1997), Eastern Europe (Beyme 1996, Offe 1997, Bunce 1999), as well as the three major regions of the developing world (Diamond et al. 1989a, 1989b, 1989c). Finally, impressive efforts were made to put the transitions of the last quarter of the twentieth

century in historical perspective, through cross-regional analyses of Europe and Latin America ranging across the nineteenth and twentieth centuries (Rueschemeyer et al. 1992, Collier 1999).

The richness of this literature is undeniable. Indeed, it offers a wealth of ideas on the causes of transitions, a great amount of nuanced data on very complex processes, and some fruitful comparative analyses that have generated a number of important and surprising findings. This literature has demonstrated that, contrary to the longstanding conventional view, level of economic development is not a good predictor of democratic transitions. It has also shown that democratic transitions do not occur through a single process but rather through multiple paths defined by factors such as the power and strategies of elites and masses and the source of impetus for political reform. Moreover, an important degree of cumulation of knowledge has been achieved through efforts to codify these distinct paths of democratic transition. A closely related finding involves the growing evidence that the path toward democracy that a country follows is strongly influenced by its type of old, nondemocratic regime. Thus, depending on the type of old regime, pacts may be a necessary condition for a successful transition to democracy, and nationalist movements may weaken, rather than enhance, the prospects of democracy. Finally, this literature has shown that issues of regime change are closely linked with those of the state, conceived in Weberian terms. In this regard, a key finding is the 'no state, no democracy' principle, which holds that processes of regime change that lead to state decay or state collapse reduce the prospects of democracy.

3. *Explanatory Variables and Theoretical Integration*

The considerable accomplishments of this body of literature notwithstanding, the agenda of research on democratic transitions faces some considerable challenges. One such challenge concerns the need for greater theoretical integration. The evolution of the literature on democratic transitions has been characterized by the frequent introduction of new causal factors considered critical to an explanation of why democratic transitions occur. These new explanatory variables sometimes reflect the experience of new cases of transitions to democracy, which have brought to light factors that had not seemed important in the cases until then considered. In other instances, the focus on new variables has been driven more by an effort to rescue insights from older bodies of literature. The downside of this theoretical fertility, however, is that the introduction of a large set of explanatory variables has given a somewhat disorderly quality to theoretical debates.

As challenging as the task of theoretical organization and integration is likely to be, it is facilitated somewhat because theoretical debates have evolved around a number of central axes. One main axis contrasts short-term factors and the choices made by actors (O'Donnell and Schmitter 1986, Przeworski 1991) to medium-term factors, such as the characteristics of the old regime (Linz and Stepan 1996), and long-term, more structural factors, such as the mode of production or the model of development (Rueschemeyer et al. 1992, Castells 1998). Another axis of debate contrasts elite-centered explanations (Dogan and Higley 1998) to mass-centered explanations, which focus either on class actors (Rueschemeyer et al. 1992, Collier 1999), social movements (Foweraker 1995, Chap. 5, Tarrow 1995), or ethnic groups (Offe 1997, Chap. 4). Yet another axis contrasts political to economic determinants of transitions (Haggard and Kaufman 1995, Przeworski and Limongi 1997). And one more critical axis of debate opposes domestic factors to international factors (Whitehead 1996), an axis along which one might also locate explanations centered on stateness and nationality issues that might be labeled as 'intermestic' (Linz and Stepan 1996). Thus, the further development of a theory of democratic transitions is likely to hinge on efforts to build upon this implicit organization of the debate and to explicitly formulate a framework that integrates and synthesizes these diverse explanatory factors.

4. *Data Collection and Comparative Analysis*

Another challenge concerns the collection of data and the conduct of comparative analysis. The literature on democratic transitions has evolved in a way that has given primacy to selective rather than encompassing comparisons. The reason for this strategy is obvious, in that the comparison of a small number of cases can provide a sufficient basis for introducing new ideas into the debate and for doing so rapidly. Hence, this strategy has been well suited for the initial stages of theorizing. But this strategy has also had its downside. The key problem is that data has not been collected on all the explanatory variables across all the relevant cases. Indeed, though this literature has generated a great amount of nuanced data, researchers have not always been systematic enough in terms of gathering the same data for all the cases they analyze, let alone all the cases that are discussed in this literature as a whole. As a consequence, the ability of researchers to test their theories systematically and draw strong conclusions has been somewhat constrained.

The ability of scholars to engage in systematic comparative analysis, however, is hampered by a serious practical limitation. A review of the existing literature on democratic transitions shows that there is

a very steep trade-off in the level of nuance of data and hence the explanatory arguments tested as one moves from the literature based on intensive but relatively narrow comparisons of a small set of cases to the statistical literature based on a large number of cases. Thus, concerning the task of data collection and comparative analysis, a multitrack approach is highly recommended.

One such track would consist of the collection of data that can be used for statistical studies. In this regard, the challenge is to collect data, on a large number of cases, on factors other than the standard economic and institutional ones which have long been the staple of statistical analyses (e.g., Przeworski and Limongi 1997). Indeed, the full benefits of statistical tools are unlikely to be felt in the debate on democratic transitions until data sets are generated with information on the kind of actors involved in the process of democratic transitions, the choices these actors make, and the sequence of events whereby democratic transitions unfold. This is a formidable task but one with important payoffs and thus well worth pursuing.

Another track would consist of the application of the research strategy which has contributed so much to this debate, the intensive analysis of a small to medium number of cases, to some relatively unexplored questions. Though some significant works offer a historical perspective on the democratic transitions that have been the focus of the debate, those occurring in the last quarter of the twentieth century, much remains to be learned by cross-time comparisons as well as by a reanalysis of older cases of transitions in light of new theories. In addition, though some thought has been given to the differences and similarities between the explanations currently used to account for democratic transitions and the earlier explanations of democratic breakdowns (O'Donnell 1973, Linz and Stepan 1978, Collier 1979), very little has been done to pursue this potentially illuminating comparison in a systematic manner. Finally, a whole new perspective that needs to be developed concerns the cases of failed transitions. Indeed, while scholars of democratic transitions have learned a lot by focusing on positive cases, where transitions to democracy did occur, an important question that remains to be fully answered is: why did many countries that saw the collapse of old regimes during the last quarter of the twentieth century have transitions that did not lead to democracy? The continued use of qualitative methods, thus, is likely to be highly rewarding.

5. *The Need for Disaggregation*

As the new century begins, scholars of democratic transitions have a lot to build upon but also a lot to do. Thus, it is absolutely essential to devise ways of making this research agenda manageable. Many different options in this regard are available. One option that bears highlighting is suggested by the very definition of a democratic transition offered at the outset of this article. This definition consists of three elements which countries may attain at different paces and in different orders: competitive elections, mass suffrage, and elections for all main political offices. Thus, even though democratic transitions are often portrayed as a single event, they may actually be studied as a series of events, a new perspective that has important implications. If research shows that countries follow different paths, characterized by different sequences of events, as Dahl (1971, pp. 4–6) has suggested, then the challenge facing scholars of democratic transitions might be disaggregated and hence broken down analytically and greatly facilitated. Indeed, if the challenge of explaining transitions could focus on the more manageable task of accounting for a number of influential patterns, the problem of theoretical integration would be simplified and data collection could be organized around a set of priorities. A fascinating but somewhat daunting agenda of research would thus be transformed into a fascinating and manageable agenda.

Demographic Analysis: Probabilistic Approach

1. Random Variation in Demographic Behavior

Demography is one of the many fields of science where statistical theory can be put to good use. Typical events of interest to demographers are births, deaths, the formation and disruption of marital and nonmarital unions, and geographical migration. The quintessential determinants of demographic behavior are sex, age, and cohort or calendar period, and other typical individual-level factors are race, social and family background, ethnicity, religious orientation, labor-force participation, and educational attainment. There may also be contextual determinants, such as institutional settings, laws and regulations (including public policies), and other collective features that individuals face. Aspects of aggregate behavior in the same population may also be important. (When many people already cohabit in nonmarital unions, individuals may find it easier to form such a union themselves. When divorce is common, dissatisfied spouses may find it easier to dissolve their own marriage.) To handle this multitude of features, individual demographic behavior is described in terms of event-history models where individuals move between predefined statuses under the influence of personal or group characteristics, of their own personal history, of contextual factors, and of period influences in the population they belong to.

Since any human population has finitely many members, there is an amount of random error in analytic procedures based on individual-level data. If life histories are selected in some random manner from a larger population, as in a survey sample, then some identifiable part of the error may be due to the sampling procedure, but another part is caused by the fundamental randomness of the individual process paths. Stochastic variation does not only arise from sampling variation in survey data, or from deliberate randomization of experiments. Whether the data were obtained for a sample or for the whole population segment in question is a separate issue. The size order of the random variation involved usually depends on the number of contributing individuals, not on whether the data comes from a sample survey or not. As was expounded by Westergaard (1880) more than a century ago and repeated many times over by people like Udry et al. (1979) and by Brillinger (1986) and his discussants, random variation is intrinsic to data on demographic behavior, just as it is for data from other social and behavioral sciences.

Demography may be special in that some of its data come from populations large enough to permit the investigator essentially to disregard randomness in the corresponding vital rates. In such cases, the challenge is to explain any irregularities in plotted curves of vital rates as local variations of substantive interest, or as caused by systematic registration errors. Significance tests and similar statistical tools may then become less important. This does not preclude random variation from being prominent in data from small populations and from smallish segments of national populations.

2. The Event-history Approach

In event-history analysis, demographic events are seen as transitions between states in a suitable state space. The factors that influence the transitions may be fixed or change over time, they may be exogenous to the individual history or endogenous to it, recorded in an available set of individual-level data, or unobserved causes of observable selectivity. Early behavior on a

Figure 1
A state space for the analysis of first-birth intensities under the influence of civil status and enrollment in education

process may impact on later behavior on the same process, as when age at first birth is shown to influence an individual's later childbearing behavior; this is one of the most persistent findings in family demography. Individual behavior in one arena may interact with that in another arena, as when a woman's educational attainment and labor-force participation are seen as influencing her childbearing while conversely having children determines her chances of improving her educational level or maintaining her ties with the labor market.

The states between which transitions are made are demographic (and other) statuses like 'never married,' 'in a consensual union,' 'married,' 'childless,' 'of parity n' (having had precisely n live births), 'under education,' 'in the labor force,' and so on. When the state space is not too complex, it can sometimes be represented graphically as in Fig. 1, where the boxes represent the various statuses in question and the arrows indicate possible transitions for an analysis of first births before and in first marital or nonmarital unions. There are moves in three dimensions in Fig. 1, namely (a) changes in civil status (never married, married, in consensual union), (b) school enrollment (under education or not in school), and (c) parity (in this case childless or of parity 1). Arrows are formatted to indicate transitions of prime interest, competing risks, and other transitions. As is typical for such diagrams, some states and transitions have been left out to simplify the graphic, namely (a) the moves in and out of education for individuals living in partnerships, and (b) the disruption of existing partnerships. In empirical analyses one would account for (though possibly not analyze) such transitions as well.

A focus of attention is the *intensity* or *hazard* $\lambda_{ij}(t; x(t))$ of transition from some state i to some other state j at time t, for a suitable set of pairs (i, j) and a suitable vector $x(t)$ of determinants. The basic time variable t typically is the individual's own age or else the duration since a given event (duration of partnership, age of youngest child). Theories about individual demographic behavior are reflected in the specification of these elements, including the choice of t, the selection of covariates in the vector $x(t)$, and the form of the intensities λ_{ij}. For instance, an investigation of stepfamily fertility may address the hypothesis that for comparable partnerships, the rate of arrival of their first common child should be independent of the number of children that each partner had before the union was formed (*the union-confirmation hypothesis*). This would be reflected in a specification of a first-birth (or first-conception) intensity, say $\phi(t; n_1, n_2, y(t))$, that at each union-duration t would depend on the parities n_1 and n_2 of the partners at union formation and on some set of fixed and time-varying covariates collected in the vector $y(t)$. Confirmation of the hypothesis would consist in demonstrating that the intensity does not depend on n_1 and n_2.

In general the intensity λ_{ij} is the probabilistic counterpart of the empirical rate of transition from i to j. In the simplest case the latter is an occurrence/exposure rate $\hat{\lambda}_{ij}(g) = D_{ij}(g)/R_i(g)$ (also called a *vital rate of the first kind*) of some population group g in a given range for t during a particular period. The occurrences $D_{ij}(g)$ and exposures $R_i(g)$ are recorded for the group g in question. Under such circumstances, $\hat{\lambda}_{ij}(g)$ is the maximum-likelihood estimator for the intensity, it is asymptotically normally distributed with the intensity as its mean and an asymptotic variance that can be estimated by $\hat{\lambda}_{ij}(g)/R_i(g)$, and different such rates are asymptotically independent of each other. This means that there exists a statistical theory for conventional demographic rates, a theory which can be used for the purpose of estimation, testing of hypotheses, the computation of confidence intervals, and so on, in the normal manner of statistical analyses.

Various ways of computing demographic occurrence/exposure rates are discussed in *Demographic Techniques: LEXIS Diagram*. Keiding (1990) has given a probabilistic interpretation of the Lexis diagram in epidemiological research. Many other demographic practices can similarly be given a useful underpinning in statistical theory, as we show in what follows.

3. *Individual-level Demographic Models*

For many events, demographers typically compute vital rates for a sequence of age groups and thereby produce a *schedule* $\{\hat{\lambda}_x : x = 1, 2, \ldots\}$ *of age-specific rates*

(of the first kind). The next step is often to fit some parametric mathematical function to this schedule, for instance Thiele's (1871) mortality function

$$\lambda_x = a_1 \exp\{-b_1 x\} + a_2 \exp\{-\tfrac{1}{2}(x-c)^2/\sigma^2\} + a_3 \exp\{b_3 x\}$$

with $a_1 + a_2 + a_3 = 1$. Fitting such a formula to the $\{\hat{\lambda}_x\}$ is an exercise in what actuaries call analytic graduation, for which a statistical theory also exists (Hoem 1972) and is useful for the selection of fitting criteria, variance computations, testing of hypotheses, and so on. When a formula has been established, it is often called a *demographic model*. Occasionally the model is developed for a corresponding schedule of binomial probabilities $q_x = 1 - e^{-\lambda_x}$, as in $q_x = \phi_x/(1+\phi_x)$ with

$$\phi_x = A^{(x+B)^C} + D \exp\{-E(\ln x - \ln F)^2\} + GH^x$$

This three-part expression, which was developed by Heligman and Pollard (1980), is based on considerations similar to those of Thiele's mortality formula. In an unorthodox approach, Ansley Coale (1971) fitted a model for first-marriage formation to first-marriage rates 'of the second kind,' i.e., to rates where the number of marriages formed at a certain age is divided by the *total* person-years at that age, including person-years lived after first-marriage formation, and not only divided by the person-years exposed to risk as in a rate of the first kind. (See *Demographic Models* and *Demographic Techniques: Rates of the First and Second Kind*.) The statistical theory for rates of the second kind is useful for the legitimacy it gives them in empirical analyses and for the further developments it has led to (Finnäs 1980; Borgan and Ramlau-Hansen 1985).

Another class of procedures that can benefit from being brought into the realm of statistical theory is what demographers know as Brass's *relational models* (Brass 1974, etc.). They can be described in elementary probabilistic terms as follows. Given a 'standard' probability distribution function $H(x)$, a whole family of further distribution functions $\{H_{ab}(x); -\infty < a < \infty,\ b > 0\}$ can be generated by the 'relational transformation' $\lambda\{H_{ab}(x)\} = a + b\lambda\{H(x)\}$, where for $0 < y < 1$ $\lambda(y)$ is some function with a positive derivative everywhere. Brass chose $\lambda(y) = \ln\{y/(1-y)\}$ and $\lambda(y) = -\ln(-\ln y)$. He used the former for a relational transformation of $H(x) = 1 - \lambda_x$ and the latter for a corresponding transformation of $H(x) = F(x)/F(50)$, where $F(x)$ is a set of age-specific fertility rates cumulated up to age x. If we let $\Psi(x) = \lambda^{-1}(x)$, then $\Psi(x)$ is another probability distribution function and $\lambda(y)$ is its percentile function. Brass's two choices of $\lambda(y)$ give $\Psi(x) = 1/(1+e^{-x})$ and $\Psi(x) = \exp(-e^{-x})$, a logistic distribution and an extreme-value distribution, respectively. We can rewrite the generating relation as

$$H_{ab}(x) = \Psi\{a + b\Psi^{-1}[H(x)]\}$$

Once it has been established that we are dealing in parameters in a class of statistical models, then the usual considerations from statistical theory can be brought to bear on the issues involved. If H and Ψ are given, then a and b can be estimated in the usual way for statistical parameters, and their statistical properties may be known. If one does *not* want to use an outside 'standard' distribution for H, this function can perhaps be estimated from the data by a method whose statistical properties one knows. In either case, statistical principles are useful. One of these may be that $\mu_{ab}(x) = h_{ab}(x)/\{1 - H_{ab}(x)\}$ is more sensitive to subgroup differences than the distribution function $H_{ab}(x)$ itself is. (With $h_{ab}(x) = \mathrm{d}H_{ab}(x)/\mathrm{d}x$, $\mu_{ab}(x)$ is the hazard function of H_{ab}.) Optimal fitting may not be what one strives for, but when it is, one may be well advised to use the hazard as a basis for model fitting, model testing, and so on, as usual. In this connection it may pay to heed the warning that Feller gave against fitting models to sigmoid curves as far back as in 1940 (Feller 1940).

Demographic models for schedules of age-specific rates (and other similar schedules) are valuable in the analysis of inaccurate or incomplete data and as tools for population forecasting and other kinds of 'technical' computations. They have a place in data-quality assessment, though such usage should be tempered by the fact that the demographic models themselves may be inaccurate representations of reality. (This is demonstrated by the perennial need to revise model life tables and by amusing report titles asking why we get such lousy fits; see Lockridge and Broström 1983.) Demographic models are also useful for smoothing age-specific demographic schedules, and some such efforts may be for the purpose of removing random variation. In most cases, the probabilistic approach provides useful guidelines and helpful operational procedures. In one case, it even makes certain demographic procedures redundant. The whole theory of increment-decrement life tables may be replaced by parts of the theory of time-continuous Markov chains and some elements of numerical analysis (Hoem and Funck Jensen 1982).

For more information about these issues, see *Demographic Models*, *Multistate Transition Models in Demography*, and *Demographic Techniques: Rates of the First and Second Kind*.

4. Standards and Standardization

Brass's use of a 'standard' probability distribution H_x follows an old tradition in demography. Finding and using a 'standard' schedule plays a prominent role in much demographic analysis of rate schedules $\{\hat{\lambda}_x\}$. Such a standard is often sought outside of the current data set and is used to highlight special features of the data in hand. Once the relation to statistical theory has been established for an empirical procedure, the need for an outside standard may be removed and all

parameters may be estimated from the current data, as was demonstrated by Xie and Pimentel (1992) for the celebrated Coale-Trussell formula (1996) for marital fertility. (See *Demographic Models*.) This approach can sometimes provide solutions to problems that have pestered the discipline for a long time. For instance, the competition between *direct* and *indirect standardization* has been settled in favor of the latter (Hoem 1987), in the sense that when standardization is fully legitimate there exists an improved form of indirect standardization based on a maximum likelihood estimator which has minimal variance. This result relieves the user of the onerous job of demonstrating the suitability of a selected outside standard population for use in direct standardization, which is suboptimal in any case. Here is a sketch of the basic ideas.

Suppose that for each of a number of subpopulations, indexed by k, one has a schedule $\{\hat{\lambda}_{xk}: x = 1, 2, \ldots\}$ of occurrence/exposure rates, $\hat{\lambda}_{xk} = D_{xk}/R_{xk}$. In *direct standardization* a 'standard' population age distribution $\{P_x\}$ is specified and a quantity like $\hat{v}_k = \Sigma_x \hat{\lambda}_{xk} P_x / \Sigma_x \hat{\lambda}_{x1} P_x$ is used as a measure of the risk level of subpopulation k relative to that of subpopulation 1. (Note that $\hat{v}_1 = 1$.) For *indirect standardiz ation*, a 'standard' age schedule $\{\tilde{a}_x\}$ of risk is specified instead of $\{P_x\}$ and a quantity like $\hat{w}_k = D_{\cdot k}/\Sigma R_{xk}\tilde{a}_x$ measures the relative risk. The dot symbol in the subscript denotes summation, so $D_{\cdot k} = \Sigma_x D_{xk}$. (In mortality studies, $\hat{w}_k$ would be called a *standardized mortality ratio*.) Demographers, epidemiologists, and surely others agonize a lot over the choice of a standard population $\{P_x\}$, and they should perhaps agonize as much over $\{\tilde{a}_x\}$, though normally one simply chooses $\tilde{a}_x = D_{x\cdot}/R_{x\cdot}$. Correspondingly, one could choose $P_x = R_{x\cdot}$. With these latter choices, no outside standard is involved, of course.

In event-history analysis, $\hat{\lambda}_{xk}$ would be regarded as an estimator of an underlying model parameter λ_{xk}, in the spirit of our account toward the end of Sect. 2 above, and λ_{xk} would be a level-parameter in a piecewise-constant transition intensity. Suppose that $\lambda_{xk} = a_x b_k$ with $b_1 = 1$, which means that schedules are essentially proportional to each other and that $\{a_x\}$ operates as a baseline schedule, since $\lambda_{x1} \equiv a_x$. (Standardization is usually considered fully legitimate only when such a multiplicative specification holds.) Then both $\hat{v}_k$ and $\hat{w}_k$ are estimators of the proportionality factor b_k, but both are suboptimal, for one can find maximum-likelihood estimators $\{a_x^*\}$ and $\{b_k^*\}$ from the relations

$$a_x^* = \frac{D_{x\cdot}}{\sum_k R_{xk} b_x^*} \quad \text{and} \quad b_k^* = \frac{D_{\cdot k}}{\sum_x R_{xk} a_x^*}, \quad \text{with } b_1^* = 1$$

using an iterative numerical procedure to provide a solution. Breslow and Day (1975) have shown that conventional indirect standardization appears as the first step in one such procedure and thus may be regarded as a first approximation to the optimal solution. The approximation is usually excellent. Note how $\hat{w}_k$ has the same form as the second of the maximum-likelihood relations.

5. Population-level Models

Beside the focus on individual-level behavior, a large part of demographic analysis is concerned with the dynamics of entire populations, collected in the theory of stable populations and its ramifications. The purpose is to investigate how the consequences of individual-level processes work their way up to the population level. In this connection as in others, a probabilistic approach gives a more satisfactory basis for the mathematical derivations and opens the way for results that cannot be formulated, let alone proved, in deterministic theory. Extinction theorems and stochastic ergodicity theorems in stable population theory fall in this category (Cohen 1979, 1982, Tuljapurkar 1989, and others). The probabilistic approach has inspired a new treatment of uncertainty in population forecasts (Cohen 1986). Keiding and Hoem (1976) have directly addressed long-standing concerns of demographers in a probabilistic vein.

For more information about *population dynamics*, see *Population Dynamics: Theory of Stable Populations*, *Population Dynamics: Classical Applications of Stable Population Theory*, *Population Dynamics: Momentum of Population Growth*, *Population Dynamics: Theory of Nonstable Populations*, *Population Dynamics: Mathematic Models of Population, Development, and Natural Resources*, and *Population Dynamics: Probabilistic Extinction, Stability, and Explosion Theorems*. For material about *population forecasts*, see *Population Forecasts* and also *Demographic Techniques: Small-area Estimates and Projections* and *Families and Households, Formal Demography of*.

6. Conclusions

The present Encyclopedia article has been devoted to the merits of the probabilistic approach to demographic analysis. Such an approach is generally accepted in other fields of application (biostatistics, epidemiology, insurance mathematics), but in demography there is still considerable tension between those who feel that probabilistic notions are essential to the field's methodology and others who largely regard them at best as the icing on a cake. It is our contention that it does not pay to develop demographic procedures of analysis in isolation from statistical principles any more than it pays in other disciplines. The probabilistic

approach is the way to a deeper understanding of inferential techniques as well as to further methodological development beyond intuitive reasoning.

Demographic Data Regimes

Demography is the study of human populations, including size, structure, distribution over space, socioeconomic characteristics, households and families, migration, labor force, and vital processes (birth, death, formation and dissolution of marital, and other unions). A central feature of this study is the collection, compilation, and presentation of demographic statistics. The most important single instrument is the census, an effort to enumerate the number of inhabitants and, historically, often households and/or families. In recent centuries, more detail has been collected than simple counts, namely such information as age, sex, race, nativity, language, marital status, occupation, industry, fertility, mortality, income, residence, and family and household structure. Censuses may either be complete counts or statistical samples of the population. The other mainstay of demographic data gathering is the continuous registration of vital events (births, deaths, marriages, divorces, and sometimes migration). This has been achieved through the establishment of parochial (church) or civil systems for the collection of such events. In recent decades, a number of nations have developed population registration systems that simply keep a continuous record of demographic events. A census can be taken by enumerating the register at any point in time. These modes of record-keeping have been augmented by sample surveys, especially where the cost and difficulty of taking a census are large, such as in many developing nations. Surveys also provide a means to calculate vital rates via indirect methods of estimation. Other administrative instruments have been used to study populations, including tax lists, military muster and conscription rolls, budgetary surveys, wills and bequests, and insurance data.

1. Prestatistical Regimes

The ancient civilizations of Egypt, Babylon, China, Palestine, and Rome took censuses. These were used for administrative purposes, such as determining fiscal, labor service, and military obligations. Heads of households, males of military age, adult citizens, and taxpayers usually were counted. Women and children were often omitted. Few of these records survive. The Bible mentions several, including one of the Israelites at the time of the Exodus and one by King David around 1017 BC. Rome conducted its censuses for about 800 years, first counting citizens and property in Italy for tax and military purposes, and later extending this to the entire empire. Joseph and Mary traveled to Bethlehem in response to such a census. The ancient empires of China took periodic censuses, the first relatively accurate one being in AD 2. They counted 'doors' (households) and 'mouths' (persons). These counts have allowed us an approximate reconstruction of China's population over the last 2,000 years. The Inca empire of ancient Peru is said to have taken censuses, but the *quipu* recording system has never been deciphered. Similarly, the pre-Columbian Mexicans are known to have collected tribute censuses, but no codices recording this have survived.

More recently, the Domesday Inquest of England by King William I in 1086 provides us with a population benchmark for England. Such periodic fiscal and administrative surveys have functioned as quasicensuses for demographic historians, other examples being the French hearth tax lists of 1328, the English poll tax list of 1377, and the English hearth tax returns of 1690.

In England, a parish registration system of baptisms, burials, and marriages was instituted in 1538 for the new Church of England. France began such a system piecemeal, but the registers appear to be of acceptable quality by about 1670. In 1563 the Council of Trent decreed that all Catholic countries should keep parish registers. Other European countries followed suit. Ancient China created a system of family registers that was adopted in Japan and made official in 1721. National totals were compiled from the registers in Japan every 6 years up to 1852. Korea also instituted the register system, and compilations were made with some frequency from 1395.

2. Demographic Regimes of the Eighteenth and Nineteenth Centuries

The modern regime of demographic data collection on a national basis had its origins in the Scandinavian countries (Sweden, Denmark, Norway, Iceland, and, at times, Finland). Parochial registers were begun in the seventeenth century, using the clergy of the national, Lutheran churches. In Sweden, registration was made compulsory in 1686, in Norway in 1685, in Denmark in 1645/46, and in Finland in 1628. Annual data on births, deaths, and marriages were not published, however, until the eighteenth century, beginning in 1735/36 for Norway, Denmark, and Sweden. These nations also created census-like results from these registers, but actual household enumerations of a modern type were undertaken in 1749 in Sweden and in 1769 in Denmark and Norway.

Although the Scandinavian nations were forerunners, censuses had been taken elsewhere on more local level. In New France and Acadia in North America, 16 enumerations were made between 1665 and 1754, and a comprehensive system of parish registration was set up from the onset of French colonization (1608). For the British colonies in America, no fewer than 124 censuses were undertaken between 1623 and 1776. Some parish registers were set up, particularly in New England. Several Italian principalities (e.g., Sicily, Naples) enumerated their populations in the seventeenth and eighteenth centuries.

Later in the eighteenth century, some European nations took irregular and often rather incomplete censuses, including Spain (1768/69, 1787, 1797) and Portugal (1768). Regular enumerations truly began with the United States, whose Federal Constitution (1788) mandated a decennial census for the apportionment of seats in the House of Representatives. The first census was taken in 1790, and since then 22 national censuses have been taken. A much more general trend to regular national-level enumerations began in the early to mid-nineteenth century, both for governmental and general scientific purposes. This required the improvement of the bureaucratic mechanisms for collecting, tabulating, and publishing the results. There was also an increase in the types and detail of the types of information collected. More detail by age and sex was taken, and information on economic activities (e.g., occupation, industry) was also collected. Special censuses of agricultural and manufacturing units came to accompany the population inquiries. Among the nations commencing or continuing such activities in the early nineteenth century were the United Kingdom (England and Wales (1801), Scotland (1801), Ireland (1821)), France (1801), the Netherlands (1816), Portugal (1801), Prussia (1816), Bavaria (1816), Switzerland (1837), and Belgium (1831). As new nations were created, they began data collection for the new consolidations of former states: the German Empire took its first census in 1871 and the new United Kingdom of Italy in the same year. As the century progressed other nations joined: Spain (1857), Serbia (1834), Greece (1856), Russia (1897), Romania (1899), Austria (1869), Hungary (1857). Overseas nations also began the process: Canada (1851), Japan (1872), New Zealand and parts of Australia (1851), and many of the new nations of Latin America (e.g., Argentina (1869), Brazil (1872)). For a number of these nations, early

efforts at enumeration were only partly successful. Colonial authorities took censuses in various other areas, especially in the Caribbean and in Asia (e.g., India (1881)). Many of these enumerations were seriously incomplete. Africa was the least well measured (and remains so).

One important issue for the promotion of demographic data sources was the creation of national statistical offices. In many cases, statistical collection functions were distributed among a variety of venues. In the United States, the census initially was collected by a temporary agency created for each census. The United States Bureau of the Census did not attain permanent status until 1902. Many European nations had statistical offices responsible for the collection and publication of demographic data by the middle of the nineteenth century (e.g., Statistics Sweden in 1858), and some had created institutions for similar functions for colonial areas. Many national-level annual statistical yearbooks were being published by these offices by the 1870s and 1880s.

An important impetus in this direction was the creation of a series of international statistical congresses, the first being in 1853. A series of recommendations were made concerning the need for regular censuses meeting basic standards. These resolutions were modified and expanded in subsequent congresses and were reinforced by the creation of the International Statistical Institute (1853). This work was continued by such bodies as the International Labor Office (1920), the Committee of Statistical Experts of the League of Nations (1920), the Inter-American Statistical Institute (1940), the World Health Organization (1948), and the Population Division of the United Nations (1947).

Vital registration did not expand as quickly. The countries of Scandinavia, Britain, France, many German states, and other European nations had the advantage of existing parochial registration systems. Some results from these systems were aggregated and published, such as in Scandinavia and England, or as 'Bills of Mortality' elsewhere, These systems gradually were converted to civil registration and thus became the basis for modern vital statistics collection. France secularized its parish registration under the Napoleonic Code in 1804. England and Wales instituted civil registration in 1837 and commenced published tabulations in 1838, but the system was only likely reasonably complete by the 1860s. The United States, a forerunner in regular enumerations, was a laggard in vital registration. The process was left up to individual states and, consequently, was accomplished unevenly. The state of Massachusetts was the first to have statewide vital registration (1842), but a partial national Death Registration Area was not even set up until 1900 (with 10 states and the District of Columbia, covering about 25 percent of the population). A Birth Registration Area was not created until 1915, and the system did not cover the entire nation until 1933. Canada experienced similar problems with provincial registration, and the system there was not complete until 1926. Although the German Empire immediately created an Imperial Statistical Office in 1871, the various state statistical offices were only able to furnish basic counts immediately. Deaths by age, sex, and cause were not available for the whole empire until 1901.

Additionally, many nations established controls of the movement of persons across their borders, especially in the late eighteenth and in the nineteenth centuries. The consequence was the collection of international migration statistics, especially about arrivals but subsequently (and partially) on departures too. For instance, the United States was a major recipient of European migrants before World War I and began collecting data on arrivals in 1819 but on departures only from 1906. Also, publication of details was often uneven.

3. *The Twentieth Century*

In the period 1855–64, 24 sovereign nations took population censuses, 17 of them in Europe. During 1895–1904, 44 nations or colonies took a census, 23 in Europe and seven in North America and the Caribbean, but also five in South America and seven in Asia and Oceania. This progress continued. For the period 1945–54, 65 nations or colonies took censuses (28 in Europe, 12 in North America and the Caribbean, eight in South America, 15 in Asia and Oceania, and two in Africa). At that point, basic population counts were available for about 80 percent of the estimated world population, though detail was much more limited. For example, population classified by single years of age and sex was reported for only about 46 percent of the estimated world population. By the end of the twentieth century, almost all of the 233 countries in the United Nations had taken a census within the last two decades of the century. In some cases, nations with advanced continuous population registers (which collect information on a wide variety of social and demographic events) have supplemented or replaced censuses with estimates from their registers (e.g., the Netherlands, Sweden, Norway, Denmark, Belgium).

In terms of vital statistics, only about 53 percent of the estimated world population was covered in 1955, varying from 98 percent in North America, 94 percent in Europe, 43 percent in Asia, to 37 percent in Africa. Many of the systems in developing countries seriously under-registered both births and deaths. Sample surveys, such as the recent Demographic and Health Surveys, have supplemented knowledge of vital processes in all regions. As of 1992, of the 48 countries in Europe, all but three very small entities were categorized by the United Nations as having complete birth and death registration. In contrast, only 13 of the 57 countries of Africa were classed as having complete

registration of deaths and only 10 as having complete birth registration. For Asia the proportions were 20 out of 52 for birth registration and 18 for death registration. Of the 14 countries of South America, seven were listed with acceptable registration for both births and deaths. The United Nations standard is rather liberal: to be classified as complete a system must have achieved a coverage of at least 90 percent.

A considerable advance in the collection of mortality statistics was made in 1900 when a conference of the International Statistical Institute approved the first international list of causes of death (*ICD-1*). This has been revised a number of times since then and is now under the auspices of the World Health Organization; the revision being operated is the ninth [*ICD-9* (1979)]. As medical and scientific knowledge has improved, there has been a movement away from symptomatic cause attribution and toward etiological, organic, and epidemiological diagnosis.

Overall, although there have been substantial changes in demographic data regimes, especially in the twentieth century, the world is far from having a reliable and complete coverage. Recent political and economic tendencies do not indicate that the situation will improve. Sample surveys and indirect estimation of vital rates based on census and survey data would seem to be the answer for the immediate future for many developing nations, particularly in sub-Saharan Africa.

Demographic Measurement: General Issues and Measures of Fertility

1. Introduction

1.1 General Overview

The phenomena measured in demographic analysis are events, states, attributes, and cumulative experience. Classically, the core demographic activity consists in estimating the frequency of vital events, births and deaths, and of related events—migration, marriage (or, in more recent times, the formation of sexual unions), and divorce (or the dissolution of such unions). Other events studied in demography include conception, pregnancy, spontaneous and induced abortion, household formation and dissolution, family changes, and widow(er)hood. States of demographic interest include marital status, both legal and informal, and type of family or household to which individuals belong. The classic attributes of demographic interest are age and sex, along with ethnicity and socioeconomic characteristics such as educational level and social class. Cumulative experience is examined using proportions ever having experienced an event such as marriage, or estimates of the average number of a specified event experienced in a lifetime or by a specific age.

Events can be thought of as changes in state and, correspondingly, states can be considered to result from the occurrence and nonoccurrence of events. For example, the event of first marriage changes a person's marital status from single to married, and a person who has married and has not yet experienced the dissolution of their marriage is in the state of being currently married. In addition, the concepts of 'cumulative experience' and 'state' are to some extent interchangeable, for example, a woman who has had n live births (cumulated experience) is said to be of parity n (state). Measures of cumulative experience that do not refer to individual states are also used in demography, and these will be considered presently. The current entry does not deal with methods of collecting and classifying demographic data, but with the use of data once it has been collected and processed, ready for analysis.

Demography is concerned in general with aggregate phenomena at the population level, where populations vary from global to local in extent. The units whose events and states are aggregated can be individuals, couples, families, or households. Some demographic measures are, however, strictly aggregate in type, for example, a population growth rate, population density per unit area, or a population dependency ratio all have meaning at the aggregate level only. Demographic measures focus on level, timing, and distribution: the frequency of events or prevalence of states (level), the age at or time between events

(timing), and distributional aspects such as age structure.

The need for demographic rates and other measures is readily stated. Absolute numbers, whether population size or numbers of vital events, are certainly of demographic interest, particularly in an applied context, and are frequently the key input or output for policy purposes. However, population analysis is conducted in terms of the underlying phenomena—mortality, fertility, migration, and so on—that determine population change. For example, population projections are usually carried out by the component method, applying assumptions about fertility, mortality, and migration *rates*, rather than by extrapolating birth, death, or population *numbers* using mathematical models. Rates, proportions, and other indices are required also for comparative purposes, whether tracking time trends or making comparisons between (sub)populations. Spatially and temporally, populations vary in size and also in structure, and so measures that abstract from size and structure are required to compare the demographic metabolism, so to speak, of different populations.

Demographic rates and measures are numerous. The variety stems both from the widely varying forms in which data are available and from the nature of the phenomena themselves. Data may come from vital registration systems, from censuses and surveys, from parish registers, or from administrative records. These sources may differ in the kinds of information recorded, in questions asked, and in details published. Fertility is the area in which measures are probably most numerous, a result of the complexity of the phenomenon: births are repeatable events, they can occur to women inside and outside of marital or cohabiting unions, their order in a birth history can be of significance, and they can be associated with several dimensions of personal time—age, union duration, duration since previous birth, and so on.

1.2 Rates, Probabilities, Proportions, and Ratios

A demographic rate expresses the number of events occurring relative to person years at risk of the event in a defined population for a specified time and place. It may be expressed per person year, per 1,000 person years, per 100,000 person years at risk, and so on. The denominator, person years at risk, is often estimated by means of the mid-year population or by the average of two end-year population figures, each of these being an approximation to the average population during the year. Francophone demographers distinguish between type 1 rates (*taux de première catégorie*), in which the denominator of a rate is confined to those who have not yet experienced the event in question, and type 2 rates, where no such restriction is made (*taux de deuxième catégorie*) (see *Demographic Techniques: Rates of the First and Second Kind*). No special terminology is commonly accepted for this purpose in English-language demography, the distinction between such rates being implicit in the specification of the rate, but the English version of the French terminology will be used occasionally for brevity and precision. A probability is the likelihood that an individual will experience an event. It is estimated by the number of events occurring during a defined period or at a particular age to a specified group divided by the numbers of individuals present at the start of the period or age. A proportion is defined in the usual way, as the number with a given attribute at a given time point divided by the total population in question at that time. Finally, demographic measures also take the form of ratios, for example, the sex ratio at birth is the ratio of the numbers of male to female births. Ratios generally refer to aggregates, although anthropometric measurements in ratio form relating to individuals are also found in the medical demographic literature.

1.3 Crude Rates and Degree of Specificity

Demographic measures vary in their level of detail. The simplest are crude rates, expressed as the number of events per 1,000 (or other multiple) of the total population, without any further specificity. The two most common are the crude birth rate (CBR)—the number of births per 1,000 population in a year—and the crude death rate (CDR)—the number of deaths per 1,000 population in a year. They give basic information but do not allow refined analysis. Crude rates are of value in setting out the basic demographic parameters of a population and are used for descriptive purposes, for instance, when data needed for more detailed measures are either unavailable or unreliable.

Demographic rates and other measures are influenced by the composition of the numerator in respect of any factor by which the frequency of the phenomenon under study varies. Most importantly, crude rates are influenced by the age structure of a population, because of the pervasive association between age and demographic event rates, and also by sex composition, since demographic event rates usually vary by sex. Accordingly, specific rates may be calculated by restricting the numerator or the denominator, or both. Specificity may be introduced for one or more factors. For example, age-specific rates may be influenced by composition in respect of marital status, duration in a particular state, parity (number of children already born to a woman), urban/rural residence, and so on. So, the analyst might choose to calculate rates specific for a number of dimensions. For some purposes, variation according to specific factors may itself be the focus of interest. In

other contexts, variation with respect to, for example, age is taken as given and is not the subject of study. If so, the analyst will wish to remove the compositional effect from the comparison to be made. Traditionally, one of two procedures is used to remove the influence of such (nuisance) factors. Rates may standardized for the factors concerned or may be disaggregated progressively so as to arrive at rates specific for groups with greater (or in theory perhaps complete) internal homogeneity. Standardization may be through the conventional direct or indirect methods or by calculating a synthetic indicator of some kind (see Sect. 2.1.3 below).

Both procedures have disadvantages. Standardization, whether by the conventional direct or indirect methods, or by constructing synthetic indicators, is well known to be valid only where there are no interactions between the factors for which the standardization is carried out, or when there are no interactions between them and the categories, populations, etc. to be compared. Since such interactions are often found, straightforward standardization is inappropriate in many instances. Progressive disaggregation of rates has the disadvantage of producing potentially large numbers of rates that are not readily summarized and perhaps not readily interpretable. Modern methods of model fitting can in many instances provide a more general and rigorous solution to the pervasive need for standardization in demographic analysis, and can offer a considerable advance on the progressive disaggregation approach. Hoem (1987) and his predecessors have shown that indirect standardization can be seen as a first step in an iterative estimation procedure for intensity regression based on a multiplicative hazard model.

2. *Measures of Fertility*

2.1 *Level*

2.1.1 Crude and specific rates. The definition of the most common fertility measures is set out in Table 1. The CBR is widely used in cross-national comparison, particularly since the data required (an estimate of total births and of total population) are generally available. The general fertility rate (GFR) is more specific, in that it restricts the denominator to those at risk of experiencing a birth, that is, women of childbearing age (most commonly taken as ages 15–44). Age-specific fertility rates (ASFRs) introduce a further level of detail by age and have importance both in indicating the pattern of childbearing by age and as the basis for calculating the total fertility rate (see below). Age-specific fertility rates may be disaggregated further to obtain age-specific marital fertility rates and age-specific nonmarital fertility rates. Fertility rates may also be calculated specific for duration of partnership or marriage, in place of or jointly with age.

In the last few decades, fertility rates that are specific by order of birth have come into prominence. Such rates are particularly informative since time trends may vary by order of birth, particularly in modern contracepting populations or in populations where the use of contraception is on the increase. They are of two distinct types. Less detailed are rates in which the numerator only is disaggregated by order of birth, giving, for example, age-order-specific fertility rates. These are demographic rates of type 2 (see *Demographic Techniques: Rates of the First and Second Kind*), since the denominator includes all women of a given age, although the numerator is specific by order of birth. They should be distinguished from the more detailed age-parity-specific fertility rates in which the numerator consists of births of order i to women aged x and the numerator of women of parity i–1 who are aged x. (These latter are rates of type 1; note that the term 'order' relates to *births* and that 'parity' relates to *women*.) In the case of first births, both order-specific and parity-specific rates may also be specific by duration since marriage (or start of union), either in place of or combined with age-specificity; for second and higher order births, correspondingly, duration since previous birth may be specified in place of or in addition to age. Computing measures of fertility that are specific by order of birth from vital registration data can present data problems because the order of birth as recorded in a particular system may exclude a woman's premarital births and/or births occurring in previous marriages, and so may not represent true birth order over the woman's entire childbearing history.

With the exception of the crude birth rate, which applies only to a time period, all of these fertility rates may be calculated either on a calendar-period or cohort basis.

2.1.2 Parity progression ratios. Fertility rates may vary by parity, and in modern contracepting populations always do so. Because any given overall level of fertility may be reached through differing patterns of parity-specific birth rates, measures known as parity progression ratios (PPRs) were developed in the early 1950s to summarize the lifetime outcome of such variation. The parity progression ratio of order i is defined as the proportion of women of final parity i and above who, by the end of childbearing, have had at least $i+1$ births. Here $i = 0, 1, 2 \ldots m$–1, where m is the maximum number of births to any woman in the population. These ratios express, in other words, the probability that a woman who has had a given number of live births will have at least one further birth. In their original form, parity pro-

Table 1
Selected fertility measures

Measure and *time reference*	Definition	Notes
Level		
Crude birth rate (CBR) *period*	$\frac{B}{P} \times 1000$	B = number of births in a given year or period P = total person-years lived[1] during the year or period
General fertility rate (GFR) *period; cohort*	$\frac{B}{\sum_{15}^{49} W_x} \times 1000$	W_x = number of woman years lived[1] at age x during a year or period[2]. An upper age limit of 44 is sometimes used
Age-specific fertility rates[3] (ASFR) *period; cohort*	$F_x = \frac{B_x}{W_x} \times 1000$	B_x = births to women aged x or in age group x during a year or period[2] W_x = woman years lived[1] at age x or in age group x during a year or period[2]
Age-specific marital fertility rates[3] *period; cohort*	$\frac{B_{x,m}}{W_{x,m}} \times 1000$	$B_{x,m}$ = births to married women aged x during a year or period[2] $W_{x,m}$ = woman years lived[1] while married and at age x or in age group x during a year or period[2]
Age specific nonmarital fertility rates[3] *period; cohort*	$\frac{B_{x,u}}{W_{x,u}} \times 1000$	$B_{u,x}$ = births to unmarried women aged x or in age group x during a year or period[2] $W_{u,x}$ = woman years lived[1] while unmarried at age x or in age group x during a year or period[2]
Illegitimacy ratio[3] *period; cohort*	$\frac{B_u}{B} \times k$	B_u = births to unmarried women during a year or period[2]. The multiplier k may be 100 or 1000
Age-order specific fertility rates[3] *period; cohort*	$F_{x,i} = \frac{B_{x,i}}{W_x} \times 1000$	$B_{x,i}$ = births of order i to women aged x or in age group x during a year or period[2]
Age-parity specific fertility rates[3] *period; cohort*	$\frac{B_{x,i}}{W_{x,i-1}} \times 1000$	$W_{x,i-1}$ = woman years lived[1] while of parity $i-1$ and age x or in age group x during a year or period[2]
Total fertility rate[3] (TFR) *period; cohort*	$\sum_{15}^{49} F_x$ The upper limit of the summation may be 44 rather than 49	F_x is the age-specific fertility rate defined above. When rates are for five-year age groups, the sum is multiplied by 5. The cohort TFR is simply the mean family size of women in the cohort
Gross reproduction rate[3] (GRR) *period; cohort*	$\sum_{15}^{49} F_x^f$	F_x^f is the age specific rate of female births. The sum is multiplied by 5 if five-year age groups are used
Net reproduction rate[3] (NRR) *period; cohort*	$\sum_{15}^{49} F_x^f L_x^f$	L_x^f is the average number of person-years aged x in the stationary female life table, with a radix of 1.
Parity progression ratio[3] *Cohort; period version differs: see text*	$a_i = \frac{N_{i+1}}{N_i}$	N_i = number of women who have i births

Table 1
Continued

Measure and *time reference*	Definition	Notes
Timing		
Mean age at birth[3] (crude) *Period; cohort*	$\frac{\sum_{15}^{49} xW_x^b}{\sum W_x^b} + 0.5$	W_x^b = the number of women aged x last birthday having a birth during a year or period[2]
Standardized mean age at birth[3] (crude) *Period*	$\frac{\sum_{15}^{49} xF_x}{\sum_{15}^{49} F_x} + 0.5$	
Median age at birth[3] (crude) *Period; cohort*	Median age of women having a birth in a period or, within a cohort, median age of women at childbirth	
Standardized median age at birth[3] *Period*	Median of the age-specific fertility distribution	
Mean age at i-th birth[3] (crude) *Period; cohort*	$\frac{\sum_{15}^{49} xW_{x,i}^b}{\sum_{15}^{49} W_{x,i}^b} + 0.5$	$W_{x,i}^b$ = women aged x last birthday having a birth of order i during a year or period[2]
Standardized mean age at i-th birth[3] *Period*	$\frac{\sum_{15}^{49} xF_{x,i}}{\sum_{15}^{49} F_{x,i}} + 0.5$	$F_{x,i}$ = age-order specific birth rate of order i, during a year or period defined above (type 2)
First birth interval *Cohort; for synthetic period version, see text*	Duration from marriage (or start of union) to first birth	Less useful where moderate to high proportions of first births occur outside of a union
Second, third, etc. birth interval *Cohort; for synthetic period version, see text*	Duration from first to second birth, second to third birth and so on	Caution: cannot be calculated from the mean ages at births of each order, unless specifically for women with i+births; see text.

1 In the specification of demographic rates, person-years lived, woman-years lived, or man-years lived (whether overall, or at a particular age or in a given state) is the true denominator. For practical purposes, person-years lived in a period is estimated in various ways by different statistical agencies. In the UK and USA, it is usually estimated by the mid-year population (overall, or of a particular age, etc.). See also *Demographic Techniques*: *Rates of the First and Second Kind*.
2 Where the rate relates to a year or period, events and person-years lived are those occurring during the year or period in question. A cohort rate is based on events experienced and person-years lived by the cohort concerned.
3 These quantities can be defined analogously for men, but in most cases the male versions are rarely used.

gression ratios are calculated on a cohort basis, although they are meaningful for any group of women aged 45 plus. Methods for estimating these for women who have not reached the end of childbearing have also been proposed (Brass and Juarez 1983).

2.1.3 Synthetic or hypothetical cohort indicators. Since there are many specific fertility rates of any particular type, it is convenient, indeed a practical necessity, to have single-figure indices that summarize them. Such indices are also of value in producing estimates of lifetime experience on the basis of a single period's data, both because cohort data are often not available and because cohort data represent cumulative past rather than current experience. Synthetic or hypothetical cohort indicators are used for this purpose. A synthetic summary indicator is obtained by combining the specific rates of a calendar period to obtain an overall figure representing the lifetime fertility outcome that would result if a cohort of women experienced the period rates in question throughout their childbearing years. The component rates are combined in one of two ways: either multiplicatively, as in a life table, or by adding the age-specific rates at each age. In the first type of procedure, the denominators include only 'survivors,' that is those who have not yet experienced the event by the age or duration in question (rates/probabilities of type 1). The second type of procedure is used when the denominator of each age-specific rate includes both those who have and those who have not yet experienced the event (rates of type 2). The exact details depend on the type of rate in question and are mentioned below in each case.

The most widely used such summary indicator in the fertility arena is the classic period total fertility rate (TFR), obtained by adding the age-specific fertility rates (i.e., type 2 rates) of a given year or period across ages 15 to 44 or 15 to 49. The result can be interpreted as the average number of children that women would bear, if they were to experience throughout their childbearing years the age-specific rates of the period

in question. (For a modern underpinning of this classical interpretation, see Borgan and Hoem 1988.) It can also be seen as the average number of children per woman if the age-specific rates in question were to remain in force over a long period. Closely related to the classic total fertility rate are the gross reproduction rate (GRR) and the net reproduction rate (NRR). The GRR is simply the TFR confined to female births, and so represents the average number of *daughters* a woman would have if she experienced the age-specific female birth rates of a particular period. The NRR is obtained by modifying the GRR to take account of the probability that a newborn female may die before reaching reproductive age (see Table 1); it represents thus the average number of daughters who would reach reproductive age per woman of reproductive age that would result if a period's age-specific female fertility and mortality rates were to remain fixed. In a stable population, in which vital rates are and have been fixed over a lengthy period, the NRR represents the extent to which generations replace themselves. In these circumstances an NRR of $< 1, = 1$, or > 1 means that successive generations are, respectively, declining, stationary, or growing in numerical size, and so that overall population numbers are changing correspondingly. The GRR is roughly half the size of the TFR; the NRR is less than the GRR, with the gap between them depending on the level of female mortality at ages under 45 or 50: the higher the mortality level, the greater the disparity between the GRR and the NRR. The TFR, GRR, and NRR can also be specified on a male basis, that is using male age-specific fertility rates, and male survivorship, and the results will in general differ from the female values. Female rates being more widely available and more reliable, they are in general preferred to male rates.

An advantage of the TFR, the GRR, and the NRR is that they are standardized for age, the standard population being one imaginary woman proceeding through 30 or 35 years of childbearing. Synthetic or hypothetical cohort indicators in general—whether of fertility, nuptiality, mortality, and so on—can be criticized for the fact that they express period events in a metric of lifetime experience, and that this is conceptually at variance with the usually short period of calendar time whose demographic processes they represent (Ní Bhrolcháin 1992). Two points can be made in answer to this difficulty. First, the discrepancy between time series of summary cohort indicators and corresponding period synthetic summary indicators such as the TFR is well known, and the origins of the discrepancies between them have been widely discussed. Second, synthetic indicators can be thought of simply as convenient statistical summaries of the specific rates obtaining in a particular period—as a rough summary of the overall level of a phenomenon.

The major and well known source of discrepancy between cohort and period time series of the TFR, originally identified by Hajnal (1947) in relation to the GRR and NRR, is that time trends in the period TFR are influenced not only by the level of fertility but also by changes in the timing of childbearing. Where successive cohorts are moving to an earlier pattern of childbearing, the period TFR will be inflated, and where cohort fertility is slowing in pace the period TFR will be deflated, relative to the cohort series.

A related source of inaccuracy in these summary measures is that the additive (although not the multiplicative) method of combining a period's rates takes no account of past experience, at earlier ages or durations, of that event, particularly in the case of fertility. Past experience of events is likely to influence current type 2 rates, for example, if proportionately more of a given age group have already had a first birth, the (type 2) age-specific first birth rates can be expected to be lower than if proportionately fewer of the group have already begun childbearing. Furthermore, in a population where age-specific rates vary from year to year—almost always the case in real situations—the past experience of age groups in successive calendar periods (or, equivalently, successive cohorts) will differ. Thus, any additive summary indicator will be influenced by the composition of each age group with respect to past experience.

A final difficulty is that additive synthetic indicators may sometimes produce results that are impossible if the summary is interpreted as relating to a real cohort: for example, the sum of period age-specific first birth rates may exceed one, which appears to imply more than one first birth per woman. This last weakness is not present in multiplicative summary indices.

One solution to the difficulties inherent in the classic TFR is to use cohort fertility series to supplement period information. Hajnal (1947) suggested that the fertility experience of successive cohorts be deployed to reflect long-run trends, and that period fertility be employed to reflect recent and current trends, a practice that has become firmly established in demographic analysis since that time. Another alternative has become available more recently: synthetic or hypothetical cohort indicators calculated on a multiplicative basis. Such measures correct in part for differences in composition resulting from past experience, and have the advantage also that they do not produce results that would be impossible in a true cohort. The best known of these in current use in the fertility arena is the period parity progression ratio (PPPR), devised originally by Henry (1953). PPPRs are constructed from the parity-and age- and/or duration-specific probabilities obtaining in a period, yielding one summary indicator of the level of progression to each order of birth in a period. The (type 1) probabilities at each age or duration are essentially assembled as a life table, with age or duration as the measure of elapsed time, and the proportion having experienced the event (i.e., not 'surviving') by some specified age or duration estimated in the conventional

way (see *Life Table*). This proportion represents the parity progression ratio that *would* result *if* a cohort were to experience during their lifetime the parity- and age- and/or duration-specific birth probabilities of a particular period. For the specification of these indices see Feeney and Yu (1987), Ní Bhrolcháin (1987), and Rallu and Toulemon (1994). The PPPRs can be used to obtain an estimate of the period TFR that is alternative to the standard TFR, generated as

$$TFR^{pppr} = a^p_{0,t} + a^p_{0,t} \times a^p_{1,t} + a^p_{0,t} \times a^p_{1,t} \times a^p_{2,t} + \ldots + a^p_{0,t} \times a^p_{1,t} \times a^p_{2,t} \ldots a^p_{m-1,t} \quad (1)$$

where $a^p_{i,t}$ is the period parity progression ratio of order i for period t, and m is the maximum number of births occurring. (A standard notation is not yet in use for these quantities.)

This version of the TFR has the advantage over the conventional (additive) TFR that its components, the PPPRs, standardize to some extent for past experience and remove part of the timing influence, but it shares with the classic TFR the weakness that a single-figure summary may conceal parity-, age-, or duration-specific variation in probabilities that go beyond pure differences of level.

The issue of how best to summarize specific birth rates to obtain period time series is the subject of current research and debate (Ní Bhrolcháin 1992, Bongaarts and Feeney 1998). The classic TFR is recognized as too crude in many instances, and period parity progression ratios have been accepted as offering considerable clarification, especially in low-fertility societies and in societies in the course of fertility decline. One question at issue is to identify correctly the precise nature of time trends or cross-national differences, so that explanatory inquiry can be accurately focused on these, rather than on a potentially misleading summary indicator. Another objective is to make the best use of existing information in order to evaluate past and likely future trends. Further developments may be anticipated in this area in coming years.

2.2 Timing

Measures of fertility timing are somewhat less numerous than indicators of fertility level. The mean and median age at birth are the most basic ones. Somewhat more precise is the mean or median age specific by order of birth: mean or median age at first birth, at second birth, and so on. Mean and median ages may be obtained from either period or cohort data, and as with measures of the level of fertility, time series of these will generally differ. Whether or not specific by order, the period mean or median age at birth can be calculated in crude or standardized form, and published sources do not always indicate which of these is presented. The period crude mean age at birth (or at first birth, second birth, etc.) is obtained simply as the arithmetic mean age of all women having a (first, second, etc.) birth in a given period. The crude mean age at birth is widely used but has the disadvantage, in a period context, of being influenced by the age structure of women of childbearing age, which can vary through time and especially from one country to another. Far better for the purposes of period analysis, although more demanding of data since population denominators are required, is the standardized mean age at birth, or at first birth, second birth, and so on. Standardization is unnecessary in a cohort framework, which is self-standardizing, although care should be taken in comparisons of cohorts widely differing in mortality during the childbearing years. The standardized mean age at birth is obtained by weighting by the relative period age-specific fertility rates at each age (see Table 1) and so is, in fact, the mean of the age-specific fertility distribution. Similarly, the standardized mean age at i-th birth uses as weights the relative age-order-specific fertility rates (type 2, *not* type 1 rates; see above). The standardized mean age at birth is not a pure measure of fertility timing since it is influenced by the overall level of fertility. Two populations could have identical (standardized) mean ages at births of each order but the standardized mean age at birth could be later in one than in the other because proportionately more women in the first population go on to have births of higher orders. A measure of fertility timing encountered mostly in the historical demographic literature, the mean age at last birth, is used as an indirect indicator of the presence of birth control. This measure can be calculated without bias only for women who have reached the end of reproduction (age 45 or 50).

Another set of indicators of fertility tempo is the mean or median duration of birth intervals. The first birth interval is the time from marriage (or start of informal union) to the first birth. (This interval may be of limited value where a large proportion of births occur outside of formal or informal marital unions.) Later intervals are obtained as the duration from first to second birth (second birth interval), from second to third birth (third birth interval), and so on. Birth intervals calculated from the ages of a group of women at births of successive orders are incorrect because the ages at successively higher orders of birth are based on women of differing ultimate family sizes. The problem is that women who at the end of childbearing have larger families are usually younger at births of any given order than are those with smaller completed families. The i-th birth interval is calculated instead as (a) the time from birth $i-1$ (or start of union when $i = 1$) to birth i among women with i or more births, or equivalently as (b) the age at birth i minus the age at birth $i-1$ (or start of union when $i = 1$) among women with i or more births. Where individual level data are available, means or medians may then be calculated. If aggregate data only are available, median intervals

cannot be calculated accurately by differencing successive median ages at birth within parity groups. The median may be preferred to the mean birth interval, since birth interval distributions are typically positively skewed. Synthetic or hypothetical mean or median birth intervals for time periods may be obtained from the life tables used in constructing PPPRs, thus giving a period measure of birth timing analogous to, and supplementing, the standardized mean age at birth (Ní Bhrolcháin 1987).

Of importance in stable population theory is the mean length of a generation, which is the time it takes a stable population to grow by the factor *NRR*. It is represented in stable population theory by the symbol T and is given by $T = (\ln NRR)/r$, where r is the intrinsic growth rate of a stable population (see *Population Dynamics: Theory of Stable Populations*).

Demographic Measurement: Nuptiality, Mortality, Migration, and Growth

In the article *Demographic Measurement: General Issues and Measures of Fertility*, we saw that demographic measures are required for comparisons through time and space, and between subpopulations. Well-specified measures are needed because the rate of demographic events varies particularly by age, and with other dimensions of personal time, and because populations vary in size and in composition with respect to age and other factors influencing demographic event rates. *Synthetic* or *hypothetical cohort* measures were introduced, their purpose being to summarize an array of specific rates pertaining to a period and to estimate the (hypothetical) lifetime consequences of the set of rates obtaining in a calendar period. Synthetic cohort measures may be calculated either additively or multiplicatively and the merits and demerits of these procedures are presented in the aforementioned article.

Let us now consider some further types of demographic behavior.

1. Marriage, Cohabitation, and Union Disruption/Divorce

Measures of marriage and divorce are much less numerous than are those of fertility. We consider them under the headings of level and timing.

1.1 Level

The most basic of the 'flow' indicators are the *crude marriage rate*, defined as the number of marriages per 1,000 population, and the *general marriage rate*, defined as the number of marriages per 1,000 population aged 15 (say) and above (those eligible to marry; the legally allowable minimum age at marriage varies between countries). These rates are influenced both by the structure of a population across age and sex (since marriage rates vary by both age and sex), and by the proportions already married. To deal with the second of these, a general marriage rate may be defined per 1,000 *unmarried* persons. Age–sex variation in rates is handled in the conventional way by defining marriage rates specific by age and sex. Age–sex specific marriage rates may be refined by restricting the denominator to the unmarried. Further detail may also be introduced by calculating marriage rates specific by order of marriage. Such rates can be either of type 1 or 2, as outlined in *Demographic Measurement: General Issues*

and Measures of Fertility. (This terminology is not in widespread use in English.) Thus, the numerator of age–sex specific first marriage rates is confined to first marriages and the denominator may include either single (i.e., never-married) persons (type 1) or all persons (type 2) in that age–sex group. Remarriage rates are generally of type 1, i.e., they express the number of remarriages (by age and sex) per 1,000 divorced and widowed persons, but they too can be calculated in type 2 form (remarriages per 1,000 persons in an age–sex group, irrespective of marital status). All rates may be calculated on either a period or a cohort basis. The crude and general marriage rates can be standardized for age, using conventional standardization methods.

As an adjunct to, or sometimes in place of, period or cohort marriage rates, the cross-sectional distribution of marital status by age and sex may be used to depict the nuptiality of a population. Such figures have the advantage that they can be obtained from any census or survey in which individuals' current marital status is recorded and so do not require vital registration information or annual population estimates by age and sex. They reflect the past marriage, divorce, and widow(er)hood rates of the various age groups and so do not represent current propensities in the population concerned. However, if detailed marriage histories are collected in a survey, or even only the date of first marriage, marriage rates in preceding years may be reconstructed for what will usually be relatively short time series. Retrospective reports may, of course, be inaccurate.

Measuring the frequency of nonmarital cohabitation and of other types of informal partnerships, such as visiting unions, is less straightforward and hitherto there are no widely-agreed standardized methods of doing so (see Murphy 2000 for a discussion of some methodological issues). Because such partnerships are, by their very nature, not recorded in vital registration systems, current status information and retrospective questions in cross-sectional censuses and surveys are a primary source of information. In developed nations particularly, where the prevalence of cohabitation has increased substantially in the last three decades or so, and in areas such as the Caribbean, where visiting unions have long been common, the absence of good quality information on informal unions limits the accurate description of the *de facto* union status of a population. Among the indicators commonly used to evaluate the frequency of informal unions are: the proportion (of all or of the unmarried) currently cohabiting, the proportion of those married (or married at some time) who cohabited with their marriage partner (or with any partner) prior to marriage, and the proportion of informal unions among all unions, formal and informal—all of these being more useful if classified by age and sex. Where suitable data are available, the proportion ever having lived in an informal union by specified ages may be calculated. Analogous measures may be specified for visiting unions.

The *crude divorce rate* is analogous to other crude rates, being defined as the number of divorces per 1,000 persons in a population. It is influenced not only by the age–sex structure of a population but also by the proportions married by age and sex, and also by the distribution of marriages by duration, since divorce rates are closely tied to duration of marriage. Where data are available, a slightly more detailed measure is to be preferred: divorces per 1,000 existing marriages in a population. (Note that this is not the same as the number of divorces occurring in a year per 1,000 marriages *occurring* in a year, a measure that is neither recommended nor used by demographers.) As with other events, divorce rates are more informative if specific by age and sex (divorces in an age–sex group per 1,000 married persons in that age–sex group). However, in specifying divorce rates, duration of marriage is usually preferred to age since divorce risk varies substantially by marriage duration. Divorce rates may, if data allow, be specific by both age at marriage and duration of marriage, as well as by sex, since the risk of divorce is generally higher among those who marry at younger ages.

Where birth cohort information is available, the cumulative proportions ever having married by specified ages are useful indicators of both the level and the pattern of marriage within and across generations. Birth cohort proportions ever having divorced or ever having remarried can be obtained for the same purpose, though in this case the figures may be influenced by the cohort proportions ever having married or ever having divorced, respectively. To deal with this issue, it may be more appropriate in some circumstances to calculate the proportions ever having divorced (by duration of marriage) for marriage cohorts, rather than birth cohorts, and to obtain the proportions ever having remarried for divorce cohorts.

1.1.1 Synthetic or hypothetical cohort measures. The *total marriage rate* is often used to summarize the overall level of marriage for each sex in a population. It is obtained by adding the (type 2) age–sex specific marriage rates and would, if age–sex specific marriage rates were constant through time, represent the average number of marriages a woman or man would experience in a lifetime. The *total first marriage rate* is defined similarly as the sum of the age–sex specific (type 2) first marriage rates and can be interpreted as the proportion of women or men who would eventually marry, if age–sex specific first marriage rates were to remain fixed. Both of these summary measures have the same strengths and weaknesses as the conventional (additive) total fertility rate (TFR), to which they are analogous (see *Demographic Measurement: General Issues and*

Table 1
Selected measures of marriage and divorce

Measure and *time reference*	Definition	Notes
Level Crude marriage rate *Period*	$\frac{M}{P} \times 1000$	M = number of marriages during a specified year or period. P = total person-years lived[a] during a year or period.
General marriage rate *Period*	$\frac{M}{P_{15+}} \times 1000$	P_{15+} = person years lived[a] at ages 15 and above during a year or period[b].
Age–sex specific marriage rate (type 2) *Period; cohort*	$N_x^f = \frac{M_x^f}{P^f} \times 1000$	M_x^f = women marrying at age x during a year. P_x^f = woman-years lived[a] at age x or in age group x during a year or period[b]. Analogous definition for men.
Age–sex specific first marriage rate (type 2) *Period; cohort*	$\frac{M_{x,1}^f}{P^f} \times 1000$	$M_{x,1}^f$ = single women aged x or in age group x marrying during a year or period[b]. Analogous definition for men.
Age–sex specific first marriage rate (type 1) *Period; cohort*	$\frac{M_{x,1}^f}{P_{x,u}^f} \times 1000$	$P_{x,u}^f$ = woman years lived[a] while single and aged x in age group x during a year or period[b]. Analogous definition for men.
Total marriage rate *Period*	$\sum_{15+} \frac{M_x^f}{P_x^f}$	Where age is in five-year groups, the sum is multiplied by five. Analogous definition for men.
Total first marriage rate *Period*	$\sum_{15+} \frac{M_{x,1}}{P_x^f}$	Analogous definition for men.
Gross nuptiality *Period; cohort*	$1-\prod_{x=15+}(1-n_x^f)$	n_x^f = probability that a single woman aged x exactly will marry before $(x+1)$th birthday. Age range used may vary. Analogous definition for men.
Net nuptiality *Period; cohort*	Cumulative proportions ever marrying in a double decrement life table with marriage and mortality as decrements	Age range used may vary. Defined for males and for females.

Measures of Fertility). On the one hand, they are standardized for age and so are an improvement on the crude marriage rate. However, like the conventional TFR they are influenced by timing changes and they do not take account of past history, since they are not standardized for marital status. As a result, a period-specific total first marriage rate can, and has been observed to, exceed one first marriage per person—an impossible result, if it is interpreted as applying to a cohort.

Again, multiplicative summary indicators are available to overcome the deficiencies of the additive

Table 1
Continued

Measure and *time reference*	Definition	Notes
Timing		
Mean age at marriage (crude) *Period; cohort*	$\frac{\Sigma_{15+} x M_x^f}{\Sigma M_x} + 0.5$	Analogous definition for men.
Mean age at marriage (standardized) *Period*	$\frac{\Sigma x N_x^f}{\Sigma N_x^f} + 0.5$	Analogous definition for men.
Singulate mean age at marriage (SMAM) *Period*	$\frac{5 \sum_{0(5)5}^{45} S_x^f - 50 S_{50}^f}{1 - S_{50}^f}$ or assuming no marriage prior to age 15, $15 + 5 \frac{\sum_{15(5)5} S_x^f - 35 S_{50}^f}{1 - S_{50}^f}$	${}_5S_x^f$ = the proportion of women single in the five-year age group x to $x+5$. S_{50}^f is estimated by the mean of the proportions single in age groups 45–49 and 50–54. Analogous definition for men.

Notes: a In specifying demographic rates, person-years lived, woman-years lived and man-years lived (whether overall, or at a particular age or in a given state) is the true denominator. For practical purposes, person years lived in a period is estimated in various ways by different statistical agencies. In the UK and USA, it is usually estimated by the mid-year population (overall, or of a particular age etc.). See also *Demographic Techniques: Rates of the First and Second Kind.* b Where the rate relates to a year or period, events and person years lived are those occurring during the year or period in question. A cohort rate is based on events experienced and person years lived by the cohort concerned.

measures. Two such summaries of the level of marriage in a population are *gross nuptiality* and *net nuptiality*. Gross nuptiality is so called because it assumes that all survive to the latest age considered (usually 50, but sometimes an arbitrarily chosen later age). It is obtained, for each sex, by assembling the age-specific first marriage probabilities (type 1) of the unmarried as a life table and computing the proportions ever marrying (not 'surviving') by 50 (or an alternative later age), according to normal life table procedures (see *Life Table*). Net nuptiality, on the other hand, takes account of the fact that death may intervene before marriage, and thus that marriage and death while single are competing events for single persons. It is obtained by constructing a double-decrement life table, with marriage as one source of decrement and death while single as a second source of decrement (see *Life Table*). Gross nuptiality may be interpreted as the proportion who would marry if they were to experience at each age the age-specific probabilities of marriage pertaining to a given period and if there were no mortality before age 50 (or by the upper age limit chosen). Net nuptiality, on the other hand, may be taken to represent the proportion of a cohort who would marry by 50 (or some other specified age), if they were to experience, while single and at each age, the probabilities of marriage and of death pertaining to the single in a particular period. A practical difficulty with both gross and net nuptiality is that they require more detailed information than is needed to obtain the total marriage rate—namely first marriages by age and sex together with population estimates by age, sex, and marital status in the case of gross nuptiality, and additionally, mortality rates by sex, age, and marital status in the case of net nuptiality. As with life table proportions 'surviving' or 'not surviving' in general, they are standardized for age structure.

The level of divorce in a population may also be summarized through hypothetical cohort indicators. Analogous to the *total marriage rate* is the male or female *total divorce rate*, defined as the sum of age–sex specific type 2 divorce rates and representing the average number of divorces per person if the age–sex specific divorce rates of the period in question were to remain fixed or were to be experienced throughout a person's lifetime. As before, a multiplicative life table based indicator is to be preferred to the additive measure. The most common indicator used for the purpose is a life table estimate of the proportions who would divorce by a specified duration of marriage, at the rates current at each marriage duration, if these divorce rates were to be experienced by a couple throughout their marriage. As with analogous multiplicative indicators, this standardizes for the distribution by marriage duration and also takes some account of past history. This is probably the best available summary measure of the divorce propensity implied by current divorce rates, but it is demanding of data and is as subject to biases resulting from timing changes as are analogous measures of fertility and marriage. If successive marriage cohorts are moving to an earlier pattern of divorce, the high divorce rates of

early-divorcing couples may be combined with the high divorce rates of later-divorcing couples who had lower divorce rates at early durations, to produce an overall hypothetical proportion ever divorcing that is higher than that of any real cohort. At present, there is no specific name in use for this summary indicator.

1.2 Timing

Age at marriage may be calculated from period data in either crude or standardized form, though sources do not always indicate which measure is presented and, as with births, the terms 'crude' and 'standardized' are not in universal use in this context. The *crude mean age at marriage* is simply the mean age of those marrying in a period. The *standardized mean age at marriage* is analogous to the standardized mean age at birth and is the mean of the schedule of age-specific marriage rates (type 2). A crude and standardized *median age at marriage* may also be obtained. It is often useful to distinguish marriage age by the order of the marriage since the proportion of remarriages among all marriages can vary substantially through time or cross-nationally. Thus, we have the *mean* or *median age at first marriage* or *at remarriage*, either crude (of all those marrying for the first time or for the second or later time) or standardized (using age-specific first or remarriage rates of type 2). Equivalent averages can be calculated for birth cohorts and, as usual, do not require standardization. Mean and median ages at marriage can also be obtained from either gross or net nuptiality tables. Care is needed since the e_x column of a nuptiality table does not give the expected age at or years to marriage. Rather the column gives the expected number of years lived *while single* at and after age x. Since some never marry, this is not the same as the expected number of years to marriage among those who marry (see *Life Table*).

Average age at marriage can be estimated from cross-sectional proportions single (never married) by age, by an indirect procedure developed by Hajnal (1953). It gives what is termed the *singulate mean age at marriage* (SMAM). Based on the hypothetical cohort principle, the procedure is appropriate where marriage rates by age have been reasonably stable and assumes that neither migration nor mortality rates are associated with marital status. Should the proportions single be found to increase over any part of the age range, this indicates that one or more of the assumptions does not hold and so the calculation is not valid. Details are given in Table 1.

Mean and median ages at divorce may be calculated. Of particular interest in relation to divorce is the mean/median etc. duration of marriage at which the divorce occurs. A distinction should be made between the duration of marriages in general (those terminated by either divorce or death) and the duration of those marriages that end in divorce. Crude or standardized versions of these indicators may be obtained; for most purposes, standardized indicators are to be preferred.

2. Mortality

The *crude death rate* (CDR)—deaths per 1,000 population—is widely used as a basic measure of the level of mortality (see Table 2 for selected mortality measures). It is particularly strongly influenced by the age composition of a population because of the wide variation in death rates by age. *Age-specific mortality rates*—deaths at a particular age per 1,000 population of that age—are at the next level of detail, usually specific by sex. Where good quality information is available, rates that are specific for single years of age are produced, in preference to five-year age groups. Rates specific by single years of age are of particular importance at the younger and older parts of the age range, since in these age ranges differences in rates between adjacent single years of age may be sizable. Age may be grouped in a variety of ways, according to the refinement required in analysis and the nature of available data. However, even where five-year groups are used, the age groups zero to one and one to four are often distinguished, because of the relatively high death rate of infants, even in low mortality countries.

The measurement of mortality is simplified to some extent by the fact that death occurs ultimately to all and occurs only once. These twin aspects mean that crude and age-specific death rates are necessarily of type 1 (see *Demographic Measurement: General Issues and Measures of Fertility*): the risk of death is universal and, death occurring only once in a lifetime, nobody currently at risk of death can have experienced the event previously. Death rates are so closely and systematically associated with age, and to a lesser extent sex, that specificity by age and sex is adequate for most demographic purposes. Other dimensions of personal time are required much less often in specifying death rates. However, mortality rates may also be specific by social class, race/ethnicity, income, area of residence (urban/rural or subnational region), marital status, and other such socioeconomic characteristics. Analysis by such factors is of interest in examining social and economic variations in health and for actuarial and public health purposes. With such subspecifications, death rates may also be of type 2.

The *infant mortality rate* (IMR) is reported and published extensively, partly as a demographic indicator but also as an indicator of socioeconomic development. It is defined as the number of deaths of infants (children under the age of one year) per 1,000 births in a given year. It is, thus, not a rate as normally specified since the numerator is not an estimate of the person-years at risk of the event and will be inaccurate for this purpose to the extent that there are year-on-

Table 2
Selected mortality measures

Measure	Definition	Notes
Crude death rate (CDR) *Period*	$\frac{D}{P} \times 1000$	D = the number of deaths occurring during a particular year/period. P = person years lived[a] during the year or period.
Age-specific death rate *Period; cohort*	$M_x = \frac{D_x}{P_x} \times 1000$	D_x = deaths at age x during a year or period[b]. P_x = person years lived[a] at age x or in age group x during a year or period[b].
Infant mortality rate (IMR) *Period; cohort*	$\frac{D_0}{B}$	D_0 = deaths of infants under 12 months during a year or period[b]. B = births during a year or period[b]
Infant death rate *Period; cohort*	$\frac{D_0}{P_0}$	P_0 = person years lived[a] at ages under one year during a year or period[b].
Maternal mortality ratio (sometimes referred to as the maternal mortality rate) *Period; cohort*	$\frac{D_m}{B}$	D_m = maternal deaths during a year or period[b].
Maternal mortality rate *Period; cohort*	$\frac{D_m}{P^f_{15-49}}$	P^f_{15-49} = woman years lived[a] at ages 15–49 during a year or period[b] (age limits may vary).

Notes: a In specifying demographic rates, person-years lived, woman-years lived and man-years lived (whether overall, or at a particular age or in a given state) is the true denominator. For practical purposes, person years lived in a period is estimated in various ways by different statistical agencies. In the UK and USA, it is usually estimated by the mid-year population (overall, or of a particular age etc.). See also *Demographic Techniques: Rates of the First and Second Kind.* b Where the rate relates to a year or period, events and person years lived are those occurring during the year or period in question. A cohort rate is based on events experienced and person years lived by the cohort concerned.

year fluctuations in births. It is, however, a convenient measure since it can be obtained from simple counts of vital events and does not require population estimates by age. It has a correctly specified counterpart in the *infant death rate*, the number of deaths of infants (under the age of one year) in a year per 1,000 person-years lived under age one. Several mortality rates are distinguished also during the first year of life, both because of the steep decline in death rates over the first 12 months of life and because of the changing role of endogenous (genetic, intrauterine, perinatal) and exogenous (environmental, external) causes of death. Endogenous causes predominate in the earliest post-partum period, with exogenous factors growing in importance thereafter. The *perinatal mortality rate* is defined as the number of late fetal deaths plus the number of deaths within one week of birth per 1,000 total late fetal deaths plus live births. The *neonatal mortality rate* is defined as the number of deaths within one month (28 days) of birth per 1,000 live births, and the *post-neonatal mortality rate* as deaths between 28 days of birth and one year of age per 1,000 live births. The probability of dying between birth and the fifth birthday is widely referred to in the current demographic literature as the *child mortality rate*, though the latter is more correctly defined as the number of deaths of children under the age of five years per 1,000 person-years in the age group. The probability definition (also sometimes termed *child mortality risk*) has become widespread because under-five mortality is of particular interest in high-mortality, less-developed societies, for which the indirect methods (see *Demographic Techniques: Indirect Estimation*) used to evaluate child mortality estimate a cohort probability rather than a rate. High-mortality societies do not usually have good vital registration statistics and it can be difficult to formulate accurate assumptions about the average number of years lived by those who die, and thus to obtain an estimate of person-years lived.

Maternal deaths are those that occur during pregnancy or within 42 days of the end of the pregnancy, due to a cause related to the pregnancy or a condition

aggravated by pregnancy; the term thus includes abortion-related deaths. Maternal mortality is most often represented by the *maternal mortality ratio*: the number of maternal deaths per 100,000 live births in a period. This indicator is referred to by many authors and in many sources as the *maternal mortality rate*, although it is not in fact a true rate. Strictly, the *maternal mortality rate* is the number of maternal deaths per 100,000 women of reproductive age in a period, and some authors employ the term in this sense. It should be clear from the context which definition is in use.

Mortality specific by cause of death, of which maternal mortality is an instance, is the principal way in which mortality indicators are disaggregated beyond age and sex. The International Classification of Disease, currently produced and revised from time to time by the World Health Organization, is the standard scheme by which cause of death is classified. Measures of mortality by cause of death are of two kinds. Cause-specific mortality rates refer to the number of deaths from a particular cause during a period per 100,000 population, and may be specific also by age and/or sex. A multiplier larger than 1,000 is normally used for the purpose, since deaths from any one cause will usually be relatively small in number. Cause-specific mortality ratios, on the other hand, relate to the percentage of all deaths that result from a particular cause, either overall or by age and sex, and are of value where information on population denominators is inaccurate or unavailable. Proportional mortality analysis is used particularly in the study of occupational mortality.

2.1 Age Standardization

Because of the substantial variation in death rates by age (and in age structure across time and place), cross-national, areal, or time comparisons of the level of mortality require that death rates are standardized for age. Direct standardization, in which a standard age distribution is employed, yields a *directly standardized death rate*. Indirect standardization, in which a standard set of age-specific mortality rates is chosen, yields two indicators: the *standardized mortality ratio* (SMR) and the *indirectly standardized death rate*. The SMR gives an index figure expressing the level of mortality in the index population relative to that of the standard population, set usually to 100: it is simply the ratio of observed to expected deaths in the index population, with expected deaths based on the standard population's age-specific rates. Multiplying the SMR by the CDR in the standard population gives the *indirectly standardized death rate* in the index population. Direct standardization requires that the age-specific mortality rates are known and precisely estimated in the populations to be standardized. Where the age-specific rates are either unknown or subject to sizable errors, the indirect method must be used. Statistical theory singles out a version of indirect standardization as optimal when a multiplicative model holds for the force of mortality.

2.2 Life Expectancy and Life Tables

Life expectancy at birth, e_0, can be considered both an indicator of the 'timing' of mortality and also a summary of the overall level of mortality in a population. It measures timing in that it represents the expected or average number of years lived by a person or group subject, throughout their lifetime, to a given set of age-specific mortality rates. Because death occurs universally and removes an individual permanently from the population, any increase in death rates at any age is necessarily reflected in a shorter life expectancy, while a decline in death rates at any age is necessarily accompanied by an increase in life expectancy. The expectation of life is influenced both by the level of mortality in a population and by the pattern of mortality by age. As a result, two populations with the same overall life expectancy may differ in their patterns of age-specific death rates. Life expectancy is calculated from a life table (see *Life Table*), and so is standardized for age. The life table in question may be based on the age-specific mortality rates obtained in a calendar period or those of a birth cohort. Where based on a period life table, the expectation of life and other life table functions are synthetic cohort measures and share the shortcomings of all synthetic multiplicative measures (see *Demographic Measurement: General Issues and Measures of Fertility*).

The life table is a central analytical technique in demography, having a large variety of uses. It is, however, fairly demanding of data since it requires information on age-specific death rates and thus on the distribution of deaths by age as well as population estimates by age. Because detailed data of this kind are often unavailable for historical populations and for less developed nations, sets of model life tables have been developed corresponding to varying levels and patterns of mortality (Coale et al. 1983, United Nations 1982). Such compilations allow estimates of the level and/or age pattern of mortality to be made from information that is insufficient in itself to determine these (see *Demographic Techniques: Indirect Estimation*).

3. Migration

Along with births and deaths, migration is the final component of population change. Migration is classified according to whether it is into an area (*in-migration*) or out of an area (*out-migration*). The sum of in- and out-migration is termed *gross migration* and

the difference between them, in-migration minus out-migration, is known as *net migration*. For many purposes it is the absolute values of these quantities that are of interest. Crude and specific rates are also used. The *crude in-migration* (or *immigration*) *rate* is the number of in-migrants per 1,000 population and the *crude out-migration* (or *emigration*) *rate* the number of out-migrants per 1,000 population. The *crude gross migration rate* is the sum of these and the *crude net migration rate* is the difference between them. Like other demographic events, migration is patterned by age and so rates of all four kinds may be specific by age. For example, the *age-specific out-migration rate* is the number of out-migrants of a given age per 1,000 population of that age during a specified period. Cumulative migration experience is represented by whether a person has ever migrated from their place of birth (lifetime migration) or during a specified time (e.g., the last year, the last five years). Migration can be decomposed further according to types of area between which the move was made: for example, between or within urban and rural areas.

4. Population Growth

The difference between the crude birth rate and the crude death rate is known as the *crude rate of natural increase* (CRNI) and represents the rate at which a population is growing or declining in a year purely as a result of vital events. Since migration also influences population growth, the overall population growth rate is CBR–CDR $\pm$ the crude net migration rate. Where population growth rate is inferred from the change in total population during a period of t years, the growth rate is estimated as $r = \ln (P_t/P_0)/t$. The *intrinsic rate of natural increase* is a theoretical quantity, referring to the growth rate of a stable population (see *Population Dynamics: Theory of Stable Populations*) having a fixed set of age-specific mortality and fertility rates. It can be calculated for a real population, but should be interpreted with care since it represents the growth rate that would be obtained in the hypothetical circumstance that current age-specific rates were to remain fixed and that the population were closed to migration. The difference between the actual population growth rate and the intrinsic rate of natural increase is between the observed growth rate and the hypothetical growth rate that would apply if current vital rates were to obtain in a stable population. Further indicators relevant to the theoretical analysis of population growth are outlined in the article *Demographic Measurement: General Issues and Measures of Fertility*: the gross and net reproduction rates (GRR and NRR; see also *Population Dynamics: Theory of Stable Populations*). While the GRR and NRR may be calculated for actual (empirical) populations, an important proviso must be borne in mind: since the NRR accurately reflects growth prospects only in populations that are stable (see *Population Dynamics: Theory of Stable Populations*), when calculated for an actual population it takes no account of prospective growth/decline resulting either from migration or from future changes in mortality, nor does it take account of the growth potential inherent in population age structure (see *Population Dynamics: Momentum of Population Growth*). The same is true of the *total fertility rate* (TFR). A TFR of 2.1 in low-mortality countries is widely referred to in the demographic literature as 'replacement level fertility,' that is, the level of fertility necessary for population replacement in the long run. But this is potentially misleading. Low-mortality populations with a TFR of below 2.1 can and do continue to grow because of in-migration, declines in mortality, and/or population momentum. Equally, low-mortality populations with a TFR of 2.1 or more can and do decline because of out-migration, changes in mortality, and/or population momentum.

Demographic Models

The term 'demographic models' can have two meanings, one broad and one narrow. In its broad meaning, demographic models refer to all mathematical, statistical, forecast, and microsimulation models that are applied to studies of demographic phenomena. In its narrow meaning, demographic models refer to empirical regularities in age patterns of demographic events. Demographic models in the broad definition can be found in various entries related to demography (see, among others, *Demographic Analysis: Probabilistic Approach*; *Multistate Transition Models in*

Demography; *Event History Analysis: Applications*; *Population Dynamics: Theory of Stable Populations*; *Population Forecasts*; *Microsimulation in Demographic Research*). This article is concerned with demographic models in the narrow definition.

1. Age Patterns of Demographic Events

In a classic statement, Hauser and Duncan (1959) defined demography as 'the study of the size, territorial distribution, and composition of population, changes therein, and the components of such changes' (p. 2). In the Hauser–Duncan definition of demography, the study of population changes goes hand in hand with the study of the components of population changes. This is necessitated by the need to decompose a population into components and then study changes in the components before arriving at an overall understanding of the changes in the population. The most elementary, and also the most important, form of population decomposition is by sex and age. Since men are only indirectly involved in reproduction, demographic analysis is often simplified by focussing on women. Such simplification is called 'one-sex' modeling (see *Population Dynamics: Two-sex Demographic Models*), as is commonly seen in fertility and nuptiality models. In mortality models, however, men and women are always kept distinct, and there are substantial mortality differentials in favor of women.

The treatment of age is of significant concern in demographic research. Without exception, the occurrence of all demographic events is age-dependent. Here, the correct interpretation of age-dependency is one of life-course, that is, the likelihood of the occurrence of an event changes as a person (or a cohort) ages. This is true even though most demographic methods and models use cross-sectional data, capitalizing on age-gradients of vital rates in any given population. The use of period-based data usually is necessitated by the lack of cohort-based data.

Demographic models of age schedules are developed on the observation that age patterns of demographic events often show some regularity. Two cautionary notes are in order. First, age regularity is not universal, either across space or over time. Second, all that is assumed is empirical regularity; theoretical reasons behind such regularities are typically neither well established nor well understood. Nonetheless, demographic models capitalizing on empirical regularities are very useful in practice and may provide the basis for theoretical work. A brief discussion of the main uses of demographic models is given as follows.

2. Use of Demographic Models

Demographic models are intended to summarize empirical regularities in age patterns of demographic events, ideally in simple mathematical formulas. Such models can prove very useful in demographic research. One type of use of demographic models concerns data quality. For example, demographic models may be used to detect and correct faulty data, impute missing data, and allow researchers to infer from partial data. Not surprisingly, this use of demographic models is often found in historical demography and research in less developed countries, where quality data are scarce.

The second type of use is substantive and commonly it is found in research with a comparative focus, be it over time (trends) or across societies, regions, or subpopulations. Age-schedule models are also useful for actuarial calculations of life-insurance premiums and premium reserves and for the computation of national or regional population forecasts (e.g., Lee and Tuljapurkar 1994). In demographic applications, cross-group variations in age patterns are typically parameterized as functions of two components: a shape component to capture age effects and a modification component reflecting group membership. Ideally, we would like the second component to be as parsimonious as possible. When demographic models are fully parametric, the two components are integrated, with the functional form being the shape component and the parameter values being the modification component. However, parametric models are not the norm in demography. Parametric models and semi-parametric models will be discussed separately below, with concrete examples taken from research on mortality, nuptiality, and fertility. Coale and Trussell (1996) give a more detailed account of some of the models.

3. Parametric Models

Gompertz (1825) is accredited for the discovery that mortality rates in human populations increase nearly as an exponential function of age. This regularity holds true only after early adulthood (ages 25–30). According to 'Gompertz's law,' the force of mortality (or hazard) is a parsimonious loglinear function of age

$$\ln(\mu_x) = A + Bx \tag{1}$$

where μ_x denotes the force of mortality at age x. Naturally, A is the parameter characterizing the level of mortality at early ages and B is the parameter characterizing the rate of increase in mortality with age. While very parsimonious, the Gompertz model does not always fit empirical data well. Other researchers have modified the model either by adding additional terms or by changing the functional form. For example, Makeham (1867) altered the simple loglinear relationship of Eqn. (1) by adding a time-invariant term intended to capture cause-specific 'partial forces of mortality.' Heligman and Pollard's (1980) three-component model is another such extension.

In studying age patterns of first marriages among women, Coale (1971) found a basic form that is common in different populations. Through trial-and-

error, Coale was able to characterize the typical age pattern of first marriage by a double-exponential curve

$$r_x = (0.174)\exp[-4.411\exp(-0.309x)] \quad (2)$$

where r_x denotes the hazard rate (or risk) of first marriage at age x. This mathematical function was shown later to be approximated closely by the density function corresponding to the sum of distributions representing demographic processes (Coale and McNeil 1972).

To fit observed age patterns of fertility, Brass (1960) proposed a model using polynomial functions. Although Brass' parametric model is very flexible, it requires the estimation of four unknown parameters. Since fertility rates typically are given in a limited number of 5-year intervals, this method leaves very few degrees of freedom for evaluating goodness-of-fit. An evaluation of various parametric models based on empirical data is given by Hoem et al. (1981).

There are three notable problems with parametric models. First, parametric models often do not fit observed phenomena. Demographers have dealt with such empirical deviations through (a) restricting the applicable age range and (b) allowing for further parameterization. Both solutions have surfaced in research using the Gompertz model.

The second major disadvantage associated with parametric models is the lack of behavioral interpretations for key parameters. This problem arises from the fact that almost all parametric models have resulted from exercises of curve-fitting. Parametric models may reproduce observed age patterns of demographic events, but theoretical interpretation of involved parameters is often unclear.

Finally, parametric models are not always convenient to use for comparing populations or subpopulations even though this was one of the motivations for developing them in the first place. This problem is apparent, for example, in the case of a polynomial model. When several parameters in a polynomial function differ between two populations, it is difficult to characterize one population as having higher or lower rates than the other population.

4. Semiparametric Models

In response to these problems with parametric models, semiparametric models have been developed. Semiparametric models are similar to parametric models in specifying parsimonious mathematical functions but differ from parametric models in allowing age-dependency to be unconstrained and subject to empirical estimation, that is, semiparametric models do not impose any global constraint limiting the age pattern to the rigidity of a parametric mathematical function. Instead, the age pattern is estimated freely and empirically from observed data or calculated from external sources. One manifestation of the semiparametric approach is the use of model schedules or model tables. While allowing for the flexibility in a common age function, model tables place constraints on the variations in the age pattern across populations or subpopulations. Such constraints are often motivated by substantive knowledge of demographic phenomena.

In the area of mortality studies, for example, model life tables have been in wide use, primarily as a tool for correcting faulty data and estimating missing data. In essence, a model life table allows for a typical age schedule of mortality shared by a set of populations that differ mainly in their levels of mortality. The age pattern is flexible and empirically determined over all ages but constrained across populations; and cross-population variability lies in the overall level of mortality. The earliest model life table was developed by the United Nations (1955) for all national populations. Subsequently, Coale and Demeny (1966) added more flexibility by identifying four regional model life tables based on distinctive age patterns of mortality and refined the technique for constructing model life tables.

As an alternative, Brass (1968) developed a system of relational life tables, in which a standard mortality schedule is modified by two parameters through a logit equation

$$\text{logit}(p_{xj}) = \alpha_j + \beta_j \,\text{logit}(p_x^*) \quad (3)$$

Here p_{xj} is the probability of survival to age x in population j, p_x^* is the probability of survival to age x in a selected standard table, and α_j and β_j are parameters characterizing population j. In the Brass system, α determines the level of survival, whereas β changes the shape of survival parametrically.

In fertility research, Henry (1961) posited the existence of natural fertility with a peculiar age pattern. According to him, for physiological and social factors, different populations not exercising fertility control may have different levels of fertility but exhibit the same age pattern. Coale and Trussell (1974) later formalized this idea into the *Mm* method for studying age patterns of marital fertility. Let the marital fertility rate for the xth age of the jth population be denoted by r_{xj}. The Coale–Trussell *Mm* method parsimoniously describes the cross-population variation in age patterns of marital fertility with

$$r_{xj} = n_x M_j \exp(m_j v_x) \quad (4)$$

Here n_x is the standard age pattern of natural fertility; v_x is a typical age-specific deviation of controlled fertility from natural fertility, and M_j and m_j measure the jth population's fertility level and control, respectively. Eqn. (4) then states that marital fertility can be modeled as a product of natural fertility and a factor reflecting fertility control. The former is represented by $n_x M_j$; the latter by $\exp(m_j v_x)$. Coale and Trussell estimated n and v and suggested that these age schedules be taken as known in all applications. This approach has been superseded by Xie (1990) and Xie

and Pimentel (1992), who suggested that n and v be regarded as parameters to be estimated along with M and m from any set of empirical fertility rates r_{xj}.

5. Statistical Demography vs. Mathematical Demography

The construction and derivation of parametric and semiparametric demographic model age schedules have been accomplished through mostly mathematical and sometimes graphical methods. From the outset demographic modeling has been regarded as part of mathematical demography. Since the 1980s, however, a mainline statistical approach has played an increasingly important role in the development of demographic models (e.g., Clogg and Eliason 1988, Hoem 1987, Xie 1990, Xie and Pimentel 1992; see also *Demographic Analysis: Probabilistic Approach*) for a number of good reasons.

First, the advancement of demography has brought with it more, richer, and better data in the form of sample data, and the use of sample data requires statistical tools. Treating sample data as exactly known quantities induces the danger of contamination by sampling errors. Second, while the method of disaggregation commonly used in mathematical demography may easily lead to inaccurate estimation due to small group sizes, statistical methods more efficiently utilize covariates to examine group differences. Third, because observed data may sometimes be irregular or simply missing, statistical models can help smooth or impute data. Conversely, the strength of empirical techniques developed around demographic models (e.g., indirect estimation, age patterns of fertility, model life tables, etc.) is that they provide descriptions of age patterns that can be utilized to improve statistical analysis.

Demographic Techniques: Data Adjustment and Correction

Demographic data suffer to varying degrees from errors of coverage and of classification. Such errors are more common or more serious in populations with lower levels of education and economic development. Errors in the classification of an individual's age and parity (number of live-born children) are the most common and most problematic for demographic measurement and estimation. Methods of data evaluation and correction rely on mathematical formulae or on the relationship between demographic processes (birth, death, and migration) and the age distribution.

1. Errors of Coverage

In censuses, errors of coverage comprise the underenumeration or occasionally overenumeration of the population. Such errors usually vary by age and sex and possibly by other variables. For example, young children are often omitted from enumeration in some countries, as are young unmarried adults temporarily absent for work. Less frequently, migrants may be enumerated twice, at both source and destination. The

completeness of a census enumeration may be assessed through a postenumeration survey. Incomplete coverage is also a common deficiency of vital registration data. Since year of registration rather than time of event is the usual basis of compilation, late reporting adds to the inaccuracies involved. Death registration, where it occurs, is usually fairly timely since registration is often a legal requirement for burial, though in some populations such requirements are often ignored, notably in rural areas.

Nonresponse to individual questions in censuses and surveys also raises issues of representativeness and should be minimized. Responses may sometimes be imputed from the respondent's other characteristics during data editing. For most variables, nonresponses are omitted from analysis, only their extent being reported. For age, however, nonresponses are often distributed on a *pro rata* basis for each sex because of the need to maintain population size in demographic measurement.

2. *Errors of Classification*

Errors of classification may affect all demographic variables and arise from incorrect reporting on the part of the respondent and/or enumerator. Errors may also arise during coding and editing. Errors in the reporting of age (age misreporting) include digit preference (or age heaping) and under- and overstatement.

2.1 *Age*

Digit preference occurs where real age is not known and its estimation involves the 'rounding' of age (or year of birth) to end in a preferred digit such as 0 or 5. Digit preference is best detected graphically (see Fig. 1). Various indices have been devised to measure the extent of digit preference, but they do not offer a means of correction (US Bureau of the Census 1973). Whipple's index measures the preference or avoidance of the digits 0 and 5 over the age interval 23 to 62, though other multidecennial intervals can be used. Myers' blended index measures preference or avoidance of all 10 digits. Since neither index is theoretically precise, Bachi derived a composite index without this deficiency. These indices assume rectangularity or linearity within quinquennial age groups. Later indices, developed by Carrier and by Ramachandran, take account of age structure and variable digit preference over the age range. In practice, the Bachi, Carrier, and Ramachandran indices were laborious and are used less frequently.

Age misstatement may occur with or without digit preference and generally involves a directional tendency often related to cultural factors. Age understatement may occur among women of lower parity than average for their age, especially in cultures with high fertility. Age overstatement often occurs at older ages, particularly among males, in cultures where status is gained with age. Sex-specific age misstatement may also occur, for example, young female children generally are reported as younger than their male peers. The inaccurate reporting of age affects data on both population and vital events.

In many cases, it is impossible to distinguish between age misstatement, differential coverage by age, and digit preference. Further, one error may offset another. The pattern of overall error may be seen by examination of age ratios and sex ratios for 5 or 10-year age groups. These may be compared with ratios from suitable model life table populations. An indication of the overall accuracy of age reporting is given by the United Nations age-sex accuracy index (or 'joint score') (United Nations 1955). Irregularities arising from such factors as past changes in fertility or age-sex-specific migration should be taken into account.

Error may be assessed through comparison with expectation based on external data using demographic relationships. If accuracy permits, a previous enumeration can be 'updated' using data on births, deaths, and net migration to derive an expected age distribution. Comparison of the cumulated age distribution with model stable distributions identifies distortion due to misreporting (United Nations 1983; see *Population Dynamics: Theory of Stable Populations*). The completeness of birth and death registration may be assessed by indirect estimation techniques (see *Demographic Techniques: Indirect Estimation*).

The effects in demographic measurement and estimation of both digit preference and age misstatement can be reduced by the use of wider (than standard 5-year) age intervals, but this is not always practicable and involves greater approximation. Similarly, the effects on standard quinquennial age groups can be reduced by adopting nonstandard age groups, the optimum choice of which is based on Myers's index (US Bureau of the Census 1973), but these are generally inconvenient. For some purposes it may be appropriate to smooth or graduate the age distribution. For indirect estimation involving simultaneous estimation and detection of error (see *Demographic Techniques: Indirect Estimation*), or when data on population and vital events are obtained from a single source (e.g., a vital statistics survey), unadjusted data are required.

Methods of smoothing an age distribution include the use of graphs (manual smoothing), moving averages, and curve-fitting. Mathematical graduation is used to smooth narrower age groups within broader age groups. The following Carrier–Farrag and Karup–King–Newton formulae treat all age groups the same, whereas the Arriaga formula treats the first and last differently (Arriaga et al. 1994). In the following

Figure 1
Digit preference in the 1950 Census of Albania

formulae, ${}_nP_x$ represents the population aged x to $x+n-1$, x and n being integers. The Carrier–Farrag ratio method is based on the assumption that the relationship of a 5-year age group to its constituent 10-year age group is an average of such relationships in three consecutive 10-year age groups and is

$${}_5P_{x+5} = {}_{10}P_x/[1+({}_{10}P_{x-10}/{}_{10}P_{x+10})^{1/4}]$$

The Karup–King–Newton formula assumes a quadratic relationship between three consecutive 10-year age groups, that is ${}_5P_x = {}_{10}P_x/2+({}_{10}P_{x-10}-{}_{10}P_{x+10})/16$. The Arriaga formulae are based on second-degree polynomials passing through the midpoints of three consecutive 10-year age groups. Then

$${}_5P_{x+5} = (8\ {}_{10}P_x+5\,{}_{10}P_{x+10}-{}_{10}P_{x+20})/24$$

when the 10-year age group is the first,

$${}_5P_x = (-{}_{10}P_{x-20}+5\ {}_{10}P_{x-10}+8\ {}_{10}P_x)/24$$

when it is the last, and

$${}_5P_{x+5} = (-{}_{10}P_{x-10}+11\ {}_{10}P_x+2\ {}_{10}P_{x+10})/24 \text{ otherwise.}$$

In all cases, the second 5-year age group is derived by subtraction.

When age misreporting is more severe, the totals of all age groups need potential modification through averaging. The United Nations formula lightly smooths 5-year age groups, based on five consecutive 5-year groups, and gives the smoothed population aged x to $x+4$ as

$${}_5P'_x = (-{}_5P_{x-10}+4\ {}_5P_{x-5}+10\ {}_5P_x\ {}_5P_{x+5}-{}_5P_{x+10})/16.$$

For heavier smoothing, three consecutive 10-year age groups are used to derive the central smoothed age group as

$${}_{10}P'_x = ({}_{10}P_{x-10}+2\ {}_{10}P_x+{}_{10}P_{x+10})/4.$$

Neither formula smooths the youngest and oldest age groups. Since smoothing changes overall population size, the smoothed age groups subsequently are adjusted proportionally to achieve their overall enumerated total. The Arriaga (or other such) formulae are then applied to smoothed and adjusted 10-year totals to derive smoothed 5-year age groups.

A single-year distribution may be derived from grouped data by adopting the within-group distribution of a suitable unabridged life table population, but discontinuities at age-group junctions are inherent in this approach. A smoother distribution is obtained

by mathematical interpolation, either osculatory or polynomial. Osculatory interpolation gives a smoother distribution, especially for irregular data, because of the constraint of continuity at junctions. The widely-used Sprague multipliers employ fourth- and fifth-difference osculatory interpolation to smooth single-year data within 5-year age groups without changing the totals. They are less satisfactory for the first and last two age groups and where there is marked curvature. Sprague multipliers can be employed with any continuous data including rates, for any age partition (e.g., tenths), and with unequal age intervals. A blended distribution can be derived by averaging smoothed distributions obtained by osculatory interpolation within the five possible age groupings (with terminal digits 0–4, 1–5, 2–6, 3–7, 4–8). Spline interpolation is a type of osculatory interpolation. It involves extensive iteration requiring modern computers and gives a smoother distribution (US Bureau of the Census 1973).

2.2 Parity

Errors in the reporting of parity often involve the omission or understatement of live births. Where adoption is common, overstatement may occur due to both the natural and adoptive mother reporting the birth. The reporting of stillbirths as livebirths also results in slight overstatement. Omissions may be detected and corrected by indirect estimation (see *Demographic Techniques: Indirect Estimation*). Further error arises when childless women are recorded as 'parity not stated' due to the ambiguous use of the dash symbol (–) by interviewers. If these apparent not-stated cases are excluded, average parity is overestimated. If all not-stated cases are included and treated as childless, average parity is underestimated. The El-Badry correction estimates the proportion of women with parity not stated who are in fact childless (El-Badry 1961). Based on the observed high correlation between true proportions childless, $Z^*(i)$, and proportions with parity not stated, $NS(i)$ where $i = 1$ to 8 represents the age groups 10–14 to 45–49, El-Badry assumes $NS(i) = \alpha\ Z^*(i) + \beta$, where α is the proportion of truly childless women who are erroneously recorded with parity not stated and β is the constant true proportion not stated. Since the reported proportions childless, $Z(i)$, equal $(1-\alpha)\ Z^*(i)$, then $NS(i) = [\alpha/(1-\alpha)]\ Z(i) + \beta$, and $\alpha/(1-\alpha)$ and β can be estimated by ordinary least squares based on the first four or five age groups. Then, β is used to estimate the number of women in each age group for analytical purposes, and true proportions childless are estimated by $Z^*(i) = Z(i) + NS(i) - \beta$. This correction is based on all women. If data on parity are available only for ever-married women (in which case all never-married women are generally assumed childless), the procedure can be applied on the assumption of a linear relation between the proportions of ever-married women who are childless and who have parity not stated.

3. Other Adjustments

The smoothing of mortality rates or of the survival function can be achieved through use of a device like the Brass logit life-table system, which involves fitting observed data to a suitable standard such as a model life table (Brass et al. 1968; see *Demographic Models*; *Demographic Analysis: Probabilistic Approach*). Similarly, the smoothing of fertility rates is done through use of the Brass relational Gompertz model with an appropriate standard such as the Booth standard (Brass 1974, Booth 1984; see *Demographic Models*).

Other adjustments include shifting the population to refer to a specified date. This is achieved by linear or exponential interpolation of each age group between two dates for which enumerations are available; or by adjusting the total population exponentially (the growth rate is required) and assuming the same age-sex structure as at the enumeration. The structure of the open-ended age group can be derived using a suitable model stable population (see *Population Dynamics: Theory of Stable Populations*). When demographic events in a time reference period are reported retrospectively, errors of timing occur. For births, such errors are corrected through indirect estimation (see *Demographic Techniques: Indirect Estimation*).

Demographic Techniques: Family Reconstitution

1. The Technique

Family reconstitution is the technique of linking records of demographic events, usually of an ecclesiastical nature, within and between individual lives, in order to recreate individual life histories and the histories of families. While genealogists have always pursued such linking, the intent of demographers is not simply to record chains of descent and marriage but rather to compile information on the *demographic rates* pertaining to the *population* of which the individuals and families were a part.

Family reconstitution revolutionized the study of historical population processes, allowing estimation of demographic rates that was virtually impossible by other means. Demographers would ordinarily estimate vital rates by comparing counts of vital events to counts of the population at risk. For example, the general fertility rate could be estimated by dividing the number of births in a year by the number of women aged 15–49. However, accurate censuses contemporary with records of vital events are rare in the past. Family reconstitution not only overcame this difficulty by counting both events and persons, but also afforded a methodological alternative that is superior in many ways to estimation from census data, because the reconstitution data are on *individuals*, so that the characteristics of persons at risk are more specifically known. For example, estimates of fertility can be specific for unmarried, married, first-married, and remarried women, can include information on duration of marriage as well as age, and so on. It would be very rare to find information tabulated in such detail in published censuses, even in modern times. The technique of family reconstitution also led to important insights. For example, it showed (in contrast to the expectations of Notesteinian theory) that the decline of fertility in some places occurred well before economic modernization and before any decline in mortality.

1.1 History and Scope of the Technique

Family reconstitution as a demographic technique was developed initially by Swedish demographers (Edin 1915, Hyrenius 1942, 1958) and advanced by the French (Fleury and Henry 1985, Gautier and Henry 1958, Henry 1956, 1967, Henry and Blum 1988), then by English scholars (Wrigley 1966, 1969, 1972, 1973, 1997, Wrigley and Schofield 1973, Wrigley et al. 1997). It linked by *names of persons* the parish records of baptisms, burials, and marriages of individuals (hence the technical phrase, *nominal data linkage*). Genealogists had always used the linking of disparate records by names of individuals. Its large-scale use by historical demographers was an innovation. It is of course now commonplace, especially using unique identifiers, in the management of medical, insurance, taxation, police, and other data, especially by computer. In the hands of historical demographers, the ecclesiastical ceremonies noted in parish records served as *proxies* for the underlying births, deaths, and onsets of cohabitation. It must always be remembered that the events in parish records are not the same as the underlying demographic events, e.g., a baptism is not a birth. With that caveat, a family reconstitution should provide information on the dates of birth, marriage, widowhood, remarriage, dates of the birth of children, and of death for individuals. It is possible in principle to continue such linkages across succeeding generations, or across collateral lines. Historians and demographers can examine family reconstitutions for patterns of fertility, mortality, and nuptiality, and to a limited extent those of migration in historical populations. The technique can be extended to the study of any other type of social or biological phenomena supported by the particular dataset or other data such as medical, notarial, or tax records that can be linked to it, e.g., heritability of cause of death, marriage patterns between social groups, fertility by social class, etc. For example, family reconstitution can be used in investigation of genetic characteristics (Bean 1990), or the relationship between fertility patterns and socioeconomic and cultural characteristics (Hammel 1995), or in patterns of fertility change within and between family lines (Hammel and Goldstein 1996).

2. Related Methods and Expansions

2.1 Genealogies

Genealogies are records of the linked lives of persons related by consanguinity and affinity and can, like reconstituted families, be used to extract demographic information. They are usually very selective, however, and unlikely to be representative of the broader population. Aristocratic and wealthy families and lineages are more likely to be recorded than those

more characteristic of the population. Within genealogies, persons who do not leave descendants are more likely to be forgotten. Males are more likely to be remembered than females. Females may be less well remembered if they have fewer male children of consequence with progeny, so that events linked through females are likely to be lost (especially if the females were in informal liaisons with the males of the lineage). We might expect such biases to shift in matrilineal societies, but no data on such differences have been brought to light.

2.1.1 Ortssippenbücher. An important exception to some selection biases of genealogies are the *Ortssippenbücher* of some German regions, compiled by local genealogists from parish registers primarily to demonstrate the ethnic purity of families. These are genealogies of the common folk (but of course selective as their purpose indicates), and have been used for demographic estimation (Knodel 1988, Knodel and Shorter 1976).

2.1.2 Qing Dynasty genealogies. A second exception to some of these biases are the imperial genealogies of the Qing Dynasty in China, which were continuously compiled for all descendants of the founder and have also been used for demographic estimation (Lee et al. 1993). Females are relatively well recorded in these data.

2.2 Civil Vital Event Registers

Civil registers of vital events have the same potential as parish registers. They are intended to cover all faiths in a civil jurisdiction, but they may under-report some population segments such as vagrants or the poor. In some regions, civil registers can serve as a continuation of earlier parish registers and are especially valuable if secularization progresses and observation of ecclesiastical ceremonies declines.

2.3 Population Registers

Historically, civil and ecclesiastical population registers were periodic listings of the inhabitants of residential units. They have the advantage of preserving the identity of the residential unit (usually 'households') within which the demographic events occurred, although just what that unit was is itself often problematic, since actual and legal residence might be confused, and even long-term out-migrants might sometimes be continued in the listings. (Such continuation is not unknown in some parish records as well, e.g., births to out-migrant former inhabitants.) Population registers accomplish what is most difficult in family reconstitution, namely the nominal data linkage within and between individual lives, because local recorders presumably knew the identities of the persons and would not ordinarily confuse one John Smith with another John Smith. Thus, the families discernible in population registers are not so much reconstituted as preconstituted. The occurrence of vital events is implied through changes in household membership. However, the longer is the cycle according to which the registers were updated (usually at best annually), the more uncertain are the precise *dates* of the events leading to changes in membership, each update being only a *terminus ad quem*, and thus the more uncertain the exact periods of risk.

2.3.1 Civil population registers. Perhaps the most celebrated historical population registers are the household registers of Tokugawa Japan c. 1650–1868 (Hayami 1969, Smith et al. 1977) and later of Japanese-occupied Taiwan c. 1904--45, but registers were also kept in some European countries, e.g., Belgium (Gutmann and van de Walle 1978) and Italy (Kertzer and Hogan 1989). Records in such registers may sometimes be linked to independently kept vital event registers, both civil and ecclesiastical. (The Tokugawa registers actually had an ecclesiastical purpose, namely surveillance of the spread of religious sects, i.e., Christianity.)

2.3.2 Libri status animarum. *Libri status animarum* ('books of the state of souls') were ecclesiastical population registers that often contained not only registration information (e.g., which members of a household had been catechized, or which had been confirmed) but also the dates of these events and of baptism, marriage, and burial. Known by various terms in Catholic and Protestant regions, they vary in continuity and the diligence with which they were kept. Among the best are the Swedish catechitical and similar records (Lext 1984).

3. Methods of Family Reconstitution

The work of family reconstitution was from its inception strongly dependent on the paleographic and historical skills and intuition of the scholar. The earliest efforts were done by hand, starting with a marriage record, then attempting to find the burial and any remarriage records of the spouses, then the baptismal records of the children, then the marriages and deaths of those children. Such data were entered on a 'marriage fiche' or 'family reconstitution form' for later collation and analysis. Account had to be

taken of the literacy of scribes, variations in spellings of the same names, variations in standardization of surnames, and of course the completeness of the records themselves. Later attempts were assisted by computers, but final judgments often still depended on intuition in deciding between two or more equally plausible linkages. Efforts have been made to completely automate the linkage procedure, including the use of mathematical programming methods to resolve ambiguities, although it is not clear whether the algorithms themselves may not simply substitute new for old biases (Wrigley and Schofield 1973, Welford 1989, Shannon et al. 1989, Skolnick 1973, Schofield 1992, Nault and Desjardins 1989, Bouchard 1992, Bengtsson and Lundh 1991, 1993). It is difficult to know when the correctness of the nominal links in a dataset has been maximized, especially when data are scanty or contain errors. For example, if surnames are often omitted in the parish documents, and especially if the stock of first names is small (e.g., 'John married Mary, June 1, 1712'), the number of alternative linkages can be very large because many Johns may have married Marys on that date. In principle linear programming methods can be used to obtain the best solution, one that maximizes the density or quality of linkage, but that solution may not be historically correct. Estimates of central tendency (e.g., the general fertility rate) will not be biased by such presumably random error, but variances will be, as will be any associations with other variables if guesses are more likely to be bad for some classes of persons. The results of nominal record linkage may be compared to population registers, but population registers also have problems of accuracy. Such problems of optimizing linkages are of course less when data are detailed (e.g., Swedish parish and population register records) or contain ethnographically validated clues to linkage (e.g., interfamilial patterns of godparenting in some South Slavic contexts wherein children of a marriage tend to have the same godparents, who also serve as marriage witnesses, etc.).

4. *Limitations of the Technique*

Although a powerful tool, family reconstitution has important limitations caused by missing data. Some stem from the nature of the sources.

4.1 *Data Quality and Coverage*

While some parish records (e.g., Florence, Istria) go back to the fifteenth century, most do not commence until the sixteenth, and many are not reliable until the eighteenth century. Civil event and population registers are generally no older than the nineteenth, but ecclesiastical registers are often as old as the corresponding event registers. *Libri status animarum* were only irregularly kept in many areas, and all ecclesiastical records were subject to variations in quality depending on the abilities and dedication of the recording priest, attempts by higher authorities (both ecclesiastical and civil) to collect sufficient and standardized information, and the vagaries of copying and preservation. Ecclesiastical records are known for Catholic and Protestant populations but seldom for Orthodox Christians (not to mention Muslims, Jews, or others). Thus in areas of mixed religion, for example, in nominally Catholic Croatia or parts of Bosnia, large non-Catholic proportions of the population would not be included in the data and investigation of regional patterns would be hampered. Remarkable discontinuities in the data can occur in periods of shifts in religious adherence, as for example sharp swings between conformity and nonconformity in English parishes, or the widespread conversion of Catholics to Islam in the western Balkans. Similar problems would arise in using missionary records outside of Europe and the Americas. *Civil* event and population registers are by their nature relatively independent of religious bias, although they may miss subpopulations whose members for other reasons are under-registered.

4.2 *Statistical Biases Caused by Sample Selection*

Probably the most serious problems for family reconstitution are selection bias and truncation, issues addressed early by L. Henry (1956, 1967).

4.2.1 Selection by data quality. Where data are in general of acceptable but varying quality, there is an inherent tendency to want to analyze records that are only of the best quality. The socioeconomic condition and demographic regime of a part of a population that has good records may be quite different from those of another part that has poor records. Analysis limited to only the best data may give a misleading picture of the whole, either with respect to entire parishes or to subpopulations within parishes. This kind of selectivity bias is similar to that experienced in the analysis of genealogical data.

4.2.2 Selection by migration. Because the work of linkage is so tedious, even with computer assistance, most reconstitutions have been limited to single parishes. Out-migration from such parishes will ordinarily go unremarked in parish records (and even sometimes in household registers). Since the kinds of

persons who complete their lives within a parish may be quite different from the kinds who leave it, building a demographic picture of a parish based on completed lives may be misleading. These and similar problems (see below) can be partly overcome by analysis of a set of contiguous parishes, especially if migration tended to be short-range. Migration effects may be powerful where migration flows were strong (viz. Ruggles 1992, Kasakoff and Adams 1995, cf. Wrigley 1994). Reconstitution data have been used to examine migration *per se* (Bideau and Brunet 1993).

4.2.3 Truncation and censoring. The time actually spent in a parish by a person who was not born in it or did not die in it may be unknown, and thus the time at risk of some demographic event may not be known. Many demographic measures cannot be properly estimated if time at risk is not known. For example, a woman may have had recorded births but no recorded death. The amount of time she was actually at risk of having the next birth cannot then be accurately estimated. Thus, the fertility of women at her achieved parity or at ages higher than that of her last recorded birth cannot be estimated accurately. For example, estimating the total fertility rate for the population would demand knowledge of the age-specific fertility rates by the usual five-year age groups or by single years, and the loss of information on some women who died without record within such spans would deflate the denominators of the rate calculations.

In general, observation on individuals at risk of some event is said to be truncated if the size of the cohort at risk to which the individuals belong is unknown and censored if the number of individuals at risk is known but the events are unobserved or if observed events are recorded only in time intervals instead of accurately (see *Event-history Analysis in Continuous Time*). Examples are: (a) death records lacking age so that date of birth is unknown and the number of persons in the birth cohort cannot be recovered from birth records (truncated on the left); (b) death records with age recorded but birth records unavailable so that information is obtained only on persons who died at each age, not on those who survived that age (truncated on the right); (c) no marriage records but death records with age information showing survival and marital status so that the birth cohort size is known but the date of marriage is not (censored on the left); (d) birth and marriage records but no information on death so that observation ceases on the date of marriage (censored on the right). If statistical methods take censoring into account, censoring induces no bias in the computation of rates or probabilities of occurrence of an event, or in event-history analyses (see *Event History Analysis: Applications*). By contrast, truncation does induce such bias. As a general rule, the onset or cessation of observation of an individual at risk should not be correlated with the event of interest.

Solutions to the problem of missing data in sets of life histories are various but problematic. They include using the occurrence of another event to the same individual (e.g., next births if interest is in mortality), random censoring, occurrence of an event to a close family member (thus implying continued residence and at least potential registration of an event), or statistical imputation of the censoring point, etc. (Hammel 1993, Trussell and Guinnane 1993).

4.2.4 Bias from delays in recording. Bias may also be created by delays in the recording of demographic events or in the ceremonies that recognize them. An individual may die or move before an event is recorded and therefore be missed. Such delay is especially problematic for births and infant deaths. If the date of recording is accepted as the date of birth, long delays will make infants seem younger than they are, biasing any age-related computations. If an infant dies before it can be baptized, there will be no record of the birth, and often there will be no record of the death since unbaptized infants often received no formal burial. If the death is recorded and an age at death is given, the date of birth can be imputed and thus recovered. If death is unrecorded, mortality may be underestimated. Where both birth and death are unrecorded, infant mortality will also seem to be lower than it really is. Since in many historical populations up to a third of infants died in their first year, and half of those died in their first month, such statistical biases can be very important.

5. *Prospects*

The most promising outlook for family reconstitution and related techniques include the extension and elaboration of computer-based mathematical programming methods for rigorous and testable nominal data linkage, the combination of multiple data sources such as parish event registers, population registers, tax and notarial records, etc. to increase the accuracy and scope of data, and the use of event-history techniques to overcome problems of missing event dates.

6. *Summary*

Despite difficulties imposed by the quality and coverage of the historical data and the possibility of biased inference, family reconstitution has given demographic and historical scholarship a remarkable window on the demographic past, unachievable by any other means. In so doing it provides information for

much longer spans of time than do modern data and often for periods before any effects of industrialization or modernization have been felt. It thus allows examination of longer term trends under broader socioeconomic conditions, and like all historical enterprises allows scholarship to escape the constraints imposed by modern conditions.

E. A. Hammel

Demographic Techniques: Indirect Estimation

Noted Princeton University demographer Ansley Coale jokingly described indirect estimation as 'making bricks without straw.' Straw, in this case, consists of the traditional data sources for producing basic descriptive measures of demographic processes: civil registration for numbers of events and population censuses for exposure to risk. Many countries, particularly in the developing world, lack complete or accurate traditional data. Events may not be registered, components of the population may not be enumerated in the census, or information about key demographic characteristics such as age, may be reported with substantial error. Indirect estimation techniques were developed to try to obtain valid estimates of demographic measures in situations where the traditional data were not directly usable. Key characteristics of such techniques are that they be simple to implement and that they be robust to standard patterns of reporting error. The father of such techniques was William Brass. It was he who realized that simple demographic models could be used to simulate population processes, and provide a basis for converting indirect indicators into standard demographic measures. Although numerous authors have developed or refined indirect methods, they all owe an intellectual debt to Brass. The methods are only outlined here, but many of them are described in detail in United Nations (1983).

For conceptual purposes, it is useful to divide estimation techniques into two broad families. One family consists of true indirect estimation techniques. The strategy underlying indirect techniques is to find a readily measurable indicator that is largely, but not entirely, determined by the parameter of interest. Simulations developed using demographic models are then used to explore the relationship between the indicator and the parameter of interest, and to develop a simple approach to adjusting the indicator for other confounding factors, to provide a pure estimate of the parameter itself. An example of such an indicator is the proportion of dead among children ever borne by women of a given age group. This proportion is an indicator of the level of child mortality, but it is also affected by the age pattern of childbearing.

The second family is made up of consistency checks. Different indicators of the same demographic process are compared, either using models or formal demographic relationships. Differences are interpreted as indications of data error. Assumptions about the nature of data errors can sometimes justify adjustment of one set of indicators for presumed error in order to arrive at an improved overall estimate of the underlying process.

1. *Indirect Methods*

Reverse projection can be used to estimate recent aggregate fertility levels from the population age structure by allowing for mortality. The approach has a long history, but has not proved particularly useful. First, a common error in age distributions is for the population under age five years, to be under-recorded. This error causes recent fertility estimates based on reverse projection, to be too low. Second, the method is sensitive to the assumption of no (or not known) migration. Third, mortality rates have to be known at least approximately. Fourth, the fertility indicator estimated is the birth rate or General Fertility Rate; no detail about age patterns of fertility is provided.

This last shortcoming is avoided by the 'Own Children' variant of reverse projection (Cho et al. 1986). Children are matched to a likely mother within each household using criteria such as age and parity. Information on age of child provides a time period for the fertility measure, and in combination with age of putative mother provides the age of the mother at the time of the birth. Unmatched children are distributed proportionately, and both children and women are reverse-projected using appropriate mortality estimates. A suitably-matched age distribution thus provides estimates of age-specific fertility rates for calendar years prior to the census or survey. Results remain sensitive to age reporting errors, however, and the other problems of standard reverse projection.

Fitting stable population models to an observed age distribution in combination with one other indicator

such as the population growth rate or probability of dying by age five years represents another way of indirectly estimating fertility. Stable population analysis is of limited value today, because widespread declining fertility has affected age distributions worldwide. Preston (1983) has developed an elegant approach based on a generalized equation of age structure and a logit transformation of a standard life table survivorship function. The reciprocal of the proportion of the population of a particular age a, $c(a)$, inflated by the exponentiated sum of population growth rates (adjusted if necessary for migration) up to age a, $\exp(R(a))$, is linearly related to the logit of the standard survivorship function to age a, $(1-p^s(a))/p^s(a))$. The intercept of the straight line is the reciprocal of the current birth rate, $1/b$, and the slope is an indicator of the actual mortality level relative to that of the standard survivorship function, itself divided by the birth rate, (γ/b). Thus

$$1/\{c(a)\exp(R(a))\} = 1/b + (\gamma/b)\{(1-p^s(a))/p^s(a)\} \quad (1)$$

This method is an excellent example of how the mathematics of population age structures can be used to improve demographic estimation techniques.

The best-known and most widely applied indirect estimation method is the Brass (1964) method for estimating child mortality from women's reports of the number of children born alive and the number that have died. It is argued that these reports, which involve no reporting of dates of events, are likely to be accurate in most populations, even those with substantial levels of illiteracy. The key indicator is the proportion dead of children ever born: the higher the level of child mortality, the higher the proportion dead, other things being equal. Brass' contribution was devising a method to make other things equal. First, the data are classified by age of mother as a crude control for the average duration of exposure to risk of dying of a mother's children. However, the age pattern of childbearing still affects average exposure time. For women of a given age group, average exposure time of the children will be longer in an early childbearing population than in a late childbearing population. Brass used models of fertility and child mortality to evaluate adjustment factors $k(i)$ for each five year age group of mother i needed to convert proportions dead $PD(i)$ into life table probabilities of dying in childhood, ${}_nq_0$, for a range of age locations of childbearing. In a particular application, the age location of childbearing was identified by the ratio of average parity for 15–19 year olds to that of 20–24 year olds, $P(1)/P(2)$, and appropriate values of $k(i)$ were obtained by interpolation from a standard table.

The original Brass method has undergone numerous refinements. Perhaps the most crucial development, however, was the insight by Feeney (1980) that under conditions of changing mortality, approximate reference dates could be put on estimates from different age groups of mother: the older the mothers, the further in the past the child mortality reflected by the survival of their children. Methods were developed not only to estimate levels of child mortality indirectly but also to estimate the recent time trend. Figure 1 shows the application of the method to data from the 1989 census of Kenya, together with direct estimates from the 1993 Kenya Demographic and Health Survey.

Figure 1
Application of Brass method to child survivorship data, Kenya 1989 Census

The Brass method and the developments of it have been very widely applied. It revolutionized knowledge of mortality conditions, particularly in sub-Saharan Africa but also in Latin America. It also gave rise to a concerted effort to find indirect estimation methods for adult mortality and migration. As such, it has proved one of the most influential ideas of demography.

The Previous Birth Technique is another indirect method for child mortality estimation. Where information is available or can easily be collected concerning the survival of the birth immediately preceding a current delivery, the proportion dead among the preceding births can be calculated (Brass and Macrae 1984). The proportion dead turns out to be a good indicator of the probability of dying by age 2, ${}_2q_0$. Some information on average birth intervals permits refinement of this equivalence. The method is very easy to apply, but suffers from concerns about selection bias since reports are typically obtained from health facilities.

A number of indirect estimation methods have focused on adult mortality. One group relies on information on survival of close relatives. Adult survivorship can be estimated from information on survival of mothers or fathers (Brass and Hill 1973). The age of the respondent is the exposure time, the age distribution of parents at the time of the births of a

group of respondents, the confounding variable that needs to be controlled. An ingenious approach to the estimation of maternal mortality has been the development of the Sisterhood method (Graham et al. 1989). Data are collected on survival of sisters with additional information for reported deaths about the timing of death relative to pregnancy. Despite the ingenuity of these approaches, questions remain about their accuracy.

A second group is made up of various forms of intercensal survival methods. Females aged 20–24 in 1990 will be aged 30–34 in 2000, so in the absence of net migration the ratio of females aged 30–34 in a 2000 census to females aged 20–24 in a 1990 census approximates the life table survivorship ratio ${}_5L_{30}/{}_5L_{20}$. Age distributional effects will be modest, but age misreporting and changes in census coverage can have large effects on such ratios, which as a result tend to be of little value in most developing countries. Generalized age structure equations involving age-specific growth rates have been used to minimize the effects of local age misreporting (Preston and Bennett 1983), but the method does not reduce effects of systematic age bias or coverage change.

The measurement of migration is problematic in many situations, because even sophisticated recording systems miss events. Net migration is often estimated as a residual from intercensal survival. In the example above, if the survivorship ratio ${}_5L_{30}/{}_5L_{20}$ is known, a predicted number of females aged 30–34 in 2000 can be calculated by multiplying the number of 20–24 year olds in 1990 by this ratio. The difference between the observed and expected number of females aged 30–34 in 2000 is then an estimate of net intercensal migration by the 20–24 cohort. An alternative estimation procedure (Hill 1987) is available using the Demographic Balancing Equation: the change in size of an age group between two censuses is equal to the difference between intercensal entries (birthdays across the younger boundary of the age group plus in-migrants of the age group) and intercensal exits (birthdays across the upper boundary of the age group, deaths of the age group and out-migrants of the age group). Net migration can then be isolated and estimated from the other components. This latter approach has the advantage of producing estimates for age groups rather than cohorts. Both approaches, however, estimate migration as a residual, and are thus very sensitive to even quite small errors. Unlike most indirect estimation techniques, the indicator variable (change in population size) may be determined more by the confounder (mortality) than by the parameter of interest (migration). Results are therefore not robust.

Efforts have been made to estimate emigration from information on residence of relatives, particularly of children as reported by mothers and of siblings. These methods have not achieved widespread acceptance, however.

2. *Consistency Checks*

The best-known consistency check and adjustment technique is the Brass (1964) P/F Ratio Method for fertility estimation. Records of births in a year by age of mother provide age-specific fertility rates. Information on children ever born by age of mother, provides measures of lifetime fertility. If fertility is not changing over time and the data are consistent, cumulated age-specific fertility to a particular age group will be the same as lifetime fertility or parity for that age group. Brass developed a simple way for cumulating current age-specific fertility rates to approximate parity equivalents ($F(i)$) in order to check consistency with parities ($P(i)$) for each age group i. However, he also went further, to hypothesize that typical errors in records of numbers of births might be proportionately constant by age of mother, so that the age-specific fertility rates would have the correct shape, but at a potentially incorrect level. Typical errors of reporting of children ever born, however, were hypothesized to vary by age, but to be smallest for younger women. Ratios of $P{:}F$ for successive age groups, thus not only reflect consistency but, for younger women, represent potential adjustment factors for the age-specific fertility rates.

The assumption of unchanging fertility can be relaxed if information is available on average parity for two points in time (Zlotnik and Hill 1981). Parity changes by cohort between the two sources can then be cumulated to obtain a period-specific parity distribution that can be compared with cumulated period-specific fertility rates. If the other assumptions hold, adjustment can be made even under conditions of changing fertility.

Consistency checks with the option for adjustment in the measurement of adult mortality have largely focused on comparisons of the age distribution of

Figure 2
Application of stable and general growth balance methods to data for China females

deaths with the age distribution of the population. The first such method was proposed by Brass (1975). In any population with negligible migration, the entry rate into any open-ended age segment $a+$ is equal to the growth rate of the segment plus the death rate in the segment. In a stable population, the growth rate r is constant at all ages, so if $b(a+)$ is the entry rate and $d(a+)$ is the exit rate,

$$b(a+) = r + d(a+) \tag{2}$$

If deaths are recorded with a completeness c (assumed constant at all adult ages) relative to the population, the recording of which is also assumed to be of constant completeness at all ages, and $b(a+)$ is estimated from the population age distribution alone,

$$b(a+) = r + (1/c)d^o(a+) \tag{3}$$

where $d^o(a+)$ is the observed death rate over age a. There is thus a linear relationship between the entry rate and the observed death rate, the intercept of which is the stable growth rate and the slope of which is the reciprocal of the completeness of death registration.

The assumption of stability can be relaxed if two successive population counts are available and growth rates over ages a can be measured directly (Hill 1987). If census coverage is constant within, but not between, the censuses,

$$b(a+) - r^o(a+) = k + (1/c)d^o(a+) \tag{4}$$

where $r^o(a+)$ is the observed growth rate over age a and k is the natural log of the change in coverage from the first to the second census. Figure 2 shows the application of both growth balance methods to Chinese census data for females, using the 1990 age distribution and deaths by age for the stable version, and 1982 to 1990 population change together with the distribution of deaths by age for the general version. The improved smoothness of the general version for this destabilized population is evident.

Other equations for population age structure can also be used as the basis for similar consistency checks. In an influential paper, Bennett and Horiuchi (1981) use the exponentiated sum of age specific growth rates above age a to expand the deaths at each age to equate deaths above age a to population age a. Though error patterns are likely to affect these methods in slightly different ways, there is no consensus as to which should be preferred in different situations.

3. Future Directions

Indirect estimation is an interim solution to data problems. Data quality will improve, rendering these techniques unnecessary. Birth histories have shown that reasonably accurate direct estimates of fertility and child mortality can be obtained by survey methods. However, for the foreseeable future, indirect estimates of child mortality based on census data will remain the only viable approach to studying small-area differentials in many parts of the world, and indirect estimates of adult mortality and migration still remain important approaches even at the national level.

Demographic Techniques: Inverse Projection

1. The Character of the Method

Inverse projection is a logical inversion of conventional projection techniques. The method uses crude data—annual totals of births and deaths, and an

Table 1
Eight inverse projection algorithms for estimating population dynamics from birth and death series

Author, year	Age structure (and size) of population				Age structure of mortality	Crisis mortality	Sexes: unisex or two	Comment
	Method	Initial	Final	Net migration				
Lee 1971, 1974	forward quinquennial	model or empirical	—	population at t1 − t0 + births–deaths	adjacent model life table Lxes	—	unisex	First inverse projection program: projected quinquennial estimates for both sexes combined; used adjacent life table functions and large open-ended age group (55+); estimated life expectancy poorly for low mortality populations
Brunborg 1976	forward quinquennial	model or empirical	—	population at t1 − t0 + births–deaths	bounded higher/ lower model life table Lxes	—	unisex	Extended age groups to 80+; used high/low model life tables to improve life expectancy estimates; calibrated method using Norwegian data, 1735–1974; suggested significant technical improvements for implementing forward inverse projection method
Wrigley and Schofield 1981	back quinquennial	—	empirical required	polynomial estimation	Coale and Demeny Region North	—	unisex	Projected English population dynamics back from 1871 to 1541; migration estimated by polynomial methods

Table 1

Author, year	Age structure (and size) of population				Age structure of mortality	Crisis mortality	Sexes: unisex or two	Comment
	Method	Initial	Final	Net migration				
McCaa and Perez Brignoli 1989, 1991	forward quinquennial or annual	model or empirical	optional	population at t1 − t0 + births–deaths	bounded high/low model life table functions or empirical rates	threshold, empirical death rates by age or model functions	female, two, or unisex	Projects female and male populations separately or combined; allows interactive comparisons in a single session; facilitates the incorporation of a wide range of models or empirical data for any interval in a projection; interpolates missing data; requires minimal inputs; widely tested
Bonneuil 1990, 2000	trend, optimized annual	—	empirical required	closed population	Lederman single parameter life table functions	threshold	unisex	Estimates underregistration of deaths; permits special treatment of crisis years; newer version uses simulated annealing methodology to produce a stochastically optimized admissable reconstruction of available data

Table 1
Continued

Author, year	Age structure (and size) of population				Age structure of mortality	Crisis mortality	Sexes: unisex or two	Comment
	Method	Initial	Final	Net migration				
Oeppen 1993	general annual or other	either or both		polynomial estimation	empirical or model life table functions	—	female, two, or unisex	Maximizes fit to a wide range of available data or hypothetical constraints using non-linear optimization techniques
Bertino and Sonnino 1995	stochastic annual	empirical required		population at t1 − t0 + births– deaths	empirical or model life table functions	empirical death rates by age or model functions	partial two sex	Uses nonhomogeneous Poisson microsimulation methods to estimate standard errors; forward and back versions permit sensitivity tests; uses initial age structure for males and females, but deaths by sex not required
Rosini 1996	differentiated annual	empirical required		population at t1 − t0 + births–deaths	empirical or model life table functions	empirical death rates by age	two or unisex	Applies age-specific mortality rates, when available; projects female population independent of male

estimate of initial population size—to infer refined demographic statistics—life expectancy, gross and net reproduction ratios, and even population age structures. Instead of deriving counts from age-specific rates, as with conventional cohort projection, inverse projection estimates age-specific rates from counts. Where authentic age details for the initial population or age pattern of mortality are unavailable, model data often yield acceptable results. The technique is particularly suited for studying populations of the past where age details are scarce.

Surprisingly accurate demographic statistics can be computed with the inverse projection method. As with most demographic techniques, the better the data, the better the estimates. What is startling about inverse projection is how little data is required to simulate the demographic history of places, large and small, over long periods of time within a range of a few percentage points (Lee 1985, McCaa 1989, McCaa and Vaupel 1992). Recent innovations (see Table 1) fine-tune the method to offer several different algorithms, including a stochastic microsimulation process which estimates not only a wide range of age-dependent demographic rates and measures but most importantly their standard errors (Bertino and Sonnino 1995).

Inverse projection is a method for estimating basic demographic statistics where the vital or parish registration system is relatively efficient, but where population censuses or surveys are lacking, infrequent, or unreliable. The technique requires a count of births and deaths year by year, and the size of the initial population. In the absence of reliable empirical age data, model age structures of mortality, fertility, migration, and even the initial population may be relied upon. In contrast to family reconstitution (see *Demographic Techniques: Family Reconstitution*), inverse projection requires only aggregate data of births and deaths, tallied by year. Thus, the demographic history of large areas is easily reconstructed with inverse methods. Where family reconstitution is labor intensive, inverse projection demands little effort to tally and computerize annual counts of births and deaths. Finally, family reconstitution's stringent methodological rules exclude a sizeable fraction of births and deaths from the calculations. The reconstitutable minority is unlikely to be representative of the majority of the population. Inverse projection applies powerful nonlinear models to data for the entire population. It is superior to stable population methods because no assumption of stability is required.

The inverse method has been used to construct population histories of states (England 1541–1871, Norway 1735–1974, Sweden 1750–1875, Denmark, the Philippines, Valencia 1610–1899, Italy 1750–1911, Chile 1855–1964, Bulgaria, Costa Rica, and Cuba 1900–59), regions (Northern Italy 1650–1881, the Canary Islands 1680–1850, Sardinia 1862–1921, and Scania 1650–1760), cities, parishes, and even missions (Colyton 1545–1834, Pays de Caux 1530–1700, Lucerne 1700–1930, Berne 1720–1920, Amsterdam 1680–1921, Velletri 1595–1740, and California). This list, although incomplete, includes studies which test a wide range of demographic hypotheses, from models of population change in industrializing Europe to demographic responses to epidemics.

2. *History and Scope*

Since Lee first created inverse projection in 1971, seven additional implementations of the method have been developed (Table 1). In each case, macrodemographic data for a parish, city, region, nation, or other geographical or administrative unit are required. The algorithms differ in the use of models to supplement missing or unknown parameters. In recent decades, as computing power increased, so has the sophistication and computational demands of the various methods.

Lee's classic forward inverse algorithm (1974) remains the simplest and most straightforward. Total population is required to initiate the projection. Counts of births for each period (quinquennia in Lee's first program) are added and deaths subtracted to obtain the population at the end of each interval. Where a count of the total population is known for a subsequent period, the projected total is subtracted from the observed to obtain an estimate of net migration, which is apportioned equally among the intervening periods.

The initial age structure of the population may be obtained from either a census or a model. Lacking an empirically derived age structure, the demographically naive might stop at this point, but Lee (1974, 1985) and others have shown that even an arbitrarily chosen model age structure yields remarkably robust estimates (Brunborg 1976, Wachter 1986, McCaa 1989, McCaa and Vaupel 1992, McCaa 1993). Moreover, the bias of a poor choice rapidly disappears as the stream of vital rates molds the projected age structure period by period with births added to the base of the pyramid at age zero and deaths subtracted from the slope, age by age.

'Vital rates, not initial states' is the inverse projectionist's mantra, but this is not a matter of faith. The theoretical foundations of inverse projection lie in the 1920s with the work of H. T. J. Norton on the weak ergodicity theorem, and in the 1960s with its rediscovery by Alvaro Lopez (Wachter 1986). The method rests on what Kenneth Wachter has called 'the cornerstone of formal demography': the notion that, in the long run, vital rates, not initial states, determine what a population will look like. Lee has shown that population age structures are quickly forgotten, even when punctuated by demographically critical events such as epidemics, wars, baby booms, and baby busts

(Lee 1985). The weak ergodicity theorem teaches that when it comes to age distributions, populations have no memory. As populations are projected through time, the initial age structure is displaced by consequences of birth, death, and migration rates. For all practical purposes, populations subject to the same initial population size and identical streams of births, deaths, and migration will converge, even though they may begin from radically different age structures. A century into a projection erases even the most peculiar initial age structure. On the other hand, population size remains a powerful constraint. If it is mis-specified and the population growth rate is negative, distortions will mushroom. Where the population is growing, the effect of this bias diminishes over time (McCaa and Vaupel 1992).

The ingenuity of Lee's method is how, in the absence of data, deaths are apportioned by age (Lee 1974). As a first approximation, an arbitrary set of age-specific death rates from a single-parameter family of life tables is applied for the quinquennium. The product of these rates and the age structure at the beginning of the interval yields an estimate of the number of deaths for each age group. Adding over all groups and dividing by the total number of observed deaths yield an adjustment factor called the normalized death ratio. This factor is a measure of the discrepancy between the observed number of deaths and the number projected given the age structure and level of mortality from model life-table rates (see *Demographic Models Demographic Models*). As a second and final approximation, the normalized death ratio is used to compute the exact number of deaths at each age. These numbers will add up to the total fror the entire interval. This is accomplished directly by, first, subtracting age-specific rates between the model life table used in step 1 and an adjacent table from the same family. The result is a domain of mortality variability at each age. This domain is used to interpolate an adjusted age-specific death rate. This is accomplished by multiplying the normalized death ratio and the mortality domain at each age and adding the result to the first approximation. This yields a final estimate of deaths for each age group. Added up, they equal the total deaths for the period. Net migration by age is apportioned crudely as a function of age-specific rates and a level parameter for each period. Where migration is minor relative to mortality, this solution—required due to lack of data—produces acceptable results. Fertility statistics are by-products of inverse projection, and are wholly independent of age estimation and projection. The number of births for each time interval is determined by the stream of vital events. What is lacking is a summary fertility statistic which takes into account the age structure of the population. A solution common to all inverse projection algorithms is the estimation of the gross reproduction ratio from the number of births, the age structure of the population, and a normalized age pattern of fertility.

3. *Expansions*

Four important expansions of Lee's inverse method emerged in the last decades of the twentieth century: a full range of age groups, annual projections, crisis mortality, and two-sex models. To reduce computation costs, Lee's 1971 algorithm crudely lumped the oldest ages into a group for ages 55 and over. Extending the number of age groups beyond age 55 and over so that the final, open-ended group accounts for only a small fraction of total deaths was the first, most significant, and least controversial innovation in inverse projection methods. Brunborg (1976) quickly discovered that this shortcut introduces a substantial bias, particularly where a large fraction of total deaths occurs in the final age group. As long as life expectancy at birth is less than 30 years, the effect of lumping is small, but where life expectancy is moderately good, highly variable, or improving, error becomes substantial. Brunborg's algorithm and all subsequent ones allow the user to apply a more reasonable upper-age interval, such as 75, 90, or even 100 years and older.

A second important enhancement of the inverse method was the development of single-year projections in place of five- or 10-year periods. Anticipated by Lee and Brunborg, annual projection cycles were first implemented by Bonneuil's trend method (1993). Initially, there were objections to annual projections as spurious precision until Bonneuil demonstrated that aggregation into five- or 10-year periods can introduce serious distortions. Aggregation flattens mortality variation, and thereby flattens the population age structure whenever a mortality crisis occurs. With quinquennial or decennial projections, mortality domain interpolation dampens variation throughout the population age structure. Annual mortality spikes are transformed, at best, into waves which continue to undulate through the age pyramid over subsequent cycles. Now that computation costs are no longer a constraint, annual projections are becoming common, although some inverse projection algorithms still permit quinquennial or even decennial projections as an option.

Crisis mortality, due (say) to epidemics, famine, or other demographic catastrophes, is poorly approximated by model life tables. For the inverse projectionist, the alternative is either to apply a special set of age-specific death rates (empirical or model) for the crisis years (Bertino and Sonnino 1995) or to fix a crude death-rate threshold to mimic the impact of crises on the population age structure (Bonneuil 1993, McCaa 1993). In crisis years, mortality domain interpolation will assign too many deaths to age groups in which the spread is greatest, principally to infants, children, and the oldest or open-ended age group. The optimal solution is to use empirically derived age-specific death rates peculiar to the type of crisis. Less desirable, although widely used due to the scarcity of age-specific data for these situations, is to set a mortality threshold,

say a crude death rate of 40 per thousand population (Bonneuil 1993, McCaa and Vaupel 1992, McCaa 1993). Deaths below the threshold are apportioned according to standard inverse methodology. Any excess is then apportioned at a flat rate for each age group. Although this is an arbitrary fix, the effect is to produce more robust estimates of life expectancy and population age structure than that provided by the standard method.

Single-sex projections were the norm with the first inverse projection programs, produced when computer time was scarce. Now that this is no longer a constraint, two-sex projections are becoming frequent where births, deaths, and population size are readily available by sex. Precision is an obvious benefit, and so is the ability to model gender differences in mortality and migration.

4. Related Methods

Back projection was developed as a means of dealing with the closure problem. Wrigley and Schofield used back inverse projection for their massive reconstruction of the population of England, 1541–1871 (Wrigley and Schofield 1981, Oeppen 1993b). In the long run, most populations are not closed, and that of England is no exception. While forward inverse projection takes into account authentic migration data, Lee's method cannot produce migration flows (Lee 1993). Back projection seeks to generate migration estimates from a terminal age structure by backcasting the population against the flow of births and deaths. While it might seem commonsensical to begin with the best, i.e., most recent, data and project backward, Lee argues that this ignores the weak ergodicity theorem. In Lee's words (1993), 'the problem originates with the attempt to resurrect people who have died into the oldest age group, an attempt that is, in practice, hypersensitive to error.' The Cambridge team used iteration procedures to settle upon a single series of best estimates.

Generalized inverse projection is a response to Lee's criticisms of back projection, and broadens the method into an analytical system which exploits whatever data are available as well as a broad range of assumptions or constraints, including components derived from back projection (Oeppen 1993a, 1993b). Generalized inverse projection uses a standard method of demographic accounting and standard nonlinear optimization algorithm to overcome a range of empirical and theoretical problems. Among these is the temptation to estimate migration endogenously by means of smoothing parameters.

Other flavors of inverse projection were developed, on the one hand, to extend projections back to the first years of parish registration, where either the birth or death series begins somewhat earlier than the other (Bonneuil 1993, 2000), and, on the other, to maximize the use of data available in specific countries, such as population censuses or *status animarum* containing age details (Rosini1996). The most innovative recent algorithm is stochastic inverse projection, a microsimulation technique which seeks to assess the variability in a population's evolution (Bertino and Sonnino 1995). Instead of a single deterministic solution as with forward inverse projection, the stochastic method offers many solutions by simulating individual mortality events as a nonhomogeneous Poisson process. Three additional assumptions are required: deaths must be uniformly distributed over the year, they must be independent of each other, and every person must have the same mortality function as contemporaries at each point in time.

5. Calibration and Limitations

Lee first calibrated the method against family reconstitution results for the parish of Colyton, 1545–1834 (Lee 1974). In addition to confirming the general findings of an excellent family reconstitution study of Colyton, Lee was able to gain new insight on periodic shifts in fertility and mortality that are not readily discernible with the family reconstitution method. For example, he placed life expectancy at birth for the plague years 1645–9 at less than nine years. A second important calibration was Brunborg's reconstruction of the population history of Norway, which he compared with statistics derived from highly accurate age-specific data over the course of more than a century (Brunborg 1976). The results were remarkably consistent, tracking the official life expectancy at birth figures from a low of 43.7 years in the 1830s to a high of 74 years in the late 1960s. Average error was roughly two years. What most surprised Brunborg was how little difference the various mortality suppositions made on the estimates of life expectancy and age structure.

The most important lesson from Brunborg's experiments was that the quality of data is the critical factor for successful inverse projections. Later his findings were confirmed by a series of wide-ranging tests by a skeptical demographer, who challenged an inverse projection enthusiast to a double-blind experiment, indeed to a dozen such experiments (McCaa and Vaupel 1992). Vaupel used conventional cohort component projection techniques to simulate a wide range of demographic histories and challenged McCaa to reproduce the results for each from the bare minimum required for inverse projection: the birth and death series, and initial population size. The results were spectacularly successful; so much so that they led to the discovery of a flaw (bug) in the benchmarking program.

Vaupel's challenge led to the discovery that the required model age data could be ascertained directly by minimizing the normalized mortality ratio. This statistic can be used as a measure of goodness of fit where model age data are required, such as for the

initial population and the age structure of mortality (McCaa 1993). The k ratio is an indicator of the age-standardized intensity of mortality relative to the initial age structure of the population and to the pair of age-specific mortality schedules used to project the population by age to the next period. The sum of squares of this ratio is a useful measure of goodness of fit when the birth and death series and initial population size are held constant. In other words, where two inverse projections differ only in terms of model age structures of mortality or initial population, the squared ratio can be used to identify the better-fitting models. Best-fitting models have the lowest squared ratios. However, if the statistic is to be a reliable guide, the stream of counts and initial population size must remain the same to compare projection results.

Vaupel's challenge confirmed that data quality remains the most important constraint for successfully applying the method. Careful attention should be given to spikes in mortality or surges in migration. They may confound the normality assumption of how these events should be distributed over the age structure.

6. *Prospects*

The inverse method requires good vital registration data. For historical studies, this limits its usefulness primarily to the European cultural area. Nevertheless, even here, only a small number of potential applications have been attempted. Lee's challenge that the method be extended to the modeling of marriage and legitimate fertility has gone unanswered. The inverse method could also be extended to other demographic measures where authentic scale parameters are available and age patterns can be modeled, as in the case of parity progression ratios (Feeney 1985). The most important contribution of the method is its illumination of demographic processes in the past. In the case of England, for example, thanks to inverse projection we now know that the great surge of population in the late eighteenth century was due to a rise in fertility, rather than to a fall in mortality, as had long been supposed (Wrigley and Schofield 1981).

Demographic Techniques: LEXIS Diagram

The quintessential building block of demographic analysis is a set of occurrence/exposure rates computed by dividing the number of occurrences of a selected demographic event in a (sub) population into the corresponding number of person-years under risk. The event may be repeatable, which means that it may occur more than once in the life course of an individual, such as geographical moves and the birth of children. Alternatively the event occurs only once in a lifetime, such as a first birth or a first marriage, or at the end of life, namely death. For repeatable events, the occurrences recorded for each age group are divided by the total number of person-years observed in the same age group, and one gets quantities like births per 1000 woman-years at ages 30 to 34. For non-repeatable events, the occurrences in the age group are divided into the number of person-years observed among population members who have not yet experienced the index event, and one gets quantities like first births per 1000 person-years among childless women. Demographic rates may be computed for a calendar period or for a birth cohort, by age attained at the time of occurrence or at the end of the calendar year of occurrence. Demographers keep track of this plethora of rates by means of a simple graphical device that has become known as the LEXIS diagram. The purpose of the present Encyclopedia article is to explain this diagram and show how it can be of help in describing usage of rates in each particular analysis.

Demographic rates are computed according to different conventions in different countries, and some countries have changed their practice over time. This makes it difficult to compare series of rates across countries and sometimes over time. To enable analysts to improve comparability, we will also provide conversion formulas that can be used to compute selected types of rates from the ingredients originally intended for the computation of other rates. We also provide methods to eliminate biases produced when standard procedures are applied to unsteady flows of births caused by major political events like wars. Such biases only affect certain birth cohorts, but in the disturbed cohorts all ages are involved.

1. The LEXIS Diagram

The LEXIS diagram provides a visual representation of occurrences and exposures across age and time. Since age and time increase in lockstep, a basic ingredient in the diagram is the lifeline of a person, showing age plotted against time on a 45-degree line starting at the time t_0 of birth and at age zero. If an event occurs to the person at a given time t, the age $t-t_0$ of that person at the time of occurrence is the ordinate of abscissa t on the lifeline.

Figure 1
Lifeline of a person born at time t_0

The LEXIS diagram pertains to the residents of a given territory. The start of a lifeline may be the birth on the territory. In that case, the lifeline begins at the horizontal axis. When a person immigrates at age x at time t, the lifeline starts at the point (t, x). The end of the lifeline corresponds to the death or outmigration by the person.

Major vital events (births, deaths, marriages, divorces) are typically recorded through a vital registration system, which provides breakdowns of events by the age of the persons concerned. Residents are periodically enumerated through censuses, which record the date of birth (or the completed age on the census day) of the respondents. At least at the national level, censuses are sometimes updated every year on a fixed date, most often January 1, so that the distribution of residents by single year of (completed) age is usually available annually. The number of persons whose completed age at time t is i is the number of lifelines that cross the vertical segment $(t, [i, i+1])$. These persons were born between times $t-i-1$ and $t-i$.

Two events that occur simultaneously are located on the same vertical line in the LEXIS diagram. Two non-simultaneous events that occur to persons having the same age at the time of occurrence are located on a horizontal line. Two non-simultaneous events that occur to persons born at the same time are located on a 45-degree line.

The events that occur during a given period (e.g. a given calendar year) are located in a vertical strip, between the vertical lines corresponding to the beginning and the end of the period (Fig. 2). Those that occur to persons whose age at the time of occurrence belongs to the same age group are located in a horizontal strip. Those that occur to persons born during the same period (i.e., who belong to the same birth cohort), are located in a 45-degree strip.

Figure 2
Regions in the LEXIS diagram. (a) Events occurring during the same period to persons of various ages. (b) Events occurring during the same year to persons who had the same age in completed years at the time of occurrence (members of two cohorts). (c) Events occurring to persons whose age was in the same age group at the time of occurrence. (d) Events occurring during the same year to persons who attained the same birthday during that year (members of the same cohort). (e) Events occurring to persons who belong to the same cohort. (f) Events occurring during two consecutive years to members of the same cohort who had the same age in completed years at the time of occurrence

2. Age

The exact age of a person on a given date t is a continuous variable. It is equal to the exact duration from the date of birth to date t. In most connections and in common language, exact age is grouped to take only integer values, however, and this makes age a discrete variable. We then refer to it as age at last birthday, or age in completed years, or completed age. The distribution of residents by age on a given date is a breakdown of the population by completed age. If the date is January 1 of year n, persons then aged i in completed years are the residents born during the year $n-i-1$.

Tables classifying the events that occurred to residents during year n by age, may be presented either by completed age at the time of occurrence or, based on the year of birth, by the age that has been or will be attained during year n. The events of year n that correspond to completed age i (as measured at time of occurrence) are located in a square of the LEXIS diagram. Those that correspond to the same year of birth i.e., to the same age i attained during the course of year n or, in other words, to the same completed age i on December 31 of year n, are located in a parallelogram with vertical sides. A third possibility that combines the two consists in retaining completed age but distinguishing persons according to whether the birthday they celebrated in year n fell before or after the occurrence of the event. When the latter distinction is made, the numbers of events refer to triangles in the LEXIS diagram, the lower triangle of the square concerns persons whose birthday in year n was before the occurrence of the event, the upper triangle those for whom it was after. Note that persons for whom an event was recorded during year n at completed age i were half a year older than those who had it recorded at attained age i on 'average' at the time of occurrence. The former had an 'average' exact age equal to $i+\frac{1}{2}$, the latter an 'average' exact age equal to i. (What we mean by 'average' here will be made clear later.) This half a year difference may be of some importance. For example, teenage fertility, defined as fertility below age 20 years, may differ by as much as 25 percent if age is defined in terms of completed age instead of age attained during the year.

3. Rates of the First and Second Kind

Suppose that one's interest focuses on a given demographic (or other) event. For each region in the LEXIS diagram where the data are available, the analyst may record the number of occurrences of the event in question. For repeatable events, one may also add up the lengths of all lifelines that intersect the given LEXIS region (or their projections on the time axis) to get the total person-years of exposure to the risk of occurrence of the event in question. The ratio between the number of occurrences and the latter exposures is the corresponding occurrence/exposure rate.

For non-repeatable events one can compute two kinds of rates. The rate of the first kind (or occurrence/exposure rate) is computed using lifelines interrupted at the time of event occurrence. Their denominator is again the 'total person-years exposed to risk.' A corresponding rate of the second kind (or occurrence/population rate) uses the same occurrences, but the denominator is computed in the same manner as for repeatable events i.e., lifelines are not interrupted at the time of event occurrence. If the non-repeatable event always terminates a lifeline, the rates of the first and second kind coincide and there is a single occurrence/exposure rate for the given region. This is of course the case if the event is death or out-migration.

Rates of the second kind are sometimes computed because the aggregate data do not provide the person-years exposed to risk but only the total number of person-years for the LEXIS region selected i.e., the person-years at risk plus the person-years for members of the population who are no longer at risk. A case in point is when first marriages observed in the relevant population segment are referred to the total resident population in the same segment, instead of only to the person-years for the never-married, perhaps because the latter exposures are not available by sex and single years of age on an annual basis. Another example arises when births of a given order are divided by the total number of person-years lived in the same population segment instead of only by the corresponding number of person-years for persons of the previous childbearing parity. This article is concerned with rates of the first kind. Rates of the second kind are discussed in a companion article, as is the connection between the two kinds of rates (see *Demographic Techniques: Rates of the First and Second Kind*).

To avoid using many decimals, the rates are normally multiplied by a convenient factor like 1000, 10,000 or 100,000 before tabulation. If the factor is 100,000, such a rate is said to be computed 'per 100,000 person-years,' where for rates of the first kind the latter are years of exposure to risk.

4. A Mathematical Framework of the Study of Occurrence/Exposure Rates

4.1 Repeatable Events

Let us consider a person exposed between ages α and ω to the occurrence of a *repeatable* event E, and let us reason as if the person is not exposed to any other event (in particular, no migration and no death). Let $\lambda(x)\,\mathrm{d}x$ be the probability that E occurs to this person

between exact ages x and $x+\mathrm{d}x$. Outside the interval (α, ω), $\lambda(x)$ is zero. Then function λ is called the risk function of the repeatable event E.

By the properties of a Poisson process, the expected total number of occurrences of E to this person is $\int_\alpha^\omega \lambda(x)\,\mathrm{d}x$. If we let $f(x) = \lambda(x)/\int_\alpha^\omega \lambda(u)\,\mathrm{d}u$, we can regard this as the density of a probability distribution with mean $m = \int_\alpha^\omega xf(x)\mathrm{d}x$ and variance $V = \int_\alpha^\omega (x-m)^2 f(x)\,\mathrm{d}x$. If the field of study is fertility and the event E is the birth of a child to a woman, the integral $\int_\alpha^\omega \lambda(x)\,\mathrm{d}x$ is called the cohort-completed fertility (CCF) and is the average number of children per woman. The mean age at occurrence is called the mean age at childbirth.

4.2 Non-repeatable Events

If the event E can happen only once in a lifetime, then $\lambda(x)\,\mathrm{d}x$ is the probability that E occurs to a given person between exact ages x and $x+\mathrm{d}x$, provided it has not occurred by exact age x. According to standard single-decrement life-table theory (see *Life Table*), the probability that the event E does not occur to a given person before age $x > a$ is $\ell(x) = \exp(-\int_\alpha^x \lambda(u)\mathrm{d}u)$. The probability that event E occurs between ages x and $x+t$, given that it has not occurred before age x, is

$$ {}_tq_x = 1-\exp\left(-\int_x^{x+t} \lambda(u)\,\mathrm{d}u\right) $$

The probability of ever experiencing E is $1-\ell(\omega) = 1-\exp(-\int_\alpha^\omega \lambda(x)\,\mathrm{d}x)$. Note that this probability is less than one if and only if $\int_\alpha^\omega \lambda(x)\,\mathrm{d}x < \infty$.

The density of the age at which E occurs, given that it ever does, is $\lambda(x)\ell(x)/[1-\ell(\omega)]$. The mean age at occurrence is

$$ m = \alpha + \int_\alpha^\omega \frac{\ell(x)-\ell(\omega)}{1-\ell(\omega)}\,\mathrm{d}x $$

The higher moments of this distribution are defined similarly. If the event E is death, considered from birth (which means that $\alpha = 0$ and ω is the maximum human life span) i.e., if the field of study is overall mortality, then the mean age at occurrence is called the life expectancy at birth. The quantity we have denoted $\lambda(x)$ is called the force of mortality at age x and $\ell(x)$ is the survival function at age x. If the event E is death considered only after a given age $a > \alpha$, the difference between the mean age at occurrence and a is called the life expectancy at age a; it is the average number of years remaining to a person still alive at age a.

If event E is first marriage below completed age 50, $1-\ell(50)$ is the proportion ever married by age 50 and $\ell(50)$ is called the final celibacy. The mean age at occurrence is the mean age at first marriage (below 50).

If the event E is the birth of a child of order k ($k \geqslant 2$) to a woman and time is recorded not from the birth of the woman but from the date of birth of her preceding child, $1-\ell(\omega)$ is the proportion who reach parity k among women reaching parity $k-1$. This is also called the parity progression ratio from order $k-1$ to order k. For $k = 1$, time is recorded from the birth of the woman or from any other suitable origin (e.g., the moment of marriage if the field of study is marital fertility) and $1-\ell(\omega)$ is the proportion of women who have at least one child. The frequency of childlessness is $\ell(\omega)$.

5. Annual Record of Events for Both Time of Occurrence and Age at Occurrence

5.1 Rates

Tables classifying events that have occurred during one calendar year, say year n, by single year of age of the person concerned, may be established by squares or by vertical-sided parallelograms in the LEXIS diagram. We let the current value of age completed be the integer i. In both cases, we have to estimate the probability of occurrence of event E within a doubly annual figure. In the mathematical framework presented above, we face three difficulties. *First*, we do not have a single person to consider but a discrete cohort born during calendar year $n-i$ in the case of a vertical-sided parallelogram, or two consecutive discrete cohorts (born in years $n-i-1$ and $n-i$) in the case of a square. In the parallelogram, each member of the cohort is exposed to risk during exactly one year (unless the person dies or migrates), but in the square the members of the two cohorts are exposed to risk during periods of variable duration ranging from 0 (for those born close to January 1 of year $n-i-1$ or close to December 31 of year $n-i$) to one year (for those born close to January 1 of year $n-i$). Furthermore, the risk function $\lambda(x)$ may now well vary with the time of birth g, in which case we should rewrite the function as $\lambda(x, g)$.

Second, the statistical data available may not be the full individual-level information, which would consist of the date of birth of each person and the various dates of occurrence of event E if it happens to occur to that person. We typically just know the *total number* of events inside the parallelogram or the square and the corresponding exposures.

Third, since our mathematical theory was developed for a single event E, migration and death (or only migration if event E is itself death) complicate the situation. The total number of events recorded includes those occurring to in-migrants or to persons who die or out-migrate subsequently to an occurrence inside the region in the LEXIS diagram; migration and deaths are duly taken into account in the total number of residents classified by age at both year-ends. But in

Figure 3
(a) Events observed in a vertical-sided parallelogram. (b) Events observed in a square

aggregate data the exact date of death, in-migration or out-migration of each person exposed to risk in the territory considered is not known. For these reasons, we will now reformulate our mathematical framework. We do it in two steps: first a simple one and second by a more sophisticated one.

5.2 First Simple Assumption: Constant Risk Function

Our simple reformulation holds for any kind of event, whether repeatable or not, and is as follows: Let us assume that the risk function λ is constant inside the age bracket concerned (exact ages i to $i+1$ in the case of a square, $i-1$ to $i+1$ in the case of a vertical-sided parallelogram). The probability that event E occurs is $\lambda\,\mathrm{d}g\,\mathrm{d}x$ for a resident who is born between times g and $g+\mathrm{d}g$ and whose exact age is between x and $x+\mathrm{d}x$, for every g and x inside the LEXIS-diagram region. Then the occurrence/exposure rate (of the first kind) is the maximum likelihood estimate of λ in the case of squares as well as of parallelograms. Let us furthermore assume that the number of entries due to in-migration, and exits due to death and out-migration, lead to a uniform balance: the net number of entries of persons born between g and $g+\mathrm{d}g$ when their exact age is between x and $x+\mathrm{d}x$ is $s\,\mathrm{d}g\,\mathrm{d}x$, where s is a constant.

As we already stated, net 'in-migrants' are supposed to have the same risk λ as the non-migrants. The quantity s can be approximated by $s_i^n = P_i^{n+1} - P_{i-1}^n$ inside a parallelogram with vertical sides on the basis of the numbers of residents at year-ends by single year of age. Here P_i^n is the number of residents of completed age i on January 1 of year n. (If event E is death, s_i^n is equal to $P_i^{n+1} - P_{i-1}^n - D_i^n$, where D_i^n is the number of deaths occurring during year n of residents born in year $n-i$.) If events are observed in squares, then s_{i+1}^n is an approximation to s_U in the upper triangle of the square, while s_i^n is an approximation to s_L in the lower triangle.

5.2.1 Vertical-sided parallelograms. When events are observed in vertical-sided parallelograms, the P_{i-1}^n residents on January 1 of year n, born in year $n-i-1$, who attain their ith birthday during year n, are all at risk during one year each, and the s net 'in-migrants' are at risk during half a year on average, so that the sum of exposures to risk is

$$R_i^n \approx P_{i-1}^n + \tfrac{1}{2}\,s = \tfrac{1}{2}(P_{i-1}^n + P_i^{n+1})$$

The estimate $\hat{\lambda}$ of λ is the observed occurrence/exposure rate $\hat{\lambda} = VSP_i^n / R_i^n$, where VSP_i^n is indicated in Fig. 3(a).

5.2.2 Squares. When events are observed in squares, we estimate the exposures to risk in each triangle of the square. We consider the upper and the lower triangle, one at a time. In the upper triangle, there are P_i^n persons in the population on January 1, or rather $P_i^n + \frac{1}{2}s_U$ persons who attain their $(i+1)$th birthday during year n and who are exposed between 0 and 1 year. If we introduce $m(G)$ as the average location inside year n of the birthdays attained during that year by persons born in year G, their average exposure to risk is $m(n-i-1)$. Total exposures equal $(P_i^n + \frac{1}{2}s_U)\,m\,(n-i-1)$. However, the $s_U/2$ net entries

have an average duration at risk of $\frac{1}{3}$ year. The corresponding exposures must be deducted since they are unduly included in the previous total. Thus the total exposure in the upper triangle is

$$\left(P_i^n + \frac{s_U}{2} \right) m\,(n-i-1) - \frac{s_U}{6} \approx P_i^n\, m\,(n-i-1) + \frac{s_U}{12}$$

Since $m(G)$ is anyhow close to $\frac{1}{2}$ and s is small compared to P_i^n. In the lower triangle, $P_i^{n+1} - \frac{1}{2}s_L$ persons attain their ith birthday during year n. They are exposed during an average period of $1-m(n-i)$, and there are $s_L/2$ net entries with an average duration of $\frac{1}{3}$ year, leading to total exposures of

$$\left(P_i^{n+1} - \frac{s_L}{2} \right) [1-m(n-i)] + \frac{s_L}{6}$$

$$\approx P_i^{n+1}\,[1-m(n-i)] - \frac{s_L}{12}$$

Adding up the exposures in the triangles, we get total exposures in the square of

$$P_i^n\; m(n-i-1) + P_i^{n+1}[1-m(n-i)] + \frac{s_U - s_L}{12}.$$

If the two consecutive cohorts born in years $n-i-1$ and $n-i$ are similar in size, if the mean locations of birthdays in each year for these cohorts are both close to $\frac{1}{2}$, and if migration balances are similar in the two triangles, then the exposures are close to $(P_i^n + P_i^{n+1})/2$ and the constant risk function λ is estimated by

$$\hat{\lambda} = \frac{SQ_i^n}{(P_i^n + P_i^{n+1})/2}$$

where the occurrences SQ_i^n are indicated in Fig. 3(b).

On the other hand, if cohorts born years $n-i-1$ and $n-i$ are quite dissimilar in size or if the mean locations of birthdays are quite different in these two cohorts, the latter formula may prove inaccurate. This is the case when a major disruption in the birth rate such as that provoked by the outbreak of a war occurs during the course of either of the 2 years. The consequence is then a multiplicative bias of approximately

$$\frac{B(n-i)[\frac{1}{2}-m(n-i)] - B(n-i-1)[\frac{1}{2}-m(n-i-1)]}{[B(n-i)+B(n-i-1)]/2}$$

in the above estimate of λ. Here $B(G)$ denotes the absolute number of births recorded in year G. The bias is approximately a constant percent of λ. For example, rates calculated for Belgian and French cohorts born in 1915 and 1916 are systematically biased upwards by almost 15 percent. This bias has almost the same magnitude for any kind of event (fertility, nuptiality, or mortality) and for any age. Rumanian cohorts born in 1966 and 1967 show a bias of a similar size caused by the huge increase in births subsequent to a change in the legislation on abortion in October 1966.

To avoid such biases, one should observe demographic events in vertical-sided parallelograms rather than in squares when the age-pyramid shows irregularities due to major historical events. Contrary to common language, 'statistical' age at the time of occurrence is preferably age attained during the calendar year rather than completed age at the occurrence of the event.

Note that if E is a non-repeatable event, the probability of occurrence of E during a one-year period, given that it has not occurred before the beginning of the period, is $1-e^{-\lambda}$ under the assumption of a constant risk function equal to λ, and if the observed rate r is small, the probability is estimated by $1-e^{-r} \approx 1/(1+\frac{1}{2}r)$.

The value of $m(G)$ hardly changes over years n for a given cohort G; mortality and migration do not alter substantially the characteristics of the distribution of birthdays of the cohort through time, even when these characteristics are exceptional. These characteristics can then be approximated by their value at the time of birth i.e., on the basis of the monthly distribution of births that occurred during year G. They can also be estimated from census data i.e., on the basis of a breakdown of the resident population by year and month of birth.

5.3 *More Sophisticated Assumption: Variable Risk Function*

In our second step we now turn to more refined approximations. We still assume that the risk function is independent of the time g at birth but we now allow (soft) variations with age x. The risk of occurrence of the event E at an exact age comprised between x and $x+\mathrm{d}x$ among the $N(g)\mathrm{d}g$ residents born between g and $g+\mathrm{d}g$ is $\lambda(x)\,\mathrm{d}x\,\mathrm{d}g$. The risk function λ will be assumed to be a quadratic polynomial inside several adjacent regions of the LEXIS diagram in the case of a repeatable event, and a linear polynomial in the case of a non-repeatable event. In the latter case, especially if E is death, we may alternatively assume that it is $\log[\lambda(x)]$ that varies linearly over an interval of a few years of age. This corresponds to the Gompertz law of mortality, which is generally valid at higher ages (say at ages over 30 or 40) below the oldest old. The density s of net entries due to migration (or to deaths if E is not death itself) is still assumed to be constant inside each vertical-sided parallelogram in the LEXIS diagram.

For the following reason we need to estimate the integral of $\lambda(x)$ over a 1-year interval, say between a and $a+1$, where a is either i or $i-\frac{1}{2}$. For repeatable events the mean number of occurrences per person be-

tween ages a and $a+1$ is $\int_a^{a+1}\lambda(x)\,\mathrm{d}x$. For non-repeatable events the probability of recording E between ages a and $a+1$ among those who have not recorded it before age a is $1-\exp(-\int_a^{a+1}\lambda(x)\,\mathrm{d}x)$. In both cases the integral plays a central role.

If the derivatives λ' and λ'' are not too large (i.e., if λ indeed has 'soft' variations), the integral can be estimated on the basis of available estimates of λ, λ' and λ'' as follows. We get

$$\int_i^{i+1}\lambda(x)\,\mathrm{d}x \approx \lambda(i+\tfrac{1}{2})+\frac{\lambda''(i+\frac{1}{2})}{24} \approx \lambda(i)+\frac{\lambda'(i)}{2}+\frac{\lambda''(i)}{6},$$

and

$$\int_{i-1/2}^{i+1/2}\lambda(x)\,\mathrm{d}x \approx \lambda(i)+\frac{\lambda''(i)}{24}$$
$$\approx \lambda(i+\tfrac{1}{2})-\frac{\lambda'(i+\frac{1}{2})}{2}+\frac{\lambda''(i+\frac{1}{2})}{6}$$

5.3.1 Vertical-sided parallelograms. Under the above assumptions, the number of events occurring in the vertical-sided parallelogram for a repeatable event is

$$VSP_i^n = N[\lambda+\lambda'(m-\tfrac{1}{2})+\frac{\lambda'}{2}V(\tfrac{1}{3}-m+m^2+V)]+s\frac{\lambda'}{6}$$

and for a non-repeatable event it is

$$VSP_i^n = N\left[\,1-\mathrm{e}^{-\lambda-\frac{\lambda'}{2}(1-2m)}\,\right]\mathrm{e}^{\lambda m-\frac{\lambda'}{2}(m^2+V)+\frac{\lambda^2}{2}V}$$
$$+\frac{s}{2}\left[\,2-\mathrm{e}^{\frac{\lambda}{3}-\frac{\lambda'}{6}+\frac{\lambda^2}{36}}-\mathrm{e}^{\frac{\lambda}{3}-\frac{\lambda'}{6}+\frac{\lambda^2}{36}}\,\right]$$

In these formulae, N is the number of persons who reach their ith birthday during year n. (This is estimated by the mid-value of P_{i-1}^n and P_i^{n+1} in the case of a repeatable event, and by the mid-value of P_{i-1}^n and P_i^{n+1} plus half the difference between the number of occurrences of E in the upper triangle and in the lower triangle of the parallelogram, in the case of a non-repeatable event.) Furthermore, λ, λ', and λ'' are the values of the risk function and of its two first derivatives at exact age i, s is the density of net entries inside the parallelogram, and m and V are the mean and variance of the locations of birthdays in the cohort born in year $n-i$. (If the distribution of birthdays in the cohort is *uniform*, m is equal to $\frac{1}{2}$, V to $\frac{1}{12}$, and the third moment μ is zero. When the actual distribution of birthdays differs from uniformity only due to usual seasonal variations in the number of births, there is no need to take care of non-uniformity because m is then close to $\frac{1}{2}$ and V to $\frac{1}{12}$.)

If we know N, m and V, and if we estimate λ' and λ'' on the basis of the values of λ at neighboring ages, the appropriate formula above yields an estimate for λ. This is done iteratively and the iteration process is stopped when λ has stabilized for all i. In the first iteration, λ' and λ'' are set equal to zero. In subsequent iterations, $\lambda'(i)$ may be estimated by $\frac{1}{2}[\lambda(i+1)-\lambda(i-1)]$ and $\lambda'(i)$ by $\lambda(i+1)+\lambda(i-1)-2\lambda(i)$, where λ values are those obtained in the previous iteration at adjacent ages $i-1$, i, and $i+1$.

5.3.2 Squares. The corresponding equations in the case of squares are for a repeatable event

$$SQ_i^n = N_1\left[\,\lambda m_1+\frac{\lambda'}{2}(m_1-m_1^2+V_1)\,\right]$$
$$+\frac{\lambda''}{2}\left(\frac{m_1}{4}-\frac{m_1^2+V_1}{2}+\frac{m_1^3}{3}+m_1V_1+\frac{\mu_1}{3}\right)$$
$$+N_2\left\{\,\lambda(1-m_2)-\frac{\lambda'}{2}[m_2-m_2^2-V_2]\right.$$
$$\left.+\frac{\lambda''}{2}\left[\frac{1}{12}-\frac{m_2}{4}+\frac{m_2^2+V_2}{2}-\frac{m_2^3}{3}-m_2V_2-\frac{\mu_2}{3}\right]\right\}$$
$$+\frac{s_2-s_1}{6}\left(\lambda+\frac{\lambda''}{40}\right)$$

and for a non-repeatable event it is

$$SQ_i^n = N_1\left[\,\mathrm{e}^{\lambda m_1+\frac{\lambda'}{2}[m_1(1-m_1)-V_1]+\frac{V_1}{2}\lambda^2}-1\,\right]$$
$$+N_2\left[\,1-\mathrm{e}^{-\lambda(1-m_2)+\frac{\lambda'}{2}[m_2(1-m_2)-V_2]+\frac{\lambda^2}{2}V_2}\,\right]$$
$$+\frac{s_1}{2}\left[\,1-\mathrm{e}^{\frac{\lambda}{3}+\frac{\lambda^2}{36}}\,\right]+\frac{s_2}{2}\left[\,1-\mathrm{e}^{-\frac{\lambda}{3}+\frac{\lambda^2}{36}}\,\right]$$

In the two latter formulae, $_1$ refers to the upper triangle (or to the cohort born in year $n-i-1$), $_2$ to the lower triangle (or to the cohort born during year $n-1$), N_1 is the number of persons reaching their $(i+1)$th birthday during year n, N_2 the number of persons reaching their ith birthday during year n, λ, λ' and λ'' are the risk function and its two first derivatives at exact age $i+\frac{1}{2}$, s_1 and s_2 the densities of net entries inside the parallelogram containing the upper and the lower triangle, respectively, m_1, m_2, V_1, V_2, μ_1, and μ_2 the means, variances and third centred moments of the locations of birthdays in the cohorts born in years $n-i-1$ and $n-i$, respectively.

If we know N_1, m_1, V_1, μ_1, N_2, m_2, V_2, and μ_2, and estimate λ' and λ'' from the values of λ obtained in the previous iteration at neighboring ages (with λ' and λ'' set equal to zero in the first iteration), it is possible to derive λ from the number of events in the square using the appropriate formula. The iteration process is again stopped when λ has stabilized for all i.

On the basis of the above formulae, it is possible to estimate the integral of λ over a one-year range (between exact ages i and $i+1$ and also between exact ages $i-\frac{1}{2}$ and $i+\frac{1}{2}$), whatever the LEXIS diagram region

in which occurrences were observed (squares, vertical-sided parallelograms, or triangles). This leads to an estimate of the risk regime at all relevant ages during any year of observation. These formulae make it possible to reach international comparability in spite of the diversity of national practices. (Some countries observe events in vertical-sided parallelograms, others in squares.) For countries where the national statistical office has changed from one system to the other, it also becomes possible to compute a complete time-series with comparable terms.

5.4 The Special Case of Mortality at Ages 0 and 1

The above formulae hold for fertility, nuptiality, and mortality at any age, except for mortality at age 0 and, to a lesser extent, at age 1. The reason is that the risk function $\lambda(x)$ of mortality decreases very sharply from birth i.e., from exact age 0. This makes the polynomial approximation invalid over the age-interval (0, 1) and even the interval (1, 2). We now provide a solution even for infant mortality.

Let us denote by D_L^0 and D_U^0 (with $D_L^0 + D_U^0 = SQ_0^n$) the numbers of deaths in the lower and the upper triangles of the first square (i.e., between exact ages 0 and 1), D_L^1 and D_U^1 the similar numbers of deaths in the triangles of the second square (i.e., between exact ages 1 and 2), D_L^2 and D_U^2 those in the triangles of the third square (i.e., between exact ages 2 and 3).

Under the assumption that there is no migration inside the first square and that distributions of birthdays within cohorts born in year $n-1$ and year n are identical (in practice: both departing from uniformity only due to 'usual' seasonal variations), the infant mortality rate $IMR^n = 1 - \exp(-\int_0^1 \lambda(x)\mathrm{d}x)$ can be estimated by

$$IMR^n = 1 - \left(1 - \frac{D_U^0}{P_0^n}\right)\left(1 - \frac{D_L^0}{B^n}\right)$$

where P_0^n is the population of completed age 0 on January 1 of year n and B^n is the number of live births of the corresponding sex during year n. If net migration is not zero inside the first square, we rewrite the preceding formula as

$$IMR^n = 1 - (1-a)(1-b)$$

Two estimates of each term a and b can be provided. The term a refers to the upper triangle. The first estimate assumes that migration during year n within the cohort born in year $n-1$ takes place exclusively on January 1 of year n. The second estimate assumes that migration during year n within the cohort born in year n takes place exclusively on December 31. We then get the following estimates:

$$a_1 = \frac{D_U^0}{P_1^{n+1} + D_U^0 + D_L^1} \quad \text{and} \quad a_2 = \frac{D_U^0}{P_0^n}$$

The term b refers to the lower triangle, and our first estimate assumes that migration during year n within cohort born during year $n-1$ takes place exclusively immediately after birth. Our second estimate assumes that migration during year n within cohort born in year n takes place exclusively on December 31 This gives

$$b_1 = \frac{D_L^0}{P_1^{n+1} + D_L^0}, \quad b_2 = \frac{D_L^0}{B^n}$$

It follows that a set of lower and upper bounds of IMR^n are

$$1 - [1 - \min(a_1, a_2)][1 - \min(b_1, b_2)]$$

and

$$1 - [1 - \max(a_1, a_2)][1 - \max(b_1, b_2)]$$

If migration balances are small during year n both inside the vertical-sided parallelogram corresponding to the cohort born in year $n-1$ ($s_U = P_1^{n+1} - P_0^n + D_U^0 + D_L^1$) and inside the lower triangle ($s_L = P_0^{n+1} - B^n + D_L^0$), the two bounds are naturally close to each other. For example, the lower and upper bound of the estimated infant mortality rate were 5.30 and 5.36 per 1000 male live births and 4.16 and 4.13 per 1000 female live births, respectively, in France in 1997. For most practical purposes, the differences are negligible in contemporary Europe.

A satisfactory estimate of the infant mortality rate requires that the numbers of deaths are available for triangles in the LEXIS diagram. If the information available is limited to the total number of deaths SQ_0^n inside the first square, a rough estimate of the infant mortality rate is made possible nonetheless via a preliminary estimate of the breakdown of SQ_0^n into D_U^0 and D_L^0. In contemporary Europe, D_L^0 is approximately 90 percent of SQ_0^n.

The same procedure can be applied to the estimate of the probability of death between exact ages 1 and 2. The lower and upper bounds of that probability are

$$1 - [1 - \min(a_1, a_2)][1 - \min(b_1, b_2)]$$

and

$$1 - [1 - \max(a_1, a_2)][1 - \max(b_1, b_2)]$$

with

$$a_1 = \frac{D_U^1}{P_2^{n+1} + D_U^1 + D_L^2}, \quad a_2 = \frac{D_U^1}{P_1^n},$$

$$b_1 = \frac{D_L^1}{P_1^{n+1} + D_L^1}, \quad \text{and} \quad b_2 = \frac{D_L^1}{P_0^n - D_U^0}$$

The lower and upper bounds of the probability of death between exact ages 1 and 2 are usually even

closer to each other than the two estimates of the infant mortality rate. For example, the lower and upper bounds were 4.839 and 4.843 per 10,000 male live births and 4.102 and 4.106 per 10,000 female live births, respectively, in France in 1997. In contemporary Europe, the share of the lower triangle in the second square (between exact ages 1 and 2) is only slightly over 0.5 (around 52 to 55 percent).

5.5 Literature

The LEXIS diagram got its name from the German statistician Wilhelm Lexis, who published a treatise on the subject some 125 years ago (Lexis 1875). Like so many methodological innovations, the device is really older (Vandeschrick 2000, Keiding 2000). Most straightforward computational formulas above have a similar ancestry, but the more sophisticated ones were developed by the author in a series of publications between 1984 and 1999.

Demographic Techniques: Rates of the First and Second Kind

National vital statistics normally contain 100 age-specific death rates for each sex every year, namely for single years of age from age 0 through 99. There are some 30–35 age-specific birth rates for women aged 15 through 44 or 49. Corresponding rates of first marriage, when available, are also for men and women separately. Occurrence/exposure rates for nonrepeatable events (like first birth and first marriage) are called *rates of the first kind* (or of *type 1*) if the denominator of the rate is the appropriate number of person-years at risk of the event in question. For instance, a first-marriage rate of the first kind has the number of person-years recorded for the never married in the denominator. In a corresponding *rate of the second kind* (or of *type 2*), the denominator also includes the number of person-years for married and previously married members of the same population. In a first-marriage rate of the second kind, a first marriage is treated counterfactually as if it were a repeatable event. This hybrid is sometimes computed when it is impossible to separate out the person-years for the never married from the person-years of the whole population of each age. It is useful because an aggregate of age-specific rates of the second kind over ages for a birth cohort has a meaningful interpretation, as we shall see in the following.

1. Summary Measures for a Cohort

As in *Demographic Techniques: LEXIS Diagram*, let members of a given birth cohort have an intensity or risk function $\lambda(x)$ at exact age x for an event of interest. If the event is repeatable (like the birth of a child), the integral $\int_a^b \lambda(x)\,\mathrm{d}x$ would be the mean number of such events between exact ages a and b to a cohort member if there were no mortality and out-migration (see *Demographic Analysis: Probabilistic Approach* for an explanation of such a 'partial' quantity). This interesting integral can be estimated by adding up the age-specific occurrence/exposure rates over ages from a through $b-1$ in the cohort in question.

For a nonrepeatable event with the risk function $\lambda(x)$, the quantity ${}_{b-a}q_a = 1-\exp\{-\int_a^b \lambda(x)\,\mathrm{d}x\}$ would be the corresponding probability of experiencing the event before exact age b for a cohort member who had not experienced the event by exact age a. The integral $\int_a^b \lambda(x)\,\mathrm{d}x$ plays a central role for the analysis of nonrepeatable events as well, but its function is quite different from the corresponding integral for a repeatable event.

The probability ${}_{b-a}q_a$ may be estimated in two different manners, as follows.

(a) If a sequence of age-specific rates of the first kind is available for a cohort, adding them up for ages a

through $b-1$ produces an estimate $\hat{I}$ of $\int_a^b \lambda(x)\,\mathrm{d}x$, from which an estimate ${}_{b-a}\hat{q}_a = 1-\exp\{-\hat{I}\}$ of ${}_{b-a}q_a$ can be computed.

(b) If a sequence of age-specific rates of the *second* kind is available for the cohort, then adding them up over ages a to $b-1$ produces a sum that is an estimate ${}_{b-a}q_a^*$ directly. This simple fact had been understood intuitively for many years before it was proved in great generality in a sequence of papers by Hoem (1978), Finnäs (1980), and Borgan and Ramlau-Hansen (1985).

While we have described summary measures by aggregation over age for birth cohorts, similar aggregation is equally meaningful for other kinds of cohorts when age is replaced by duration since the formation of the cohort. For example, marital fertility rates can be computed by marriage duration, and adding them up over duration produces corresponding summary measures for marriage cohorts. It will not be equally meaningful to aggregate marital fertility rates across *age* groups, for not all members of a marriage cohort are at 'risk' of childbearing from the lowest age at marriage, simply because some marry at a later age.

2. Summary Measures for a Period

2.1 The Total Fertility Rate

Formally, summary measures can be computed for a calendar year, say, by aggregating over age in the same manner as for a cohort. The resulting period index is often said to be computed for a synthetic cohort (see *Demographic Measurement: General Issues and Measures of Fertility* and *Demographic Measurement: Nuptiality, Mortality, Migration, and Growth*). For a repeatable event the index is called a total rate, such as the total fertility rate, which is computed by adding up age-specific fertility rates for a calendar year over all ages.

As was pointed out by Hajnal (1947) already, it is important not to misunderstand the meaning of such a period index. The total fertility rate of year n is expressed in the same units as a cohort completed fertility (CCF), namely as an average number of children per woman, but it is *not* even some sort of average of the CCFs of the cohorts who are at fertile ages during year n. In fact the TFR^n for year n may even lie outside the range of the corresponding CCFs. To see what TFR^n actually is, suppose that the rates are computed by age attained in vertical-sided parallelograms (see Fig. 3(a) in *Demographic Techniques: LEXIS Diagram*). Let P_i^n be the number of women at age i at the beginning of year n, let R_i^n be the number of person-years recorded for women who attain age i during the year, and let B_i^n be the number of liveborn children to these women during the year. (R_i^n must perhaps be approximated by $(P_{i-1}^n + P_i^{n+1})/2$.) Then the corresponding birth rate is $f_i^n = B_i^n/R_i^n$ and $B^n = \sum_i B_i^n$ is the total number of liveborn children to women of all ages. A trivial calculation shows that

$$B^n/TFR^n = \bar{P}^n,$$

where

$$\bar{P}^n = \sum_i \frac{f_i^n}{TFR^n} R_i^n$$

is a weighted average of the mean sizes of the cohorts of women who are at fertile ages during year n. Thus, $TFR^n = B^n/\bar{P}^n$, which means that as of a fashion the total fertility rate can be seen as the number of births in year n per woman in the cohorts who are at fertile ages during that year.

The value of the total fertility rate has been around 1.4 children per woman for the European Union as a whole over a number of recent years. This means that annual cohorts of newly-born children in the EU have been one-third smaller than the mean total numbers in generations of young female adults during the same years (for $1.4/2.1 = 2/3$). If we disregard the effect of female mortality before age 30 (which has become very low today), the total number of adults at age 30 in about 30 years will be

(a) one-third lower than the mean total number of young adults in the baseline period ('today') if there is no net migration in the meantime;

(b) equal to the mean total number of young adults in the resident population today if net in-migration leads to a percentage of in-migrants one-third higher than the corresponding proportion of out-migrants born in the given area;

(c) lower than, equal to, or larger than the mean total number of young adults today according to the net percentage of in-migrants in the resident population.

In other words, compared to the present situation there will be a reduction in the total number of adults within a generation if net migration leads to a percentage of in-migrants less than approximately the rate of out-migration plus one-third.

2.2 The Total First-marriage Rate

The total first-marriage rate (TFMR) has a similar meaning. It is computed as the sum of age-specific first-marriage rates of the second kind for a given calendar year. A TFMR of 0.5 is close to the values commonly observed in Europe nowadays, and it means that the number of single women who get married during the year is half the average size of female cohorts who are at the ages of first marriage. An observed low value, say, of the TFMR may result from a *low* average level of nuptiality during the year,

Figure 1
Sweden 1911–98. Female total first marriage rates based on age-specific rates of the first and second kind and cohort-based proportions ever married by age 50, shifted by the period-based mean age at female first marriage. Dotted lines: cohort proportions estimated by freezing rates at their values observed in 1998. Circles indicate years of observation (empty circles) or birth cohorts (filled circles) that are multiples of five

or alternatively from a *high* nuptiality in corresponding cohorts in previous, and possibly in subsequent, years.

The (period-based) total first-marriage rate computed from rates of the second kind may well exceed 1, despite the fact that no one can enter first marriage more than once. For cases in point, see for instance Vogt (1964). The corresponding total first-*birth* rates were above 1 in many countries during the baby-boom years after World War II. See Whelpton (1954) for the United States, for instance. A corresponding *cohort*-based aggregate rate can never exceed 1, nor can the single-decrement computation of the proportion ever married (or of the proportion who ever get a first birth) in a synthetic cohort based on first-marriage rates of the first kind for a calendar year ever produce such a value. The rates of the first kind for a calendar year may add up to more than 1, but this only means that the corresponding probability ${}_{\omega-\alpha}q_{\alpha}$ is larger than $1-e^{-1} \approx 0.63$ (when $\lambda(x) > 0$ only for $\alpha < x < \omega$).

Figure 1 contains total rates of first marriage (based on rates of the second kind) for women in Sweden for calendar years 1946 through 1977 along with corresponding proportions ever married by age 50 for cohorts born in 1890 through 1960. (For cohorts born after 1948 marriage rates at higher ages have been estimated.) The plot also contains aggregated first-marriage rates of the *first* kind (similarly called corresponding 'total rates' on the graph) for years 1911 through 1998. None of the total rates of the *second* kind exceed 1 in this draft, but many of the 'total rates' of the *first* kind do and often indicate a period-based value of ${}_{35}q_{15}$ in excess of 2/3. (We have used $\alpha = 15$ and $\omega = 50$ in these computations.) There was a huge peak in Swedish nuptiality in 1989 caused by a change in the regulations concerning public widow's pensions that led a substantial number of couples to marry before the end of the year, particularly among cohabiting partners (Hoem 1991).

3. *Conversion of Rates of the First Kind into Rates of the Second Kind, and Vice Versa, for Birth Cohorts*

It is useful to be able to convert cohort rates of one kind into corresponding rates of the other kind, both ways. Consider therefore a nonrepeatable event like first marriage, and let p_i^n be its rate of the second kind and π_i^n the rate of the first kind, both observed at age i during year n. Suppose that the population is closed and that there is no death and no migration in the age

bracket $[\alpha, \omega]$, α being the minimum legal age at marriage for the sex under consideration and ω being age 50 as before. Moreover, to be concrete let us assume that these rates are expressed in terms of age attained during the year.

The proportion never married at the beginning of year n among persons then of completed age $i-1$ can be computed in two equivalent ways, and we get

$$1-\sum_{j=\alpha}^{i-1} p_j^{n-i+j} = \prod_{j=\alpha}^{i-1}(1-\pi_j^{n-i+j}). \tag{1}$$

If we write out the same relation for a year later and subtract the latter from Eqn. (1) we obtain the following formula to convert π rates into p rates:

$$p_i^n = \prod_{j=\alpha}^{i-1}[\pi_i^n(1-\pi_j^{n-1+j})]. \tag{2}$$

If we divide the initial identity for year $n+1$ by that for year n and reorganize, we get, conversely, the following formula to transform p rates into π rates:

$$\pi_i^n = \frac{p_i^n}{1-\sum_{j=\alpha}^{i-1} p_j^{n-i+j}}. \tag{3}$$

The total rate for year n, based on rates of the first kind is

$$1-\prod_{i=\alpha}^{\omega-1}(1-\pi_i^n) = \prod_{i=\alpha}^{\omega-1}\left[\frac{1-\sum_{j=\alpha}^{i} p_j^{n-i+j}}{1-\sum_{j=\alpha}^{i-1} p_j^{n-1+j}}\right],$$

which differs from the similar total rate for year n based on rates of the second kind, namely,

$$\sum_{i=\alpha}^{\omega-1} p_i^n = \sum_{i=\alpha}^{\omega-1}\left\{\prod_{j=\alpha}^{i-1}\left[\pi_i^n(1-\pi_j^{n-i+j})\right]\right\}.$$

This does not prevent the aggregate rate of occurrence of the event in question for the cohort born during any year G to be the same for either kind of rates:

$$\sum_{j=a}^{\omega-1} p_j^{G+j} = 1-\prod_{j=\alpha}^{\omega-1}(1-\pi_j^{G+j}),$$

as in Eqn. (1) with $i=\omega$ and $G=n-i$.

The derivation of Eqn. (3) is a simplification of material already in the literature (Shryock and Siegel (1976 p. 292, formula 32), Finnäs (1980), Borgan and Ramlau-Hansen (1985)).

In the equations above, we have disregarded migration and mortality. In an open population, these relationships hold only if disturbing phenomena (migration and death) are independent of the event under study. For example, if the event is first marriage, this assumption essentially means that the proportion ever married among in-migrants arriving at age x is the same as in the nonmigrant population of the same age, and that never-married immigrants arriving at age x have the same propensity to marry according to age as nonmigrants in the host country. Moreover, it presupposes that only a negligible number of in-migrants who arrived as never-married marry in their home country while residents of the host country and have their marriage go undetected by the vital registration system of the host country. In some cases these latter issues are unproblematic (Finnäs 1980).

Demographic Techniques: Small-area Estimates and Projections

'Small area' refers to an administrative unit that is part of a larger area, normally a country. Frequently, more detailed information is available for the large area. Survey data or administrative records are used to estimate the corresponding totals and sex-and-age distributions for the small area via statistical modeling.

In demographic forecasting small areas differ from larger areas primarily because of the greater role of migration. With the development of the geographic information systems (GIS), small area estimation and forecasting will no longer be limited by administrative boundaries.

1. Smallness

Small area is usually administratively defined. It can be a county, province, city, or municipality within a state or country, for example. In some cases one is interested in a subset of the large population defined by criteria other than geographic affiliation, such as age, sex, income, educational level, health status, etc. The latter subpopulations are referred to as *domains*.

The 'smallness' of a subpopulation can be understood either in terms of its size or in terms of the data available for it. In the case of municipalities or city blocks, populations can be small in the sense that they may vary considerably over time. Domains of a particular educational or health status may be especially variable. This poses challenges for the evaluation of educational policies or for environmental epidemiologic studies, for example. On the other hand, large cities or counties may have populations in the millions, so the populations of interest can be stable over time.

Frequently direct population estimates are available for the large area only, and survey data or administrative records must be used to estimate the population totals for the small areas. When survey data are used, the sample size available for each small area is often small and sampling variability is high. Independently of the size of the target population, estimation is then uncertain. If administrative records or other symptomatic data from the small area are used, then the biases of such data and of the statistical models used, may also be major sources of inaccuracy.

From an administrative point of view, all such estimates may have a similar status. This is the case in the allocation of funds, or apportionment of political representation, based on population size, for example.

2. Data for Small Area Estimation

Direct estimates of small area populations are continuously available for countries with high-quality population registers. In principle, direct estimates of population by educational level and subarea may similarly be obtained from computerized registers in real time. Primary problems in the statistical analysis of small area data are then caused by changes in administrative classifications, the timeliness of information updates, and quality of registration. Moreover, there are typically domains that cannot be distinguished in the register data. An example is the distribution of population by health status. It is also possible that the register based information refers to a legally resident (*de jure*) population, whereas the information needs involve the population that is *de facto* present in the area.

In countries that rely on censuses for population estimation, demographic bookkeeping, administrative records, or sampling techniques are used for small area estimation during intercensal periods. Data on births, deaths, and migration can be used for population estimation. Migration may be estimated from symptomatic data, such as school enrollment, for example.

Population estimation can also be based on *housing units* and estimates of persons per unit. The latter may be further decomposed into a product of an occupancy rate and persons per occupied housing unit. Estimates of the number of housing units can be difficult to obtain and update if there are many unauthorized additions, demolitions, or conversions. Natural disasters may also wipe out housing units. In addition to housing units, it is possible to use the number of registered passenger cars, income tax returns, etc. to estimate the population. Statistical regression analysis can be applied to census data to estimate the relationship between population or population change, and such symptomatic variables.

If the completeness of a population register (or a census) is in doubt, then the so-called *capture–recapture* (or *dual systems*) methods can be used to evaluate the level of *undercount* for small areas. It is possible to recount the population for a sample of the small areas and deduce the number missed by the registration system (or the census) in demographic, ethnic, or social domains. If not corrected, differential undercount may create biases if population data are used to allocate funds to small areas, for example.

3. Methods for Survey Based Estimation

Small area estimation may involve many other types of totals besides population. It can be income, unemployment, crop and live stock production, volume of wood in forests, etc. Such estimates may have similar administrative uses as population figures. Data on income or unemployment can be used in the allocation of funds, for example. On the other hand, for crop and forest statistics there may be additional data sources such as images taken by satellites.

In the so-called *synthetic* estimation method it is assumed that small areas have the same relevant characteristics as the large area. For example, suppose the average income is accurately known by age and sex for the large area from a sample survey, but the sample is too small for reliable estimation for small areas.

Assume that the population size is known by age and sex for a small area. Then, the synthetic estimate of the total income in the small area assumes that the area has the same average income by age and sex as the large area. The estimator has a low variance, but it can be severely biased if income varies between areas. Sample average from the small area is an unbiased estimate of income, but it has a high variance. The *trade-off between bias and variance* is the basic problem of small sample estimation.

Composite or *combined* methods try to alleviate the biases inherent in synthetic methods by using weighted averages of estimators derived according to different principles. A natural approach is to try to find weights that would *minimize the mean squared error* of the estimator. One problem in the use of such weights for administrative purposes is whether or not the same weights can be used for all small areas. Weights that have been tailored for each area separately may be statistically unstable and their use may be difficult to defend in a political process involving monetary allocations, for example.

Better accuracy is available if realistic statistical models can be developed to represent the relationship between the variable of interest (such as income) and possible auxiliary variables (such as age and sex). Possible spatial correlations across small areas may also be accounted for. Regression models that include *random effects* are typically used.

In the so-called *Empirical Bayes* method the bias of the regression model is represented by an area-specific random effect. An optimal weighted average of the regression estimator and a direct sample based estimator is, in principle, obtained by weights determined by the variance of the random effect and the sampling variance of the direct estimator. Both must be estimated from the data so exact optimality is difficult to achieve. The estimation of the variance of the random effect is particularly challenging. Different approaches have been proposed that use both analytical approximations and simulation techniques, such as *bootstrap*. The computationally intensive *Hierarchical Bayes* methods solve the problem in a unified probabilistic framework that offers conceptual advantages.

Depending on the spatial setting, complex interrelationships between the small areas are possible. Several layers of random effects may be warranted, and the effects need not be hierarchical. Such models are also called *variance component* models or *multilevel* models.

4. *Forecasts of Small Area Populations*

Migration typically has a bigger effect on forecasts of small areas than on forecasts of national populations. International migration is frequently concentrated on certain small areas so its relative impact may be large. Internal migration related to labor markets can be highly volatile. In countries without a population register, direct data on both types of migration are often lacking. Estimates must then be based on symptomatic techniques of the type discussed above. In consequence, the uncertainty of small area forecasts is typically higher. Probability theory provides a way to describe the uncertainty to forecast users in a realistic manner.

Should one forecast the populations of the small areas separately, and then aggregate to the national level, or should one forecast the national population first and then disaggregate to small areas? If the former method is applied independently for each small area by a local authority, say, then the sum of forecasts is often too high, because administrative units are reluctant to forecast declines in population for fear that it might become a self-fulfilling prophecy. On the other hand, if the forecasts are prepared by a central authority, there are many technical difficulties. The simplest approach is synthetic: one assumes that changes in the populations for small areas are a fixed proportion of a forecasted national change. At the other end of the spectrum is a multistate cohort-component model that describes migration in terms of full origin–destination migration flows by age and sex. The difficulty with the latter models is that the number of migration flows can be large. In a system of n areas it is $n(n-1)$. A compromise is to forecast out-migration for each area separately, and to pool the out-migrants. In-migrants are then forecasted synthetically as fractions of the pool for each receiving region. As in other applications, the synthetic method may lead to biases.

5. *From Administrative Units to User Defined Areas*

Much of the interest in small area estimation and forecasting comes from administrative uses such as allocation of funds. However, small area data are also used in social and medical research to measure the effects of interventions, for example. Administrative boundaries are frequently not well suited to such analyses. Domains of interest may intersect several areas, or they may be too small for their effect to be discernible in small area data. A new development in small area estimation and forecasting is the introduction of the geographic information systems (GIS). When all housing units are given geographic coordinates, the data user may define new aggregates based on the coordinates, irrespective of any existing administrative boundaries.

Estimation methods from spatial statistics will then become an essential part of small area estimation. Special care is needed when user defined regions are used to locate disease clusters, for example. Both the random variation inherent in small populations and

the selection effects must be properly handled. Existing techniques of forecasting must similarly be modified because information about migration may be more difficult to describe. On the other hand, user defined regions provide opportunities for more meaningful estimates of the population at risk.

Demographic Transition, Second

The term Second Demographic Transition was introduced into demographic literature in the mid-1980s (Lesthaeghe and van de Kaa 1986b; van de Kaa 1987). By then it had become clear that the demographic developments observed in the countries of Northern and Western Europe during the two preceding decades followed a trajectory which would not lead to a new equilibrium between the components of growth as the classical transition theory predicted. It seemed, instead, that dramatic changes in family formation and unprecedented low levels of fertility would engender population decline.

1. The Components of Growth

The decline of fertility to below replacement level is an integral part of the Second Demographic Transition, but the second transition does not consist of this fertility decline alone. [JMH: No need to be defensive.] It is constituted by a series of interlinked demographic changes resulting from a quite purposeful shift in behavior by men, women, and couples, a shift that occurred with striking simultaneity in many countries. As was the case during the first transition the demographic changes were the combined effect of structural, cultural, and technological factors. In both transitions changes in value systems played a crucial role (Lesthaeghe and Meekers 1986a). The essential change took place in people's mind. What one sees is a 'translation of cultural representations.' Again, in both transitions the three determinants of population growth moved in conjunction with each other (Coleman 1996), as follows:

(a) Europe became a region of immigration; the early recruitment of guestworkers may be regarded as the initial manifestation of that new international constellation. It was followed by family reunification, by the inflow of refugees and asylum seekers, and by immigrants seeking to enter illegally.

(b) The decline in mortality, especially at higher ages, and the quite surprising increase in life expectancy during the mid-1970s that resulted, may be interpreted as the lagged response to the behavioral choices men and women made at least a decade earlier. Eating healthier food, giving up smoking, and taking more exercise obviously affect mortality only after a certain delay. National and regional population projections now customarily assume that women will soon experience a life expectancy at birth of 85 years or more.

(c) In the area of nuptiality and fertility, the availability of new, highly effective contraception, commonly followed by increased access to abortion and sterilization, played a catalytic role. Even in the official perception of things, having sexual relations no longer presupposed being married. Male dominated contraception was replaced by means dominated by the female partner. Preventive contraception was replaced by self-fulfilling conception. The changes in fertility and family formation appear to have followed a distinct sequence, partly, no doubt, because of their logical ordering; but also because of the systematic way in which choices were made from available options (van de Kaa 1997).

In the typical pattern, a decline in fertility at the higher ages of childbearing was followed immediately by the avoidance of premarital pregnancies and of 'forced' marriages. Initially, the age at first marriage may have continued to decline, but it rose once the postponement of childbearing within marriage became more common. The, lower-order birth rates declined, and cohabitation gained ground. And, while cohabitation may have begun as a statement of defiance by a few trendsetters, and may have remained deviant for a while after that, it increasingly came to be looked upon as an alternative to marriage. Nonmarital fertility rose, voluntary childlessness became increas-

Figure 1
A schematic representation of trends in the components of population growth showing the onset of the successive demographic transitions of the early nineteenth century and the mid-1960s.

ingly significant, and union disruption became dominated by informal unions rather than marriages.

A common feature was that the postponement of childbirth away from younger ages drove total fertility down to well below replacement level. And, while a compensatory effect may occur through increased childbearing at higher ages, the upper part of the reproductive life span appears insufficient to bring cohort fertility up to replacement level in most countries. [JMH: The Nordic countries appear to be an exception, cf. recent findings by Calot and Tomas Frejka, now in the process of being published.] Ultimately the crude death rate is expected to exceed the crude birth rate. In the absence of international migration, population decline would then become inevitable.

Figure 1 illustrates how the shift from first to second transition appears to have evolved. The sinuous lines of the classical transition pattern are followed by the flat lines of the second. During the second transition the migration process is not expected to develop freely until saturation occurs. Immigration is assumed to remain controlled, but it will compensate only part of the shortfall between births and deaths.

2. *Interpretation*

This sketch fits the patterns observed in northwestern Europe quite well. An important and interesting question obviously is whether the Second Demographic Transition will prove to be as universal and ubiquitous as the first. Demographers disagree on this point. Some even doubt that the concept of a second transition is appropriate and prefer to see the developments since the mid-1960s as a temporary disturbance in the demographic transition process which began in the nineteenth century (Cliquet 1991, Vishnevsky 1991, Roussel and Chasteland 1997).

Much depends on the interpretation given to the events observed (Lesthaeghe 1995). For a while it seemed as if the second transition could be compared to a cyclone irresistibly sweeping south from Scandinavia and gradually engulfing the South of Europe before turning East and, most probably, to other parts of the developed world. It is now less evident that such a metaphor is appropriate. Three observations should be made to clarify that point. It is, first, obvious that at any point in time each region or country has its own demographic heritage and cultural endowment. The reaction to the diffusion of innovative forms of behavior will depend partly on how well new ideas can be incorporated into existing patterns and traditions.

Since the European countries represent a harlequin's mantle of experience and conditions, some specificity in reaction is to be expected. Second, It would appear that the Second Demographic Transition has a strong ideational dimension. In the 'translation' of cultural preferences and represent-

ations into behavior, deeply rooted cultural differences between large regions will make their presence felt. That, so far, southern Europe has not embraced cohabitation as an alternative to marriage and does not show wide acceptance of nonmarital fertility may well reflect a fundamental difference between the 'protestant' North and the 'catholic' South. It should, third and finally, be recognized that if socioeconomic and political conditions are unfavorable to these novel patterns of behavior, a diffusion process may be much delayed.

This probably partly explains the difference in demographic patterns (trends?) between the previously socialist countries of Eastern and Central Europe and the rest of the developed world. Conceivably, such differences and lags may disappear very rapidly once crisis conditions abate, the economic situation improves, and generations exposed to mass culture from the West during their adolescence reach the age at which union formation begins. The Czech Republic has shown extremely rapid shifts in the handful of years between 1992 and 1996, and this may signal developments elsewhere in years to come.

Whether all countries of the world will, ultimately, undergo a Second Demographic Transition is much too early to tell. If Inglehart (1997) is correct in his conclusion that at a certain stage of their social and economic development countries reach an inflection point, and then leave the trajectory of modernization to start moving on the trajectory of postmodernization, a universal second transition is not at all unlikely. He sees postmodernization as a '… pervasive change in worldviews.' 'It reflects a shift in what people want out of life. It is transforming basic norms governing politics, work, religion, family, and sexual behavior' (Inglehart 1987, p. 8). Measuring postmodernization (in demographic behavior?) is not particularly easy (van de Kaa 1998).

It essentially implies that at an advanced stage of social and economic development people begin to question the meta-narratives which underpinned the process of modernization for several centuries (e.g., the belief in progress, in the value of working hard, in religion, in obedience to—secular—authority). This means that, just as has been well documented for countries of the European Union after the mid-1960s, concerns about law and order, physical security, and the standard of living give way to higher order needs. The quality of life becomes of prime importance and is placed above material assets in people's perceptions. People seek personal freedom and gender equality, and emphasize the right to self-realization and self-expression. They express support for emancipatory movements and express concern about the maintenance of human rights, biodiversity, and the ability to sustain modernization style developments (more than even before?).

The probable association of the Second Demographic Transition with long term processes of development in Europe's societies and/or civilization needs to be researched very rigorously before firm evidence can replace plausible conjectures.

Demography, History of

Demography is the study of processes of change in human populations. Statistical measures of fertility and mortality and their dynamic inter-relationship are

at its core. Demography consists of three inter-related intellectual activities: the collection of appropriate evidence, analysis using a body of mathematical and statistical techniques which avoid certain pitfalls, and the interpretation of the relationship between demographic processes and the political, social, economic, cultural, and natural environment.

As an organized academic subdiscipline it is a recent arrival in the social sciences. There were only a handful of established academic posts in demography, mostly privately funded in US universities, before the Second World War. Yet, by virtue of its obvious importance in terms of *raison d'état*, enumeration of populations for fiscal, military, administrative, and colonial purposes dates back to the world's ancient civilizations (and the Domesday Book demonstrates its sporadic occurrence in the medieval period, too). Furthermore, compilation of family genealogies and maintenance of vital registers of births, marriages, and deaths for religious and for legal purposes both have venerable histories, now proving to be of value for demographic historians of early modern Europe, North and South America, Japan, and China. Proper demographic study requires two kinds of information: accurate and regular census details (now taken decennially in most countries) on the stock of the defined population (numbers of each sex alive at each year of age); and information on the continuous flow of vital events, the numbers of each sex born alive, and the numbers dying at each exact age. This permits calculation of the age- and sex-specific rates of fertility and mortality necessary for genuinely comparable measures of a population's principal dynamic demographic characteristics, while also allowing for the effects of net in- or out-migration. Many further kinds of demographic analysis can be undertaken if the appropriate information is collected.

The study of populations of any size presupposes an official apparatus of data collection of some considerable size and sophistication and demography is therefore unique among the social sciences in the extent of its intimate involvement with the priorities of governments and officials and the wider influences of politics upon the state. Until recently only government bureaucracies could command the clerical resources required for the statistical analysis. Hence, government census bureaux provided the initial demand for automated punch-card tabulating machines and later for the production of the first nonmilitary electronic computers (the US Census Bureau's Univac, commissioned for the 1950 census). The subsequent proliferation of cheap computing resources has undoubtedly been a necessary precondition for the expansion of demography as an academic discipline with numerous independent, nonofficial practitioners.

Demography has therefore had a close historical association with the rise of nation-states throughout the entire modern period. But demography's early development has also been strongly influenced at times by the needs of smaller, subnational polities, such as the municipalities of Britain since the seventeenth century or the federated states of eighteenth-century Germany. Furthermore, the institutional and intellectual character of demography's rapid disciplinary growth since World War II has been much influenced by explicitly transnational institutions such as the UN and the World Bank and major independent (though mostly American) philanthropic organizations, such as the Population Council, the Rockefeller and the Ford Foundations. Nevertheless, national governments remain the principal collectors of continuous series of demographic data, so that the nation remains the typical 'population' addressed.

Modern demography's origins are conventionally traced to the practitioners of 'political arithmetic' in Restoration England. From the sixteenth century onwards it was increasingly the practice of European cities to compile bills of mortality—weekly death records—as an early warning system for epidemics, particularly of plague. In London the existence of this data provided the immediate context for the first recorded efforts at demographic analysis by John Graunt (1629–74), 'the father of modern demography.' In his *Natural and political observations made upon the bills of mortality* (1662) he also used records of London christenings to develop a rudimentary Life Table. This is the fundamental technique for the correct analysis of mortality because it divides the population into age sections and gives statistics for the probability of dying at each age, which can then be arithmetically summed to a single average life expectancy at any age, enabling populations with vastly different age structures or mortality regimes to be compared. Graunt had thus grasped the two fundamental demographic insights: that the age and sex composition of a population powerfully influences the incidence of vital events; and this means that population processes are all significantly interdependent.

Life table techniques developed very gradually over the ensuing century, with notable work by Sir Edmund Halley (1656–1742), the Dutchman Willem Kersseboom (c.1690–1771), the German Johann Sussmilch (1707–67), the Frenchman Antoine Deparcieux (1703–68), the Swiss-born Leonhard Euler (1707–83), and a host of British contributors to the so-called 'population controversy' (over whether or not the kingdom's population had increased since the Glorious Revolution of 1688–9, when the civil servant Gregory King had compiled, from tax returns, the only detailed estimate of a European nation's population made in the early modern period). Finally, the first technically correct empirical life table was published in 1815, for commercial actuarial purposes, by Joshua Milne (1776–1851), using accurate census and vital registration data collected for public health purposes in Carlisle during the years 1779–87.

During the nineteenth century the principal vehicle for the further development of demographic analysis

was the General Register Office (GRO) in London. This British lead was an unlikely development, in that the British census was not even established on a permanent basis (it had to be invoked by a separate Act of Parliament every 10 years), whereas the Scandinavian countries of Iceland (1703) and Sweden (1749) had already instigated regular census-taking, while the new, expanding American federation had also committed itself to regular censuses, as integral to its process of political representation. The French and Belgians, with Condorcet, Laplace, Duvillard, Fourier, and Quetelet led the world in the relevant mathematical fields of probability and the application of statistics to human affairs.

The British lead that opened up was due to a chain of chance occurrences. The GRO was created by statute to oversee from 1837 a national civil registration system of births, deaths, and marriages (created not for public health or demographic purposes but as a liberal legal reform granting dissenters a record of their vital events independent of the registers of the Established Church). As a temporary expedient this small department of government then became vested in 1840 with responsibility for taking the nation's fifth census of 1841 (the first was in 1801). The Registrar-General's statistical assistant, recently appointed through Court patronage in the as yet unreformed civil service, was an unknown man of humble origins, medically trained and a self-taught statistician (partly on a visit to Paris). A representative member of the European-wide generation enthused by the promise of a statistical science of society inspired by the Belgian astronomer, Adolphe Quetelet (1796–1874), William Farr (1807–83) immediately seized the opportunity presented by his responsibility for processing the two essential sources required for demographic analysis. He launched a four-decades long career of innovative demographic and comparative epidemiological work. Britain was at this time in the throes of a profound mortality crisis in its industrial cities (in addition to rural Ireland's fatal famine) and Farr saw his work as a public health campaign.

Thus, while it was in a Parisian publication that the term 'demography' was first coined in 1855—by Quetelet's countryman, Achille Guillard—it was in Britain that it was most intensively practiced and developed as 'vital statistics.' Significant work was certainly done in other official statistical offices. Indeed, the most important subsequent technical innovation was the Lexis diagram invented by the German statistician, Wilhelm Lexis, in 1875 for representing the relationship between cohorts (or generations) and period effects (events).

The GRO's lead was surprising in another sense in that the single English name most famously associated with the origins of demography is not the civil servant William Farr with his primary medical focus on preventable mortality, but the cleric and academic Thomas Robert Malthus (1766–1834), whose focus was on the economy and preventable fertility. His conservative polemic, *An essay on the principle of population*, published anonymously in 1798, enunciated that 'Population, when unchecked, increases in a geometrical ratio. Subsistence increases only in an arithmetical ratio.' Malthus, who held the first ever Chair in Political Economy in Britain and regarded Adam Smith as his principal mentor, thereby applied the fundamental economic problem of scarcity to demography and produced an analysis which famously stimulated Darwin to apply a similar logic to the problem of the origin of species, with profound intellectual results.

Malthus was the seminal influence on demography, in terms of the third intellectual activity outlined above, interpretation. His forthright axioms and policy implications demanded a response from the intellectuals of every country and secured a permanent place in the social and biological sciences for the discussion of population problems. In the much revised and extended editions of his *Essay* he continued to feed the debate, further analyzing and exploring the manner in which aggregate population change, mortality and migration, and individuals' and families' reproductive behavior is integrated into the encompassing natural, social, and economic environment, while using examples drawn from across the world to show how profoundly they were also influenced by customs, beliefs, and politics. He notoriously drew the wrath of Marx for his support for the radical reduction of the nation's welfare net with the amendment of the Poor Law in 1834, on the grounds that its 'generosity' was discouraging prudence among the prolific poor, who married too young and so had too many children.

Throughout the remainder of the nineteenth century most of those studying demographic phenomena were gentlemen scholars in local and national statistical societies, medical men, municipal and some state officials scattered all across Europe and North America. From mid-century they met periodically at International Congresses of Statistics, then of 'Hygiene and Demography' and eventually of 'Eugenics.' But it was not until the interwar decades of the twentieth century that demography began to emerge with an independent disciplinary and professional identity, marked initially by the formation in 1928 of the International Union for the Scientific Study of Population, followed in 1931 by the foundation of the Population Association of America.

However, this formative era from the late nineteenth century onwards had also witnessed the rise of nationalist and imperialist rivalries and associated racist, social Darwinist ideologies. This came to exert a dominant (though not uncontested) influence over the practice of demography during the interwar years. French demography was perhaps the first to experience this overtly nationalist and xenophobic current, in the form of a defensive pronatalist popular reaction

to defeat in the Franco-Prussian war of 1870–1. This was partly ascribed to her extremely low birth rate, the French being the first nation in the world to have practiced widespread family limitation. The titles of the works of France's leading demographers, such as Arsène Dumont, Jacques Bertillon, and Adolphe Landry repeatedly referred to 'Dépopulation' and 'decadence' while her great novelist, Zola, writing in exile in London after the Dreyfus affair, mourned France's lost *Fécondité* (1899).

The study of population problems in the interwar period became increasingly subsumed within this social Darwinist agenda. With its continuing necessary association with the state, demography was inevitably heavily implicated in the work done under the Fascist and Nazi regimes with their totalitarian ideologies. For this reason international conferences in both Rome and Berlin in the 1930s were partially boycotted and disrupted. But even in more liberal Britain, USA, or social democratic Sweden, demographic analysis became obsessed with class-differential fertility, 'problem families,' and fears of a 'flight from parenthood' associated with a succession of illiberal movements for national efficiency, eugenics, and 'social hygiene.' Only in the USSR was population analysis relatively free from this association (until Stalin's own pronatalist drive during the war) but this was primarily because of the absence of demographers, due to Marx's historic demonization of Malthus as the ultimate apologist of the bourgeoisie and their 'dismal science' of political economy. Given the bitter interwar political legacy in Europe, it was only in France and Britain that institutions for demographic research, L'Institut National d'Etudes Demographiques under Alfred Sauvy (1898–1990) and the Population Investigation Committee of the London School of Economics under David Glass (1911–78), positively flourished in the immediate aftermath of the war, both founding their respective journals in 1946, *Population* and *Population Studies*.

The decade of the Second World War marks a significant shift in which the center of gravity of the discipline of demography migrated from Europe to the USA. It was symbolic of this coming change that in work published between 1907 and 1939 a European-born but American-naturalized mathematician, Alfred Lotka (1880–1949), devised the proofs for the equations of renewal processes which underlie stable population theory (showing that populations always come to exhibit a constant age structure and growth rate if their fertility and mortality rates are unchanging). This has proved to be the most important mathematical advance in demography since the perfection of the Life Table technique (which applied to nonrenewal processes). Intriguingly, unknown to Lotka, Euler had already solved these equations in the eighteenth century. Indeed, Lotka's work remained largely unexploited until after the Second World War, both facts which demonstrate that technical advances within disciplines do not in themselves necessarily cause change but are dependent on the institutional context and on 'demand' factors external to the discipline.

After the Second World War, demography rapidly responded to the 'demand' of the growing global preoccupation with planned economic growth, propelled in this direction by US strategic interests in the context of the Cold War rivalry with the USSR for client states among the many decolonizing peoples of the less developed world. Consequently, the second half of the twentieth century has become a relatively clearly demarcated third era in the history of demography when, in some senses, it has returned to the original Malthusian agenda of a preoccupation with economics and with policies to promote fertility restraint, especially among the world's poor. The idea of 'demographic transition' has dominated the discipline's approach throughout this era. This is a general historical model, promoted and adapted by Frank Notestein (1902–83), the highly influential and well-connected first Director, 1936–59, of the Princeton Office of Population Research (OPR), the most important institutional center for the new American-led demography. Demographic transition 'theory' proposes that in order for a nation to achieve sustained long-term economic growth it must reduce both its mortality and, especially, its fertility levels to those attained by the 'modernized,' liberal democratic Western countries. The model has surprisingly little consistent support in either the historical or contemporary record but it has survived repeated revisionist challenges and has undoubtedly served the discipline well as an overarching ideological position which has successfully elicited a continuous flow of funds for both research and family planning programs.

It was in this policy context that the demand for various applications of stable population theory arose. Within the dominant postwar liberal consensus of 'modernization theory,' economic growth was seen as a generic process, such that less developed countries could be engineered to repeat the experience of the developed countries. Fertility restraint and mortality reduction were important population policy inputs to permit the occurrence of incremental capital:output ratios, considered essential for industrialization. This would be jeopardized by too great a demographic dependency burden (too many young and invalid old in the population) diverting income into current consumption instead of into savings and capital accumulation. Stable population theory enabled model life tables to be devised by A. J. Coale (Notestein's successor as Director of OPR) and indirect estimation techniques to be formulated by W. Brass (1921–99) of the London School of Hygiene, which permitted the measurement of demographic parameters in many of the less developed countries where primary information, particularly vital regis-

tration, was defective. A further application, for the same reason, has been its use in back projection and generalized inverse projection in historical demographic work. Along with the use of ground-breaking work by Louis Henry, this has enabled E. A. Wrigley and his colleagues at the Cambridge Group for the History of Population to utilize parish registers to reconstruct the detailed demographic record of the first industrial nation, England, back to the mid-sixteenth century, thereby, incidentally, demonstrating the invalidity of the demographic transition model in this important case.

Demography has achieved a considerable degree of disciplinary and institutional success, in many senses enviable by the standards of the other social sciences. Since 1945 training institutions have proliferated, primarily under the aegis of the Population Council, so that demographers are now trained in many centers in all the continents. By plausibly reducing, for certain purposes, the complexity of human affairs in matters of reproduction, morbidity and mortality, migration and mobility to tractable mathematical models, demography has achieved considerable analytical power. Like classical and neoclassical economics, conventional demographic analysis embraces a positivist epistemology. It also starts from the liberal and 'democratic' foundational fiction that each individual can in principle be legitimately treated as an equivalent accounting unit (a presumption that could only make sense in a post-Lockean world, where a working man could be deemed to count for the same as a prince, hence demography's first text by John Graunt came from the hand of an exact contemporary of John Locke's, another survivor of the modern world's first overthrow of a supposedly divinely-appointed sovereign). The resulting accounting system has provided the epistemological basis for an increasingly elaborate range of useful technical developments (such as, most recently, multistate and multiregional demography), for which the separate entries on 'Demography' may be consulted.

Inevitably, however, there is an intellectual cost for the preservation of demography's analytical rigor. Exceptional as it is, this has rather cut off demography from the rest of the social sciences and humanities, such that the entire 'linguistic turn' has gone largely unremarked in this discipline. Like all scientific activities, demography socially and ideologically constructs its objects of study but there has been little explicit acknowledgment of the implications of this. Thus, for a discipline which has devoted much energy to refining, for instance, calibration of the proximate (biological and physiological) causes of fertility variation, there has been much less interest in understanding how the demographers' own concept of fertility itself has arisen, and this applies to other social categories, such as 'population,' 'family,' or 'household.' This disinclination to engage in critical reflexive practice has undoubtedly had significant and, for such an applied and policy-oriented discipline, real consequences. For many decades vast resources have been devoted to 'family planning' programs aiming to transplant 'modern,' 'western' contraceptive practices into an enormous variety of diverse cultures. More policy effectiveness might have been forthcoming if both fertility and birth control had been initially approached as culturally variable entities, whose meanings had to be researched in any population before attempting to modify them.

The future of demography, established as it now is in all the world's major cultures, is likely to include much more active discussion of the relationship between its inherited inventory of 'Western' social categories and those of other peoples, something also likely to follow from the increasing sophistication of historical demography. It is likely to be less consumed with the problems of engendering economic growth and more with social equity and public health issues, including those of longevity and 'aging,' along with ecological problems of the uses and distribution of material wealth. This would represent a return, on a global scale, to the issues which so preoccupied the mid-nineteenth century demographic observers of the human disruption wreaked in Britain and Europe by the world's first great wave of rapid economic growth. At the same time greater reintegration of demography into the intellectual concerns of the other social sciences seems long overdue and likely to be mutually beneficial. In particular, with its technical core in an abstract accounting approach, demography has remained relatively gender-neutral in its analyses, in the sense that it has singularly failed to attempt to grapple with the linguistic and epistemological complexities that arise from acknowledging a negotiated and dialectical relationship between the two sexes in all that they do. A genuinely two-sex demography is likely to constitute the next fundamental advance.

Demography: Twentieth-century History

Achille Guillard first used the word 'demography' in 1855 to describe a new science of population dynamics, by which he meant the statistical study of the size, condition, and movement of populations. Malthus, a half century earlier, had initiated a period of speculation on population growth's constraining effect on prosperity, but only by mid-century had the collection of population statistics become extensive enough in Europe and the USA for a 'science' of population to be imagined. The rise of industrial capitalism in Europe and its overseas extensions increased the pace of social, demographic, and economic change, stimulated the development of state structures aimed at directing these changes, and made obvious the usefulness of accurate population statistics. As India's first census in 1868 reflects, such usefulness extended to the administration of colonies as well. In 1882 the fourth International Conference on Hygiene (Geneva) included a section on demography. By its next meeting in 1884 (The Hague) the conference included demography in its title and sections on 'the science of statistics applied to the social well-being of people' were presented. Although the growing body of population statistics was being discussed at international meetings, as the nineteenth century came to an end a unified discipline of demography, with a distinct body of theory and method, had yet to emerge.

For an intellectual activity to become a discipline certain things are needed: a significant interaction among those performing the activity; an organization that directs its investigation and teaching; and entities outside itself who value and use its findings. Using this definition, demography lacked the status of a discipline for much of the twentieth century. The century began with a diverse group of individuals considering themselves population specialists: statisticians, public health officials, biologists, economists, sociologists, geographers, historians, lawyers, political activists, and politicians. There was haphazard interaction among this group and the teaching of demography had yet to find a clear place within the academy. While basic population statistics had an undeniable utility for those engaged in pragmatic planning activities, there had yet to develop a consensus about the larger significance of modern population changes. In fact, while consensus was developing about the causes of modern population changes, the twentieth century began with growing dissension about their societal consequences. Those engaged in examining population trends warned of very different population problems and recommended conflicting population policies. With such disparate voices speaking about population, a harmonizing core discipline was difficult to detect. The lack of a unifying theoretical perspective that explicated why population mattered, and the presence of a fractured population policy agenda were

two factors that obstructed the development of a distinct discipline of demography; these factors continued to inhibit disciplinary development throughout much of the twentieth century.

During the nineteenth century social movements aimed at influencing population trends arose that attempted to provide the unifying theoretical perspective and clear policy agenda for the study of population statistics. Neo-Malthusianism, based on the belief that growing populations are a major cause of poverty and that lowering fertility by making contraception more accessible will facilitate prosperity, originated in Great Britain early in the nineteenth century and spread gradually throughout Europe. The British Malthusian League was established in 1877, followed by neo-Malthusian leagues in Holland (1885), Germany (1889), and France (1895). But by the time the leagues united at the first International Neo-Malthusian Conference (Paris) in 1900, fertility decline had so spread among urbanizing and industrializing societies that the crisis aura surrounding population growth and large families largely had abated. For countries like France, which were beginning to face the specter of depopulation in the context of an increasingly quarrelsome Europe, it had become less clear that population growth was a social evil or that small families were a social good.

The fertility decline experienced in more developed societies generated new population movements as the twentieth century began. The upper and middle classes were embracing the small family norm more quickly and more fully than other classes. The rediscovery of Mendel's research and the power of Weismann's work on an inviolable germ plasm had convinced many that heredity played a transcendent role in molding human destiny. The educated of the period were much inclined to use social class position as a surrogate measure of biological quality, and they bemoaned the 'race degradation' that resulted from the 'less fit' lower classes contributing an increasing proportion of future generations.

As early as 1891 Sir Francis Galton, addressing the demography section of the International Conference on Hygiene and Demography in London, was urging that the issue of heredity and fertility be dealt with in the 'practical politics' of member states. As the twentieth century began, eugenics movements were forming in a number of countries. In the USA's an active immigration restriction movement allied itself with those expressing eugenic fears. Restrictionists railed against the flood of 'inferior' Eastern and Southern European immigrants who were 'degrading' the high quality of the largely Anglo-Saxon and Northern European 'stock'; they even claimed that the increased number of the 'inferior' was a major cause of fertility decline among the 'superior.'

The eugenists and restrictionists feared changes in population composition and quality, not population quantity and growth. The trend that neo-Malthusians praised, fertility decline, was the same one that they bemoaned. Most eugenists fought to keep access to contraceptives restricted, contending that only the 'more fit' higher classes were sufficiently disciplined to limit their family size. Into this amalgam of population movements Emma Goldman, Margaret Sanger, and Marie Stopes attempted to add 'birth control' movements in the USA and Great Britain. During a period when high-ranking politicians were reminding educated women publicly of their patriotic duty to marry and have children, they began mobilizing citizens to legalize a woman's access to contraception.

With most academic population experts at the time producing works that fed the eugenic-based fears of elites, the task of birth controllers was to develop convincing counter-arguments as to why legalizing contraception was socially beneficial. The socialist arguments that Emma Goldman presented—that working-class women could improve their class' negotiating position with capitalists by restricting the production of new workers—had limited public appeal. Margaret Sanger attempted to attract the allegiance of experts and a wider public by deftly weaving together eugenic and neo-Malthusian themes: restrictive laws do not keep contraception out of the hands of the educated classes and only serve to slow the adoption of birth control among the less motivated 'inferior' classes, an adoption that would benefit both the individual and the society. During the 1920s the pace of fertility decline increased in developed societies, fears of actual depopulation grew, and additional controversy swirled around population trends.

Many consider demography a discipline that is either defined by its specialized techniques or delimited by its particular area of study: the causes and consequences of population change, especially the mortality and fertility transitions that have so dramatically swept the world since the 1750s. But for the first third of this century, for a variety of reasons, those engaged in both areas of research found themselves enmeshed in population controversies that made them less able to focus their energies on disciplinary development. For instance, when Louis Dublin and Alfred Lotka developed 'intrinsic' vital rates in 1925 that controlled for the age structure's influence on crude birth and death rates, they applied their technique to the study of US vital rates and dramatically announced that the average American woman in 1920 was having only half a child more than was needed to maintain a stationary population. Dublin then was moved to write articles identifying excessive birth control as a national problem and attacking Margaret Sanger for fostering a one-sided socially harmful movement. In the late 1920s the technical demographer was hard to distinguish from the movement advocate.

Similarly, experts studying the causes and consequences of modern population movements found the 1930s to be an era in which nationalistic chauvinism made discussion of these trends fraught with contro-

versy. The International Union for the Scientific Investigation of Population Problems was launched in 1928, an outgrowth of the 1927 World Population Conference sponsored by Margaret Sanger in Geneva. The IUSIPP (later to become the IUSSP) planned to hold its first meeting in Rome in 1931. Mussolini's rise to power and hints that the meeting would be used to promulgate his racial theories caused the leadership of the IUSIPP to 'dis-establish' the Rome meeting and convene a hastily planned counter conference in London. The IUSIPP's next official meeting was Berlin in 1935, and was even more controversial. Several national committees, correctly fearing that the conference would be used as a platform from which to spread Nazi racial theories, boycotted the meeting. The first two IUSIPP meetings were exercises in divisiveness, and certainly not venues for establishing a new discipline.

Even the academic study of the causes of modern population dynamics proved controversial during the interwar period. By the early 1930s a number of students of population (Warren Thompson in the United States, Adolphe Landry in France, and A. M. Carr-Saunders in Great Britain) arrived at a quite similar summation of modern population dynamics: as agrarian societies become industrial there is a shift from high to low vital rates during which mortality declines more quickly than fertility, producing a period of population growth. Northern and Western Europe and the United States had largely experienced this 'demographic revolution' (Landry's term), Eastern and Southern Europe and Japan were in the middle of their expansion stage, and much of the rest of the world had just begun the revolution.

Although demographic transition theory was to play a central role in the institutionalization of demography 20 years later, its development in the 1930s proved awkward. Both Germany and Japan were using *Lebensraum* rationales for their imperialist moves into their neighbors' land, claiming that their growing populations needed room to expand. Any summation of modern population dynamics that seemed to confer scientific legitimacy on these claims lost attractiveness to a number of Western policy makers. Explicating the causes of modern population changes during this era did little to establishment a firm foundation on which to build a disciplinary infrastructure for demography.

The end of World War II, however, began a most propitious period for establishing such a foundation. War-torn nations, both allied and axis, entered into a period of state-planned national reconstruction. The production and analysis of population statistics were vital for such planning. The National Institute of Demographic Studies (INED) was established in France in 1947 as a planning arm of the Ministry of Social Affairs and National Solidarity. Although not engaged in the teaching of demography, INED did much to enhance the reputation of the discipline, as did the publication of the first volume of *Population* (Paris) in 1946. One year later *Population Studies* made its debut in London. The establishment of two scholarly journals that focused exclusively on publishing analyses with a distinct demographic focus did much to solidify the boundaries of demography as an academic subject. On a more functional level, the Population Division of the UN Secretariat was established in 1946 and worked to standardize demographic measures and promulgate a common set of techniques for demographic analysis.

The war's conclusion also resolved many of the more fractious issues that had fueled earlier population controversies, and the link between population discourse and divisive controversy weakened considerably. Knowledge of the enormity of the holocaust led to the eugenics movement quickly dissipating. A widespread post-war baby boom dispelled many countries' worries of depopulation. The removal of German and Japanese military threats broke the association between transition accounts of modern population dynamics and population-pressure rationales for imperialism. In fact, in the postwar world the transition framework would provide Western policy makers with a needed policy tool: a way of interpreting the unprecedented demographic changes arising in the world's underdeveloped regions during the 1950s and 1960s.

The rapid decolonization of the world that followed World War II produced a 'Third World' of newly independent governments that became a Cold War battleground where the USA and the Soviet Union fought for supremacy. Unprecedented mortality decline resulting from the use of newly developed antibiotics and the application of effective methods for combating malaria produced rapid population growth throughout much of the developing world. Such growth was especially problematic when considered from the perspective of the post-war versions of demographic transition theory promulgated by US demographers working at Princeton University's Office of Population. If the economic strains associated with rapid population growth prevented the transformation of traditional agrarian societies into modern industrial ones, then rapid population growth might forestall the very socioeconomic changes that would induce fertility decline. Without fertility decline, the Third World's period of population expansion would come to an end with mortality rising as starvation and disease increased. Starvation, economic stagnation, and growing poverty were judged propitious for the spread of communism. Inducing fertility decline in still agrarian societies came to be seen as the only way to humanely resolve the Third World's population dilemma; and, additionally, it would protect the geopolitical interests of the Free World.

This vision of the postwar global population situation was promulgated by Princeton demographers during the decade from 1945 to 1955, especially by

Frank W. Notestein and Kingsley Davis. During the early 1950s John D. Rockefeller III and the leadership of the Ford and Rockefeller foundations accepted the validity of this vision and worked to establish a neo-Malthusian movement with a global focus. Their goal was to set up family planning programs throughout the Third World, lower fertility, and lessen population growth. They recognized that only governments could implement effective family planning programs, and their immediate task became converting government leaders, in both developed and Third World countries, to the position that high fertility was a major social problem in need of state intervention. They determined that a dramatic increase in academic research on international population issues was a necessary first step in this conversion process. During the next two decades they expended millions of dollars to develop demographic research centers that focused on international population issues.

These expenditures on demographic research had a profound impact. In the USA in 1950, for example, courses in demography could be found at the graduate level in only three universities. Between 1951 and 1967 major population research centers were established at 16 US universities; all owed their existence to foundation funding, largely from the Ford Foundation. Similar expenditures helped established internationally oriented population centers at a number of major universities in Europe and Australia. Funding from the Population Council, a foundation established by John D. Rockefeller III in 1952 to provide a leadership role for the international population control movement, established UN regional centers for demographic training and research in Bombay, India (1957), Santiago, Chile (1958), and Cairo, Egypt (1963).

Additionally, its fellowship program brought hundreds of Third World students to major population research centers in developed countries for graduate training in demography. The research generated by the rapidly expanding number of demographers found its way into print in the many demographic and family planning journals that foundation funds were instrumental in launching: *Studies in Family Planning* (1963), *Demography* (1964), *Family Planning Perspectives* (1969), *Population and Development Review* (1975), and *International Family Planning Perspectives* (1975). This conscious cultivation of demographers engaged in addressing Third World population issues had the desired effect. While no government leader thought that lowering the fertility of couples was a legitimate state function in 1950, a substantial number did so 20 years later. As governments adopted fertility control policies and implemented family planning programs, additional funds for demographic research became available, as did additional employment opportunities for the alumni of population research centers.

The vast expansion in resources made available for demographic research by leaders of the international population control movement from 1950 to 1975 was largely responsible for establishing demography as an academic discipline worldwide. All the prerequisites for an intellectual activity becoming a discipline—a significant interaction among those performing the activity, an organization that directs its investigation and teaching, and entities outside itself who value and use its findings—were deliberately assembled by this leadership. The decision to fund graduate level demographic training programs at leading Western research universities assured that there would be a significant and continuing interaction among those engaged in demographic research. It also assured that academic programs in demography would be established and that standards for the teaching of the discipline would be developed. The many private and government contracts for fertility control research generated a demand for this new discipline's findings by outside entities, a demand that no doubt impressed university administrators.

These resource flows, however, did not simply impact the disciplinary development of demography in positive ways. There were costs as well. The neo-Malthusian impetus behind the institutionalization of demography caused the discipline itself to be tinged with an ideological aura. During the 1950s and 1960s Soviet and Chinese population specialists consistently questioned the objectivity of Western analyses of Third World population issues. The major premise of the international population control movement was that rapid population growth had deleterious effects on development, and this was certainly the premise that guided the vast bulk of orthodox demographic research. It was, however, more hypothesis than fact. Although it is not uncommon among the social sciences to have certain perspectives represented within a discipline that are based on premises not subject to empirical verification, the discipline itself is usually composed of a multiplicity of such perspectives. Except in France, where a pronatalist tradition among French demographers made many suspicious [?] of neo-Malthusianism, significant counter-perspectives did not develop within Western demography until a stream of 'revisionist' literature began to develop in the late 1970s. Until that lively debate over the relationship between population growth and economic development developed, demography's close association with the international population control movement worked to politicize it. At occasions such as the World Population Conference at Bucharest in 1974, demographers found not only the validity of their research findings questioned but also their motives.

The neo-Malthusian impetus for much foundation and government funding of demographic research also made it subject to the shifting fortunes of that movement. Population research centers were establish on the basis of grants with time limits and lacked departmental status. Many of their positions were

'soft money' nontenured ones, although all had core faculty with permanent positions in established departments, usually sociology, economics, or public health. During the 1950s and 1960s few universities were willing to subsidize population research centers internally, and the survival of demographic training programs required the continual influx of outside funds. Foundation support for the international population control movement remained strong during the 1950s and 1960s but declined dramatically during the 1970s.

Northern government support of the movement tended to be significant but did vary with elections; the end of the Cold War, however, has dissipated a powerful source of Northern concern over problems associated with Southern population growth. Academic demography has responded to the funding vagaries caused by these movement shifts by becoming leaner, more embedded within the university framework, and less oriented to an international fertility control agenda. In the North, where the discipline still finds its center, every country faces a significant aging of its population and many countries face problems associated with long-term below replacement fertility. These domestic population concerns increasingly are the disciplinary focus of Northern demographers and population research centers. A similar transformation is taking place in many Southern countries where fertility is approaching replacement levels. Only in those Southern countries whose fertility levels remain high does demographic research remain synonymous with fertility reduction research. International migration, not fertility control, is increasingly the population trend garnering the attention of both Northern and Southern demographers. In a world with a global economy and with great disparities in national wealth, the mass movement of individuals across national borders can only increase in intensity.

At the end of the twentieth century the most notable development in the field of population has been that a discipline of demography, much like that envisioned by Achille Guillard in 1855, finally has emerged. The study of the causes and consequences of population dynamics is now a widely recognized intellectual activity that is investigated and taught within an academic setting by individuals with academic credentials who are paid for their specialized knowledge and who reproduce themselves with new generations of demographers. The institutionalization of this discipline in the second half of the twentieth century was largely the result of a confluence of events happening at mid-century, the most notable of which was the rise of an international population control movement.

Demography still lacks an overarching theory capable of linking individual and societal demographic action, but currently possesses a significant disciplinary cohesiveness that arises from having a well defined subject matter and, increasingly, from having a common policy focus. Because most populations have neared completion of their mortality and fertility transitions, a common nexus of population trends is present: population aging in nearly every region; below replacement fertility in much of the North; declining population growth in much of the South. This particular set of demographic trends has so far produced few divisive debates over population policy. The twenty-first century begins, therefore, with demography's immediate disciplinary future assured.

Dental Health: Psychosocial Aspects

Dental health is a topic of both practical and theoretical interest. Practically speaking, the pain and loss of dentition that can be a result of dental ill health is a cause of much distress and disability. Although dental ill health is rarely life threatening, it can have severe and long-lasting effects on quality of life. Theoretically speaking, the ways in which people cope with anxiety and seek to maintain oral health can provide many opportunities to test the accuracy of theories of human distress and motivation. In this article, the ways in which psychologists and sociologists have sought to understand dental anxiety and to improve oral health are examined.

1. *The Term 'Dental Health'*

Dental health can be defined and measured both objectively and subjectively. Objectively, dentists often use the decayed, missing, and filled teeth (DMFT) index as an indicator of dental health, but this may be more appropriately seen as a measure of dental history rather than health. Subjective assessments given by patients may not correspond to professionally developed objective measures. For example, Heyink et al. (1986) found only weak associations between dentists' and patients' appraisals of dentures. For dentists, clinical indicators such as fit, stability, and bite force were important, but for patients, denture quality depended on how well they functioned in practical everyday terms. It is useful to recall the World Health Organization's (1980) distinction between impairment (the objective pathology such as tooth loss), disability (limitation on activities such as not being able to eat certain foods as a result of tooth loss) and handicap (inability to perform social roles, such as being reluctant to accept invitations to dinner because of the potential social embarrassment of not being able to eat the food that might be served). Although it is possible to define dental health in any of these ways, it is useful to consider impairment primarily as an objective measure of health, while disability and handicap are more subjective in nature. Seen in terms of disability and handicap, dental disease is widespread. Cushing et al. (1986) found that 26 percent of adults had experienced dental pain, 20 percent had difficulty in eating and 15 percent had associated problems of communication within the previous year.

Psychologists and sociologists have been keen to understand the causes of dental ill health, partly with a view towards reducing disease and partly with a view towards using the dental setting to test and develop theories of health behavior. Two areas which have received considerable attention are (a) the development and alleviation of dental anxiety and (b) the exploration of why some individuals engage in regular preventive dental care whereas others place less emphasis on this aspect of their physical well being.

2. *Dental Anxiety*

Research in this area has addressed three questions. First, there is the issue of the nature of dental anxiety (see *Anxiety Disorder in Children*). Like other forms of anxiety, it has behavioral, somatic, and cognitive components. Second, there is the issue of etiology of dental anxiety. Despite the development of modern anesthetics, it is widespread: depending on how it is measured, 3–5 percent of the general population can be said to have a debilitating level of dental anxiety. Third, there is the issue of treatment. Several treatment approaches show consistently good results.

2.1 *Components of Dental Anxiety*

Historically, the behavioral aspects of dental anxiety have received the most attention. This is probably due to the consistent finding that anxiety is a powerful barrier to the receipt of professional care. For example, Curson and Coplans (1970) interviewed patients in an emergency clinic and 38 percent reported that they did not make regular visits to a dentist because they were too afraid to do so. Of these, only 12 percent made and kept further appointments for a course of treatment at the clinic. The extent of behavioral difficulties has been measured through both observational and self-report methods. Melamed et al. (1975) used an observational schedule which contained a series of behavioral indices of anxiety in children (crying, refusal to open the

mouth, verbal complaints), rating these activities at 3 min intervals during the appointment. Kent et al. (1996) designed a self-report scale to measure the extent to which dental phobics avoided and were troubled by dental stimuli. Physiological measures of anxiety are less easily taken, but they too show a consistent relationship with self-reported anxiety. Patients are more likely to show increased heart rate at certain points of an appointment, especially at the beginning of treatment. Perhaps the most commonly used self-report measure of anxiety is Corah et al.'s (1978) dental anxiety scale, which asks people to indicate how relaxed or tense they are in the dental setting.

An interest in the cognitive aspects of dental anxiety has developed in the late 1990s. As in other forms of anxiety, anxious patients are more likely to engage in catastrophic thinking. They are more likely to ruminate on the worst possible outcomes of an appointment, of an 'Any moment now the dentist will get the nerve and then it will really hurt' kind. For many anxious patients, it is not a question of *if* they will experience pain, but *when*. De Jongh et al. (1995) have developed the dental cognitions questionnaire, which contain such items as 'They will find something terribly wrong with me' and 'They might drill too deep.'

2.2 The Etiology of Dental Anxiety

The research strongly supports the notion that, especially for children, dental anxiety is a classically conditioned response to dentistry (ter Horst and de Wit 1993). Given that modern anesthetics are thought by dentists to be very effective in alleviating discomfort during dental treatment, and given that the need for invasive treatment has declined for many people owing to the introduction of fluoride in the water supply of many areas, it is surprising to find that levels of dental anxiety have not declined to the expected extent in the latter part of the twentieth century. There seems to be several reasons for this. First, it appears that many more patients experience discomfort during treatment than is often assumed. Depending on how it is measured, up to 77 percent of patients report that they feel some pain during their visits to the dentist. Second, it has been argued that the notion of 'preparedness' is particularly relevant here. Just as humans might be innately prepared to become anxious about small animals such as spiders and rats because they posed a realistic threat in our evolutionary past, so too might sitting in the dental chair, with an adult placing sharp instruments in our mouths be one in which anxiety is quick to develop. It might take only the slightest degree of discomfort for anxiety to occur. Although classical conditioning is generally seen as the prime mechanism for the onset of dental anxiety, other learning modalities may also contribute. There is evidence that dental anxiety can be modeled by hearing about someone else's discomfort (Corkey and Freeman 1994). Finally, the role of biological factors merits attention. Dentally anxious individuals score higher on personality questionnaires measuring emotional lability or neuroticism, and children who have a 'difficult child' type of temperament are more likely to be dentally anxious. Such research suggests that dental anxiety might be more likely to develop in individuals who have other psychological difficulties (Aartman et al. 1997).

One of the most important methodological issues in this area concerns the retrospective nature of almost all studies. Although it is likely that negative experiences contribute to onset, it is also likely that current levels of anxiety affect interpretations of dental experiences. Owing perhaps to hypersensitivity, an anxious patient might interpret sensations felt in the dental chair as painful, whereas a nonanxious patient may interpret such sensations differently. Certainly, highly anxious patients expect to experience more pain than patients with low anxiety, even if their actual experiences do not differ. Memory processes may also play a role. Kent (1985) asked patients after their appointment to indicate the amount of pain they felt. Three months later, they were asked to indicate the level of pain they remembered having experienced. Whereas those with low anxiety gave reports that corresponded closely to their immediate postappointment ratings, those with high anxiety recalled much higher levels of discomfort. In fact, their reports corresponded most closely to their preappointment expectations. Such studies indicate that retrospective studies are open to severe criticism.

2.3 Treating Dental Anxiety

Interventions designed to assist people to deal with their dental anxiety are similar to those designed to help people with other types of anxiety. There is the fundamental importance of graded exposure to the dental setting in combination with the provision of coping strategies (see *Stress Management Programs*). Before discussing these interventions, however, it is helpful to outline some of the research pertaining to the prevention of dental anxiety.

2.3.1 Prevention. Two factors stand out as critical in reducing the likelihood that dental anxiety will develop, particularly in children. The first concerns the alleviation of pain, in that a reduction in the need for invasive treatments is likely to reduce anxiety. One study that has not been performed is a comparison of the levels of dental anxiety between areas that do and do not have fluoridated water supplies. The second factor concerns the nature of the relationship between the patient and the dentist. A number of studies have indicated that warm and nurturant dentists can help patients to overcome

their dental anxiety when it has been acquired but also that they can reduce the probability that anxiety will develop, even after a painful experience (Bernstein et al. 1979).

2.3.2 Interventions. As noted above, most interventions for the alleviation of dental anxiety rely on traditional methods of graded exposure to the feared stimulus. There is much consistency between individuals concerning the most feared aspects of dental care (usually extractions followed by drilling and injections) and fear hierarchies can usually be constructed without difficulty. There is considerable evidence that systematic desensitization, relaxation, hypnosis, and modeling can all have positive effects (Kent and Croucher 1998). As in other areas of psychological intervention, ~60 percent of patients report substantial improvement in their difficulties, regardless of the type of approach used. This may be because all types of intervention serve to enhance patients' sense of control over the situation. In this context, the use of stop signals—where the patient is invited to indicate a wish to take a break from treatment—can be a simple yet effective method for increasing a sense of control over the dentist's behavior. Pharmacological treatments—especially using nitrous oxide—can not only be effective for the alleviation of anxiety in the short term but may also have longer-term beneficial effects. The alleviation of uncertainty and the provision of information are particularly relevant to dental anxiety. Because it is closely associated with the presence of catastrophic thinking, realistic information can not only dispel some irrational fears about the nature of professional care, but can also provide patients with knowledge about when invasive treatment might cause discomfort. An interesting theoretical and practical issue here concerns the amount of information provided. There are indications that patients who have a blunting coping style show greater distress when given detailed information, whereas those with a monitoring coping style are most likely to receive benefit (Auerbach et al. 1976).

3. *Maintenance of Oral Health*

The maintenance of oral health is largely a function of behavior (see *Health Behaviors*). Although fluoridated water supplies have led to a substantial reduction of dental caries in some areas, most dental ill health could be prevented if people took the appropriate actions. These actions are mainly of two types: a reduction in the frequency of eating sugar to reduce caries, and an increase in the use of brushing, dental floss, and regular dental visits to reduce the amount of plaque (which leads to gingivitis and tooth loss through the destruction of supporting tissue).

3.1 *Educational Approach*

The notion that education could improve dental health is based on the findings concerning the generally low levels of relevant knowledge in the general population. Many people are unaware that the occurrence of caries is most closely associated with the frequency of eating sugar, rather than the absolute amount. Similarly, many people do not realize the importance of reducing plaque for the maintenance of healthy gums. Theories of health behavior (Connor and Norman 1996) predict that patients' levels of knowledge will have an effect on what they do to maintain good health. According to these models, people will begin to make changes to their behavior—or at least move from one stage of preventive care to another—only when they appreciate the importance of regular dental care and have a correct interpretation of symptoms.

Horowitz et al. (1976) provide a good example of an experiment on intensive dental education. One group of children was given 10 sessions of 30 min on plaque removal, being taught in small groups by a dental hygienist. They were informed about plaque, how to identify it with disclosing agents, and how to remove it. Plaque removal was practiced under supervision every day for the next 6 months. The comparison group of children were not given any of this extra information or practice. At the baseline, the two groups were similar on both measures. At the 8 month assessment, there was a significant decline in gingivitis scores in the education group compared with the comparison group, but at 12 months there was no difference. There was no long-term effect, and there were never any differences between the two groups in caries levels or amount of plaque. On the basis of such typical results, it seems that educational programs have little or no long-term effects, but it should be noted that most training has been given in school and there has been little attempt to integrate what children have learned in the school environment with what they do at home. Another possible reason for the lack of an effect is that the education approach is only part of the answer to changing behavior. Educational approaches may make some difference by increasing knowledge, but they may not provide sufficient motivation to put this new-found information into practice. In order to accomplish this, a motivational or behavioral approach may also be needed.

3.2 *Motivational Approaches*

In terms of the stages of change model, people will move from the contemplative and preparation stages to the action and maintenance stages only when they can see some kind of clear benefit in doing so (see *Health: Self-regulation*). Furthermore, the benefit needs to be apparent in the short term rather than some years in the future. From the viewpoint of

behavioral analysis, it is crucial to identify actual and potential reinforcers in the person's environment. One of the important difficulties facing those who wish to change patients' behavior is that there are many positive reinforcements maintaining undesired behavior (e.g., the sweetness of foods) and few negative ones which might lead to desired changes (e.g., caries might develop months or years in the future).

This issue is particularly relevant for children who will have difficulty in seeing the relevance of regular brushing in the present to ensure that they will not lose their teeth through gingivitis decades in the future. Thus, behavioral programs to encourage preventive dental behavior have focused on the use of immediate reinforcements to increase the likelihood that people will monitor their sugar uptake, brush daily, and floss regularly. There are several evaluations of such programs, most showing positive results (Kent and Croucher 1998). Monetary reinforcers have been used for both children and their parents, but often stars on a calendar can be similarly effective.

Dependency Theory

Dependency theory is a school of thought in contemporary social science which seeks to contribute to an understanding of underdevelopment, an analysis of its causes, and to a lesser extent, paths toward overcoming it. It arose in Latin America in the 1960s, became influential in academic circles and at regional organizations, spread rapidly to North America, Europe, and Africa, and continues to be relevant to contemporary debate. This article examines the history of its chief concept, describes its evolution over time, analyzes its influence, and evaluates its validity and prospects for social science in the future.

1. The Dependency Concept

The facts to which dependency refers have existed for a long time, not only in connection with the emergence, consolidation, and evolution of the present-day historical-social system of capitalism, but also with former world systems, all of them asymmetrical: comprised of units located at their core, their semiperipheries, and their peripheries. They are linked by domination–subordination relationships, which are structural because they stem from and are driven by the principles which govern the system as a whole, and hence, the location of the different units.

For the current system, those principles are anchored in the accumulation of capital and in its varying forms, generating modes of international division of labor that comprise and shape the relations among the center, semiperiphery, and periphery. The classical political economy of Adam Smith, David Ricardo, and others in the eighteenth and nineteenth centuries recognized the worldwide nature of capitalism, though

they saw the international division of labor among the system's units (countries) as a source of the wealth of nations, operating through Ricardo's theory of comparative advantages. Marx's critique of classical political economy viewed that division as a source of inequalities and asymmetries among peoples, and therefore posed the need to construct a true social model of the whole system in the long term (Wallerstein 1974, pp. 388 ff.). Though his imitators 'froze' Marx 's model and stripped it of its historical nature, his successors continued to focus on the evolution of inequalities and asymmetries. This was especially the case of the theorists of imperialism (Lenin, Bukharin, Hilferding, Luxemburg) and of unequal and combined development (Trotsky and his followers).

Subsequent to the interpretations based on Marxism and imperialism theory, efforts were made in the political economy to understand the nature of 'backwardness' and the causes of poverty in many societies; this line is represented by Arthur Lewis and Gunnar Myrdal, and later by Albert Hirschman and Amartya Sen, to name only a few significant authors (Rist 1997, pp. 69).

Oddly, the dependency concept did not acquire a central theoretical status in either of those two areas of analysis, but was accepted in its most rudimentary form: Certain economies depend on others to buy or sell raw materials and manufacture. It was only with the appearance of studies on the subject of development in Latin America and the Caribbean that 'dependency' became a social-scientific term, though a very controversial one.

2. *External Dependency*

The term 'dependency' appears for the first time in the 'developmentalism approach,' so called because its key concept (and chief concern) was development, pursued in order to overcome 'underdevelopment' (a term coined at that time), which emerged from the UN Economic Commission for Latin America and the Caribbean (ECLA). Following the proclamation and adoption of the United Nations' Charter, in addition to the Security Council, responsible for finding peaceful ways to resolve conflicts among nations, the Economic and Social Council (ECOSOC) was created to coordinate activities in the UN's other main field of action—promoting the development of peoples. To help the ECOSOC fulfill its mission, economic commissions were designed for the five continents. Despite the initial resistance to its institutionalization by the USA, ECLA was founded in 1948 and received that country's blessing in Point Four of President Truman's January 1949 State of the Union address, referring to the need to overcome underdevelopment (Rist 1997, p. 70). It became the most intellectually creative of all the commissions, and the most active one in designing and applying development policies (Sonntag 1994, p. 228).

Developmentalism's diagnosis begins with a critique of the classical (Ricardian) theory of comparative advantages: The economic relations between the core and the periphery tend to reproduce the conditions of underdevelopment and increase the distance between the developed and underdeveloped countries. Paraphrasing Cardoso, the invisible hand of the market appeared, not as a mother but as a stepmother, intensifying inequalities rather than correcting them. The reason for that outcome is that productivity grows faster in the central countries' manufacturing industries than in the peripheral countries' production, and that growth cannot spread to primary (agricultural or mineral) production through equalization of the prices of both sets of products, because of union pressures and the presence of oligopolies in the developed countries. The end result is the trend toward deteriorating terms of trade and a growing concentration of technical progress in the manufacturing or core countries (Sonntag 1988, pp. 24–5).

Therein lies the key: with this center–periphery axiom ECLA posits a discontinuous worldwide development of capitalism. It identifies the (structural) place of the economies in which capitalist techniques of production are first adopted as the core, and that of the economies which are further behind in technological and organizational terms as the periphery. This dichotomy is constantly reproduced by the dynamic of the international division of labor, to the point where the periphery tends to transfer part of the fruits of its technical progress to the core while the latter retains those of its own progress (CEPAL/ECLA 1969, 160 ff.).

This latter assertion poses the concept of external dependency. Dependency lies in the peripheral economies' reliance on the determinant dynamic of the world system of which they are part: that of the core countries, simultaneously reinforced by the transfer of part of the peripheral countries' surplus to them. An odd feature of this school of social science thought is that, in spite of ECLA's clear analysis of external dependency, in its strategic proposals to achieve development it fell into a voluntaristic confidence in the utility of foreign investment, the industrialized countries' cooperation, and a transformation of international trade.

3. *Structural Dependency*

A debate began at ECLA during the first half of the 1960s on the results of the development policies grounded in developmentalism and intensively applied in most Latin American countries. That also implied a theoretical reorientation in two distinct directions: a renewal of developmentalism itself, and the emergence of dependentism (Sonntag 1988, p. 31 1994, p. 230).

This new approach not only drew on the debates over developmentalism, but also reflected: (a) the rediscovery of Latin American authors from earlier

decades with critical ideas (Sergio Bagú, Caio Prado Jr., José Carlos Mariátegui, etc.); (b) a renewal of Marxism during the 1950s and 1960s, through Baran's *Political Economy of Growth* and Baran and Sweezy's *Monopoly Capital*; (c) studies by authors such as A. Gunder Frank on the capitalist nature of underdevelopment; and (d) Latin American interpretations inspired by a less orthodox Marxism than that of the previous period, advanced by authors in different countries. There is considerable controversy about the significance of these influences: while Cardoso (1976, p. 4) estimates them less, Dos Santos (1998, pp. 103) and Rist (1997) attribute far greater importance to them.

The first texts of what was rapidly to become a new paradigm of thought on underdevelopment in Latin America (and also in Africa, where it contributed to Samir Amin's school of worldwide accumulation of capital, in the developed countries, and to a lesser extent in Asia) initially circulated as mimeographed discussion papers among the members and associates of the Latin American Institute of Economic and Social Planning (ILPES), since 1961 ECLA's think-tank and cadre's school. Two of these papers, those of Cardoso and Faletto (1976a) and Quijano (1977), were the sources of dependentism. Those that followed drew on these initial efforts, some opposing their theoretical proposals and political conclusions, others assimilating them and incorporating them into their own studies.

The first dependentists started with a critique of the modernization theory introduced by ECLA in the late 1950s, and posited an integrated analysis of development combining the study of social change processes in the economic sphere with that of transformations of structures of classes, social sectors, and groups, plus that of the changes occurring within the system of domination. The accent is on sociological interpretation in the strict sense, that is, on the transformations of the social structure and system of domination, since they are the epicenters of the dynamic of development. The latter is the outcome—always subject to change—of the attempts by the different social actors, alone or in alliances, to achieve their goals through their collective actions (Sonntag 1988, p. 63).

The dependentists hold fast to the center–periphery axiom, but redefined the concept of dependency, positing that it 'directly alludes to the conditions and the existence and operation of the economic system and the political system, showing the linkages between the two in both the internal dimension of countries and the external one.' The aim is 'to seek to demonstrate that…the mode of national economies' integration into the international market implies defined and differing forms of interaction by the social groups of each country, among themselves and with external groups' (Cardoso and Faletto 1976a, pp. 24, 28). Accordingly, the relations of political struggles among groups and classes, on the one hand, and the history of the economic-political structures of internal and external domination, on the other, are the key questions. So, they are interested in inquiring into the meaning of the basic structural relations and their phases of development in their dual determination: within the local systems of domination, and their relations with the international order (Cardoso and Faletto 1976b, p. 1). Thus dependency becomes a framework which influences the fundamental tendencies of development in the subordinated societies, by leading to and producing change, impregnating and modifying all aspects of the social structure, social psychology, and cultural institutions, including those of sectors which had been relatively untouched by sociocultural influences prior to the beginning of dependency (Quijano 1977, p. 23).

The dependency concept thus acquired a dialectical content. The relations implied are not perceptible in terms of 'structures,' but rather in terms of collective actors and their practices stemming from their interests and motivations. Change processes are not automatic mechanisms but the outcomes of those practices. That is, dependentism—in its first formulations—tries to restore the subjective actor(s) to history and the dynamic dimension(s) to social-scientific interpretations. It is, once again, a 'global analysis' (Cardoso and Faletto 1976b, p. 4) which stresses the multiple mediations among actors and structures.

A division soon appeared within the field of dependentism. One group, led by Dos Santos (1970) and Marini (1969), claimed that it had achieved the status of a theory of dependency, while another, led by Cardoso and Faletto, insisted on dependentism as a methodological approach. While the former were known as neo-Marxists (Dos Santos 1998, p. 105), the latter asserted that the dependentist approach only implied 'an empirical analytical effort to reconstruct a "concrete whole."' For Dos Santos, Marini, and their followers dependency as a 'theory' implied that a formal and testable body of propositions was inherent to the concept, while Cardoso and his group feared that thus the approach would be formalized (Cardoso 1976, p. 14).

The debate between the two groups was fiery, long, and sometimes bitter. It addressed metatheoretical issues, but focused chiefly on political ones: whether capitalist development was viable or not under conditions of dependency. The 'theoreticians' asserted the impossibility of any such development, while Cardoso, Faletto, and others would not agree with that idea and its assumption that, to improve the quality of analysis, dependency theory had to be formalized (Cardoso 1976, p. 24). They argued thus against the mechanical-formal style of those who believed in the ultimate ends of history, guaranteed by the necessary structural inability of dependent capitalism to expand and reproduce itself.

Dependentism, in either of its two versions, oriented social scientific analysis from the 1960s through part of the 1980s and fostered—as the proponents of both schools agree—a far deeper, more complete and more dynamic understanding of the social reality of underdevelopment.

Special mention should go to what Cardoso (1976, p. 8) has called 'the consumption of dependency theory in the United States.' There interest centered on first, the historical debate over the supposed Latin American feudalism; second, the relations among the dependent countries' social, economic, and political structures and the international capitalist system; third, research on and denunciation of the forms of 'foreign aid,' the CIA, and the Machiavellian actions of the multinational corporations, and so forth. This concern was politically legitimate and drew attention to real aspects of the contemporary process. But little by little it ended up restoring the priority of the external over the internal (Cardoso 1976, p. 13).

Criticisms of dependentism is as old as the approach theory itself. Especially scholars of industrial societies emphazised (a) the absence of an analysis of political power in the relations between core, periphery, and semiperiphery (political scientists), and (b) dependentism's blame of all problems of underdevelopment to external factors (economists). Both criticisms are dubious. On the one hand, the question of power was in the very center of dependentism's emphasis on the structures of internal–external domination. On the other, the insight of the dialectics between external and internal factors was essential, at least to dependentism as approach.

4. *The Future of Dependentism*

Studies inspired by the dependency theory or approach are part of the constantly renewed effort to restore a tradition based on an analysis of the structures of wealth and domination, which does not undermine the historical process as the movement derived from the permanent struggle among groups and classes. It does not accept the existence of a given course of history, but conceives it as an open process. Hence, if structures limit the range of oscillation, the imagination and actions of human beings reinvigorate and transform them, even replace them by others that are not predetermined. However, these studies had a special characteristic: Instead of being limited to the abstract historical dimension and the analysis of narrowly defined problems, they used the 'nonvulgar' historical-structural method to analyze concrete situations and sought—by returning to the subject of development—to pose questions of importance for national policy and the relations among the central capitalist economies and the dependent and nonindustrialized periphery (Cardoso 1976, p. 7). In this sense, contemporary criticism to dependentism as limited to the nation-state as unit of analysis (Grosfoguel 1996, p. 146) is scarcely justified.

The dependency approach and even theory is today a part of historical sociological analysis as it is understood by Wallerstein (1974). But within it an important function may be performed: since the latter tend to give priority to the systemic interpretation of the world-system, dependentism could focus on studying the behavior of concrete peripheral (and semiperipheral) societies in the context of that system, precisely because it stresses the collective actors, their interests, their practices, and the outcomes within them (as well as their repercussions on the system as a whole). So understood, dependentism would not disappear into the broader context of historical sociology, but would combine with it to form a complementarity that would permit more incisive approaches to each society's particular characteristics within the framework of its place in the world-system, in this era of globalization (Dos Santos 1998, Sonntag 1988, 1994).

To achieve that goal, 'it is necessary to have a sense, not so much of proportion as of being ridiculous, and avoid the simplistic reductionism so common among the modern butterfly collectors who abound in the social sciences': they classify in history types of dependency, modes of production, and laws of development, in the misconception that their discoveries may free history of its ambiguities, speculations, and surprises (Cardoso 1976, p. 25). It is, on the contrary, necessary to have the patience for disciplined research, to arrive at a dialectic which is neither lazy nor limited to the construction of general and abstract formulas as if they were synthetic.

In this assertion lies perhaps the challenge not only to this school of thought but also the entire sociology/social science of underdevelopment, particularly in these times of 'globalization,' uncertainty, and complexity.

Depression

This chapter describes how over the past ten years a solid neurobiological database has emerged that has left no doubt that depression is a complex clinical condition where interaction between genetic endowment and exogenous factors determines the phenotype. The various hypotheses for central nervous system dysfunction that may precipitate depression are examined and the ways in which studies related to stress hormone regulation have led to hypothesis-driven drug discovery strategies are discussed. In the future, the descriptive behavioral aspects of psychiatry will be replaced by more medically oriented schemes where abnormal behavior and mood are viewed as the functional readout of impaired gene environment interaction. Thus, traditional diagnostic schemes, presently still entirely based on behavioral and demographic data, will be modified by the new and exciting database that is emerging from functional genomics. Notably, most types of behavior depend on the interplay between environmental factors and multiple genes.

Based upon the complete genome sequences of humans, the clinical management of depression will become more individualized on the basis of functional phenotyping with laboratory tests and genotyping, once appropriate maps for polymorphisms have been established. The future knowledge base that will include not only behavioral, but also functional and genetic information about the patient will be so powerful that we will wonder how we ever practiced clinically without it.

1. *The Socioeconomic Burden of Depression*

Depression is one of the most common medical conditions worldwide. A national survey conducted in the United States of America has shown that the average 12-month prevalence in the general population is 10.3% with a 1-month prevalence ranging between 1.5% and 2.5%, amounting to a lifetime prevalence of 17% (Kessler et al. 1994). New research has also led to the abandonment of the view that depression is a byproduct of stressful life styles in industrialized countries. In fact, studies conducted under the auspices of the World Health Organization (WHO) indicate that the situation may be even worse in poor countries where malnutrition and infection make the brain more susceptible to mental disorders. Notably, five out of the ten leading causes of disability worldwide are psychiatric conditions. Using a sophisticated method for assessing the duration and severity of a disability, disability-adjusted life years (DALY), it has been calculated that depression will become a leading cause of disability in the coming decades, second only to ischemic heart disease (see Table 1).

It is also abundantly clear that one consequence of depression is a fourfold risk of developing ischemic heart disease and further, that patients who develop depression following a myocardial infarction, have a 15% higher mortality rate within the first six months following the attack than those without depression.

One of the most dramatic sequelae of depression is suicide. Official suicide rates drastically underestimate the actual level of suicide by varying extents. According to conservative estimates suicide claims over a million deaths per year, and among the younger population suicide is a leading cause of death second only to accidents. Given these facts and focusing on prevalence rates, it needs to be emphasized that these rates represent only diagnosed cases, and therefore only a fraction of the total prevalence because de-

a One DALY is one lost year of healthy life

pression is frequently overlooked but precedes suicide in the majority of cases. It is estimated that only approximately 50% of the population with depression in Europe and the United States is correctly diagnosed, while in Japan the rate is much lower, not exceeding 20%.

As a consequence, depression is still widely undertreated and remains one of medicine's most costly illnesses. When combining direct costs such as inpatient and outpatient care and pharmaceutical or talk therapies with the indirect costs of lost productivity, missed work days and loss of lifetime earnings, it becomes clear that depression accounts for a major share of the overall health care expenditure. These costs were calculated to amount to US$ 43 billion in 1990 in the United States alone, and a realistic reflection of the economic size of the burden imposed by depression worldwide underscores the pressing need to increase efforts on all fronts, ranging from public awareness to pharmaceutical research. In the light of these figures and the fact that we possess the therapeutic tools to treat depression successfully it remains one of the major tragedies that depression is still underdiagnosed and undertreated.

2. *The Genetics of Depression*

After more than a century of family, twin, and adoption studies we can now state with certainty that almost all forms of behavior, including depressive psychopathology, are influenced by multiple genes. Such genes are called quantitative trait loci (QTLs) because they are likely to result in quantitative (continous) distributors of phenotypes that underlie a predisposition to depression. Specifically, this means that there is no single locus that by itself causes psychiatric syndromes: instead multiple alleles (gene variants) that interact to produce vulnerability are found at multiple loci within the genome. Genetic research in psychiatry has left little room for the supposition that a single gene at a given locus determines any given psychiatric syndrome. In other words, in different families, different gene variants are required to confer increased vulnerability. In the light of the manifold possibilities of gene–gene interaction, genetic research has provided a particularly interesting demonstration that genes do not act alone.

Genes must interact with nongenetic environmental factors to convert vulnerability into illness. This is an important aspect as much research in the past has been devoted to the understanding of the development of depression based entirely on an individual's biography, making depression one of the last hermeneutic resorts in medicine. Many studies have shown that there is little reason to doubt that major stressful experiences, in particular those that occur in early life or even during pregnancy, render an individual more liable to develop depression (Heim et al. 2000). But it needs to be recognized that the conversion of life events into severe psychopathology requires the presence of the appropriate genetic endowment. An additional level of complexity has been introduced by the studies of Kenneth Kendler, who showed that individuals with a high genetic risk of depression are more likely to expose themselves to depression-triggering life events (Kendler et al. 1997). Indeed, several studies have supported this surprising proposition, that genetic factors may indirectly influence the liability to major depression by predisposing an individual to an aversive environment.

This shows that genetic and nongenetic environmental factors are much too inextricably intertwined to be dissected with high precision. Only when functional genomics have ultimately allowed us to establish a broad enough database on the functions of individual genes and gene–gene interactions, will the influence of environmental nongenetic factors on

Figure 1
The combined dexamethasone/CRH test 1.5 mg dexamethasone orally at 23.00 hrs and 100 μg CRH at 15.00 hrs the following day was administered to patients with a major depressive episode (MDE) to probands who had never been ill but belonged to families with a high genetic load for depression (HRP) and to matched healthy controls (CP). The plasma cortisol secretion in probands genetically at risk for depression show cortisol increases that lie between patients and controls.

vulnerability to, and the onset and course of, depressive syndromes become available to analysis.

Definition of the depressive phenotype for genetic studies is extremely difficult and findings from these tudies have been largely inconclusive. Another reason for the paucity of genetic studies of unipolar major depression is the psychosocial adversity toward studies that call the stress diathesis into question. The use of association studies, which allow detection of small effects, have for methodological reasons (the need for the whole genome scan) been limited to candidate genes. The most intriguing of these studies is that of Klaus Peter Lesch, who investigated—together with colleagues from the National Institute of Mental Health, Bethesda, MD—the serotonin transporter gene, located on chromosome 17 (Lesch et al. 1996). This serotonin transporter is of particular interest as the majority of antidepressants act on this protein located in the cell membrane of presynaptic nerve terminals. By blocking the reuptake of serotonin molecules these drugs, of which Prozac® is the best known, enhance serotonergic neurotransmission.

Lesch submits that a polymorphism in the transcriptional control region of the serotonin transporter may result in a long and a short version of the promoter polymorphism. The occurrence of the short allele has been shown to be associated not only with decreased transcriptional efficiency resulting in reduced serotonin transporter expression, but also with those personality traits that are likely to be relevant to vulnerability to depression. Most studies aimed at replicating this intriguing finding have failed to do so, but this does not invalidate the experimental approach. Rather, it suggests that the means we currently have to phenotype individuals are perhaps not suited to genetic studies. Researchers have questioned the usefulness of diagnostic algorithms such as the Diagnostic and Statistical Manual of Mental Disorders of the American Psychiatric Association (DSM-IV) or the International Classification of Disease of the World Health Organization (ICD-10) for studies of causality because the psychopathological symptoms that constitute psychiatric diagnoses may be the very remote effects of genes. Therefore, it has been suggested that it would be more fruitful if genetic studies focused on more direct measures of brain function.

Such a strategy is exemplified in the Munich Vulnerability Study conducted at the Max Planck Institute of Psychiatry, where individuals with no history of illness but, being members of families with a high genetic load for depression, are investigated not only according to psychopathology but also according to laboratory measurements and other symptoms that can be objectified. Among these laboratory assessments are neuroendocrine function tests and sleep electroencephalographic-activity recordings. As illustrated in Fig. 1, the hormonal response to a neuroendocrine function test specifically designed to identify impairments in stress hormone regulation is altered in probands with a high familial risk for depression. Their stress hormone release is significantly increased compared with matched controls. What is not yet known is to what extent premorbid stress hormone dysregulation may predict an increased likelihood of developing overt clinical depression.

The idea behind the strategy is to identify patients with impaired stress hormone regulation across diagnostic boundaries and to study their genetic commonalities. Of course, other symptoms or symptom clusters, e.g., psychotic symptoms, need to be considered regardless of the diagnostic category to which the individual patient may belong. The proposed breakdown of the diagnostic description of complex behavior into simpler components including specific symptoms, together with results from neurobiological investigations (e.g., functional brain imaging, electroencephalography, drug treatment response, neuroendocrine assessment, etc.) deserve more attention in future genetic research than do traditional diagnostic attributions.

Bipolar depression, where depressive episodes alternate with manic episodes characterized by elevated mood, ideas of grandiosity, flight of thought, sleeplessness, etc., is much more easily phenotyped. Attempts to understand this disorder in terms of biographic events have also not been very successful, thus facilitating a push towards genetic research. Morbid risk in first-degree relatives is four to six times higher than the population prevalence of 1% for both men and women, making the case for genetic susceptibility

particularly obvious. Enormous efforts in the United States and Europe have allowed the study of families large enough to discover a linkage between bipolar disorder and certain areas on several chromosomes, notably 12q, 18p, 18q, 21q, 4p, and X1.

Of particular interest is a study by Nicholas Barden from Quebec, Canada, who completed a genome screen in a large French Canadian pedigree with over 100 individuals (Morissette et al. 1999). This investigator showed a linkage to chromosome 12q 23–24 in some, but not all branches of the pedigree and concluded from his data that more than one locus may be segregating in this isolated population. A smaller pedigree from the same geographic region also confirmed the linkage between bipolar depression and chromosome 12. Similar conclusions were drawn from another investigation into a family where major affective disorder was segregating with Darier's disease. The gene, whose mutation for Darier's disease encodes a calcium ion pump, was recently identified but screening for mutations in a sample of bipolar probands without Darier's disease did not identify any gene mutation, rendering it unlikely that the susceptibility gene for bipolar disorder is in close proximity to the Darier's disease gene.

This example illustrates that, despite promising results and a fairly clear phenotype (although it may well be that a bipolar case is diagnosed very late because a manic episode occasionally only becomes clinically apparent in later life), we are still far away from the identification of susceptibility genes for bipolar disorder. One conclusion to be drawn is that there are likely to be numerous susceptibility genes that influence the risk of unipolar or bipolar depression. Supported by progress in biotechnology, critical regions for each susceptibility gene will be narrowed down and candidate genes will be tested much faster than in the past. These opportunities, together with new techniques allowing the dissection of gene–gene and gene–environment interactions, will ultimately allow the identification of susceptibility genes. The future role of the clinician scientist will be to improve diagnosis-independent phenotyping and to conduct studies focused on the elucidation of potential pathophysiological roles of candidate genes (see *Mental Illness, Genetics of*).

3. *Hypotheses on the Causality of Depression at the End of the Twentieth Century*

3.1 *Hormones and Neuropeptides*

Depression is associated with a number of changes in hormonal secretion and conversely, certain endocrine disorders (i.e., hypothyroidism or Cushing's disease) are associated with excessive psychiatric morbidity, most frequently depression. Because the peripheral hormonal readout is governed by hypothalamic-releasing factors, which are themselves subject to complex regulations involving biogenic amines (e.g., serotonin, norepinephrine) and amino acids (e.g., gammaaminobutyric acid, GABA, and N-methyl-D-aspartat, NMDA) many researchers in the 1970s and 1980s had hoped that the neuroendocrine system might provide a 'window to the brain.' For example, growth hormone secretion from the pituitary was found to be blunted in patients with depression, following a variety of pharmacological interventions including the α-adrenoceptor system. Thus, the decreased growth hormone release following clonidine, an α-adrenoceptor agonist, was suggested as an indicator of desensitized adrenoceptor systems in these patients. Whereas the neuroendocrine approach that attempted to identify central neurotransmitter disturbances through measurements of hormonal responses to various pharmacological probes proved to be only of limited value in explaining the pathophysiology of depression, a new hypothesis emerged, linking stress hormone regulation to the development of depression and its course during drug treatment.

The fundament of this hypothesis is that elevated central neuropeptides accounting for increased peripheral stress hormone (corticotropin and cortisol) secretion in patients with depression, also mediate a number of psychopathological cardinal symptoms of depression. The neuropeptide in question is corticotropin-releasing hormone, CRH, that, when secreted from the hypothalamus, reaches the pituitary through portal vessels and elicits corticotropin from the pituitary and consequently cortisol from the adrenal cortex. CRH is also present in other brain areas, the frontal cortex, the amygdala, the hippocampus, and the locus coeruleus, all of which are implicated in the generation of stress-related psychopathology such as anxiety, cognitive function, sleep disturbance, appetite and sexual arousal, autonomous regulation and other features.

This has led to research activities from which clear evidence has emerged that CRH not only accounts for peripheral stress hormone secretion, but is also a key mediator of anxiety and depressive symptoms (Holsboer 1999). The question why CRH is elevated in some brain areas and not others is not yet clear, but some evidence has accumulated that a disturbed corticosteroid receptor function exists that prevents elevated cortisol levels from appropriately regulating CRH synthesis. Notably, the regulation of CRH gene expression by steroid activated corticosteroid receptors is very complex and varies across brain areas. The corticosteroid receptor hypothesis represents a paradigmatic shift inasmuch as that a therapeutic strategy has been developed from a clinical observation (Holsboer 2000). Blocking the action of CRH requires knowledge of the receptors through which this neuropeptide exerts its psychopathological effect. Molecular

Table 2
Altered norepinephrine function in depression

Norepinephrine
Increased β-adrenoceptor density in membranes of cortical neurons of depressed suicide victims
Reduced growth hormone response to α-adrenoceptor stimulation (e.g., with clonidine)
Increased stress hormone secretion after α-adrenoceptor antagonism (e.g., with yohimbine)
Reduced levels of norepinephrine transporters in the locus coeruleus
Elevated levels of tyrosine hydroxylase in the locus coeruleus

pharmacology and genetic research have helped us to identify the CRH receptor subtype (CRH_1 receptor) responsible, and the discovery of small molecules that selectively antagonize CRH actions at this receptor have allowed us to test this CRH hypothesis.

Basic studies in animals and first clinical studies support the notion that CRH_1 receptor antagonists are capable of improving signs and symptoms of stress-related clinical conditions, and that they are of potential value in treating major depression. This concept is frequently burdened by two serious misunderstandings that need to be addressed: the clinical efficacy of CRH receptor antagonists is not limited to patients showing peripheral hypercortisolemia. This endocrine symptom reflects hypothalamic–pituitary activity, a neuroanatomical axis, certainly not the primary locus of depressive pathology. CRH may be elevated in the amygdala, the hippocampus or the locus coeruleus, with or without concurrent elevation of hypothalamic CRH, peripheral corticotropin or cortisol. Second, hypersecretion of stress hormones does not reflect the emotional stress associated with depression. It is of note that many studies have shown a time-course pattern where an elevation of stress hormone release preceded the overt depressive syndrome (see *Endocrinology and Psychiatry*). Moreover, a refined neuroendocrine test, the combined dexamethasone/CRH test, has proved to be of value in identifying patients not showing depressive symptoms but being at risk of relapsing into a depressive episode within six months. This time pattern rejects the possibility that exaggerated stress hormone release is secondary to the emotional stress associated with depression (see *Peptides and Psychiatry*).

3.2 Biogenic Amines

The traditional pathogenetic concepts of depression emerged from the discovery of the pharmacological properties of current antidepressants. Investigators in the United States led by Joe Schildkrauth (1965) formulated the catecholamine hypothesis of depression, submitting that depression is associated with a deficiency of catecholamine activity (particularly norepinephrine) at functionally important adrenoceptor sites in the brain, whereas mania is associated with a relatively excessive catecholaminergic neurotransmission. Norepinephrine-containing neurons project from the locus coeruleus, a brain stem nucleus, into almost all brain areas. Notably, CRH-containing nerve terminals innervate the locus coeruleus. Examples of altered norepinephrine activity are listed in Table 2.

A number of these findings are in agreement with a norepinephrine deficit. In particular, postmortem studies have shown that the locus coeruleus of depressed suicide victims contains increased levels of tyrosine hydroxylase, the rate-limiting enzyme of norepinephrine biosynthesis. This finding is in accordance with either premortem overactivity of adrenergic neurons or a deficit in the biosynthetic product norepinephrine. Similarly, in the same brain nucleus the levels of the presynaptic norepinephrine transporter are decreased, which can also be interpreted as a compensatory downregulation of this protein in response to decreased norepinephrine levels. However, what is puzzling is the failure to induce an aggravation of depressive symptomatology in depressed patients after treatment with a drug that inhibits norepinephrine biosynthesis.

The great acceptance of selective serotonin reuptake inhibitors (SSRIs), reflected by their major (over 70%) share of the total antidepressant market, has rekindled the interest in the serotonin hypothesis of depression originally submitted by Alec Coppen (1969) in the United Kingdom. This hypothesis proposed that decreased serotonergic activity accounts for the development and course of depression. These changes in serotonergic neurotransmission may be attributable to a decreased serotonin release, fewer serotonin receptors (of which exist more than 14 different subtypes), or impaired serotonin receptor-mediated signal transduction. Evidence for a serotonin deficiency, however, is conjectural and relies on (a) decreased 5-hydroxyindoleacetic acid (a principal metabolite of serotonin) concentrations in the cerebrospinal fluid, (b) a neuroendocrine function test using the pharmacological serotonin releaser fenfluramine, which induces blunted prolactin response in depressed patients, and (c) postmortem studies where indicators for serotonergic activity were found to be reduced (Delgado et al. 1994).

It is of note that serotonergic activity and stress hormone activity are closely intertwined. For example, if CRH is elevated in the hippocampus, the stress-elicited serotonin release is reduced and if CRH_1 receptor capacity is reduced, either by targeted mutation of the CRH_1 receptor or by CRH_1 receptor antagonists, serotonin response to stress is elevated, suggesting that blocking CRH-mediated effects through CRH_1 receptor antagonists restores impaired serotonergic activity.

4. Treatment of Depression

The front line of therapy for severe major depression is drug treatment with antidepressants. The effect of these agents is assisted by psychotherapy that needs to be pragmatically adjusted to the patients' needs. The antidepressant drugs available for treatment all work through modulating the neurotransmission of biogenic amines (see above). Some of them are fairly selective such as SSRIs (e.g., fluoxetine, paroxetine or citalopram), or norepinephrine reuptake inhibitors (e.g., reboxetine), while other drugs combine both pharmacologies (e.g., venlafaxine, nefazodone). Because of their pharmacological similarity, it is not surprising that only subtle differences in the clinical profiles of these drugs exist, and that antidepressants are consequently chosen by physicians according to their safety and tolerability profiles, provided their choice is not deterred by the higher costs in countries where reimbursement is limited.

While the superiority of antidepressants over placebo is undisputed among clinician scientists, the exact figures are still a matter of discussion (Quitkin et al. 2000). This is mainly related to the fact that most studies designed to provide the requisite statistical significance for monitoring side-effects and confirming efficacy use large outpatient samples that often contain only moderately depressed patients, have high dropout rates, and include the administration of suboptimal drug dosages. All these factors favor the placebo response, frequently found to be close to 50%, whereas the active drug often does not exceed a 75% response rate. Notably, response in these studies is defined as an improvement of 50% over baseline, which is clinically unsatisfactory and certainly not the desired treatment goal. Thus, the impression emerges from such studies that antidepressants improve the clinical condition by not more than 25%, which is unrealistic. A possible consequence of these figures comes from a study by the WHO which revealed that in patients who were diagnosed with depression, only 31.9% were prescribed an antidepressant, 25.5% received tranquilizers (benzodiazepines), and 19% received 'miscellaneous' drugs such as herbal remedies.

The latter includes St. John's Wort, a drug that is prescribed to half the treated population in Germany, where psychotherapy is also much more widely available than in other countries. This reflects how diverse attitudes toward the pharmacological treatment of depression can be. A current study sponsored by the National Institute of Mental Health, will hopefully elucidate whether the widespread use of St. John's Wort is scientifically justified.

The most important impediments in the pharmacotherapy of depression are (a) the lack of differential therapeutic aids, i.e., there is no tool available to select the appropriate drug for the individual patient; (b) the lack of objective laboratory signs and symptoms to monitor adequacy of treatment; (c) the protracted onset of action, which can take weeks or even months; and (d) side-effects, which are particularly disturbing and often lead to noncompliance after the patient has begun to respond, but still needs treatment to consolidate the beneficial therapeutic effect.

Some of these unmet needs no longer seem to be unsurmountable (Holsboer 2001): (a) differential therapy will be guided by genotyping of patients, helping the physicians to identify which drug is optimally suited, ultimately leading to customized therapies; (b) neuroendocrine function tests such as the combined dexamethasone/CRH test have proved useful in providing feedback information about ongoing neurobiological pathology independently from acute psychopathology ratings. Its more widespread use holds the promise of shortening the course of treatment and hospitalization; (c) onset of action can possibly be shortened by enforced normalization of stress hormone excess via CRH_1 receptor antagonists; and (d) side-effects can be partly reduced by customized drug therapies or by a shift to drugs that target neuropeptides instead of biogenic amine neurotransmitters. Neuropeptide hypersecretion primarily reflects a pathological neuronal hyperactivity, and therefore, neuropeptide receptor antagonists are effective only if neuropeptide hypersecretion exists (see *Ethics and Psychiatry*).

5. Summary and Outlook

The lifetime risk of a major depression is high and, once suffering from depression, the morbidity for other clinical conditions, ranging from common infection to ischemic heart disease, escalates considerably. Thus, depression is already a major cause of disability and will become the most costly disease in the coming decades. In the light of this, any effort to improve the prevention and treatment of depression is justified. The evidence implicating genes as factors predisposing to depression is impressive but complex inheritance has undermined efforts so far to identify those susceptibility genes that interact with environmental factors to precipitate the disease. Despite the current excitement about the possibilities of genetics to identify ultimately a set of gene variants at many different loci that confer a predisposition to depression, I believe that the first revolutionary step will emerge from pharmacogenomics.

This research will elucidate inherited differences in sensitivity to drugs, allowing the physician to predict which particular drug would be best and which harmful for an individual patient. This possibility would be an enormous advantage over today's trial and error strategy and, once feasible, would reduce the time before the right drug at the right dosage is administered. Another forthcoming major change that will not be unanimously embraced by all psychiatrists is the departure from diagnostic categories. These

have been a stumbling block for psychiatric research in the past and will be even more so in a future that is dominated by functional genomics. Therefore, clinical research is challenged to phenotype patients more appropriately on psychopathological and neurobiological levels that cut across traditional diagnostic boundaries. The enormous potential of an interdisciplinary approach encompassing psychopathology, neurobiology, pharmacology, and genetics together, with progress in biotechnology, will lead to a body of knowledge so powerful that not only will better treatments become available, but ultimately, the causal factors underlying depression will also be exposed.

Depression, Clinical Psychology of

1. Introduction

The word 'depression' in everyday parlance covers a wide range of emotional states that range in severity from transient moods of sadness to major psychotic episodes accompanied by increased risk of suicide. Depression in the form of a brief sad mood is a universal experience; it is a normal part of living that accompanies the losses, frustrations, failures, and disappointments that all of us face. Clinical depression in contrast, is a syndrome, or constellation of co-occurring psychiatric symptoms, that affects about 20 percent of the population. Major Depressive Disorder, the psychiatric label for clinically significant depression, is characterized by at least a two-week period of persistent sad mood or a loss of interest or pleasure in daily activities, and four or more additional symptoms, such as marked changes in weight or appetite, sleep disturbance, psychomotor agitation or retardation, fatigue, feelings of guilt or worthlessness, and concentration difficulties.

People diagnosed with Major Depressive Disorder show marked impairment in their social and occupational functioning; they also have an elevated risk of death from a number of causes. In fact, the World Health Organization Global Burden of Disease Study recently ranked depression as the single most burdensome disease in the world in terms of total disability-adjusted life years among people in the middle years of life (Murray and Lopez 1996). To give but one example of the consequences of this disorder, a recent economic analysis of depression in the workplace estimated that the annual salary-equivalent costs of depression-related lost productivity in the United States exceeds $33 billion (Greenberg et al. 1996). Moreover, because this figure does not take into account the impact of depression on such factors as the performance of coworkers, turnover, and industrial accidents, it is likely to be an underestimate of the overall workplace costs of depression.

People who become depressed rarely experience only a single episode; depression is a highly recurrent

disorder. In fact, over 80 percent of depressed patients will have more than one depressive episode during their lifetime. The interval between episodes is generally short: over half of depressed patients will have at least one relapse within two years of their recovery from a depressive episode. This pattern of recurrence also appears to intensify over time: individuals with three or more previous episodes of depression may have a relapse rate as high as 40 percent within only three to four months after recovery. The high recurrence rate in depression points to the existence of factors that serve to increase people's risk for developing this disorder. In attempting to understand this vulnerability to depression, clinical psychologists have focused on two broad areas in which depressed individuals seem to experience particular difficulties: cognitive functioning and interpersonal functioning. In Sects. 2 and 3, therefore, we describe the results of research conducted to examine the cognitive and interpersonal functioning of depressed persons and of individuals who are at risk for becoming depressed.

2. *Cognitive Functioning in Depression*

In many ways, depression is a disorder of thought. Depressed individuals typically think negatively about themselves, believing that they are useless, deficient, and unattractive people. Depressed persons also express bleak views of their immediate surroundings and of their future prospects. Given the pervasiveness of these dysfunctional cognitive characteristics, scientists have theorized about the importance of cognitions in depression and have conducted considerable research examining how depressed individuals perceive and evaluate information from their environment.

The cognitive theory of depression that has had the greatest impact on research and treatment is that formulated by Aaron Beck (1976), who ascribes the onset of depression to dysfunctional cognitive processes. Beck hypothesizes that individuals who experience loss or adversity in childhood develop a set of negative expectancies, or 'schemas,' concerning loss, failure, or abandonment. These schemas serve as filters through which stimuli and events in their environment are perceived, evaluated, attended to, and remembered. The negative schemas of depressed persons lead them to perceive and evaluate neutral stimuli as negative, guide their attention to negative aspects of their environment, and facilitate their memory for negative experiences. Perhaps most importantly, Beck believes that these negative schemas characterize not only currently depressed persons, but also nondepressed people who are at a high risk for developing depression in the future. Indeed, the negative schemas are the risk factor. In these individuals, the negative schemas remain inactive until the person encounters a relevant stressful event or experience. The stressful experience serves to activate the negative schema, which leads the individual to process information in a negative manner, in turn leading to ineffective coping, culminating in a depressive episode.

Thus Beck's theory, and other similar cognitive theories of depression, predicts that depressed individuals (and individuals who are at risk for becoming depressed) are characterized by negative schemas that lead them to be more attentive to negative than to positive stimuli in their environment and to have better memory for these stimuli. Early studies attempted to examine the cognitive schemas of depressed persons by assessing their responses to self-report questionnaires measuring the negativity of their beliefs. In fact, a large body of literature has now documented that depression is associated with high levels of self-reported dysfunctional attitudes and a negative explanatory style.

Although these studies were important in describing the cognitive styles of depressed persons, their reliance on self-report measures of cognitive schemas is problematic. Perhaps most importantly, it is unlikely that self-report questionnaire measures, which require subjects to make conscious, deliberate, and thoughtful responses, are able to assess the existence and functioning of cognitive schemas, which are hypothesized to be activated automatically and to operate outside of individuals' awareness. Put more simply, because people are typically not aware of the content of their schemas, self-report measures cannot be used to assess them. To address this problem, clinical psychologists have adapted methodologies from research in experimental cognitive psychology to assess the schematic functioning of depressed individuals. Using such information-processing tasks as the emotion Stroop task and the dot-probe task, investigators have provided empirical support for Beck's cognitive theory of depression, demonstrating that depressed individuals are characterized by negative cognitive biases in both attention and memory (see Gotlib and Neubauer 2000).

Whether measured by self-report or by information-processing tasks, there is now little question that depression is associated with negative cognitive biases, a conclusion that supports a major tenet of cognitive theories of depression. Importantly, however, the causal status of these negative biases is still an open question. Cognitive theories of depression also hypothesize that negative schematic functioning is a trait-like characteristic that increases an individual's risk for developing depression. There are very few empirical studies in which investigators have attempted to predict subsequent depression from earlier measures of schematic functioning. Moreover, studies of formerly depressed persons have generally found that cognitive functioning normalizes with recovery from depression. A number of researchers have demonstrated, however, that the presence of negative mood in formerly depressed individuals can reinstate

negative cognitive processing which was not observable in the absence of negative mood (Haaga et al. 1991). If this proves to be the case, it is not difficult to see how stressful life events could generate a negative mood state, which, among vulnerable individuals, also activates a set of dysfunctional cognitions that lead to depression. Thus, although much more work remains to be done, it is clear that depressed individuals are characterized by negative schemas, and it is possible that this schematic functioning plays a causal role in the onset of depression.

3. *Interpersonal Functioning in Depression*

As is the case with cognitive functioning, depressed individuals have consistently been found to experience difficulties in their interpersonal relationships. While there is no single guiding theory of the social functioning of depressed persons that is analogous to Beck's cognitive theory, empirical research has nevertheless implicated interpersonal dysfunction as important in understanding the etiology and maintenance of depression, as well as relapse of this disorder. Early behavioral formulations of depression viewed the depressed state as resulting from a lack of environmental reinforcement, stemming in part from an inability of depressed persons to elicit reinforcement from others (e.g., Lewinsohn 1974). Indeed, numerous studies have demonstrated that depressed persons exhibit social skill deficits during interactions with others. For example, compared to nondepressed individuals, depressed persons have been found to speak more slowly and with less volume and voice modulation, to show longer pauses in their speech patterns, to take longer to respond to others, and to engage in less eye contact. They are also more self-centered in interactions and steer conversations to more negative content. Finally, and understandably, depressed persons seem to induce feelings of depression, anxiety, and hostility in those with whom they interact. It is not surprising to learn, therefore, that people ultimately withdraw from interactions with depressed individuals (Segrin 2000).

Although this negativity seems to permeate the full range of depressed individuals' social interactions, it is especially pronounced in intimate relationships. In this context, a number of investigators have focused on the nature of the relationships between depressed persons and their spouses and children. There is good reason for concern in these areas. For example, the divorce rate among individuals who have been diagnosed with depression is nine times higher than the rate in the general population (Merikangas 1984). Moreover, children of depressed parents are two to three times more likely experience a psychiatric diagnosable disorder at some point in their lives than are offspring of nondepressed parents (Gotlib and Goodman 1999). In attempting to understand the processes underlying these findings, researchers have systematically observed the interactions between depressed people and their spouses, and between depressed parents and their children.

The marital interactions of depressed persons are characterized by high levels of anger, conflict, and negative affect. Depressed spouses derogate themselves and their partners, and both spouses escalate their negative affect and behaviors over the course of the interactions. Interestingly, expressions of sad affect in the depressed spouse appear to have the effect of suppressing anger and aggression in the partner, suggesting that depression may play a functional but maladaptive role in the marriage. With respect to their children, depressed individuals report that they find it difficult to be warm and consistent parents, that they do not derive satisfaction from their children, and that they feel inadequate in their parenting role. Consistent with these self-reports, in interactions with their children, depressed mothers display sad and irritable affect and are either unresponsive or intrusive. In short, depressed parents appear to be difficult or inadequate social partners for both their spouses and their children, although it is important to also recognize the likely reciprocal nature of these problematic relationships.

Thus there is consistent evidence that depression is associated with deficits in interpersonal functioning. There is less support for the position that difficulties in social functioning serve as risk factors for the onset of a first depressive episode, although some investigators have reported that the lack of a supportive intimate relationship may leave individuals particularly vulnerable to the effects of life stress. Importantly, however, many of the interpersonal problems that characterize people while they are depressed have been found to persist following recovery. For example, in contrast to other disorders such as alcoholism, the marital relationships of people who have been depressed continue to be strained even after they have recovered from their depressive episode. In fact, like currently depressed individuals, people who have recovered from depression also report having fewer friends and close relationships than do individuals who have never been depressed. Interestingly, recovered depressed individuals do not show deficits in the overall number of their network contacts, suggesting that the interpersonal difficulties of formerly depressed persons—like those of currently depressed individuals—are most pronounced in intimate relationships. Finally, and further underscoring the importance of focusing on intimate relationships in understanding the role of interpersonal deficits in depression, the degree of hostility or criticism expressed by spouses about their depressed partners is a strong predictor that the partner will relapse into another episode of depression (Hooley and Gotlib 2000).

As is apparent from this brief review, individuals who are experiencing clinically significant depression

are characterized by negative cognitive biases in their perceptions and evaluations of their environment and by impaired interpersonal functioning. Consistent with depressed persons' difficulties in these areas, two of the most effective psychological treatments for this disorder are cognitive therapies and interpersonal therapies. In the following sections we describe these two approaches to the treatment of depression.

4. *Cognitive Treatments for Depression*

Cognitive therapies are based on the formulation that individuals' affect and behavior are largely determined by how they interpret events in their world. As we have seen, clinically depressed individuals are characterized by negative perceptions of the self, the world, and the future. Therefore, a critical premise of cognitive therapies for depression is that replacing maladaptive thoughts with more positive cognitions will result in a significant reduction in depressive symptoms. Cognitive therapies often incorporate behavioral interventions to help in altering the patient's cognitions; for this reason, these therapies are often referred to as cognitive-behavioral treatments.

Cognitive therapy for depression is time-limited, rarely exceeding 30 weekly sessions and ranging most typically from 15 to 25 sessions (see also *Cognitive Therapy*). The therapist and patient work together in a process referred to as 'collaborative empiricism' (Beck et al. 1979) to identify, evaluate, and change the patient's negative thoughts. The therapist teaches the patient behavioral coping strategies, such as problem-solving skills and assertiveness training, to help him or her bolster new positive cognitions. Often homework is assigned to help the patient identify negative thoughts and beliefs and practice adaptive behaviors that the patient has learned with the therapist. Finally, because depression has a high relapse rate, in the final sessions of cognitive therapy, the therapist works with the patient to anticipate the kinds of life stressors that he or she may encounter in the future to prevent the recurrence of depression.

Cognitive therapy and cognitive-behavior therapy for depression have been evaluated in over 80 controlled studies (American Psychiatric Association 2000). The results of these clinical trials are consistent: cognitive therapy is an effective treatment for depression. In fact, cognitive therapy is considered by the American Psychological Association to be a 'well-established treatment' for depression (Chambless and Hollon 1998). Although there have been exceptions, cognitive therapy has generally been found to be as effective as (and sometimes more effective than) alternate forms of treatment for depression, including antidepressant medication. Moreover, several studies have shown that depressed patients who received cognitive therapy are less likely to relapse following treatment termination than are patients treated with medications. Finally, there is now evidence that cognitive therapy can prevent or delay the onset of depression in persons who are at elevated risk for the disorder (Hollon et al. in press).

5. *Interpersonal Treatments for Depression*

Interpersonal psychotherapies were developed from broad interpersonal theories of psychopathology, such as those formulated by Adolph Meyer, Harry Stack Sullivan, and John Bowlby. These theories posited that the quality of current interpersonal relationships was critical in contributing to the development and persistence of many forms of psychopathology. From this perspective, therefore, the therapist's primary goal is to change the patient's patterns of self-defeating interpersonal interactions. The most systematic and widely used therapy in this area is Interpersonal Psychotherapy (IPT), developed by Gerald Klerman and Myrna Weissman for the treatment of depression (Weissman et al. 2000) (see *Cognitive and Interpersonal Therapy*: *Psychiatric Aspects*. Like cognitive therapy, IPT is conducted most frequently as a short-term therapy (approximately 16 weekly sessions), but it has also been modified for use as a 'maintenance therapy' for the longer-term treatment of patients with recurrent or chronic depression. A major goal of IPT is to improve the patient's interpersonal functioning by encouraging more effective expression of emotions, clearer communication with significant members of their entourage, and increased understanding of the patient's behavior in interpersonal interactions. The rationale underlying the use of IPT is that by solving interpersonal problems in therapy, the patient will improve their life situation and simultaneously decrease the number and intensity of depressive symptoms.

IPT for depression is divided into three phases. In the initial phase of treatment (the first 3 sessions), the therapist conducts a diagnostic evaluation for depression, educates the patient about depression, and evaluates the patient's current interpersonal relationships. The therapist then establishes which of four interpersonal problem areas are most closely related to the patient's current depressive episode: grief, interpersonal role disputes, role transitions, or interpersonal deficits. In the middle phase of treatment (sessions 4–13), the therapist uses specific techniques (outlined explicitly in a treatment manual) that are designed to address these four problem areas. Although these techniques may involve changing the patient's cognitions or having the patient engage in new behaviors, there is a clear and strong tie to the patient's current interpersonal relationships. The final phase of treatment (sessions 14–16) focuses on consolidating the changes that the patient has made through therapy and helping the patient recognize and counter depressive symptoms should they arise again in the future.

In the 1980s and 1990s, IPT has been carefully evaluated in numerous research protocols and has been demonstrated to be effective in treating depression in a variety of populations, including adolescents, postpartum depressed women, married spouses, the elderly, and patients in primary medical care facilities. In fact, IPT was one of two forms of psychotherapy (the other was cognitive therapy) tested against antidepressant medication in a large-scale treatment study of 250 depressed patients (Elkin et al. 1989). The results of this study indicate that IPT is more effective than placebo, and as effective as medication and cognitive therapy in reducing depressive symptoms. In addition, IPT was found to be more effective than cognitive therapy in treating more severely depressed patients (Elkin et al. 1989). Importantly, IPT has been shown to prevent or delay the onset of relapse episodes of depression, demonstrating its utility as a maintenance therapy.

6. *Conclusions and Future Directions*

In the 1980s and 1990s, we have made significant progress in our understanding of psychosocial aspects of depression and in the treatment of this disorder. It is now clear that depressed persons are characterized by maladaptive cognitive schemas that guide their attention to negative, as opposed to positive, environmental information, and enhance their memory for this negative information. Depressed persons also have marked impairments in their interpersonal functioning, particularly in more intimate relationships. Despite this progress, however, there are several issues that remain unresolved.

In closing, therefore, we offer three recommendations for future research examining cognitive and interpersonal functioning in depression. First, much of the research that has been conducted in this area has been cross-sectional, essentially comparing samples of depressed and nondepressed participants at one point in time. We urgently need prospective, longitudinal studies in order to clarify the causal relation of cognitive and interpersonal dysfunction to the onset, maintenance, and relapse of depression. Second, while both cognitive and interpersonal therapies have been demonstrated to be effective in the treatment of depression, there are anomalies that need to be addressed. For example, cognitive therapy is not universally effective in the treatment of depression and research must begin to identify characteristics that differentiate treatment responders from nonresponders. Similarly, despite its focus on interpersonal functioning, IPT has been found to be no more effective in improving social functioning immediately following treatment than are medications or cognitive therapy. Therefore, for both cognitive therapy and IPT, research is needed to clarify the mechanisms by which the treatment reduces patients' levels of depression. Finally, we have discussed cognitive and interpersonal functioning in depression as though they occur independent of each other. Clearly, this is not the case. It is only by explicitly integrating data concerning the cognitive and interpersonal functioning of depressed persons, and relating that data to their biological functioning, that we will be able to build a comprehensive understanding of depression allowing us to develop even more effective programs for the prevention and treatment of this disorder.

Depression, Hopelessness, Optimism, and Health

Depression is a psychological syndrome encompassing a variety of symptoms, including loss of energy and motivation; loss of the capacity to experience happiness or enjoyment; feelings of sadness, despair, and hopelessness; and sometimes a sense of guilt, shame, or worthlesssness. Depression is a debilitating problem in its own right for people who experience it. Depression can also have adverse implications for physical health and well-being.

Depression develops in people who initially were not depressed. Though the experience can be long-lasting or repeated, it does not usually last for the person's entire lifetime. Certain personality traits, however, have overtones of qualities that are part of depression. Consider the dimension of optimism vs. pessimism. Optimists are people who expect good things to happen to them; pessimists expect bad things to happen. Pessimism thus has a link to depression. Unlike depression, however, pessimism is an enduring personality trait. The personality dimension of optimism vs. pessimism has been studied a good deal in health psychology. Some of that research has found that this aspect of personality has consequences for physical well being.

The concept of hopelessness has links to both depression and pessimism. Sometimes hopelessness is used to refer to a state; sometimes it is used to refer to personality qualities. One might view the concept of hopelessness as representing a conceptual bridge between the (usually temporary) state of depression and longer-lasting traits of personality such as pessimism. People who are experiencing depression often feel hopeless about the future; people who are pessimistic are more broadly and consistently lacking in hope for the future.

This article describes some of the research that links depression, hopeless, and pessimism to health problems. As background to that research, the next section describes the conceptual basis for examining how these variables may be involved in health.

1. Pessimism, Hopelessness, and Disengagement

The concepts of optimism and pessimism are rooted in centuries of folk wisdom about the consequences of people's expectations for the future. Contemporary research on optimism and pessimism also has its roots in people's expectations for the future. In adopting that starting point, this research connects to more than a century of psychological theory (Carver and Scheier 1998, 1999). That is, the expectancy construct links this research to a collection of theories of motivation and action that are called expectancy-value theories. This link, in turn, provides a rationale for examining the way in which the traits of optimism and pessimism are expressed in motivation, behavior, and feelings. These expressions of optimism and pessimism represent a set of potential pathways by which this personality disposition may relate to health.

Expectancy-value models begin with the idea that behavior is aimed at attaining desired goals (values). Without a valued goal, there is no reason to act. The other element is expectancy: confidence or doubt about being able to attain the goal. If a person lacks confidence, again there will be no action. Only with sufficient confidence do people exert efforts and remain engaged in those efforts. These principles pertain to specific values and focused confidence, and they also apply to the more general traits of optimism and pessimism. In optimism and pessimism the 'confidence' involved is simply broader in scope.

These principles provide the basis for many predictions about optimists and pessimists: when confronting a challenge, optimists should take a posture of confidence and persistence, even if progress is difficult or slow. Pessimists should be more doubtful and hesitant. This divergence should be amplified under conditions of adversity. Optimists are likely to believe the adversity can be handled successfully, pessimists are likely to anticipate disaster. These differences in orientation can lead to differences in persistence, differences in active efforts to take precautions, differences in many decisions and actions that pertain to health risks.

People's behavioral responses to adversity are important, but overt behavior is not the only response that occurs when people confront adversity. People also experience emotions in such situations. Difficulties elicit a mixture of feelings, and variables such as optimism influence the balance among the feelings. Again, predictions are easily derived from theory. Optimists expect to have good outcomes, even when things are difficult. This confidence should yield a

more positive mix of feelings. Pessimists expect bad outcomes. This should be related to more intense negative feelings—anxiety, sadness, or despair. Though these emotional responses are not the focus of this article, a good deal of research has found evidence of such emotional differences between optimists and pessimists (Carver and Scheier 1999).

The experiences of intense distress, hopelessness, and disengagement from effort have physical concomitants; so do positive emotions and engagement in positive efforts. A number of psychologists believe that these physiological responses can play a role in health outcomes. Such processes may influence a person's probability of getting a disease in the first place, they may influence the progression of diseases, they may even influence mortality. There is a good deal of evidence that personality differences in optimism–pessimism relate to differences in health-related outcomes. Research on the precise pathways of influence is at an early stage, but enough evidence has emerged to suggest that the questions are worth examining further.

Researchers have studied the effects of pessimism and hopelessness in two ways. In some studies the variables are measured as generalized personality dispositions. In other studies they are measured as attitudes toward particular contexts or particular health outcomes. Studies that examine both sorts of pessimism typically find a moderate correlation between the two, but sometimes the relation is much weaker (raising interesting questions about the organization of personality that go beyond the scope of this article). Whether deriving from a generalized or a context-specific approach, however, evidence suggests that pessimism and hopelessness have adverse implications for health.

In the review that follows, some studies used generalized measures, others used more focused measures. A few of the studies did not measure pessimism or hopelessness directly, but rather the psychological responses they are believed to induce, such as disengagement vs. active effort.

2. *Pessimism, Hopelessness, Depression, and Health*

How do pessimism, hopelessness, and depression relate to health outcomes? This selective review of studies is organized as follows. First are examples of how behavioral reflections of optimism vs pessimism, in the form of effort vs disengagement, can influence health risk and thus well being. Then comes a more extensive section dealing with disease processes themselves—disease promotion, progression, and mortality—and their relations to pessimism and depression.

2.1 *Optimism and Health Related Actions*

Sometimes being persistent in one's goal related effort is itself an important determinant of health and well being. An example of the relevance of behavioral persistence comes from work on active health promotion (see *Health Education and Health Promotion*). Optimists, who are confident about attaining and maintaining the goal of good health, should be more likely than pessimists to continue pursuit of health promotion activities even if it entails a good deal of effort. Evidence from several studies supports this hypothesis.

One study looking at potential individual differences in health promotion followed a group of heart patients who were involved in a cardiac rehabilitation program (Shepperd et al. 1996). Optimism among participants was related to increases in exercise levels across the study period. Optimism also related to greater success in lowering levels of saturated fat, lowering body fat, and lowering an index of global coronary risk.

Another study followed coronary artery bypass patients during the period immediately after surgery (Scheier et al. 1989) and then re-examined them five years later (described in Scheier and Carver 1992). The early part of the project focused mostly on patients' responses to the surgery as an event in their lives; the later part of the project investigated their lifestyles five years postsurgery. In the early part of the project, optimists gave several indications of focusing their efforts on getting back on their feet quickly. They were viewed by the hospital staff as recuperating faster, and they reported concentrating on the rehabilitation process. Pessimists, in contrast, were more likely to be avoiding even thinking about the future. Five years later, optimists were more likely than pessimists to be taking vitamins, to be eating low-fat lunches, and to be enrolled in a cardiac rehabilitation program. Thus, both initially and later on, pessimists were less persistent than optimists in health promoting behaviors.

Heart disease is one aspect of health to which behavioral efforts are relevant. Another health risk that is related to behavior, though in a different manner, is HIV infection. Infection can occur from engaging in sexual activities with partners who are not known to be disease free (see *Sexual Risk Behaviors*). By taking steps to avoid such sexual practices—for example, avoiding sex with unknown partners—people reduce their risk of infection. One study of HIV-negative gay men found that optimists reported having fewer anonymous partners than pessimists (Taylor et al. 1992). This finding suggests that optimists were making efforts to reduce their risk, thereby safeguarding their health (see *Sexually Transmitted Diseases: Psychosocial Aspects*).

Another study relevant to this issue concerned health behavior and intentions among a group of hospital employees at risk for skin cancer (Friedman et al. 1995). Optimists were significantly more likely

than pessimists to report intentions to engage in skin cancer-relevant health prevention behaviors (e.g., regular sunscreen use). In addition, among those identified at screening as having suspicious lesions, those who were more optimistic were more likely to comply with recommended follow-up care.

Other studies have examined the health-related habits reported by groups of people with no particular salient health concerns. At least two such projects have found associations such that optimists reported more health-promoting behaviors than did pessimists (Robbins et al. 1991, Steptoe et al. 1994). In sum, these various studies suggest that optimism is associated with behaviors aimed at promoting health and reducing health risk.

It is important to note, in this regard, that optimists are not simply people who stick their heads in the sand and ignore threats to their well-being. Rather, they display a pattern of attending selectively to risks—risks that both are applicable to them and also are related to serious health problems (Aspinwall and Brunhart 1996). If the potential health problem is minor, or if it is unlikely to bear on them personally, optimists show no elevated vigilance. Only when the threat matters does it emerge. This fits the idea that optimists scan their surroundings for threats to their well-being, but save their active coping efforts for threats that are truly meaningful.

2.2 Pessimism and Disengagement

This discussion derives from the idea that optimism leads to effort and pessimism leads to giving up. Thus far the focus has been on persistence. What about giving up? Several kinds of health-relevant behaviors seem to reflect a giving up tendency. One of them is alcohol consumption, which at high levels is a health risk. Excessive alcohol consumption is often seen as occurring in the service of an escape from one's problems. If so, pessimists should be more vulnerable than optimists to alcohol abuse.

Results from at least two studies fit this picture. A study of women with a family history of alcoholism found that pessimists were more likely than optimists to report drinking problems (Ohannessian et al. 1993). Another study (Strack et al. 1987) examined people who had already been treated for alcoholism and were now entering an aftercare program. This study found that pessimists were more likely to drop out of the aftercare program and to return to drinking than optimists. These two studies converge in showing that pessimists display a form of disengagement—alcohol consumption—more than optimists.

People can give up in many ways, of course. Alcohol dulls awareness of failures and problems. People can also turn their backs on their problems by distracting themselves. Even sleeping can help people escape from situations they do not want to face. Sometimes, though, giving up is more complete. Sometimes people give up not just on specific goals, but on all the goals that define their lives, by committing suicide. Pessimism has been found in several studies to be a key indicator of suicide risk (Beck et al. 1985, Fawcett et al. 1987, Petrie and Chamberlain 1983). Although most people might not think of suicide as a 'health' outcome, suicide clearly does interfere with the maintenance of good health.

2.3 Disease Susceptibility

The examples just described all concern how people varied in their efforts to protect themselves against health risks, or how hard they tried to maintain good health, or the extent to which they engaged in behaviors reflecting a disengagement from such efforts. Such behavioral factors are important underpinnings to disease susceptibility. That is, people who take steps to avoid health risks will generally be healthier in the long run than people who do not. But are there more direct associations? Are there cases in which people differ in their susceptibility to diseases apart from their actions?

It is difficult to study initial vulnerability to disease, because doing so requires recruiting participants who are all healthy, and waiting until some of them become ill. An alternative strategy that some have employed is to recruit persons who are all in the same category of risk for a disease. One study using this procedure produced results suggesting that people's orientation to life can play a role in whether they develop cervical cancer. This study (Antoni and Goodkin 1988) examined women who were undergoing testing after an abnormal PAP smear. Some of the women later proved to have cancer, some had a precancerous condition that might eventually develop into cancer, and others showed little or no abnormality. Before testing, these women completed measures of tendencies toward hopelessness and despair about the future. Women whose abnormality ultimately proved to be more severe were the women who had reported more hopelessness.

Another study examined potential associations of pessimism with blood pressure elevation (Räikkönen et al. 1999). This study involved three days of ambulatory monitoring of blood pressure during normal activities. Results indicated that pessimists were more likely to have elevations in blood pressure than optimists. Although this study should not be taken as clear evidence of disease initiation, it suggests that further examination of the role of pessimism in hypertension is warranted.

2.4 Health Following Medical Procedures

A little research has examined pessimism and the initiation of disease, but a good deal more has

examined differences in well-being that follow the initial diagnosis or treatment of disease. Some of this work looks at responses to medical procedures. For example, the study by Scheier et al. (1989) of men undergoing coronary bypass surgery (which was described a little earlier) included measures of the patients' progress through the surgery itself. Two kinds of indirect evidence suggested that pessimists fared more poorly than optimists even on the operating table. Specifically, pessimists were more likely to display two markers during surgery that are widely taken as indicants of myocardial infarction (MI). Thus, pessimists may have been at greater physical risk during the bypass surgery itself.

Scheier et al. (1999) have more recently collected data on a second sample of bypass patients. The first analyses of data from that project focused on a problem that often arises after major surgery: the need for rehospitalization, due either to infection from the surgery or to complications from the disease underlying the surgery. Scheier et al. (1999) found that optimistic persons were significantly less likely to be rehospitalized either for problems related to post-surgical infection or for problems related to the coronary artery disease, even after controlling for medical variables and other personality measures.

Another research group has explored how positive expectations before heart transplant surgery related to later medical adherence, and health (Leedham et al. 1995). In this case, optimism vs. pessimism was assessed at several levels of abstraction. Patients completed measures of optimism prior to surgery; they were then evaluated at discharge and at 3 and 6 months postsurgery. Initial scales assessed patients' confidence about the efficacy of treatment, their expectations about their future health and survival, and broader expectations for the future. Confidence about the future predicted better adherence to the postoperative medical regimen, and strongly predicted nurses' ratings of the patients' physical health at six months after surgery. There was also a tendency for positive expectations to predict longer delays before development of infection (which is a near-universal side effect of heart transplantation).

2.5 Disease Progression

The successful management of disease can be reflected in many ways. In addition to examining responses to medical procedures, researchers have also looked at the process of disease progression. Many chronic, or incurable, diseases produce a sequence of new symptoms. An example is HIV infection, which initially has no observable symptoms, but eventually produces symptoms of a variety of types, which become increasingly debilitating.

At least two studies have examined the development of symptoms in men who were HIV-positive but symptom-free, as a function of psychological variables related to hopelessness and pessimism. In one study (Reed et al. 1999), the men completed a measure which included an index of stoic acceptance. This index reflects a fatalistic mental preparation for the worst and acceptance of the inevitable, and has been characterized as reflecting pessimistic disease-specific expectancies (Reed et al. 1994). In this sample of men who were initially free of symptoms, responses to this measure indicating greater pessimism predicted earlier symptom onset (Reed et al. 1999).

Another study (Ironson et al. 1994) examined the effect of the giving-up response that was linked to pessimism in earlier sections. This project followed asymptomatic HIV-positive men for two years after informing them of their positive serostatus. Measures of coping reactions (including a measure of disengagement—the giving-up response) were collected 5 weeks after diagnosis. Those who at the postdiagnosis assessment reported greater disengagement were more likely to have developed AIDS symptoms two years later.

2.6 Recurrence and Death

Another body of work moves the discussion from management of disease and progression of disease to disease recurrence and even mortality. Greer and coworkers have for some time studied individual differences among breast cancer patients (see *Cancer: Psychosocial Aspects*). Some patients react to their diagnosis and surgery with what has been termed 'fighting spirit,' a focused engagement with the struggle of living and regaining strength. Others react instead with stoic acceptance (fatalism) or feelings of hopelessness and helplessness. Patients who reacted to the initial cancer with fighting spirit were more likely to have recurrence-free survival at five-year follow-up than women who reacted with hopelessness and helplessness (Greer et al. 1979). This pattern held up at both 10-year follow-up (Pettingale et al. 1985) and 15-year follow-up (Greer et al. 1990).

One project bearing on psychosocial variables and survival tested a six-week group intervention in a sample of malignant melanoma patients (Fawzy et al. 1993). Among measures collected was a measure of active-behavioral coping with the illness. Active-behavioral coping was defined as trying to alter the course of the disease by activities such as exercise, relaxation, and frequent consultations with physicians. People with this coping pattern appeared to be staying engaged with the struggle to stay alive, consistent with the picture of optimism described earlier. Fawzy et al. found that higher initial levels of this pattern predicted lower rates of recurrence and death.

In the previous section a study was described in which stoic acceptance of bad outcomes had adverse effects on symptom development in HIV patients. Further evidence of the ill effects of that attitude

comes from research on survival time among patients whose disease had already progressed to AIDS (Reed et al. 1994). By the end of that study, 82 percent had died from complications related to the disease. Higher scores on the index of stoic acceptance (reflecting negative disease-specific expectancies) related to shorter survival times. It was as though individuals with this attitude were preparing to die, and death then came to them more quickly.

Another project bearing on the role of doubt and disengagement in disease progression examined a sample of recurrent cancer patients (Schulz et al. 1996). Patients were followed for 8 months, by which time approximately one-third had died. All had earlier completed a measure of pessimism about the future. Controlling for levels of symptoms at baseline, greater pessimism predicted shorter survival time. Further, the findings were specific to pessimism. Depression did not predict mortality.

One last study, conducted in Finland (Everson et al. 1996), examined the relationship between a sense of hopelessness about the future and mortality in a sample of over 2,000 middle-aged Finnish men who had been treated for cancer or heart attacks. Hopelessness was assessed by two items: 'I feel that it is impossible to reach the goals I would like to strive for' and 'The future seems for me to be hopeless, and I can't believe things are changing for the better.' These men were followed for 6 years. Those who had reported higher degrees of hopelessness had greater disease-specific mortality—and all-cause mortality—than men with less hopelessness.

2.7 *Associations between Depression and Health Outcomes*

Most of the foregoing has dealt with pessimism or hopelessness. What about depression and health outcomes (see Scheier and Bridges 1995 for broader review).

Links between depression and health are best documented for various kinds of cardiac-related events. For example, Ladwig et al. (1991) gathered psychological data from over 500 male survivors of MIs during the third week after the MI, including a measure of depression. By six-month follow-up, 12 of these patients had died from cardiac events. Death was predicted significantly by post-MI depression levels. When the data were adjusted for medical variables, the association between depression and cardiac death was weakened, but remained marginally significant.

Stronger findings relating depression to post-MI mortality have been reported by Frasure-Smith et al. (1993), using a more standardized measure of depression. They interviewed over 200 men and women who had been hospitalized for MI, during the week after the MI. Depression was assessed using an interview that gathers information used to make psychiatric diagnosis. In addition, a large number of medical variables were collected. By six months after the initial interview, 12 cardiac-related deaths had occurred, and depression was a significant predictor. Patients meeting criteria for clinical depression during the week after their MI were five times more likely than nondepressed patients to have died by the six-month follow-up. The effect of depression remained significant even after the data were adjusted for all clinical predictors of death.

Frasure-Smith et al. (1999) have more recently reported a larger (896 patients) and longer-term (one-year) study of men and women who had been hospitalized for MI. Analysis of survival data indicated that both men and women who were depressed while in the hospital were more than three times as likely to die of cardiac causes than were otherwise comparable patients who were not depressed. Again, these effects were independent of medical risk factors.

As noted, much of the evidence that depression has adverse health effects bear on cardiac disease. Some data also hint that depression may hasten HIV disease progression, though other findings have failed to confirm this (see Scheier and Bridges 1995).

Is depression a risk factor for premature death more generally? Wulsin et al. (1999) reviewed a wide range of studies in an effort to address that question. They concluded that the evidence for mortality effects is most compelling for cardiac disease, in line with studies described earlier. They also concluded that most research bearing on the question failed to include important control variables, such as degree of physical illness at baseline, smoking status, and alcohol abuse. All of these are known correlates of depression and potential predictors of premature death. This obviously is an area of investigation in which more information is needed.

It is tempting to view the evidence on depression and premature death as reflecting physical manifestations of a loss of desire to continue living. Perhaps the depressed MI patients in the studies reviewed above simply gave up the struggle to go on. This would represent a kind of disengagement response, albeit one that is quite different from the overt actions represented by suicide or alcohol abuse.

3. *Potential Moderators*

The focus of this article has been on the direct associations between health and the psychological variables of depression, hopelessness, and pessimism. However, some attention should also be paid to limitations on—or moderators of—such effects. One limitation may be extent of disease. It is possible that the effects of the psychological variables under discussion (and others) are greater among persons with disease that is less severe than among persons whose disease is advanced. That is, perhaps advancing disease affords less opportunity for psychological variables to gain leverage over the impact of the disease.

Another potential moderator is the age of the person whose health is under study. In their review of the literature, Scheier and Bridges (1995) noted that several studies had found that variables such as personality and depression had stronger influences on health among younger than older persons. For example, Schulz et al. (1996) found that pessimism predicted increased mortality among a group of recurrent cancer patients, but only among patients under age 60.

Indeed, every age difference that Scheier and Bridges (1995) encountered was one in which stronger associations between personality and health outcome occurred among younger than older persons. This observation led Scheier and Bridges to suggest that biological factors may become more important in determining disease outcomes as people grow older, and psychological factors correspondingly less important. This is another issue that should receive greater attention in the years to come.

4. Closing Comment

This article reviewed some associations that have been observed between pessimism, hopelessness, depression, and subsequent health outcomes. Evidence of associations between these psychological variables and health is fairly robust. On the other hand, it would be wrong to conclude that the mechanisms underlying these effects are well understood. In some cases the mechanism is obvious: persisting in a health-promoting exercise activity, taking steps to control one's weight, acting to lower one's health risks—all these are behavioral ways in which optimism and hopefulness can enhance health outcomes through overt behavior. In other cases, though, the mechanism is far more speculative, involving potential neuroendocrine and immune responses as mediators. The role of such mediators is presently under active investigation, but there remain many uncertainties. Despite the many questions remaining, though, the pattern seems consistent with a picture in which continued optimistic engagement with life goals promotes better health outcomes, and in which the loss of such engagement—giving up—promotes poorer outcomes.

C. S. Carver

Deprivation: Relative

A person is relatively deprived if he or she does not enjoy material or symbolic goods compared with the norm or with other people that enjoy them. Relative deprivation and the notions that are directly or indirectly linked to it constitute a strongly structured conceptual set. The related propositions make up what Merton terms a 'middle range theory,' that is, a set of propositions which combines hypotheses and empirical regularities proper to a specific domain of validity and without which these regularities would be neither accounted for, nor cemented.

Even if the concept of relative deprivation was first used by Stouffer et al. (1949) in *The American Soldier*, this idea can be found in the writings of several classical sociologists such as Tocqueville (1852), Durkheim (1893, 1897), and Weber (1904). It also features in the works of contemporary non-sociologists such as Duesenberry (1949) and Easterlin (1973). These authors underscore the importance of the notion of relative income compared to absolute income and thereby that of the comparison between two statuses of the same individual at two different time intervals. This accounts for certain paradoxical phenomena that the standard economic theory is unable to explain. Starting with the well-known study of Stouffer et al. (1949), the theory of relative deprivation has been gradually developed, particularly by Merton and Kitt (1950), Runciman (1966), Boudon (1977), and Hirschman (1981). Its application expands to various areas, mostly to those where the relations between individual contributions and retributions are crucial, just like the problems of justice and equity or revolution. This theory is also interpreted from different standpoints that are discussed later.

1. *Themes and Theory of Deprivation*

Relative deprivation is often used in *The American Soldier* to account for puzzling results whose exhaustive study was conducted by Merton and Kitt (1950). One of these results is that the most favored groups seem to be inclined to criticize the system of promotion. Thus, Military Police soldiers belonging to a unit where promotion is scarce are satisfied with the promotion system governing their military career. In contrast, men in the Air Corps, although belonging to a body where promotion is frequent, are dissatisfied with their opportunities for promotion. To explain this paradox, Stouffer et al. (1949) introduced the notions of relative deprivation and reference group: 'if at the same age, level of education, and seniority, the majority of my colleagues and I have been promoted, I will consider my promotion as normal. If, however, I have not been promoted, I will go through a feeling of injustice, which can translate into criticism of the mobility system. If the promotion is relatively scarce in the group to which I belong or refer to in my evaluations, I will be very pleased with my promotion. However, if I am not promoted I will not experience any sense of injustice since all my peers have not been promoted.' Deprivation therefore occurs only under specific conditions:

(a) The individual retains some knowledge of the system of social promotion, mobility or retributions.

(b) He or she does not get an expected good, for example promotion.

(c) This expectation is based on an evaluation and a comparison that the individual conducts between his or her position, contributions and retributions on the one hand, and those of a large number of his or her peers, who make up his or her reference group on the other hand. This condition expresses *inter alia* the principle of interdependence among social actors.

(d) He or she has a feeling of inequity, which translates into criticism of the mobility system.

Thanks to particular models illustrating the idea of deprivation, several heterogeneous paradoxical phenomena have been accounted for by the founders of sociology as well as by contemporary sociologists. In *The Old Regime and the Revolution*, Tocqueville (1852) underscores the following surprising positive ecological correlation: the higher the economic prosperity, the quicker the laws of the old regime disappear and political liberalization gains ground in certain regions, the stronger the support of these regions to the Revolution. He points out that:

> While prosperity (...) in France is growing, general attitudes seem to be less content and more anxious; public dissatisfaction is turning sour; hatred for all the old institutions is increasing. The nation is clearly heading towards a revolution. Moreover, the parts of France which should have been the major sources of this revolution are precisely those parts where progress is being shown most .... It is not always by going from bad to worse that we fall into revolution.

Durkheim (1893, 1897) also develops two partly complementary ideas linked to deprivation. In the *Division of Labor*, he maintains that happiness is not an increasing monotonic function of wealth. The relation between satisfaction and abundance of wealth is a parabolic function with a maximum corresponding, according to him, to the happy medium, to the *aurea mediocritas* of the common saying: 'happiness lies between the two extremes of wealth.' Besides, the French sociologist devotes the chapter on 'the division of constrained labor' of the same book to the analysis of the relation between deprivation resulting from the violation of meritocratic rules and the questioning of social order. Equal opportunities and congruence between distribution of talents and jobs are, in his view, the conditions of legitimacy and stability of social order. In *Suicide*, it is the pure model of anomie that expresses deprivation. When aspirations and expectations grow faster than the means of realization and when these are not set back or brought to an end, a state of anomie occurs with numerous individual and social consequences. The absence of social regulation is a source of social pathology. With no clear limits to the legitimate needs, and free from any social pressure, men like Goethe's Faust will experience the infinite dimension of desire, frustration, and torment and can go as far as committing suicide.

Hirschman (1981), as an example of contemporary authors, explains tolerance to inequality in the developing countries by his 'tunnel effect' which is directly tied to the theory of deprivation and reference group. Let us take the example of a car driver in a two-lane tunnel with two lanes going in the same direction. Suppose that, after a short period of time during which no car in either lane has moved forward, the cars on the other lane start moving. He will feel relieved and hopeful that the cars on his lane will also move forward. However, upon realizing that only the cars on the other lane keep moving, he will feel disappointed and later furious. He might end up tempted to readjust the inflicted injustice by switching to the other lane, thus violating traffic regulations. The same applies to inequalities. An improvement of the social positions of my neighbors or my peers gives me hope. In case of disappointment, I will feel deprived and try to change the order of things.

2. *Generating Mechanisms of Deprivation*

One can wonder, following Boudon (1977), if all these phenomena are not likely to be generated by social mechanisms. He sets up simple models stemming from game theory, which bring about and explain relative deprivation. In his view, this deprivation can be interpreted as the product of the structures of interaction in which individuals end up. Deprivation entails the notion of competition for good and that of objective opportunities for promotion (Stouffer et al. 1949).

Let us suppose a group of N players who can win the lot $B1$ for a stake $C1$ or the lot $B2$ for the stake $C2$ with:

$$B1 > C1,\ B2 > C2,\ B1 > B2,\ C1 > C2,\ B1 \text{ and } C1 > 0,\ B2 \text{ and } C2 > 0$$

$N1$ and $n2$ are the number of winners of the lots $B1$ and $B2$ respectively with $n1+n2 = N$.

Being rational, the players will bet on $C1$ rather than $C2$ if the expected net profit by betting on $C1$ is superior to that corresponding to $C2$.

If $x1$ players ($n1 < x1 < N$) bet on $C1$, the expectation of net profit $E1$ ($x1$) of a player betting on $C1$ is

$$\begin{aligned} E1\ (x1) &= (B1-C1)\ n1/x1 \\ &\quad +(B2-C2)\ (x1-n1)/x1 \\ &= (B1-B2)\ n1/x1+B2-C1 \end{aligned}$$

On the other hand, the expectation of net profit $E2$ of a player betting on $C2$, when $x1$ ($> n1$) players bet on $C1$ is,

$$E2\ (x1) = B2 - C2$$

Thus, $x1(> n1)$ players bet on $C1$, a player is advised to bet on $C1$ rather $C2$ if

$$E1\ (x1) > E2\ (x1)$$

Or

$$(B1 - B2)\ n1/x1 + B2 - C1 > B2 - C2$$

i.e.,

$$(B1 - B2)/(C1 - C2) > x1/n1$$

One can analyze the relationship between the game structure and deprivation which is the proportion of individuals betting on $C1$ (the highest price) but winning only $B2$ (the lowest price). For that matter, one should examine the different values of the ratio $(B1 - B2)/(C1 - C2)$ that is the ratio of the possible additional gain and the additional cost on one hand, the percentages of players $100\ x1/N$ and of the winners $100\ n1/N$ on the other hand.

The simulation shows how complex the nature of relations is between deprivation and the objective opportunities of promotion. Let us consider the following general cases:

(a) The rate of deprivation increases with the values $(B1 - B2)/(C1 - C2)$. This rate increases with the marginal rate of profitability or return on investment $\{(B - B2) - (C1 - C2)\}/(C1 - C2)$ as shown by Kosaka (1986) who systematizes the propositions of Boudon (1977) and deduces new ones, and makes 'critical points' emerge.

(b) The highest levels of deprivation correspond to cases where a small number of players win the lot $B1$, the highest one.

(c) Deprivation rate is moderated as long as the moderated value lots are distributed to players in a limited number (the case of the Military Police in Stouffer's study). This is no longer the case when the number of winners increases (the case of men of the Air Corps).

(d) We get equal deprivation rates when only a small number of players win important lots or when a large number of players win less important ones.

(e) In general, the curves corresponding to identical relative deprivation levels are complex with different plateaux (ceilings) and critical points.

The simulation confirms the idea according to which the game structure determines the deprived players and their number. It is equally possible to simulate the situations in which the players are not equal, that is when the group is stratified and each social class has its different resources and behaviors toward risk. These simple game models particularly show the conditions in which the mere fact of increasing everyone's promotion opportunities can result in further increasing promotion expectations. These models also demonstrate that the propositions of Tocqueville, Durkheim, Stouffer are not unconditionally valid: when equal opportunities increase among individuals, deprivation tends to grow under certain conditions; but it can decrease under others. The trend of the relation between promotion or social mobility depends on the structure of interdependence among individuals.

3. *Deprivation and Collective Violence: A Case Study*

Revolution theorists generally agree on the assumption that revolutions occur during a period of economic growth and political liberalization. This paradox seems to cast doubt on the hypothesis of the rationality of human behavior. One can wonder why people revolt at the very moment of prosperity. Deprivation theorists' respond that an improvement in objective living conditions tends to generate higher expectations. As the expectations grow faster than the improvement in objective conditions, a wider gap comes up and translates into a higher degree of deprivation. This model is similar to the Durkheimian theory of anomie, as shown by Besnard (1987) and Coleman (1990). The revolution theory developed particularly by Davies (1962), and Gurr (1968) is different. In their view, revolutions occur when a long period of socioeconomic prosperity is immediately followed by a sudden downturn, that is a sharp decrease in gratification accompanied by a constant increase in expectations. The rapidly widening gap between expectations and gratification generates revolution. This proposition commonly translates in an inverted J curve.

Even though the notion of deprivation in this theory is not as precisely and explicitly defined as with Stouffer, it is easy to demonstrate that it also supposes, a meaningful difference deems unacceptable between the expectation and the realization at the individual level and an interpersonal comparison. First, with regard to intra-personal comparison, the difference is at the same time relative and absolute. It is absolute if at the $t1$ moment we compare expectation with realization. It is relative if at the $t2$ moment, the difference between expectation and realization deems unacceptable or unbearable compared to what it was at the $t1$ moment. Besides, individuals with threatened social positions or subject to downward social mobility compare themselves to those with stable positions or upward mobility.

Several varieties of deprivations can be constructed. The first one relies on the theory of relative deprivation

and shows up in the works of Gurr (1968) particularly for whom 'a psychological variable, relative deprivation, is the basic precondition for civil strife of any kind, and that the more widespread and intense deprivation is among members of a population, the greater the magnitude of strife in one or another form.' The relation between deprivation and civil strife is however mediated by societal variables such as coercive potential that can deter strife, institutionalization (social and political association may provide nonviolent means for expressing discontent), facilitation (i.e., means that facilitate civil strife) and finally legitimacy of the regime.

The second variety is that of the status inconsistency that can be found in the founding father's works such as those of Tocqueville (1852), Weber (1904), and in such contemporary research as that of Lenski (1954). The rich bourgeois and the well-off farmer who, thanks to the liberalization of the rules governing the acquisition of land, end up as owners of vast lands, remain for the French aristocrat mere plebeians carrying visible stigma of their original social class. If, as Tocqueville states, the bourgeois and the aristocrats become unknown to each other, it is mainly because they evaluate each other according to values located on different scales. Whereas the bourgeoisie has economic quasi monopoly and looks forward to assuming political power and enjoying honors, the bourgeoisie can not gain access to these institutions because the noblesse get in the way. The bourgeoisie feels compelled to opt for the revolutionary solution. Conversely, in the nineteenth century, as Weber points out, while the Prussian Junker maintains his monopoly over the army and the bureaucracy, the industrialists buy lands to acquire nobility titles and gain access to political positions. Politically, as Weber states, this type of industrialist is reactionary. These two examples illustrate two special cases of the multiple effects of the status inconsistency whose complete taxonomy Cherkaoui (1995) attempts to construct.

The collective action theorists, especially those of mobilization, question the theory of revolution based on deprivation. As revolution is a collective action seeking to realize a public interest, the rational actor will face problems specific to this type of action, particularly the temptation of free-riding. Following Olson (1965), it is believed that the rational individual belonging to a latent group as a social class seeking to satisfy collective goals would rather turn to see the sacrifices accepted by the others. He would not be interested in participating in a revolutionary enterprise whose costs can be heavy. Eventually, as pointed out by several analysts of revolutionary movements as Cochin (1924) and Brinton (1965), the revolutions are the product of some élites of organized and almost unanimous conspirers toppling weak governments at periods of social disorganization. For the theorists of mobilization and social movements as Oberschall (1973), and Tilly (1978), a psychological explanation of the revolutionary phenomenon is unable to account for the shift from disenchantment to the mobilization against authorities and in particular against the state. Besides, the theory of rational choice reduces the moral and solidarity incentives, which play a key role in the emergence of collective action. This is sometimes a moral obligation for the individual who belongs to collectivities where solidarity bonds are predominant. From this perspective, it is rather the lack of participation that will be costly. Oberschall shows that the lack of bonds and the dismantling of social networks are major setbacks to mobilization.

As can be seen by trying to turn the theory of relative deprivation into a maid of all work, we put it through risks that hang over any theory whose domain of application has been excessively expanded. But despite some criticism, its underlying principles remain solid. To mention but one, the principle of interdependence is the center of its axiomatic structure that the formalization put forward by Boudon has clearly highlighted. To explain and understand, *inter alia*, the inflationary spiral of demands, the perception of inequality, the individual conception of justice and of equity, or the degree of satisfaction, the theory of relative deprivation reminds us of an obvious fact that the sociological tradition has taken for granted since the days of Montesquieu whereby the structures of interdependence between social actors are often decisive.

Desertification

1. Introduction

Despite considerable uncertainty about its meaning, the importance of desertification for the peoples of the world's drylands should not be underestimated. First, the term, for all its problems, envelops a set of processes, sometimes listed as drought, desiccation and degradation, which pose very real and severe challenges to drylands, and have strong knock-on effects on society. Second, desertification language is deeply entrenched in policy circles and in the current UNCCD (United Nations Convention to Combat Desertification), and will inevitably continue to inform the financing of development interventions in drylands.

1.1 History and Definitions

The 'Agenda 21' document of the 1992 United Nations Conference on Environment and Development (UNCED) defined desertification as 'land degradation in arid, semi-arid, and dry, subhumid areas resulting from various factors, including climatic variations and human activities.' The processes of degradation were said to be soil erosion, nutrient depletion, crust formation, salinization, reduction in pasture and agricultural productivity, loss of biodiversity, and reduction in vegetation cover in susceptible drylands. Of course, uncertainties abound, the circumstances fostering reversible or irreversible change, the resiliency of different semi-arid environments, the different roles of natural and anthropogenic driving forces, and the synergies among these elements.

Scientists were exercised as early as the 1920s with the 'the advance and spread of the desert' in Africa. It was then that France began the first studies of the process in West Africa, finding evidence of mobile sand dunes, human fossil remains in now-dry areas, and declining annual rainfall. It was concluded that the Sahara had grown, and was still growing, owing to poor land management, which had worsened under the colonial regime.

These early judgments preceded what environmental historians are now discovering to have been a much more traumatic event, the American 'Dust Bowl' of the 1930s. Sears' *Deserts on the March* (1949) evoked accusations of widespread anthropogenic degradation. He, and others, believed they had evidence of widespread environmental degradation in the drylands of the Old World, whose cause, as in the mid-western states, was also thought to be mismanagement. With these narratives very much in mind, E. P. Stebbing, a forester, identified the causes of degradation in British West Africa to be shortened agricultural fallow periods, shifting agriculture, and overgrazing (Stebbing 1935). An Anglo–French Forestry Commission toured the Niger–Nigeria border in 1936–7, and their conclusions were far more circumspect. They saw degradation as place-specific and treatable. Yet a member of this Commission, the influential French botanist Auguste Aubréville, held to the 'desert advance' hypothesis, and first used the term 'desertification' in 1949 (Warren 1996).

In dryland Africa, severe drought and famine in the 1970s, following decades of good rainfall, again revived the desertification debate, with depressing reports of desert advance appearing in scientific publications and the media. This alarm stoked the

United Nations Conference on Desertification (UNCOD), held in Nairobi in 1977. UNCOD, and the National Plans of Action agreed to at that meeting, still viewed people as the main agents of desertification.

1.2 Current Research

Research into the links between climate, management and degradation has taught us a great deal since the 1970s. Since then, many detailed studies of human—environment interactions on the local scale have been carried out in the drylands, spurred on by advances in climatology, soil science, botany, geoinformatics, agronomy, and the social sciences.

This research, conducted by numerous scholars from the natural and social sciences, offers a longer-term view of what happens as rainfall fluctuates, or when soils are lost and gained. More generally it has examined the complexity of the linkage between resources and people in the drylands, and the role of adaptive local resource management. Above all, it is now possible to challenge notions about an equilibrium state or 'carrying capacity' in these environments and from there to challenge the desertification narrative with better, if still imperfect evidence (see also *Human–Environment Relationship: Carrying Capacity*). Yet laying the desertification discourse to rest is difficult. At least six themes remain essential elements of the desertification debate.

1.2.1 Advance of desert. Large-scale Saharan expansion has not been proven within the period of the historical record. Desert advance in the Sudan has been asserted since the 1930s, but Helldén (1991) found no such evidence from satellite imagery, settlement histories, sand movements, and degradation conditions around boreholes. The current view is that the Sahara expands and contracts periodically as rainfall varies. Desert advance (as in the severe drought of 1984), and localized degradation, is usually short-term (Tucker et al. 1991, Nicholson et al. 1998).

1.2.2 Resilience of dryland ecosystems and land-use systems. Degradation is, therefore, usually localized and ephemeral (see also *Land Degradation*), largely a function of the complexity of relationships that exist between humans and natural systems. Semi-arid ecosystems, far from being fragile, exist in a range of semi-permanent 'states' dictated by disturbance, drought, fire or insect attack; they are well adapted to these forces. Similarly many indigenous management systems redistribute nutrients, plants, grazing pressure and water to create 'enriched' patches in the landscape (see also *Ecology, Cultural*).

1.2.3 Influence of grazing and livestock. The UNEP *Atlas of Desertification* (1992) asserted that 58 percent of soil erosion in dryland Africa was the result of overgrazing by livestock, lending support to Garret Hardin's 'tragedy of the commons' hypothesis (see also *Environmental and Resource Management*). Such figures gave way to more conservative estimates in the latest version of this *Atlas* (Middleton and Thomas, 1997). There is now greater confidence about the heterogeneity and patch dynamics of pastoralist grazing strategies so critical to many drylands. Less vegetation is not necessarily worse vegetation. It is difficult to overgraze in a dynamic nonequilibrium system, dominated by annual grasses, where the external forces such as drought are more powerful than the internal ones such as animal numbers.

1.2.4 Effects of increased population in rainfed, dryland agricultural systems. No necessary Malthusian link exists between elevated population levels and resource degradation. Indeed, because there is often an incentive for rural people to invest in antidegradation measures in these circumstances, more people (and labor) may mean less erosion, and the initiation of compensatory risk management strategies (see also *Agricultural Change Theory*; *Indigenous Knowledge and Technology*).

1.2.5 Soil erosion and fertility decline. Although topsoil erosion does occur in drylands and soil is blown or washed away, these processes do not themselves necessarily result in degraded landscapes. Soils are often replaceable or may be very deep, and can accumulate down-slope or down-wind where they may be more valuable to local people. Indigenous dryland soil conservation systems are impressive (see also *Indigenous Knowledge and Technology*). Yet even after decades of research, soil erosion and the values placed upon it by society are very difficult to measure.

1.2.6 Climate change. There are two issues here. Charney and Stone (1975) suggested that devegetation might induce regional drought—bare soils are cooler because they reflect more solar energy and cool surfaces discourage rainfall. This hypothesis remains disputed. Current research provides strong evidence that changes in surface characteristics, including vegetation, affect local and regional rainfall patterns significantly. Some climatologists however, find little evidence in this claim as registered in the coarser scale climate record (Williams and Balling, 1996). In addition, potential global warming and the El Niño-Southern Oscillation will have differential, and as yet uncertain effects on certain drylands, with

the majority of current models suggesting increased rainfall and temperature variability in Africa (see also *Climate Impacts*).

2. Desertification Policies

Research, policymaking and interventions are strongly linked. For example, when scientists pinpointed advancing deserts, the policy response, was 'plant green belts'! Roosevelt commissioned a study of a massive belt between Texas and North Dakota after the Dust Bowl. Stebbing (1935) recommended much the same for Africa, and UNCOD proposed a circum-Sahara green belt. The Algerian Government actually began planting trees, employing conscripts to do so. Where scientists believed that herdsmen or farmers were irrationally causing degradation, policy-makers and government officials prohibited goats, tree cutting or grass burning, and destocked herds, or, on a much more massive scale, they enforced soil conservation programs.

Antidesertification measures have been international in scope. A suite of international institutions materialized after the great Sahelian drought of the late 1960s and early 1970s. First, the UN Sudano-Sahelian Office (UNSO) was charged with combating drought, later taking on desertification issues. It was later joined by the UN Environment Programme and the FAO (Food and Agricultural Organisation) in these roles. Scientific panels and advisors produced a 'veritable sandstorm of literature' (Mortimore 1998) on the complexities of drylands. In general, the prognosis was gloomy: 10 percent of the earth's surface was human-made desert; and the process would continue. Desertification became enshrined in international policy.

African states absorbed some of UNCOD's recommendations from the late 1970s, although they were held back by poor funding. Projects were initiated, most designed to arrest soil erosion. Some were implemented without adequate local consultation or participation. Many, like the GERES project in Burkina Faso where bulldozers were used to create earthen bunds across many slopes, actually increased erosion rates. Fuelwood supply projects and the drastic destocking of indigenous pastures failed for the lack of local complicity.

Unforeseen ramifications followed in the post-UNCOD, post-Sahelian drought era. In Niger, proposals for green belts resorted to authoritarian measures for implementation, for in local eyes, as in the eyes of scientists today, they were deeply irrational. In similar vein the military rulers of Mali banned burning, counter to local know-how about the enriching powers of fire on pastures. In many countries, the cutting of fuelwood was unnecessarily proscribed (see also *Deforestation–Forestation*). Most disturbingly, the characterization of African pastures as 'overgrazed' came to infest writing about them. Attempts were thus made to reduce the numbers of livestock, to privatize grazing lands, and even to replace herding the commons with systems based on European and North American models (Warren 1996). The desertification threat was used to justify authoritarian control over natural resources and land-use practices.

A broadened, perhaps softened conception of desertification suggests a new range of policies that, given sensitive application, may prove more successful because they are more trusting of dryland populations and more aware of ecological diversity. New initiatives are based on a better understanding of the three main issues in dryland management: drought, desiccation and degradation. Drought is common currency among dryland folk. It may not be welcome, but people clearly have a portfolio of coping strategies to deal with it, and reflexive management that constantly adapts to an ever-changing situation (see also *Environmental Risk and Hazards*). These indigenous systems are now being supported, rather than replaced or obstructed. Desiccation is known to have been frequent in the history of human occupation of drylands. Large-scale shifts in livelihood practices occur under progressive aridity, but Sahelian drought illustrates that relief, restocking and resettlement are necessary when this happens. Degradation requires a range of responses. Rich repertoires of conserving indigenous techniques exist, some—like permeable contour bunds—already improved through hybrid experimentation between farmers and scientists. Drylands and dryland peoples and their economies are heterogeneous. Policies increasingly aim to protect this diversity, rather than erase it. Greater clarity of land tenure security is needed, and rangeland areas require special forms of collective management (see also *Environment and Common Property Institutions*). In brief, livelihood security is essential to good conservation.

3. The Convention to Combat Desertification

UNCED, held in Rio in 1992, breathed new life into the moribund desertification concept (see also *International and Transboundary Accords, Environmental*). Fortunately, Chapter 12 of UNCED's Agenda 21 document is far less alarmist in its tone than UNCOD's recommendations of 15 years earlier, adopting some of the findings and views of the new research reported above. For example, climate change is now seen as a major contributor to desertification, and drought preparedness, education, and strong local participation are now stressed.

The CCD came into force on December 26, 1996 (see http://www.unccd.ch/ or http://www.iisd.ca/linkages/desert/ for full details and current negotiations). Although there was skepticism about this new international effort, nongovernment organizations and other actors from developing countries had a

relatively strong involvement in drawing up the Convention. The various CCD components are legally binding on the parties, and include annexes for Africa, Asia, Latin America, the Caribbean, and the northern Mediterranean. Almost 160 countries had ratified the Convention by September 1999. The focus has moved to implementation, despite significant questions about who pays, coordinates, and monitors the activities. By late-1999 National Action Plans were drawn up by most dryland nations, but progress is hampered since there is no international CCD implementation fund available.

4. Conclusion

In the absence of well-adapted technologies, life in drylands is harsh. That degradation of these lands follows from social and climatic processes is not in dispute. That degradation amounting to desertification of the magnitude assumed in the early debates, or even in the recent Convention, has been strongly challenged by the research and other communities. Nonetheless, desertification remains a powerful narrative that has captured the imagination of certain policy makers, governments, and scientists, and it has persisted with peaks and troughs of interest since the 1930s. Its power is problematic, since 'the search for accuracy appears to be vulnerable to generalization, over-simplification and distortion for political or funding purposes' (Mortimore 1998). Desertification has certainly served specific constituencies quite well, including national governments seeking to extend their control, international bureaucracies seeking legitimacy, and scientists seeking research funding.

Tackling the various processes that the term desertification subsumes is a major challenge, given that dryland populations suffer the impacts of droughts and desiccation, and need to exploit land, water, and timber resources in ways which often result in degradation. As an explanatory term, however, desertification has been used too broadly and too loosely, and this has been counterproductive.

Deserts, Philosophical Concept of

In everyday discourse, the language of desert is prominent and pervasive. It is common to speak of certain conduct (or persons) as deserving of praise or blame, reward or punishment, and of goods or ills that are visited upon people as deserved or undeserved. The subjects of desert claims may vary: most commonly they are persons or person-related entities (such as paintings that deserve prizes or cities that deserve their reputations), but insofar as inanimate or natural objects (such as rock formations) are evaluable in some way, there may be no barrier to speaking of them also as having deserts of certain kinds. The objects of desert claims are almost always seen as goods or ills. *Inter alia* a person may deserve success or failure, a good or bad reputation, good or bad luck, a greater or lesser portion of some social resource, compensation, or fairness.

1. Desert and Merit

The terms 'desert' and 'merit' are often used interchangeably. Some writers, however, have insisted on their conceptual distinction. If, for example, the ancient tie between diligence and desert (*deservire*: to

serve zealously) is focused upon, the language of merit may be used to capture those outcomes warranted by other forms of value. Milne, for example, argues that

> a natural beauty spot is *worthy of*, or *merits*, or *rates* inclusion in a published guide to places of natural beauty, but it does not make sense to say that the inclusion in the guide is something *deserved* in the way of reward. The classification of human beauty (or intelligence, or skill) is a parallel case: the naturally beautiful person merits a certain rating, but he or she does not deserve it any more than Niagara Falls is *rewarded* by its rating as a tourist spectacle. Only insofar as effort is expended in producing the achievement or contribution, or in acquiring a skill, is there the basis of a desert-claim: a person cannot be deserving of praise or reward without trying (Milne 1986, p. 240).

The point is expressed generally by Pojman. Merit (or demerit), he claims, is the more inclusive term, referring to 'any feature or quality that is the basis for distributing positive [or negative] attribution,' whereas desert is a species of merit, 'typically or paradigmatically connected with action, since it rests on what we voluntarily do or produce' (Pojman 1999, p. 86). He then distinguishes a secondary, negative, compensatory or rectificatory use of desert, to accommodate cases in which—relatively faultlessly—a person suffers some evil and recompense is appropriately called for.

Although a distinction of sorts can thus be made, it is at best a soft one, since a great deal of current debate about desert (see below, Sect. 11) has concerned the enhancement of arbitrarily possessed advantages through diligent effort or the exacerbation of disadvantages, including some relating to effort.

2. *Preinstitutional and Institutional Deserts*

In recent philosophical discussion, a distinction has frequently been drawn between preinstitutional and institutional deserts—between deserts that are said to be 'naturally' implicated by virtue of some characteristic/activity of their subject, and those that are attributable only within the framework of some institutionalized arrangement. A person is said—preinstitutionally—to deserve his good fortune, or—institutionally—to have deserved to win a particular prize. The former is often said to be prior to the latter: 'desert is a "natural" moral notion (that is, one which is not logically tied to institutions, practices, and rules)' (Feinberg 1963, p. 70). In many of its attributions to humans, preinstitutional desert is tied to 'reactive attitudes—the sense we have of others' agency, of their sharing with us at the deepest human level' (Strawson 1962). And the rejection of preinstitutional desert is often associated with a deterministic naturalism (Scheffler 1992).

Those who contend that only institutional desert claims have a legitimate place in our understanding claim that talk of preinstitutional deserts assumes, contrary to fact, that the characteristics on the basis of which such claims are made are fairly distributed. But, such critics of preinstitutional desert argue, since people naturally and arbitrarily differ in the talents, capacities, and social environments that ground what preinstitutional desert claims would allocate to them, they cannot really be said to deserve such things, or their fruits (cf. Rawls 1971, pp. 104–6, 312–4).

Leaving these latter claims aside (though see Sect. 11), it may nevertheless turn out that the distinction between preinstitutional and institutional deserts is one of degree more than one of kind. The good weather which—it might be said—*A* deserves for her vacation makes sense in part because the social institution of providing vacations has a point (recreation) to which 'good weather' intelligibly relates. Where no social institution is in place, it is much more difficult to make a specific attribution of desert. Thus, given the institution of punishment, it is easier to argue that those who deserve it are wrongdoers, than to argue—*ab initio*—that what wrongdoers deserve is punishment. It may well be that doing good has positive deserts, and doing ill has negative deserts; but the specific character of those deserts, whether good or ill, may not be determinable independently of particular social institutions (that, admittedly, are themselves open to scrutiny). It is—in part—the difficulty in establishing what, preinstitutionally, people deserve that creates some of the moral space for contemporary debates about restorative justice. Certainly wrongdoing deserves some form of negative response: but should that response take the form of punishment (narrowly understood as fines, imprisonment), or instead as confrontation, blame, reparation, apology, penitence, and so forth?

3. *Desert and Entitlement*

But even if the distinction between preinstitutional and institutional deserts is soft, it should not lead to a conflation of desert with entitlement. '*A* deserves *p*' is not equivalent to '*A* is entitled to *p*.' Deserts seem to function comparatively or incrementally—as more or less; entitlements tend to be absolute—either we are or we are not entitled to something. Because of his talent and the effort he has put into training, *A* may be the most deserving when it comes to winning the race. But if he pulls a muscle and has to withdraw, he is not entitled to the prize, nor even to win. The purpose of a race may be to determine who is the fastest runner, and *A* may be the fastest runner and therefore deserve to win. But the rules of the race—which formalize the process of determining who is the fastest runner—will determine who is entitled to win. The entitlement rules may not always succeed in establishing the most deserving, and sometimes they may even serve to exclude the most deserving.

4. *Moral and Nonmoral Deserts*

Desert often functions as a moral notion, especially where fair distributions of social benefits and burdens are involved. But it need not do so. If a person deserves success, or deserves to win a prize, or deserves good weather, we need not be talking about moral desert. True, it may seem to align with a certain cosmic fairness, but this need not be moral in character. Even if deserts are paradigmly moral, they shade off into the nonmoral. In asserting that the Niagara Falls is deservedly famous or that the Mona Lisa deserves its reputation or even that a person's efforts deserved a better result, we are not making a moral claim. Desert is a normative notion, not necessarily a moral one.

5. *The Structure of Desert Claims*

It is generally agreed that desert claims have the implicit structure: '*A* deserves *p* in virtue of *x*,' where *A* is the subject of the desert claim, *p* its object, and *x* its basis.

For the most part, the subjects of desert claims will be persons/personal conduct (individual or collective) or people-related artifacts/constructs (such as art objects, cities, and so forth), although common parlance sometimes extends the language of desert to environmental and other natural objects (the sequoia, for example, may be said to deserve preservation or its reputation).

The range of deserved objects is vast: to those mentioned earlier may be added *inter alia* jobs, wages, grades, respect, wins, and losses. Linking all such objects is their perception as goods or ills, as benefits or burdens, as valued or disvalued. Although there may be marginal cases in which one deserves to be treated neutrally rather than well or ill (Sverdlik 1983, p. 320–1), such cases are parasitic on a context in which the distribution of goods and ills is primary. Sometimes—as in the case of *A*'s good weather—what seems to be deserved is a state of affairs rather than some mode of treatment by others or some achievement of one's own.

There is an ambiguity in the negative claim '*A* does not deserve *p*.' It may mean, '*A* does not deserve *p* (but deserves *q* instead)' or '*A* does not deserve *p* (or *q*).' In the former case we may speak of *A* being nondeserving, in the latter case of *A* being undeserving.

6. *Desert Bases*

Desert claims are more than expressions of personal assessment. They are subject to public scrutiny and criticism. In particular, some proportionality between the desert basis and deserved outcome is presupposed, though the principle of proportionality stands in need of clearer articulation than it is generally given. So, although we might be inclined to say that a person who was injured in an automobile accident—because he foolishly refused to use a safety belt—deserved the injuries he suffered (though not to be killed), we would be reluctant to say of a person who failed to wear a safety belt that he deserved to get injured (though we might want to say that if he gets injured he will deserve it).

Most writers on desert consider that desert bases must not lie in the future, but are instead constituted by some past behavior or characteristics already possessed by the deserving object (Kleinig 1971, p. 73, Sher 1987, pp. 150–93). Appeals to future consequences as bases for distributing benefits and burdens may sometimes be justified, but cannot be justified as deserts. Or, at least these consequences cannot be directly justified as deserts. As indirect desert bases, reference to future-oriented considerations may be more plausible. For example, it may be argued that though a person may deserve *p* only in virtue of his past diligence, diligence may be valued as a virtue (in part) because of its consequential/productive significance.

A few writers, however, have recently argued that a desert base might lie directly in the future (New 1992, 1995, Feldman 1995, p. 69–71). The examples used to sustain this thesis refer to some known future facts (say, death and suffering), on the basis of which its subjects are said to deserve some recognition now. It is not clear, however, that the examples show what they are intended to (Smilansky 1994): either there is some past or present commitment that is the basis for the desert or the language of desert is better replaced by that of distributional fairness.

7. *Locating Desert Bases*

It has been suggested above, and argued at length by others, that the nature of a desert base can be established only by going outside the concept of desert to external goals and values that inform the activity in relation to which *p* is said to be deserved (Cummisky 1987, Lamont 1994). That is, merely by looking at the concept of desert, we cannot tell—except in the most general terms—what a particular act or course of conduct deserves. Moreover, because the goals and values of the activities in question may differ, depending on the context, disagreements about deservedness can become intractable if this wider context is forgotten. Disagreements may also be chronically unresolvable if there is no clarity about the goals and values implicit in the activities or institutions in relation to which attributions of desert are made. In addition, of course, there may be a further debate about the appropriateness of the goals and values to the activities or institution in question, and that debate may also impact on a discussion of the appropriateness

of a particular desert basis or on the deservingness of those who are the recipients of its benefits or burdens.

Consider, for example, the institution of paying wages or a salary for work. It may not be determinable—given only a person's expenditure of productive effort outside the context of an employment contract—what she deserves: whether she should receive further opportunities, praise, good fortune, sustenance, free housing, or a wage/salary. But, given that we have in place the work-related institutions that we do, we might wish to argue that *A*'s work deserves—at a minimum—a living wage. If the work that *A* does is especially demanding and/or highly valued, we might want to say that it should be more highly rewarded. Even so—to simplify the illustration—we might view *A*'s work in at least two ways, and these may be considered separately or in combination. We may focus on the demandingness of the work, on its productivity, or on some combination of the two. If the former constitutes our focus, work that manifests great effort, even if minimally productive, will be seen as most deserving of remuneration (whatever we do about entitlements). If the latter is more significant for the particular institution, then productivity will provide the basis for remunerative desert, even if the achievement reflects native talent more than effort. Given that, for many social institutions, productivity and effort will tend to be correlated, we may decide to take both into account in determining what a person's remunerative deserts should be—though if we are not sure for how much each is to count, there may be interminable disputes about a person's deserts. In such cases, rules governing entitlements will enable the institutions to function.

Consider now the salaries earned by sports and pop stars. At one level, we might wish to claim that Michael Jordan and Michael Jackson deserve—in terms of the institutions within which they operated—the status they possess and the remuneration they have received. But it is also open to us to debate the social value our society has accorded to sporting and singing prowess and, if as a result we conclude that they are overvalued, we will also consider that they have received more than they deserved (albeit no less than that to which they were entitled).

Where, as in many human activities, effort and achievement tend to be highly valued as desert bases, it is sometimes asserted that the desert basis—whether it focuses on effort or achievement—must be something for which the deserving person is responsible or over which he or she must have a significant degree of control. So, for example, a person cannot plausibly be said to deserve punishment unless that in virtue of which punishment is said to be deserved is something for which the person can be held responsible.

It is, however, more likely that the issue of responsibility/control is to be settled by reference to the goals and values of the institution to which the desert is related rather than to some feature of desert itself. In the case of impositions such as punishment, the idea that they could be deserved without the triggering behavior being under the person's control would be deeply problematic. On the other hand, there is no great problem involved in thinking that those who deserve to win beauty contests are trading on genetic endowments more than on personal effort. And if inanimate objects—such as the Grand Canyon—can be said to be deservedly famous, the question of responsibility does not even arise.

There are, moreover, institutional contexts in which attributions of desert seem to require that one not have had control over one's circumstances. Consider, for example, deserved compensation. Here the deserving party is not usually seen as being in any way responsible for the misfortune in virtue of which he or she is said to deserve the compensation. Suggesting that the person who caused the misfortune is responsible puts the responsibility in the wrong place, and it is not adequately put in the right place by suggesting that the person who is deserving had to be nonresponsible for putting himself in the way of the misfortune. What is more, the compensation may be deserved even if the cause of the misfortune cannot be held responsible for bringing it about.

Thus the issue of responsibility too is determined by reference to the activity or institution in relation to which the desert claim is made. Prizes may be distributed to reward achievement or some combination of achievement and effort; wages may be given to reward productivity or some combination of productivity, talent, social importance, and effort. Some of these are more closely associated with personal control than others.

Among those who have wished to assert a tight relationship between desert and responsibility—or at least between desert and certain kinds of objects, such as punishments—several subsidiary discussions have ensued.

(a) One arises out of debates about personal identity. It has been argued (notably by Derek Parfit) that since our personal identity is constituted by our beliefs, a significant change in our beliefs will reconstitute our identity as other than it was, with implications for our deserts. Parfit considers the case of a person who, at ninety, after receiving the Nobel Peace Prize, confesses to injuring a police officer when he was twenty. Given the changes he has undergone, he no longer deserves punishment for what he did: 'just as someone's deserts correspond to the degree of complicity with some criminal, so his deserts now, for some past crime, correspond to the degree of psychological connectedness between himself now and himself when committing the crime' (Parfit 1984, p. 326). Although Parfit's account of identity has come in for criticism, his discussion draws attention to an important assumption about the subject of desert claims (though see Fields 1987).

(b) A problem has also surfaced in discussions of moral luck (Richards 1986; or, more generally, Rosebury 1995). If it is simply a matter of good or bad luck that certain consequences come about through *A*'s actions, should this bear on the matter of desert? Given that luck refers to something beyond one's control, it might seem as though it should not. Nevertheless, we often act as though it does. If *A* drives recklessly through the streets and—as a matter of bad luck—an innocent pedestrian happens to step out just as he passes, we will be inclined to see the injury or death as exacerbating the recklessness and making him more deserving of whatever penalty might have been due him. Richards disagrees. Deserts are, he thinks, reflective of character, and the character of an unlucky and lucky reckless driver is the same. He suggests that the difference is largely an epistemic one. We are to judge on the basis of what we have good reason to know about their deserts, and the person whose recklessness (or other failing) luckily results in no harm to others does not provide us with the epistemic basis for judging him as severely as the person who—unluckily, but not surprisingly—injures the other person. 'Luck … affects how we ought to treat him, not by changing what he deserves, but by changing the grounds on which we are obliged to judge' (Richards 1986, p. 200–1). 'To a very large extent people are lucky only in our verdicts, not in what they deserve, and their luck must affect our verdicts because it affects our grounds for reaching them' (Richards 1986, p. 206). Richards' position has not gone unchallenged: recklessness may not deserve what is normally attributed to the driver in the event of an accident (Adler 1987, p. 247); moreover, we may be in an epistemically better position to judge the lucky driver's character because of a record of his speeding tickets (Adler 1987, p. 247). Furthermore, Richards fails to give appropriate regard to the way in which the actual harm exacerbates the situation.

8. *Enumerating Desert Bases*

In the *Nicomachean Ethics*, Aristotle asserts that 'everyone agrees that in distributions the just share must be given on the basis of what one deserves, though not everyone would name the same criterion of deserving: democrats say it is free birth, oligarchies that it is wealth or noble birth, and aristocrats that it is excellence' (Aristotle 1962, pp. 118–19). For a modern reader, this well illustrates the dependence of desert bases on the goals and values of the activities or institutions within which desert attributions are made. In a world that is now characterized more noticeably by institutions and values that give greater weight—on the one hand—to individual responsibility and effort and—on the other—to achievement and social contribution, the bases for desert tend to be similarly characterized. As part of the tension between individual and collective values, a tension is also seen between desert bases that focus on individual responsibility, diligence, and effort and those that are more outcome directed.

8.1 *Effort/Diligence*

Writers who emphasize the importance of effort as a distributive desert base usually limit it in various ways. The effort must be purposeful, in the sense of being directed to the ends of the activity that grounds the desert; it must display a certain level of competence, in the sense of bearing some reasonable relation to achieving the ends of the activity in question; and the activity itself must be normatively acceptable: 'There is no question of rewarding murderers and rapists, no matter how much effort has been expended by them' (Milne 1986, p. 240).

If two people put in the same amount of effort, but one succeeds whereas the other one does not, then it might be said that they are equally deserving in virtue of their efforts. If, however, I offer a reward (or, more correctly, a prize) to the person who succeeds, then only the person who succeeds deserves it. Here the desert has been institutionalized. Our language is blurred between prizes and rewards, reflecting an overlap that sometimes occurs in competitive situations—but it should not lead us to the conclusion that achievement is 'the' proper basis for award claims.

8.2 *Achievement*

Those who focus on the importance of achievement draw attention to the inadequacy of effort unless it embodies competence—that is, is likely to be productive. If brilliant *A* can effortlessly produce the goods that diligent *B* cannot, then *A*, and not *B*, is likely to deserve whatever rewards or benefits are associated with that achievement. However, if it is sheer luck that results in the outcome for *A*, it is not so clear that *A* is more deserving than *B*. Even in cases in which the focus is on achievement, there seems to be some gesture in the direction of purposive effort.

9. *The Force of Desert Claims*

What follows from the claim *A* deserves *p*? Several possibilities have been canvassed: (a) *B* ought to ensure that *A* gets *p*; (b) *A* ought—all things considered—to get *p*; (c) *A* has a right to *p*; (d) There is a reason for giving *p* to *A*; and (e) *A* would be presumptively justified in getting *p*.

Most of these options are implausible. (a) It would be a rare desert claim that imposed a duty on some particular party. If *A* deserves to be punished, it does not follow that the state or some particular person should inflict it; if *A* deserves to succeed it is unlikely to fall to any particular person to ensure that she does so.

(b) Even if desert claims imply that someone ought to get something, they do not provide an overriding reason for it. Suppose, for example, that *A* deserves to be punished. There may, nevertheless, be countervailing—and overriding—reasons why *A* ought not to be punished: perhaps mercy ought to be shown, or the social consequences of punishment would be disastrous. The same would hold of good deserts: other considerations of social justice may take priority. (c) Is also much too strong. (d) Seems too weak—not just because there may be many other considerations (besides deserts) that constitute reasons for giving *p* to *A*—but because deserts seem to be quite strong reasons for giving *p* to *A*. (e) Represents most closely the force of a desert claim. Such claims are presumptively strong enough to justify *A*'s getting *p* even if, in a particular case, some countervailing consideration would defeat the presumption. In practice, the situation is more complicated. If, for example, *p* refers not to some preinstitutional generality, but legal punishment or a competitive prize, other conditions may be necessary if the *p* is to be justified. In such cases, a formalized desert-determining procedure (an entitling procedure) will take precedence over the nonformal assessment of deserts.

10. Desert and Justice

One way of understanding desert claims is as claims about justice. John Hospers, for example, writes, 'Justice is getting what one deserves. What could be simpler?' (Hospers 1961, p. 433). Desert claims then would have the force of claims about justice. But many have thought that this way of connecting desert with justice is too simple (Feinberg 1963, p. 90, Sher 1987, p. 49, and Slote 1973, p. 333). Even so, these writers have retained some sort of conceptual link between desert and justice. After all, when people do not get what they deserve, our immediate response is to think that they have suffered unfairly or unjustly. It is one thing to say, however, that a person's deserts constitute a factor—albeit an important one—in deciding what justice requires, and another to say—with Hospers—that deserts are the sole determinant of justice. The justice of social institutions may affect what people deserve no less than their deserts may constitute a factor in determining how they are to be justly treated (Sher 1987, p. 206–10).

11. The Rejection of Desert

Although I have argued that desert bases need not refer to conduct for which people are held responsible; nevertheless, for some distributions desert bases need to be factors for which people can be held responsible. Punishment, I noted, can hardly be said to be deserved if the conduct for which it is said to be deserved is not conduct for which the person to be punished can be held responsible.

Rawls has turned this point into a general thesis against the justice of desert-based distributions. Rawls argues that the factors that are usually adduced as desert bases in the distribution of social resources are not really things for which people can be held responsible. Those who have greater abilities and hence greater achievements have them because of their 'greater natural endowments,' not because of something for which they can be held responsible. Even a person's 'character depends in large part upon fortunate family and social circumstances for which he can claim no credit' (Rawls 1971, p. 104). It is 'one of the fixed points of our considered judgments that no-one deserves his place in the distribution of native endowments, any more than one deserves one's initial starting place in society' (Rawls 1971, pp. 103–4). Not even effort will get around this. 'Even the willingness to make an effort, to try, and so to be deserving in the ordinary sense is itself dependent upon happy family and social circumstances' (Rawls 1971, p. 74).

Although many have interpreted Rawls as taking a deterministic position on effort and achievement—seeing all effort and achievement as the inevitable outcome of native endowment and social opportunity—Rawls's rejection of desert is actually less categorical. He does not argue that we are only what we are born and bred to be, but that the task of separating out the various factors that have contributed both to our effort and to our achievement—those for which we are responsible from those that represent our endowment and opportunities—and thus enable an assessment of desert, is 'impracticable' (Rawls 1971, p. 312). Judgments about deserts should therefore be excluded from assessments of social justice. Curiously, Rawls does not draw out the same implications for his briefer discussion of retributive justice.

If we allow that deserts need not depend on things for which we can be held responsible, it might not seem so problematic to maintain both that the traditional desert bases can be used as one possible ground for distribution, and also that these are not things for which we can be held—in any strong sense—responsible. Nozick has argued that 'it needn't be that the foundations underlying desert are themselves deserved, all the way down' (Nozick 1974, p. 225). If I win a race in part because of my natural talent, I may plausibly claim to deserve the prize. My personal desert does not presuppose that my talent was also deserved.

Nozick's critique goes further. Whereas Rawls infers from the arbitrariness of natural talent that such talents should be seen as common assets, Nozick does not see how the arbitrariness and undeserved nature of their natural distribution serves to disqualify those who have them from benefiting from them. Since the holdings that come into the world are already held, is

it not plausible to assume that those who fortuitously have the holdings are 'preinstitutionally entitled' to the benefits that flow from them? Plausible, but not self-evident. We may consider it appropriate to grant the naturally talented and socially advantaged the benefits that flow from their fortuitous position, just as we may consider inherited wealth an entitlement of those who benefit from it. But it is hardly more obvious in the former case than in the latter that this is a matter of desert. If it appears so, this is because it is usually the case that the naturally talented and socially advantaged have to make something of their own of the endowments and opportunities they have received.

In its own way, the contemporary debate about personal desert reflects a much larger social debate about the extent to which our individuality—and that which might be said to flow from that by way of our share of social goods and ills—is viewed simply through the lens of our efforts and achievements, and the extent to which those efforts and achievements are considered as elaborations of a social environment that has fostered and sustained them. Because the answer is unlikely to lie at either extreme, the defense of desert will inevitably be qualified.

Design and Form: Organizational

Organization design refers to the formal structures, practices and processes through which organizations seek to accomplish organizational goals. Interest in organizational design stems from two intellectual trajectories (see Bolman and Deal 1997). Industrial analysts such as Frederick Taylor, Henri Fayol, and Lyndall Urwick were interested in using 'scientific management' to design organizations to create maximum efficiency. This work produced an interest in issues such as the specialization of tasks and the nature of hierarchy, authority, and responsibility. A second trajectory emerged through the work of Max Weber who was interested in how, as part of the increasing rationality of society, organizations were being designed according to bureaucratic principles such as impersonal authority, hierarchy, and systematic controls.

For some writers, an organization design 'emanates from an overall vision for the organization … (which) will give people the skills, direction and motivation to do the work necessary to achieve the strategic objectives' (Nadler and Tushman 1997). For other writers, 'structural designs are really rhetorical devices … (used by managers which) … are not so much descriptions but ideas about what kind of behavior is desirable in certain circumstances' (Eccles and Nohria 1992). Still other writers note that some organizations try to avoid the use of formal designs and organization charts on the grounds that these can limit the range of behaviors that may be necessary to accomplish organizational goals (Mills 1993).

Many writers, implicitly or explicitly, conceive of designs as problem-solving devices (Eccles and Nohria 1992). For example, in moving beyond a position that there is one best design, contingency theorists have directed their attention over the years to identifying which designs are best suited to solving a variety of 'problems' such as the nature of the organization's environment, strategy, technology, age, and size.

1. *Classic Designs*

Traditionally, much attention has focused on the prevalence of two organizational designs. A functional design is one that is organized into departments on the basis of the skills which individuals bring into an organization (marketing skills, production skills, accounting skills, etc). Miles and Snow (1984) suggest that identifying such a design served as a major breakthrough at the turn of the twentieth century in that it enabled organizations to grow and specialize, in terms of either particular markets or products. Such a design is suited to solving the 'problem' of stable environments in which the same goods or services are required repeatedly (e.g., the day-in-day-out delivery of a railway service). The functional design is usually hierarchically organized and focuses on ways of increasing the efficiency of delivering repetitive operations. Bedeian and Zammuto (1991) suggest that a number of advantages accrue to such organization designs. These include: retaining like interests and skills in specific departments, enabling simple communication among specialists, simplifying training and the efficient use of resources, measuring functional outputs, and enabling top management to retain strategic control over the whole organization. Disadvantages include: coordination across different functional areas, departmental rather than organizational orientation of staff, lack of development of broad management and business skills, interdepartmental conflict, low client satisfaction (as no one department has responsibility or accountability for the service or product), and the difficulty of organizational change if environmental or strategic circumstances change (since the organizational orientation is towards stability).

A divisional design—sometimes called an M-form (Multidivisional) design—is one suited to accommodate organizational growth, and market and product differentiation (Miles and Snow 1984). It is organized by divisions each of which is responsible for a particular output, be it product, market, or geographic area. The same function (e.g., marketing, research and development, and manufacturing) is likely to be found in more than one division so that each becomes specialized in orientation towards the particular product, market, or geographic area that it serves. Such a design is one which is suited to solving the 'problem' of more dynamic environments since an organization can, in theory, add a new division oriented towards a new product or service, or close down or sell nonperforming divisions as conditions change. Other advantages of the divisional design include: easy identification of divisional performance, greater coordination among functional areas as each has a similar orientation, greater attention to client needs, flexibility, and a broader business orientation. Disadvantages include: duplication, less communication among similar functional staff who are spread across different divisions, and a potential failure of staff to keep abreast of professional developments in their particular functional field (Bedeian and Zammuto 1991).

2. *Design Variations*

The matrix design breaks a classic organizing principle underlying the first two designs. This principle is what Fayol (1949) referred to as the scalar chain of command in which a single chain links the highest authority to the lowest rank. The matrix design breaks this principle by invoking dual lines of authority in which both functional and product managers share formal power and authority. Functional managers allocate staff into various project groupings, for which a product manager is responsible. At the end of a particular product or project, staff are reallocated into new groupings as the need arises. Staff, therefore, have dual reporting lines, one to their product manager and one to their functional manager. This design is one that is intended to solve the 'problem' of dynamic environments in so far as new project teams can be established or dissolved as required. The advantages of the matrix structure include the ability to meet new market demands, and to coordinate interdependent functional skills and requirements. Disadvantages are that some staff may have trouble coping with the insecurity and instability associated with such a structural arrangement which, in turn, 'creates considerable confusion, stress, and conflict, and requires from its participants highly developed interpersonal skills and considerable tolerance for ambiguity' (Mintzberg 1983).

In addition to these designs, Mintzberg (1983) identified three others. The simple structure typically is found in small organizations and is characterized by direct supervision and minimal technological systems with a dominating owner or entrepreneur having a wide span of control. The professional bureaucracy characterizes organizations such as accounting firms or hospitals that operate traditionally in relatively stable environments and utilize predetermined 'solutions' to client problems. The adhocracy often draws upon advanced technological systems and uses innovative, multidisciplinary teams to produce novel solutions to client problems.

In practice, organizations may use a combination of designs. For example, a hybrid model may combine

elements of functional and divisional designs where an organization retains central control over human resources, strategy, etc., but decentralizes to different divisions' control over marketing, production, sales, etc. Also, the classic work of Lawrence and Lorsch (1967) showed that within well-performing organizations, departments may be structured differently depending upon the nature of their contact with the environment. For example, in both stable and dynamic environments production departments may be relatively insulated and organized on mechanistic lines. However, research and development departments, being more closely oriented to the market and the environment, may be structured more flexibly in dynamic environments, compared with those operating in stable environments. They used the term differentiation to refer to the extent to which departments are designed and structured differently within the one organization, and integration to refer to the process of unifying departmental activities to accomplish organizational goals.

3. *Internal Control and Coordination Mechanisms*

Thompson (1967) argued that the coordination of activities for a given design varies according to the interdependence of work components or departments. He used the term, pooled interdependence, to refer to situations where each part of the organization is relatively independent. Where, in serial fashion, one part needs to act in order for another part of the organization to perform its actions, then this is termed sequential interdependence. Reciprocal interdependence occurs when an output for one part becomes an input for another part, whose work then becomes the input for the first part.

Adapting the work of March and Simon (1958), Thompson (1967) argued that different types of coordination are required in each instance. Standardization (internally consistent rules and routines which direct the activities of each section towards the outcome of the whole) is appropriate to pooled interdependence. Planning is a useful coordination mechanism for sequential interdependence. Mutual adjustment occurs through communication and feedback devices and is most likely to be found where situations are novel and unpredictable and where reciprocal interdependence is required.

More generally, Galbraith (1974) argued that as task uncertainty increases so does the need for lateral design mechanisms for achieving coordination. In order of increasing uncertainty, he pointed to the use of direct contact among staff (where problems are solved jointly), the use of specialized liaison roles (which can assist communication between departments), task forces representing different departments (in order to address a common, specific problem), cross-functional teams (which are longer-term in nature and consider a variety of problems common to different departments), integrating roles (such as program or product managers who liaise across different functional departments to achieve required outcomes), and managerial linking roles (which have formal position and budgetary power attached to them).

4. *Contemporary Challenges to Classic Designs*

The contingency notion that the structural form should reflect key contingencies underlies a still-growing literature that is advocating the replacement of classic structures by 'new organizational forms.' The core argument is that new ways of organizing are necessary if organizations are to perform effectively in 'hypercompetitive environments' (D'Aveni 1994) characterized by rapid and unpredictable environmental change, intensified competition, and short product life cycles.

In such an environment it is argued that organizations need to be flexible, fast moving, and innovative. However, classic modes of organizing commonly are associated with a number of characteristics that are represented as being inconsistent with these demands. Formalization, that involves the specification of formal rules and procedures, inhibits flexibility. Centralization that involves an emphasis on the location of decision-making authority at the higher levels of the hierarchy, reduces discretion at the 'customer interface.' Standardization of procedures may be inconsistent with the needs of diverse and fragmented markets. Size is an important variable because decisions about growth traditionally have been driven by an assumption that bigger is better. This is appropriate where economies of scale are all-important but can become an impediment when speed of response and customization become paramount.

Classic modes of organizing also have been characterized by boundaries, both within organizations and between organizations and key players in their environment. Within organizations, an emphasis on departmental or divisional boundaries inhibits the ability to organize around value-delivering processes. Similarly, maintaining a clear boundary between 'inside the organization' and 'outside the organization' may be an impediment when organizations compete using market-based, rather than hierarchy-based relationships.

5. *Characteristics Attributed to New Organizational Forms*

An extensive array of new organizational forms has been advocated as appropriate to hypercompetitive conditions. These include: the network organization, the virtual organization, the intelligent organization,

the boundaryless organization, the reconfigurable organization, the self-managing organization, and the centerless organization.

Despite the diverse nomenclature, certain core elements pervade these prescriptions. These include flatter structures (fewer levels in the hierarchy, wider spans of control), less rigid boundaries between functions, greater use of networks and alliances, and disaggregation into smaller business units.

What remains to be seen is whether the utilization of new forms of organizing involves the replacement of, or coexistence with, characteristics associated with classic designs.

Determinism: Social and Economic

The concept of social and economic determinism has many meanings. What seems to be common to all of them is the notion that human beliefs, practices, and actions are the results of social and economic causes. However, ambiguities arise from the fact that the boundaries of the concepts of 'social' and 'economic' are not clear and keep changing. Perhaps, more importantly, the concept of causality itself is not well understood. Although major social theorists such as Karl Marx and Emile Durkheim are often regarded as economic or social determinists, once the concept of causality is made clear, it does not seem that they ever actually held deterministic positions, as will be shown below.

1. Causality and Determinism

This idea that human beliefs, practices, and actions are the results of social and economic causes is often confused with the claim that these results are inevitable and predictable. However, results may not be predictable if either the conditions on which they depend are unknown or these conditions, even when they are known, are so complex as to make it humanly impossible to deduce their consequences. Also, although one may believe on deterministic grounds that the future course of events is inevitable, one may also believe in inevitability for mystical or spiritual reasons.

Causal deterministic laws have the form 'under conditions C, effect E will result,' in which C is said to be a sufficient condition for E, that is, in a deterministic law, the relationship between cause and effect is not merely probabilistic or statistical. However, putative causal claims put forth by those who are regarded typically as determinists usually fall short of being deterministic laws since the conditions C are almost never sufficient for E. Sometimes, at best merely necessary conditions are given. At other times, even less than that is given. This happens when a purported causal relationship between certain social or economic conditions and the beliefs and practices to which they are supposed to give rise is in reality a functional relationship, that is, the beliefs and practices in question are merely adaptations to, rather than results of, these conditions.

2. Durkheim and Social Causes

Perhaps the work of Durkheim best illustrates the need to separate carefully causal from functional hypotheses. In *The Rules of Sociological Method* (1895), he insisted that social facts are to be explained by social causes and that these social causes are to be

carefully distinguished from psychological and other sorts of causes as well as from social functions. However, it is not clear that in practice he always followed these methodological prescriptions.

2.1 The Causes of the Division of Labor

For instance, Durkheim's *The Division of Labor in Society* (1893) is often read as having made the deterministic claim that increasing labor specialization results from increasing population density. However, on a closer reading, he actually said that specialization results from an increase in what he called 'social density,' or the degree to which individual human beings form social relations with one another. He also seemed to suggest that population density, along with the rise of cities and means of communication, is merely a symptom or sign of social density. Because he made population and social density each the necessary and sufficient condition for the other, his interpreters have been confused about which is supposed to be the cause and which the effect. Durkheim then went on to explain that specialization is not caused by population or social density but is an adaptation to it, making explicit references to Darwin's principles. Durkheim even mentioned alternative responses to population pressure, such as emigration. Specialization takes place only when the social bonds among individuals are so strong that emigration is out of the question.

Furthermore, nothing Durkheim said rules out the possibility that specialization could be a successful strategy for coping with other sorts of conditions besides social and population density. For example, hunter-gatherer tribes living under low-density conditions have been known to specialize in the natural products available in their territory, trading with other tribes for other things that they need. Hence, population density does not appear to be even a necessary condition for specialization. At best, it may be what Mackie (1974) has called an 'inus' condition, or an insufficient but necessary part of an unnecessary but sufficient condition.

2.2 The Social Causes of the Categories

Later in his career, Durkheim, along with Mauss and others, advanced a sociology of knowledge according to which our basic categories of thought, including space, time, causality, and substance, are to be explained by social causes (e.g., Durkheim 1912, Durkheim and Mauss 1903). For example, they claimed that a culture's units for measuring time reflect the rhythm of its social life and its concept of space is patterned on the distribution of clans at tribal campsites. The very practice of classifying things in nature by a nested hierarchy of genera and species reflects an elementary social structure consisting of clans subsumed under phratries. However, their sociology of knowledge is ambiguous between the causal claim that these concepts result from social life and the functional claim that these concepts make human social life possible.

3. Marx and Economic Determinism

There are two different but related senses of determinism in Marxist thought. The first is historical determinism or materialism, according to which the course of history is to be explained through material or economic causes. The second is Marx' theory that what he calls the economic 'base' of a society, which consists in the modes and relations of economic production, somehow 'determines' a 'superstructure' of laws, politics, religion, and other ideological beliefs (see *Ideology: History of the Concept*).

3.1 Historical Materialism

'Historical materialism' is actually Friedrich Engels', not Marx's term. According to the materialist conception of history, there is an inevitable class struggle between the bourgeoisie and the proletariat. This belief has antecedents in earlier thinkers, most notably David Ricardo. For Ricardo, class conflict is the inevitable result of a population increase leading to the bringing of marginal lands under cultivation, which leads to wages dropping to a subsistence level. For Marx, on the other hand, class conflict was not a result of population growth but of changing modes of economic production. As new modes of production develop, they come into conflict with the social relations that existed under the previous economic system. The older social relations are encumbrances on these new modes of production. Eventually, these older relations give way to new ones that are more in line with the new form of production. Each major change in the social relations of production, from slavery to feudalism, from feudalism to bourgeois capitalism, and from capitalism to socialism, is accompanied by class conflict (see *Political Economy, History of*).

3.2 Base and Superstructure

Marx appears to have thought that there are irreconcilable differences in thought between the two classes due to their different economic positions in society. According to Marx' famous 'Preface' to his *A Contribution to the Critique of Political Economy* (1859):

> In the social production of their existence, men inevitably enter into definite relations, which are independent of their will, namely relations of production appropriate to a given stage in the development of their material forces of pro-

> duction. The totality of these relations of production constitutes the economic structure of society, the real foundation, on which arises a legal and political superstructure and to which correspond definite forms of social consciousness. The mode of production of material life conditions the general process of social, political and intellectual life. It is not the consciousness of men that determines their existence, but their social existence that determines (*bestimmt*) their consciousness.

Although this passage has been read as suggesting that individuals are the mere puppets of economic and social forces, it is not at all clear that Marx meant 'determines' in any causal or mechanistic sense. The German word *bestimmt* means 'determine' in the sense of decide, define, set limits or boundaries to, or fix something (such as a price or time). Furthermore, the very building metaphor implied in the language of base and superstructure suggests that the form of economic life is at best a necessary condition and not a sufficient cause for that which rests upon it. On the mechanistic reading of 'determines,' Marx would have been guilty of an inexcusable *non sequitor* from premises about necessary conditions to a conclusion about sufficient conditions. Finally, Marx objected to the practice of taking the causal powers of human beings and projecting them onto mere abstractions such as god, the state, or capital. In his *Theses on Feuerbach* (Marx 1845), he had criticized the materialists for doing this, and yet this is precisely what the mechanistic reading of the 'Preface' does.

It appears that Marx was attempting to say that the social and economic conditions choose or select rather than cause certain forms of thought. Marx was trying to find the right words in which to express what was then in fact a new form of explanation that Darwin, whom Marx much admired, had introduced in the *Origin of Species*, which was published the very same year Marx wrote this preface. Perhaps the clearest example of such a functional or adaptationist explanation in Marx is provided by his appeal to class interests in his account of the struggle between bourgeoisie and proletariat.

3.3 Class Interests and Functional Explanation

Under the capitalist mode of production, the bourgeoisie must strive constantly to maintain or increase their rate of profit to stay competitive. Since, to put it simply, the rate of profit is equal to the value of a product divided by the cost of its production, perhaps the best way to increase the rate of profit is to drive down the cost of production. However, part of these costs, such as raw materials and machinery, is fixed, according to Marx. Hence, the bourgeoisie must try to decrease the variable costs of labor, either by reducing wages or by replacing workers with machinery. However, as a greater and greater proportion of the costs of production go into the fixed costs of machinery and a decreasing proportion go into the variable costs of labor, it becomes increasingly difficult for the capitalist to find ways to cut costs. The capitalist is forced continuously to reinvest his profits in machinery in order to replace even more workers with machines and the remaining workers are reduced to a subsistence wage. According to Marx' law of capitalist accumulation in *Capital* (1867), the greater the wealth invested in fixed capital, the greater the misery of the proletariat. Class conflict is the inevitable result.

Economic class interests are not necessarily consciously thought by social actors, but rather are ascribed to these actors by the social scientist observing the situation. This is what Marx meant when he referred to them as 'objective' class interests. For example, to say that it is in the class interest of the bourgeoisie to reinvest their profits in new machinery is to say that those capitalists who thus reinvest their profits will remain in the bourgeoisie while those who do not act in this way will drop down into the proletariat. When Marx said that the class interests of the bourgeoisie and the proletariat conflict, what he seems to have meant is that the capitalist remains a member of the bourgeoisie only as a result of acting in a certain way which directly conflicts with the 'objective' interests of the working class. He did not mean to say that being a member of the bourgeoisie causes one to think in a certain way, which is different than the way in which the proletariat thinks; indeed, it is not all that important or relevant what individuals may actually be thinking. Thus, to say that the capitalist replaces workers with machines because it is in his interest to do so is to give a functional rather than a causal explanation (see *Interest: History of the Concept*).

Indeed, the alternative, causal determinist interpretation of Marx makes him out to be an incoherent thinker. If our ideas were really determined by our class membership, what would be the point of writing manifestoes? One might object that his writings were addressed only to the working class. However, in *The Communist Manifesto* (1848/1955) he described—with obvious reference to people such as himself and Engels—how a portion of the bourgeoisie, 'who have raised themselves to the level of comprehending theoretically the historical movement as a whole,' 'cuts itself adrift' and joins with the proletariat. On the determinist reading of Marx, these claims appear embarrassingly *ad hoc*. A functionalist reading suggests merely that people like Marx have chosen a path in life that will not make them rich.

However, as Cohen (1978) points out, orthodox Marxists tend to resist the interpretation that Marx was offering functional explanations due to their tendency to associate such explanations with the functionalist tradition in the social sciences that began with Bronislaw Malinowski. According to this tradition, a society or culture forms an organic unit, every element of which serves a function that helps to sustain the whole (see *Functionalism, History of*). Marxists

regard functionalist social science as resistant to social change and thus as politically conservative. However, as Cohen argues, the use of functional explanations does not necessarily commit one to this brand of functionalism.

3.4 After Marx

Engels, Karl Kautsky, Enrico Ferri, Antonio Labriola, V. I. Lenin, Nikolai Bukharin, and others have been read as posthumously transforming Marx' theories into deterministic ones, but there is insufficient space here to examine all their theories. Nevertheless, Marx' theories were certainly understood deterministically in their role as the official ideology of the Soviet Union (see *Marxist Social Thought*, *History of*).

4. Recent Determinism: The Strong Program

A group who defended a determinist approach with roots in Durkheim and Marx arose in the 1970s, calling themselves the 'Strong Program in the Sociology of Scientific Knowledge.' Bloor (1976/1991), a principal spokesperson for the group, laid out four tenets for this program. These are (a) that explanations of belief and knowledge should be causal; (b) that sociology should be impartial with respect to the truth or falsity, or the rationality or irrationality, of the belief to be explained; (c) that explanation should be symmetrical, in the sense that the same kind of causes would explain both true and false beliefs; and (d) that the sociology of knowledge should be reflexive, in the sense that the same principles of explanation should apply to sociology itself. The Strong Program regarded accounts of the beliefs and practices of scientists in terms of their social interests as satisfying the demand for causal explanation. Their concept of social interests included not only economic or class interests but political, religious, professional, and other interests as well.

The Strong Program was subjected to sharp criticism by philosophers and other social scientists. Philosophers insisted that scientists held the views that they did on the basis of reason and evidence. Furthermore, they argued that the tenets of impartiality and symmetry prevent the Strong Program from arguing for their position on epistemic grounds, that is, these tenets prohibit them from saying that their beliefs are any more well-founded than the alternatives. Among the social scientists who criticized them, some felt that in plumping for causal explanations, the Strong Program was trying too hard to model the social on the natural sciences. Others criticized them for taking the existence of social structure and social classes as given and not recognizing that these are constantly changing social phenomena brought about through complex human interaction. For these critics, social structure and class exist in and through the beliefs and practices of the members of society and are to be explained in the same way as any other beliefs and practices. To explain a person's scientific beliefs in terms of social interests is thus in effect to privilege one sort of belief over another.

Finally, interest accounts are functional rather than causal explanations. To explain scientists' intellectual commitments in terms of their social interests is to say that these commitments have the consequence of helping to maintain these scientists in their careers, whether or not this is their intended reason for holding these beliefs. However, when giving this sort of account, one must avoid the trap of simply pointing to what appear to be the obvious beneficial consequences of holding some belief or following some practice. One should provide actual evidence that these beliefs and practices actually helped the persons in question maintain themselves in their careers.

Deterrence

Deterrence means threatening punitive retaliation to prevent a foe from attacking. It differs fundamentally from defense, which means threatening to fight back if attacked and deny an attacker its objectives. The heart of the distinction is whether it would make sense to carry out the threat.

Although the idea of threatening war to prevent war is as old as the balance of power, deterrence was not just a new word for that old idea. The idea of deterrence originated with the atomic bomb. It was first formulated in 1946 by Bernard Brodie, who tried to capture what was revolutionary about the advent of the nuclear era. First, a nuclear warhead was not a weapon, in Brodie's view, but a terrorist device, whose blast and radiation effects made it inherently indiscriminate. Second, the atomic bomb brought home the fact of mutual vulnerability in a way that aerial bombardment had not. Before the nuclear era, a state's armed forces had to be defeated before the state and its centers of population could be held hostage or destroyed at will. Once nuclear warheads were mated to missiles in the late 1950s, the state and its populace were defenseless. The balance of terror differed in fundamental respects from the prenuclear balance of power, according to Brodie. 'The first and most vital step,' he wrote, 'for the age of atomic bombs is to take measures to guarantee ourselves in case of attack the means of retaliation. Thus far the chief purpose of a military establishment has been to win wars. From now on its chief purpose must be to avert them.' These prescient insights became a matter of considerable scholarly discourse. Regrettably they had little influence on nuclear policy.

1. Deterrence in Theory

The logic of deterrence, as Brodie and others recognized, is inherently paradoxical. To deter nuclear attack, it is deemed necessary to threaten nuclear retaliation. Inasmuch as the cost of a nuclear war is prohibitive, neither side would risk it. Yet that rational calculus conveniently overlooks the irrationality of retaliating for a nuclear first strike with a nuclear second strike. Retaliation makes no sense unless the second strike could eliminate the other side's nuclear forces and prevent it from launching another strike of its own. That deadly logic led Brodie to the paradoxical conclusion that what made deterrence work was the possibility that it might fail, making it prudent for neither side to tempt fate. The same logic led other strategic thinkers to conclude that for deterrence to work, it could not be mere bluff. The threatener had to be willing to carry out the threat. For that to happen, nuclear retaliation had to be automatic or mad. Herman Kahn (1960) captured the sense of that line of reasoning in a phrase, the 'rationality of irrationality.' Yet that line of reasoning only posed another paradox: if the deterrer was hotheaded, why would the attacker be prudent?

Even if the threat of retaliation ruled out nuclear war, that seemed to leave the world safe for war waged by other than nuclear means. That was a source of gnawing anxiety for the USA, which was committed by treaty to deter any attack by the USSR on its allies in Western Europe. It did not have the capability to do that by conventional military means alone, at least in the 1950s, so it chose to rely on the threat to initiate nuclear war. That threat was potentially suicidal.

Some strategists insisted that 'extended deterrence,' as that threat came to be called, would work if the USA had nuclear superiority. Thomas Schelling (1966) questioned whether superiority assured that the weaker side must yield to the stronger. It was impossible, he insisted, to raise the risk of a nuclear war for the other side without raising it for oneself. He spoke, instead, of a 'competition in risk-taking.' Extended deterrence still might work if Soviet leaders could not be sure the USA would shrink from first use of nuclear weapons in the event of war. Schelling (1960) called it 'the threat that leaves something to chance.' Such a cosmic bluff prompted a preoccupation with 'credibility' and a willingness to run seemingly irrational risks to shore up an incredible threat. McGeorge Bundy (1983) came up with a less demanding alternative,'existential deterrence.' So long as a state possessed nuclear arms, Bundy argued, it had a latent ability to use them, even if it did not explicitly threaten to do so. The mere existence of these arms and the incalculable costs of a nuclear war exerted a cautionary effect on potential foes.

Other strategic thinkers took a more forceful tack. British strategist Basil Liddell Hart (1946) first formulated the idea of graduated deterrence, carefully calibrated to threaten greater costs to an attacker without generating all-out war. Still others debated whether military forces or civilians were the most appropriate targets for nuclear attack. This line of thought culminated in the baroque escalation ladder of Herman Kahn (1960) and the contention of some of his followers that the USA could deter any aggression if it somehow had 'escalation dominance,' or military superiority at every level of violence, short of all-out nuclear war. Yet the idea of waging limited nuclear war and controlling escalation raised the question of how a nuclear war could stop, short of a dead end.

2. Deterrence in Practice

Deterrence, in short, did not work very well in theory. What happened in practice was in many ways worse. Deterrence did not govern the production, deployment, or military plans for nuclear arms (Ball

1978). The number of Soviet and US warheads vastly exceeded what was needed for deterrence. The warheads themselves were initially deployed in ways that made them vulnerable to attack. Dispersing them on land and at sea reduced, though did not eliminate their vulnerability, and made command-and-control all the more precarious. Because of the chance that the cosmic bluff could be called, each side drew up detailed war plans to destroy the other. Those war plans fully reflect the deadly logic of deterrence: in the event that war breaks out, nuclear arms confer enormous, some say decisive, advantage on the side that strikes first. The most urgent targets were the other side's nuclear forces and especially their command-and-control. Concern about a disarming first strike led the USA to keep some of its bombers airborne at all times and to put others on alert, ready to take off at a moment's notice. It did the same with its missiles. This hair-trigger posture, and the delegation of authority that it necessitated, raised the risk of loss of nuclear control in a crisis. Schelling (1960) called this predicament 'the reciprocal fear of surprise attack.' As first one side and then the other began mobilizing forces, the very steps taken to deter a nuclear war might provoke one. Far from exerting a cautionary effect on preparations for war, that fear led both sides to a massive buildup of arms, conventional as well as nuclear, which did little to calm the fear.

That had important implications for theorizing about deterrence. Although some theorists saw mutual deterrence as a source of stability in international politics, others saw it as potentially unstable in the extreme. The first group emphasized the need to demonstrate the capability and will to wage war, lest a potential aggressor doubt a state's strength or resolve. By this way of thinking, conciliation was dangerous because it might be mistaken for weakness or irresoluteness. A second group of theorists were led to a renewed appreciation of the security dilemma, an idea dating back to Thucydides, who noted that attempts by one side to enhance or demonstrate its military might prove self-defeating. By alarming its rival and leading it to respond in kind, these measures would leave both sides less secure. Such a vicious circle could generate an arms race, or worse, trigger pre–emptive war. These theorists saw the need to couple coercion with conciliation, lest the interaction spiral out of control. To some scholars, the difference between the deterrence and spiral logic depended on each side's perception of the other's intentions.

Where perception matters, so does the danger of misperception. The fear that war is imminent is sometimes irrational. Once it takes hold, it is not amenable to a cool calculation of costs. The possibility of pre–emptive war calls into question two major premises of most theorizing about nuclear deterrence, that statesmen will behave rationally in the heat of the moment and that they can control the operations of their armed forces. This led to critiques of deterrence theory on the grounds that it was psychologically naive and operationally uninformed. Robert Jervis (1974), John Steinbruner (1976), and Scott Sagan (1993) are leading exemplars of these approaches.

One side's strategy depended on the other's. So did its security. Their interdependence was the central feature of *game theory*. Whether the game of chicken or the prisoner's dilemma was the appropriate analogy, many scholars who formulated the logic of deterrence drew heavily on game theory for their insights.

One consequence is that deterrence is largely deductive and only weakly grounded empirically. Another reason for its weak evidentiary base is that nuclear history everywhere remains cloaked in secrecy. Without knowledge of the details of nuclear planning and operations, it is difficult to determine how much nuclear strategy is informed by deterrence theory, if at all. A more fundamental reason why the evidence for deterrence is less than compelling is the epistemological difficulty of proving why something did not happen in order to demonstrate that deterrence worked. The obvious counter to the contention that nuclear deterrence kept the USSR out of Western Europe is that it never intended to invade in the first place.

Because the side that is losing could still destroy the side that is winning, safety in the nuclear era lay in cooperation between enemies. That interdependence made nonsense of traditional strategic thought. It also called into question the very idea of strategy as a rational relationship between means and ends. War, in theory, if not always in practice, 'is controlled by its political object,' Clausewitz had reasoned. Consequently, 'the value of this object must determine the sacrifices to be made for it in magnitude and also in duration.' But what objective could possibly sustain the full measure of sacrifice in a nuclear war? As Lawrence Freedman (1981) concludes, 'The position we have reached is one where stability depends on something that is more the antithesis of strategy than its apotheosis—on threats that things will get out of hand, that we might act irrationally, that possibly through inadvertence we could set in motion a process that in its development and conclusion would be beyond human control and comprehension.' Nuclear strategy, understood this way, was a contradiction in terms.

Deterrence: Legal Perspectives

The criminal justice system (CJS) dispenses justice by apprehending, prosecuting, and punishing law-breakers. These activities also project a threat of punishment. Deterrence occurs when some would-be law breakers conclude that the price of crime is prohibitive. General deterrence refers to the crime prevention impact of the threat of punishment on the public at large. Specific deterrence refers to the impact of punishment on persons actually punished. The actual experience of punishment may alter an individual's perceptions and opportunities. Also, persons for whom general deterrence has failed may be systematically different than the population at large. For both these reasons specific deterrent effects may be smaller than the subject of this article, general deterrent effects.

1. A Brief Review of Research on General Deterrence

Deterrence research has evolved in three distinctive and largely disconnected literatures—interrupted time series, perceptual, and ecological studies (Nagin 1998).

1.1 Interrupted Time Series Studies

Interrupted time series studies examine the impact of targeted policy interventions such as police crackdowns or implementation of statutes changing penalties. The best-designed studies mimic important features of a true experiment—a well-defined treatment regime, measurement of response before and after treatment and a control group. Two classic examples are Ross' studies of the impact on drunk driving of the British Road Safety Act and of Scandinavian-style drunk driving laws (Ross 1982).

The great proportion of interrupted time series studies have examined the impact of drunk driving laws or of police crackdown, on drug markets, disorderly behavior and drunk driving. A less extensive literature has also examined the impact of gun control laws and ordinances. Excellent reviews of these studies are available from Sherman (1990) and Ross (1982).

Both reviews conclude that interventions are generally successful in generating an initial deterrent effect. One exception may be interventions that increase sentence severity. If judges or juries believe that the penalties are too harsh, they may respond by refusing to convict guilty defendants with the result that the policy increases rather than deters the targeted behavior. Indeed, Ross concludes that efforts to deter drunk driving with harsher penalties commonly fail for precisely this reason. Sherman and Ross are also in agreement that the effect is generally only transitory: the initial deterrent effect typically begins decaying even while the intervention is still in effect. However, in some instances, the decay is not complete even following the end of the crackdown.

1.2 Perceptual Deterrence Studies

1.2.1 Summary of findings. The perceptual deterrence literature examines the relationships of perceived sanction risks to either self-reported offending or intentions to do so. This literature was spawned by researchers interested in probing the perceptual underpinnings of the deterrence process.

Perceptual deterrence studies have focused on examining the connection of illegal behavior to two categories of sanction variables, the certainty and severity of punishment. The certainty of punishment refers to the probability that a crime will result in punishment whereas severity refers to the seriousness of the consequences to the punished individual, such as prison sentence length.

Perceptual deterrence studies have been based on three types of data: cross-sectional survey studies, panel survey studies, and scenario-based studies. In cross sectional survey studies individuals are questioned about their perceptions of the certainty and severity of sanctions and either about their prior offending behavior or future intentions to offend. For example, Grasmick and Bryjak (1980) queried a sample of city residents about their perceptions of the risk of arrest for offenses such as a petty theft, drunk driving, and tax cheating, and also about their intention to commit each of these acts in the future.

In panel survey studies the sample is repeatedly surveyed on risk perceptions and criminal behavior. For example, Paternoster et al. (1982) followed a sample of students through their three-year tenure in

high school and surveyed the students on the frequency with which they engaged in various delinquent acts and their perceptions of the risks and consequences of being caught for each such acts.

In scenario-based studies individuals are questioned about their perceptions of the risks of committing a crime described in a detailed crime vignette and about their own behavior if they found themselves in that situation. Nagin and Paternoster (1993), for instance, constructed a scenario describing the circumstances of a date rape and surveyed a sample of college males about their perceptions of the risk of the scenario male being arrested for sexual assault and also about what they themselves would do in the same circumstance.

The cross-sectional and scenario-based studies have consistently found that perceptions of the risk of detection and punishment have a negative, deterrent-like association with self-reported offending or intentions to do so. Such deterrent-like associations with perceived severity are somewhat less consistent, but when individual assessments of the cost of such sanctions are taken into account, statistically significant negative associations again emerge. Only in the panel-based studies have null findings on deterrent-like effects been found.

In panel-based studies respondents were typically interviewed on an annual cycle. With these data researchers examined the relationship of behavior between years t and $t+1$ to risk perceptions at the outset of year t. Their purpose was to avoid the problem of causal ordering: Is a negative association a reflection of the deterrent impact of risk perceptions on crime or of the impact of criminal involvement on risk perceptions? Generally, these studies have found only weak evidence of deterrent-like associations (Paternoster 1987).

The null findings from the panel-based studies generated a spirited debate on the appropriate time lag between measurements of sanction risk perceptions and criminal involvement. Grasmick and Bursik (1990) and Williams and Hawkins (1986) have argued that ideally the measurements should be made contemporaneously because perceptions at the time of the act determine behavior.

The argument for temporal proximity is compelling but the challenge is its practical achievement. People cannot be queried on their risk perceptions on a real-time basis as they encounter criminal opportunities in their every day lives. The scenario method offers one solution because respondents are not questioned about their actual behavior or intentions but rather are asked about their likely behavior in a hypothetical situation. On average, persons who perceived that sanctions were more certain or severe reported smaller probabilities of their engaging in the behavior depicted in the scenario, whether it be tax evasion (Klepper and Nagin 1989), drunk driving (Nagin and Paternoster, 1993), sexual assault (Bachman et al. 1992), or corporate crime (Paternoster and Simpson 1997). Thus, it seems that a consensus has emerged among perceptual deterrence researchers in support of this position.

This consensus reframes the question of the deterrent effect of sanctions from the issue of whether people respond to their perceptions of sanction threats to the issue of whether those perceptions are grounded in reality. The literature on the formation of sanction risk perception is small and narrow in scope (Nagin 1998). The dearth of evidence on the policy-to-risk-perceptions linkage also leaves unanswered a key criticism of skeptics of the deterrent effects of official sanctions. Even if crime decisions are influenced by sanction risk perceptions, as the perceptual deterrence literature strongly suggests, absent some linkage between policy and perceptions, however imperfect, behavior is immune to policy manipulation. In this sense behavior lacks rationality, not because individuals fail to weigh perceived costs and benefits, but because the sanction risk perceptions are not anchored in reality.

1.2.2 The linkage between formal and informal sanction processes. Arguably the most important contribution of the perceptual deterrence literature does not involve the evidence it has amassed on deterrence effects *per se*. Rather it is the attention it has focused on the linkage between formal and informal sources of social control. Recognition of this connection predates the perceptual deterrence literature. For instance, Zimring and Hawkins (1973, p. 174) observe that formal punishment may best deter when it triggers informal sanctions: 'Official actions can set off societal reactions that may provide potential offenders with more reason to avoid conviction than the officially imposed unpleasantness of punishment.' See also Andenaes (1974) for this same argument.

Early perceptual deterrence studies did not consider the connection between formal and informal sanctioning systems but a review by Williams and Hawkins (1986) prompted a broadening of the agenda to consider this issue. Their position was this: Community knowledge of an individual's probable involvement in criminal or delinquent acts is a necessary precondition for the operation of informal sanction processes. Such knowledge can be obtained from two different sources: Either from the arrest (or conviction or sentencing) of the individual or from information networks independent of the formal sanction process (e.g., a witness to the crime who does not report such knowledge to the police). Williams and Hawkins observe that deterrent effects may arise from the fear that informal sanctioning processes will be triggered by either of these information sources. They use the term 'fear of arrest' to label deterrent effects triggered by the formal sanction process and the term 'fear of the act' to label deterrent effects triggered by information networks separate from the formal sanction

process. The crux of their argument is that all preventive effects arising from 'fear of arrest' should be included in a full accounting of the deterrent effect of formal sanctions.

Much of scenario-based research confirms their argument. This research has consistently found that individuals who report higher stakes in conventionality are more deterred by perceived risk of exposure for law breaking. A salient finding in this regard concerns tax evasion. In Klepper and Nagin (1989) a sample of generally middle-class adults were posed a series of tax noncompliance scenarios. The amount and type of noncompliance (e.g., over-stating charitable deductions or understating business income) was experimentally varied across tax return line items. The study found that a majority of respondents reported a non-zero probability of taking advantage of the noncompliance opportunity described in the scenario. Plainly, these respondents were generally willing to consider tax noncompliance when only their money (and not their reputation) was at risk. They also seemed to be calculating; the attractiveness of tax noncompliance gamble was inversely related to the perceived risk of civil enforcement.

The one exception to the rule of confidentiality of enforcement interventions is criminal prosecution. As with all criminal cases, criminal prosecutions for tax evasion are a matter of public record. Here there was evidence of a different decision calculus; seemingly all that was necessary to deter evasion was the perception of a non-zero chance of criminal prosecution. Stated differently, if the evasion gamble also involved putting reputation and community standing at risk, middle-class respondents were seemingly unwilling to consider taking the noncompliance gamble.

The tax evasion research does not pin down the specific sources of stigma costs, but other research on the impact of a criminal record on access to legal labor markets suggests a real basis for the fear of stigmatization (Freeman 1995, Waldfogel 1994). Freeman estimates that a record of incarceration depresses probability of work by 15 percent to 30 percent and Waldfogel estimates that conviction for fraud reduces income by as much as 40 percent.

1.3 Ecological Studies

Two broad classes of ecological analyses are considered—studies of the deterrent effect of prison and of the police.

1.3.1 The impact of prison population on crime rate. Except for capital punishment, prison is the most severe and costly sanction. Except for a flurry of flawed studies in the 1970s, however, there have been few studies of the impact of this sanction. The paucity of studies is attributable to the problem of untangling cause from effect in statistical analyses of natural variation in crime rates and sanction levels as measured by indicators like prisons per capita or actual time served in prison. For example, all else equal, more crime will increase the incarceration rate. However, all else is not equal because a larger prison population will tend to reduce the crime rate. In statistical parlance, the problem of sorting out these contending impacts is called identification (Blumstein et al. 1978, Fisher and Nagin 1978).

At least one study has plausibly dealt with the identification problem. Levitt (1996) employs a clever identification strategy based on measuring the impacts on crime rates of court orders to reduce prison overcrowding. He estimates that 15 index crimes are averted for each additional man-year of imprisonment.

Can a study such as that conducted by Levitt provide an all-purpose estimate of the impact of prison population on crime rate. The answer, I believe, is no. Specifically, there is good reason for believing that policies producing equivalent changes in the prison population will not result in the same change in crime rate.

Figure 1 is a two-dimensional taxonomy of sanction policies affecting the scale of imprisonment. One dimension labeled 'Type' distinguishes three broad categories. Policies regulating certainty of punishment such as laws requiring mandatory imprisonment, policies influencing sentence length such as determinate sentencing laws, and policies regulating parole powers. The second dimension of the taxonomy, 'Scope,' distinguishes policies that cast a wide net, such as a general escalation of penalties for broad categories of crime, compared to policies that focus on targeted offenses (e.g., drug dealing) or offenders (e.g., 'three-strikes' laws).

The Levitt study is based on US data during a period in which the imprisonment rate more than quadrupled. This increase was attributable to a combination of policies belonging to all cells of this matrix. Parole powers have been greatly curtailed, sentence lengths increased, both in general and for particular crimes (e.g., drug dealing), and judicial discretion to impose nonincarcerative sanctions has been reduced (Tonry 1995). Consequently, any impact on the crime rate of the increase in prison population reflects the effect of an amalgam of potentially interacting policies. By contrast the impact estimated in the Levitt study measures the preventive effect of reductions in the imprisonment rate induced by the administrative responses to courts orders to reduce prison populations. Thus, his estimate would seem only to pertain to policies affecting parole policies.

1.3.2 The impact of police on crime rate. The largest body of evidence on deterrence in the ecological literature focuses on the police. The earliest

		Scope	
		General	Targeted
Type	Certainty	Increasing the number of police	Crackdown on drug dealing
	Severity	Broad-based mandatory minimums	'Three-strikes' laws
	Parole	Parole abolition	No parole for violent offenders

Figure 1
Taxonomy of prison sanction policies

generation of studies on the deterrent effect of police examined the linkage of crime rate to measures of police resources (e.g., police per capita) or to measures of apprehension risk (e.g., arrest per crime). These studies were inadequate because they did not credibly deal with the identification problem. If the increased crime rates spur increases in police resources, as seems likely, this impact must be taken into account to obtain a valid estimate of the deterrent effect of those resources.

A study by Wilson and Boland (1978) plausibly identifies the deterrent effect of the arrest ratio. They argued that the level of police resources *per se* is, at best, only loosely connected to the apprehension threat they pose. Rather the crucial factor is how the police are mobilized to combat crime; Wilson and Boland argue that only proactive mobilization strategies will have a material deterrent effect. In their words (1978, p. 373), 'By stopping, questioning, and otherwise closely observing citizens, especially suspicious ones, the police are more likely to find fugitives, detect contraband (such as stolen property or concealed weapons), and apprehend persons fleeing from the scene of a crime.' They conclude that the arrest ratio has a substantial deterrent effect on robbery.

An important follow-up to the Wilson and Boland study was conducted by Sampson and Cohen (1988). Their key premise was similar to that of Wilson and Boland—'hard' policing of 'soft' crime such as prostitution, drunkenness, and disorderly conduct deters serious criminality—and their findings supported the deterrent impact of this policing strategy.

An important innovation in Sampson and Cohen is that they not only estimate a population-wide deterrent effect but disaggregate this effect across segments of the population—white juveniles, black juveniles, white adults, and black adults. They do this by using arrest rates as surrogate measures of demographic group-specific offense rates. They find a negative deterrent-like association between aggressiveness and arrest rate for all groups but they also find significant differences by race and age in the magnitude of the effect. For robbery, at least, adults seems to be more deterred by police aggressiveness than do juveniles, with black adults seemingly more deterrable than white adults. Because the results for specific demographic groups are based on arrest rates, they must be qualified in a number of obvious ways. Notwithstanding, disaggregation efforts are laudable and should, where feasible, become standard in deterrence studies.

1.4 Summary Observations on Deterrence

At the outset, it was stated that the accumulated evidence on deterrence leads me to conclude that the criminal justice system exerts a substantial deterrent effect. That said, it is also my view that this conclusion is of limited value in formulating policy. Policy options to prevent crime generally involve targeted and incremental changes. So for policy makers the issue is not whether the criminal justice system in its totality prevents crime, rather it is whether a specific policy, grafted onto the existing structure, materially adds to the preventive effect. Here there is a distinction drawn between absolute and marginal deterrence. Figure 2 depicts two alternative forms of the response function relating crime rate to sanction levels. Both are downward sloping, which captures the idea that higher sanction levels prevent crime. At the status quo sanction level, S_1, the crime rate, C_1, is the same for both curves. The curves are also drawn so that they predict the same crime rate for a zero sanction level. Thus, the absolute deterrent impact of the status quo sanction level is the same for both curves. But because the two curves have different shapes, they also imply different responses to an incremental increase in

Figure 2
Marginal vs. absolute deterrent effects (curved line is A; straight line is B)

sanction level to S_2. The response implied by curve A is small. Accordingly, it would be difficult to detect and likely not sufficient to justify the change. By comparison, the response depicted in curve B is large, thus more readily detectable, and also more likely to be justifiable as good policy.

While the distinction between absolute and marginal deterrence is useful, it implies an underlying analytical simplicity of the relationship of crime rates to sanction levels that belies the complexity of the phenomenon. Contrary to the implicit suggestion of Fig. 2, no one curve relates sanction levels to crime rates. The response of crime rates to a change in sanction policy will depend on the specific form of the policy, the context of its implementation, the process by which people come to learn of it, differences among people in perceptions of the change in risks and rewards that are spawned by the policy, and by feedback effects triggered by the policy itself (e.g., a reduction in private security in response to an increase in publicly funded security). Thus, while a number of studies have credibly identified marginal deterrent effects, it is difficult to generalize from the findings of a specific study because knowledge about the factors that affect the efficacy of policy is so limited. Specifically, there are four major impediments to making confident assessments of the effectiveness of policy options for deterring crime.

First, while large amounts of evidence have been amassed on short-term deterrent effects, little is known about long-term impacts. Evidence from perceptions-based deterrence studies on the interconnection of formal and informal sources of social control point to a possibly substantial divergence between long- and short-term impacts. Specifically, these studies suggest that the deterrent effect of formal sanctions arises principally from fear of the social stigma that their imposition triggers. Economic studies of the barriers to employment created by a criminal record confirm the reality of this perception. If fear of stigma is a key component of the deterrence mechanism, such fear would seem to depend upon the actual meting out of the punishment being a relatively rare event: Just as the stigma of Hester Prynne's scarlet 'A' depended upon adultery being uncommon in Puritan America, a criminal record cannot be socially and economically isolating if it is commonplace. Policies that are effective in the short term may erode the very basis for their effectiveness over the long run if they increase the proportion of the population who are stigmatized. Deterrence research has focused exclusively on measuring the contemporaneous impacts of sanction policies. Long-term consequences have barely been explored.

The second major knowledge gap concerns the connection of risk perceptions to actual sanction policy. The perceptual deterrence literature was spawned by the recognition that deterrence is ultimately a perceptual phenomenon. While great effort has been committed to analyzing the linkage between sanction risk perceptions and behavior, comparatively little attention has been given to examining the origins of risk perceptions and their connection to actual sanction policy.

For several reasons this imbalance should be corrected. One is fundamental: the conclusion that crime decisions are affected by sanction risk perceptions is not a sufficient condition for concluding that policy can deter crime. Unless the perceptions themselves are manipulable by policy, the desired deterrent effect will not be achieved. Beyond this basic point of logic, a better understanding of the policy-to-perceptions link can also greatly aid policy design. For instance, nothing is known about whether the risk perceptions of would-be offenders for specific crimes are formed principally by some overall sense of the effectiveness of

the enforcement apparatus or by features of the apparatus that are crime specific (e.g., the size of the vice squad or the penalty for firearms use). If it is the former, seemingly targeted sanction policies will have a generalized salutary impact across crime types by heightening overall impressions of system effectiveness. If the latter, there will be no such generalized impact. Indeed would-be offenders may substitute non-targeted offenses for targeted offenses (e.g., committing burglaries in response to increased risk for robbery).

Third, the impact of specific policies—e.g., increasing the number of police—will depend on the form of its implementation across population units. Yet estimates of the deterrent effect of such policies from the ecological literature are commonly interpreted as if they apply to all units of the population from which they were estimated. In general this is not the case. Rather the estimated deterrent effect should be interpreted as the average of the 'treatment' effect across population units. For instance, the deterrent impact of more police in any given city will depend upon a host of factors including how the police are deployed. Consequently, the impact in any given city will not be the same as the average across all cities; it may be larger, but it could also be smaller. Similarly, it is not possible to make an all-purpose estimate of the impact of prison on crime. There are many ways to increase prison population by a given amount, ranging from broad-based policies such as across-the-board increases in sentence length to targeted policies like 'three strikes' statutes. It is likely that the magnitude of the preventive effect will vary materially across these options. The implication is that even though there are credible estimates of average deterrent effects of at least some broad classes of policies, the capacity to translate the average estimates into a prediction for a specific place is limited. This is a major shortcoming in the evidence because crime control is principally the responsibility of state and local government. It is the response of crime to policy in that city or state that is relevant to its population, not the average response across all cities and states.

Deterrence Theory: Crime

1. Introduction

The word *deterrence* has been linked to different topics, including nuclear deterrence (see *Oxford English Dictionary*), but the focus here is on theories about the effects of punishment on crime. Criminal deterrence pertains to the omission or curtailment of crime out of fear of legal punishment, and the first theory can be traced to the utilitarian philosophers Cesare Beccaria (1738–94) and Jeremy Bentham (1748–1832) who believed that people are motivated fundamentally to obtain pleasure and avoid pain. To the extent that potential offenders anticipate pleasure from crime, they can be deterred by increasing the pain associated with it. In particular, potential offenders can be deterred by making legal punishment *certain*, *celeritous*, and *severe*, with *certainty* being the likelihood of being caught and punished for crime, *celerity* being the swiftness of punishment, and *severity* being the amount of punishment (von Hirsch et al. 1999, p. 6). Reduced to one fairly simple statement: 'The rate for a particular type of crime varies inversely [negatively] with the celerity, certainty, and severity of punishments of that type of crime' (Gibbs 1975, p. 5).

2. Complexities

Although that statement is still the basis for contemporary deterrence theory, there are several complexities, one of which has to do with the distinction between *specific* and *general* deterrence (Stafford and Warr 1993). Whereas *specific deterrence* refers to the deterrent effects of directly experiencing a legal punishment, *general deterrence* refers to the deterrent effects of indirectly experiencing it. So when a person is imprisoned for committing a burglary and is then released, the imprisonment deters *specifically* to the extent that the released offender refrains completely from burglary, or at least curtails the amount of burglary that he or she commits, out of a fear of further imprisonment. To the extent that people other than the imprisoned offender learn about the imprisonment and refrain completely or in part from committing burglary out of fear of being imprisoned, those people have been *generally* deterred. The distinction is important because a given punishment might deter *only* specifically or *only* generally instead of both.

Another complexity is implied in the foregoing discussion of specific and general deterrence. Critics sometimes dismiss the possibility of deterrence by arguing that the commission of a crime itself is evidence against deterrence. For example, it sometimes is argued in reference to criminal justice policy to imprison drug traffickers that continued drug trafficking reveals that the threatened imprisonment did not deter potential offenders. However, the argument ignores the distinction between *absolute* and *restrictive* deterrence (Gibbs 1975, pp. 32–4). To the extent that a person refrains completely from committing a crime out of fear of punishment, that person is deterred *absolutely*. However, a person may not be deterred absolutely but, instead, be deterred *restrictively* by curtailing or limiting his or her commission of a crime, as when a person limits the amount of drug trafficking in order to reduce the risk of punishment (perhaps out of a sense of cumulative risk). With restrictive deterrence, the key question is how much crime would occur if there were either no or less threatened punishment for it.

3. Premises of Deterrence Theory

According to Gibbs (1975), there are three premises of deterrence theory:

(a) The greater the actual certainty, celerity, and severity of punishment, the greater the perceived certainty, celerity, and severity of punishment.

(b) The greater the perceived certainty, celerity, and severity of punishment, the less the crime.

(c) The greater the actual certainty, celerity, and severity of punishment, the less the crime.

Or stated diagrammatically: AP $<-->$ PP $>-<$ CR, where AP denotes actual punishments, PP denotes perceived punishments, CR denotes crime; the symbol $<-->$ denotes a positive relationship, and $>-<$ denotes a negative relationship. In contrast to the actual certainty, celerity, and severity of punishment in a given place and time for a given type of crime, perceived punishments pertain to people's perceptions of the certainty, celerity, and severity of punishment (von Hirsch et al. 1999, p. 6). For example, if the actual certainty of arrest for burglary in a particular US state in a given year is 25 percent (law enforcement officials actually make 25 arrests for every 100 burglaries committed), people may perceive the certainty of arrest for burglary to be 25 percent or they may perceive it to be higher or lower than 25 percent.

Deterrence theorists since Beccaria and Bentham have assumed that there is a strong positive relationship between actual punishments and perceived punishments (Premise 1), and that assumption is important

for two reasons. First, 'to the extent that changes in actual penal policies do not alter potential offenders' beliefs about the likelihood or severity [or celerity] of punishment, they cannot generate any … deterrence' (von Hirsch et al. 1999, p. 6). Second, demonstration of a positive relationship between actual and perceived punishments is important to distinguish deterrence from other possible preventive consequences of punishment. To illustrate, suppose there was a strong negative relationship among US states between the actual certainty of imprisonment for auto theft and the auto theft rate. It may not be fear of legal punishment (deterrence) that accounts for the relatively low auto theft rates in states with a high certainty of imprisonment for auto theft; to the extent that imprisonment serves to limit the opportunities to commit auto theft (it is difficult to commit auto thefts in prison), the imprisonment of large numbers of auto thieves can cause a low auto theft rate through *incapacitation* and not fear of legal punishment. There would be evidence of deterrence only to the extent that (1) the people in states with a high actual certainty of imprisonment for auto theft perceived it to be high and (2) there were low auto theft rates in states with high actual and perceived certainty of imprisonment for auto theft.

4. *Additional Complexities*

An additional complexity is that the deterrent effects of legal punishment may be contingent. To begin with, the deterrent effects of a particular property of punishment—say, certainty—may be contingent on the levels of the other punishment properties—say celerity, and severity. For example, Tittle (1969, p. 47) reported in a study of the relationship among US states between the actual certainty and severity of imprisonment and rates for seven crime types (e.g., homicide) that the actual severity of imprisonment acted 'as a deterrent only when there was a high [actual] certainty of punishment.' Similarly, Grasmick and Bryjak (1980) reported in a study of the relationship among individuals between the perceived certainty and severity of punishment and self-reported crime that perceived certainty has stronger effects at higher levels of perceived severity and that perceived severity has stronger effects at higher levels of perceived certainty.

The deterrent effects of legal punishment also may be contingent on *extralegal punishments*, including self-imposed punishments (e.g., guilt, shame) and socially imposed punishments (e.g., divorce or employment loss). William and Hawkins (1986, p. 561) have indicated that extralegal punishment may result from legal punishment (e.g., an offender may experience loss of employment following imprisonment) and, thus, should be 'part of the … deterrence process.' However, extralegal punishment also may be inflicted independent of legal punishment. For example, Grasmick and Bursik (1990, p. 840) have argued that offenders may experience guilt or shame from committing a crime regardless of whether they are caught and legally punished. Hence, the deterrent effects of legal punishment may vary by the likelihood of experiencing swift and severe extralegal punishment for committing crime. For example, the deterrent effects of legal punishment may be greater among those who have little to risk in the way of extralegal punishment for crime because fear of legal punishment may be their only barrier to law-violating behavior. In that connection, Burkett and Ward (1993, pp. 128–9) found that those who believed marijuana use to be sinful were unlikely to contemplate engaging in the behavior; and, hence, the threat of legal punishment for marijuana use was irrelevant for them. Only those who did not consider marijuana use sinful were deterred 'because they appear[ed] to contemplate the act and, by reasonable inference, the probable consequences of their behavior.'

Policymakers need not worry that punishment does not deter all potential offenders as long as *enough* potential offenders are deterred. However, there is evidence that legal punishment sometimes is counterproductive by causing potential offenders to commit *more* crime. In relation to specific deterrence, Sherman and Smith (1992) reported that arrests for domestic assaults produced more subsequent assaults by unemployed offenders because they did not perceive police intervention as legitimate and 'displaced [their anger about being arrested] onto their present or future romantic partners or other citizens' (Sherman 1993, p. 465). According to Sherman (1993, p. 460), legal punishment provokes such 'defiance' (persistent or more serious law-violating behavior) to the extent that offenders (1) perceive the punishment as unfair, (2) are weakly bonded to other community members, (3) perceive the punishment as stigmatizing, and (4) deny the shame associated with it.

5. *Links between Deterrence Theory and other Theories*

The connection between contemporary deterrence theory and the Beccaria-Bentham belief that people calculate the pleasure and pain associated with behavior means that deterrence theory can be linked to other, more general, theories of human behavior. Akers (1990) has argued that deterrence theory is subsumable under more general *social learning* or *behavioral principles*. 'Threat of legal punishment is one source or indicator of aversive stimulus under the general concept of differential reinforcement (balance of rewarding and aversive stimuli)' (Akers 1990, p. 658). Differential reinforcement refers to the overall

balance of rewards and punishments for a behavior, including past, present, and future rewards and punishments. General deterrence is equivalent to observational/vicarious learning in social learning theory, which involves observations of other people and how their behavior is rewarded and punished; and specific deterrence is equivalent to experiential learning, which involves direct, personal experience with the rewards and punishments for a behavior (Stafford and Warr 1993).

Both deterrence and social learning theory can be linked to *rational choice theory* in that both address the question of why people in certain situations *decide* or *choose* to engage in particular behaviors (Akers 1990). However, the meaning of 'rational' is ambiguous. To some deterrence researchers, rationality implies conscious and deliberate calculations about the rewards and punishments for crime (e.g., Bachman et al. 1992). In contrast, others deny that overt mental calculations of any kind are necessarily involved (e.g., Casey and Scholz 1991). Moreover, rational choices are sometimes conceived as willful rather than determined (e.g., Bachman et al. 1992), but Cornish and Clarke (1986, p. 13) have claimed that the 'rational choice perspective is … neutral with respect to the free will-determinism debate.'

Disagreement about the meaning of the word 'rational' stems from the existence of different versions of rational choice theory: old rational choice theory and new rational choice theory, each with different assumptions about rationality (Felson, 1993). Old rational choice theory, as set forth by such utilitarian philosophers as Beccaria and Bentham assumed that people engage in conscious and deliberate cost/benefit analysis in order to maximize the rewards and minimize the punishments for their behavior. The new version of rational choice theory entails weaker assumptions about rationality—that people intuit the rewards and punishments for a behavior and that they are imperfect processors of information and consequently must behave within the limits of their abilities to pursue what they perceive as most satisfying (e.g., Cornish and Clarke 1986). The assumption of 'maximizing' is rejected and replaced by alternative assumptions, such as 'satisficing' and 'bounded' or 'situated rationality.' As for the issue of free will versus determinism, new rational choice theory posits that 'people make choices, but they cannot choose the choices available to them' (Felson 1986, p. 119).

Like new rational choice theory, deterrence theory does not require a strong assumption about rationality. In particular, crime need not be preconceived or carefully planned for legal punishments to deter, only that potential offenders choose between crime and conformity to the law on the basis of their estimates of the rewards and punishments involved. Also like new rational choice theory, deterrence theory does not require that people have free will. Indeed, a negative relationship between properties of legal punishment (e.g., the perceived certainty of punishment) and crime is as compatible with a strictly deterministic conception of human behavior as it is with free will (Gibbs 1975, p. 24).

Deutsch, Karl W (1912–92)

Karl Wolfgang Deutsch belongs to the cohort of the 'brain drain' which, by emigrating in the 1930s from Europe, contributed to the development of the social sciences in the United States. Born in Prague on July 21, 1912, Deutsch escaped from the imprisoned continent in 1939, after having received a law degree from Charles University. Son of the first woman parliamentarian in Czechoslovakia, he moved from one privileged social stratum to another, debarking with a fellowship at Harvard University. He worked for the Office of Strategic Studies during World War Two, began teaching at MIT in 1945, then at Yale University in 1957 and, from there, taught at Harvard University until retiring in 1985. At that time, he was appointed as one of the directors of the Wissenschaftzentrum in Berlin. As is often the case with those who learn a new language after puberty, Karl Deutsch kept his distinctive German accent. He died at the age of 80 in Cambridge, MA, on November 1, 1992.

Karl Deutsch's contributions to the advancement of social sciences can be summed up in five domains:

(a) Building empirically grounded concepts and theories, such as nation-building, social mobilization, national and international integration, center–periphery, distribution of power, and understanding macrosocial processes. His definition of integration of a society is still in use in the literature: the capacity to receive and transmit information on wide ranges of different sectors with little delay. One of his writings appears retrospectively as predictive: 'Cracks in the monolith, possibilities and patterns of disintegration in totalitarian systems' (Deutsch 1954).

(b) Pioneering, cross-national research. Deutsch remains a leading figure of the first post-War generation of comparativists. In the late 1950s and 1960s, he did comparative research, using aggregate data at a time when other great comparativists, such as Gabriel Almond and Sidney Verba, preferred the survey method for comparing countries.

(c) Quantitative methodology. Karl Deutsch advanced the introduction of statistical analysis in political science. Such a vocation could be explained by the fact that, as the son of an optician, early in life, Deutsch considered the possibility of becoming one himself, and consequently studied mathematics. He did quantitative analysis on the size of government, growth of governments, foreign trade as a percentage of GDP, global modeling, two-way: channels of communication between élites and mass. Deutsch was in the forefront of the so-called 'data movement.' His contribution to *Quantitative Ecological Analysis in the Social Sciences* (Deutsch 1969) was considered as a research agenda.

(d) Work on communication theory, particularly cybernetics. He developed Wiener and Neumann's research, focusing on politics and society. The subtitle of *The Nerves of Government*, 'Political Communication and Control,' (Deutsch 1963) paraphrases Wiener's definition of cybernetics: 'Control and Communication in the Animal and Machine.'

(e) Bridges between disciplines, by importing in political science concepts and theories from various disciplines (anthropology, social psychology, economics, and biology). *Nationalism and Social Communication* (Deutsch 1953) is an eminently interdisciplinary work, where Deutsch's intimate knowledge of European history and geography appears in all chapters. Deutsch was a leading contributor to *Advances in the Social Sciences* 1900–80 (Deutsch et al. 1986).

Retrospectively, it can be said that Deutsch's most eminent book is his first, *Nationalism and Social Communication*: a*n Inquiry into the Foundation of Nationality* (1953). This is his most cited work, and has been so since its publication. The subject of this book is related to his personal experience. Born to a Sudeten German family in the Austro-Hungarian empire, a multinational state, 'Deutsch put his emotional and intellectual energy into scholarship focused upon nationalism and formation of large-scale political communities' (Merritt and Russett 1981, p. 6). As a teenager, Deutsch witnessed the collapse of three empires and the emergence of many new independent nation-states in Eastern Europe and the Balkans.

The success of this book can be explained by Deutsch's capacity to interpret statistical data with an intimate knowledge of the historical and social contexts. There are social scientists who write about countries they have only read about in books and who, in spite of their statistical virtuosity, too often offer superficial explanations. They should contemplate the following: 'We will always need the clinician who knows the problem from having seen many cases, who knows the countries, the cultures, the areas where the problem takes place, and who knows the particular syndromes. It is by equipping the clinician with the work of the technicians, by having clinical judgement and technological and scientific evidence side by side, that we are likely to make the most progress' (Deutsch 1980 p. 19).

In a survey of the most commonly cited political scientists, Deutsch's name ranked eighth between 1945 and 1960, fourth from 1960 to 1970, and tenth between 1970 and 1976. After 1980 his name still appears on the list of the three dozen most-cited political scientists. Between 1970 and 1979, his name was cited 1870 times. Between 1996 and 1999 he has been cited 60–90 times per year. Most of them concern the following three books: *Political Community at the International*

Level (Deutsch 1954), *Nationalism and Social Communication* (Deutsch 1953), and *The Nerves of Government* (Deutsch 1963).

It is interesting to note that Deutsch's two most successful books were conceived and written simultaneously, and were published only one year apart, in 1953 and 1954. Undoubtedly the fundamental ideas for these two works were already present in his mind when he escaped from the totalitarian regime. *The Nerves of Government* does not appear to be Deutsch's most popular book. It has been cited less frequently than the other two and, when it has been cited, the citations were in many cases perfunctory, the content not being commented upon. This book was published in 1963, at a time when Deutsch had already been at the front of the stage. Such perfunctory practice has been described by Robert Merton in his *Sociology of Science*.

The high 'mortality' rate of articles in political science, particularly in the field of international relations, is a well-known phenomenon. In several other disciplines, the life expectancy rate of articles is longer. Karl Deutsch published as author, co-author, editor, and co-editor a total of 16 books. In addition, between 1943 and 1980, he published 240 articles in academic journals and chapters in collective works, approximately half of them in collaboration with other scholars. According to the SSCI, which covers as sources only journals, excluding books, some of these 240 contributions were still being cited during the 1990–5 quinquennium. The content of some of Deutsch's articles has become chapters of his books, particularly in *The Nerves of Government*. Other articles, among the best *Towards an Inventory of Basic Trends and Patterns in Comparative and International Politics* (1960) and *Social Mobilization and Political Development* (1961), have become standard information and common knowledge, and, consequently, do not need to be cited. What had been previously innovative has been superseded by more recent studies based on more precise data, analyzed with more refined methods. When writing about microbes, Pasteur need not be cited. When using social indicators, Karl Deutsch, Gabriel Almond, and Daniel Lerner no longer need to be cited. The concept of social mobilization already belongs to the common patrimony of the social sciences.

In the late 1960s and 1970s, Yale's Department of Political Science was one of the most attractive for graduate students, many of whom converged in Deutsch's seminars. One of these seminars inspired the conception of an important book entitled *World Handbook of Political and Social Indicators*, which users of quantitative data had named 'the Yale bible,' by Bruce M. Russett in collaboration with H. R. Alker, K. Deutsch, and H. Lasswell (Russett et al. 1964).

The following are among Deutsch's intellectual progeny: Hayward Alker, Jorge Dominguez, William Foltz, Michael Hudson, Peter Katzenstein, Manfred Kochen, Arendt Lijphart, Richard Merritt, Donald Puchala, Bruce Russett, Charles Taylor, these and others recognized as outstanding political scientists. They honored their mentor in a collective book *From National Development to Global Community*, edited by Richard L. Merritt and Bruce M. Russett (1981).

Stein Rokkan's tribute to Deutsch's intellectual leadership deserves to be cited at length: 'Karl Deutsch taught my generation of social scientists to develop models and to test them against the data of history. My own early research was heavily influenced by Deutsch's ideas. My later work on dimensions of state formation and nation-building was directly inspired by Deutsch's path-breaking study *Nationalism and Social Communication*; he taught me to look out for the decisive characteristics of center-building networks and to study the functions of the printed media' (Rokkan 1981 p. 70).

Deutsch was an interdisciplinary scholar, comfortable in many fields. In his latter days he became interested in 'the conditions favoring major advances in the social sciences.' In 1986, he co-edited a volume focusing on this subject in collaboration with Andrew Markovits and John Platt (Deutsch et al. 1986).

Those who encountered Deutsch were impressed by his encyclopedic erudition. In his book *Nationalism and Social Communication* (Deutsch 1953) some 2000 authors are mentioned. His historical knowledge appears in a particular light in an article published in 1945 on 'Anti-semitic ideas in the Middle Ages,' based on the reading of very old literature (Deutsch 1945). This article merits to be included in any modern anthology of historical sociology.

Soon after the publication of *The Limits to Growth* by the Club of Rome in 1972, a new trend appeared in political science, imitating economists, demographers, and ecologists. Karl Deutsch had alerted the specialists: 'Computers can assist thought, but not replace it. Mathematical thought produced new ideas and techniques, such as game theory and coalition theory, scaling, latent structure analysis, matrix analysis and a succession of increasingly sophisticated models of social and political structures and processes … Some of us have tried to deal with this by over-specialization, risking to fall into the old trap of learning more and more about less and less' (Deutsch 1978). Nevertheless, in the 1980s, he was seduced by the siren of 'world modeling.' Under his directorship at the Wissenschaftzentrum in Berlin, modeling became a priority. The virtue of Deutsch's effort in Berlin was to combine mathematical modeling and solid empirical referent. Abstract mathematical modeling has attracted the attention of a limited number of political scientists outside the circle of the builders of reductionist models.

World trade was one of Deutsch's favored topics, which he discussed in several writings. He measured the ratio of foreign trade to national income for almost

half a century. He presented an impressive amount of statistical data demonstrating a decline in international trade between 1913 and 1957 (Deutsch and Eckstein 1961). But this period was marked by World War One, the Great Depression, protectionism, and autarchy practiced by several great powers in the 1930s, World War Two, and the post-War reconstruction of the devastated European countries and Japan. In the 1950s, only 6 percent of the American GNP depended on foreign trade. Deutsch did not explicitly predict a continuing decline of international transaction. More recent developments do not invalidate Deutsch's historical observation.

One of Deutsch's main ideas was the importance of intertwining economies for political integration. This thesis is still validated: half of France's foreign trade takes place with Germany, and reciprocally. Economic integration has preceded political integration of the European Union, even for Britain.

Since the publication of *Nationalism and Social Communication*, the nations of Western Europe, with the exception of Greece and Ireland, have experienced a rapid decline of nationalist tendencies, reversing a historical trend (Dogan 1993), at a moment when, in contrast, many developing countries in Asia, the Middle East, and Africa have been mobilized by movements of national independence, developing an exacerbated ethnic nationalism. The concepts designed by Deutsch and other scholars—social communication, rapidity of assimilation, rate of mobilization, spread of national consciousness, population clusters, linguistic cleavages, center–periphery—have been transplanted from the continent to which they were first applied to many new nation-states, where Deutsch's theories are more relevant.

Karl Deutsch's professional career was one of exceptional brilliance. He was elected President of the American Political Science Association in 1969 and of the International Political Science Association (IPSA) in 1976, playing an important role in the development of the research committees within IPSA. In collaboration with Richard Merritt, as program director, he organized the IPSA World Congress in Moscow in 1979, building a bridge between East and West for political scientists. A member of the American Academy of Sciences, he lectured in many European universities. Deutsch received honorary doctorates from seven American and European universities and the Commander's Cross Order of Merit from the German Federal Republic.

Dev

Development and the State

Even though making war and enforcing internal order are the state's classic roles, political survival and internal peace increasingly depend on economic success. States are, therefore, inevitably involved in development. The term 'development' has been used in the post-World War II period as shorthand for the process of socioeconomic change that has shaped contemporary societies, particularly those of Africa, Asia, and Latin America. Development has meant the transformation of agriculture, the growth of industry, and a host of accompanying social, political, and economic changes. The question is: 'When and how does the behavior of the state facilitate or impede development?'

1. Historical Perspectives on the State's Role in Economic Transformation

Calling the poor nations of Asia, Africa, and Latin America 'developing countries' implies that they are undergoing economic and social transformations that are variations of those already experienced by the industrialized countries of the North. Understanding the role of the state in earlier periods of industrialization is, therefore, important to thinking about development and the state.

Two streams of thinking are worth highlighting. First, there is the perspective of economic historians, such as Douglass North (1981), who see the provision of predictable norms and laws, particularly those which define and protect property rights, as the state's primary contribution to development. The second view sees states as actively constructing new institutions to facilitate trade and investment and mobilizing resources in ways that accelerate the growth of new productive capacities. This view is epitomized in Karl Polanyi's (1957 [1944], p. 140) classic statement: 'The road to the free market [in England] was opened and kept open by an enormous increase in continuous, centrally organized and controlled interventionism.'

Alexander Gerschenkron (1962), looking at 'late developers' in Europe, reinforced and extended Polanyi's analysis by suggesting that countries like Germany and Russia faced a more difficult economic problem than England. They had to 'catch up.' By the time they began to industrialize, existing production technology required a scale that exceeded their societal capacities. Lacking both individual capitalists able to assume risks at the scale required by modern technology or private institutions able to spread risk, the state had to serve as investment banker or bear the risks itself, bringing together the necessary funds and encouraging their application in productive activities.

2. Analyzing the State's Role in Third World Development

Perspectives, like those of Polanyi and Gerschenkron, in which development was not the spontaneous result of the activities of private economic actors but had to be explicitly fostered by the state, resonated in the Third World. In Asia, Africa, and Latin America, the gap between local capacities and the institutional scale required to be competitive with firms in the industrialized North was much bigger than the gap Russia and Germany had faced a century earlier. Local elites were too often wedded to maintaining agrarian structures that preserved their privilege at the expense of national productivity. The fact that the United States and Europe were just emerging from a period in which substantial increases in state intervention, first to combat the Great Depression and then to mobilize for World War II, made this perspective even more plausible.

2.1 Development Planning, Import Substitution, and the Entrepreneurial State

The conviction that Third World countries could not develop unless they managed to escape their traditional dependence on exports of agricultural products and raw materials was a key impetus to increased state involvement. Manufacturing products locally rather than importing them was seen as a central part of development and emerging local manufacturers needed protection from established rich-country firms if they were going to succeed at this process of 'import-substituting industrialization.' They also needed public investments in energy production and transportation. Deciding which of these investments made sense required planning. Private investors also faced a collective action problem. Investment in manufacturing would make more sense if other local entrepreneurs were making complementary investments that would provide needed inputs. Active state involvement was a way of giving entrepreneurs confidence that they were part of a general, mutually-reinforcing set of investment decisions.

Without advocating expansion of the state's role, Albert Hirschman was one of the most creative contributors to thinking on these issues. Hirschman carried Gerschenkron's argument a step further, arguing that a dearth of entrepreneurship in the simple sense of 'the perception of investment opportunities and transformation into actual investments' (Hirschman 1958, p. 35) stood in the way of 'late late industrialization' more than the lack of capital. The state could help induce private capital to become more entrepreneurial by providing incentives that made decisions harder to avoid. In Hirschman's view, inventing a national project of entrepreneurship is the key to development and the state can be an important participant in the process of invention.

2.2 *Neo-liberal Critiques of State Intervention*

Import-substituting industrialization and the state involvement that went with it resulted in impressive rates of economic growth during the 1950s and 1960s in countries ranging from India to Brazil, but by the end of the 1970s development strategies in Africa, Latin America, and South Asia were in disarray. Imports were growing faster than exports, creating balance of payments problems and state expenditures were increasing more rapidly than revenues, creating fiscal problems. One of the responses to this disarray was a renewed interest in the state on the part of neoclassical political economists.

Like Marxists, neoclassical political economists saw the state as the instrument of special interests rather than universal ones. Unlike Marxists, they applied the utilitarian logic of individual maximization to actors within the state itself. They saw the state extracting rents and giving entrepreneurs the wrong incentives rather than solving collective action problems and inducing more entrepreneurship. Theorists like Anne Krueger (1974) applied this logic to strategies of import-substituting industrialization, arguing that the desire to gain protection from foreign competition led entrepreneurs to focus on the unproductive quest for state favors rather than on competitiveness. Studies like Robert Bates' (1981) analysis of the perverse effects of state intervention on the development of African agriculture helped build the case that there were serious problems with earlier optimistic visions of the state's role in development.

These critiques were on the mark in many ways. Development planning had indeed presumed an unrealistically benign state, ignoring the self-seeking behavior of state elites. Corruption was rife in developing states. Entrepreneurs in industries like textiles did indeed continue to demand that indulgent states provide them with protection long after they should have become mature and internationally competitive. Nonetheless, these neo-liberal theorists lacked good answers as to how developing countries could overcome the weaknesses of their private entrepreneurial classes. Their theories also failed to acknowledge that there were important variations, even among poor countries, in the behavior and capacities of states.

3. *The Developmental State*

Some states fit the negative neo-liberal image. They are predatory states: aggregations of self-interested elites that extract society's surplus wealth and income, use it for their own benefit, and provide so little in the way of collective goods in return that development becomes impossible. Zaire under the rule of Mobutu in the 1970s and 1980s was a classic example. Under Mobutu, the income of Zaire's citizens shrank at over 2 percent a year, while state officials acquired multiple European mansions and Swiss bank accounts. For most states, however, the neo-liberal view is partial and therefore misleading. The state apparatus may extract, sometimes corruptly, but it also provides essential collective goods without which development could not proceed.

Most interesting is the subset of states that are able to foster long-term entrepreneurial perspectives among private elites, help solve collective action problems, and supply essential public investments in education and infrastructure. The elites that control these states may not be immune from using society's surplus for personal ends, but the nations they govern enjoy faster rates of development because of the collective goods they supply. This category of 'developmental states' is best illustrated by looking at East Asia from the 1950s through the 1980s.

3.1 *The East Asian 'Miracles'*

Japan's successful challenge of the industrial supremacy of Europe and the United States in the 1950s and 1960s was followed by the developmental success of Korea, Taiwan, and Singapore. These countries grew six times faster that the advanced industrial countries had grown in the nineteenth century during the industrial revolution. They are unique in the Third World in the degree to which they have managed to change to their position in the world economic hierarchy. These states are considered developmental, not just because the nations they governed grew, but because the transformation involved in that growth was directly related to the behavior of the state.

3.2 *The Analytical Characteristics of the 'Developmental State'*

Starting with Johnson's (1982) analysis of the Japanese case, a variety of analysts have tried to specify what makes states developmental (see, for example, Akyüz 1999, Amsden 1989, Chang 1994, Wade 1990). The debate continues, but there are surprising elements of

consensus that extend into mainstream development economics (see Meier and Rauch 2000, Chap. 9) and the international policy community (see World Bank 1997).

One key structural feature of developmental states is a capable, coherent economic bureaucracy closely connected to, but still independent of, the business community. The roots of capable bureaucracies lie, in turn, in mechanisms familiar to students of Max Weber, such as meritocratic recruitment and public service careers that offer long-term rewards commensurate with those available in the private sector. These simple indicators predict more rapid economic growth, not just in East Asia, but also across a broad range of developing countries. The qualities that allow such bureaucracies to develop close ties to private elites without being 'captured' by those elites are harder to specify. Nonetheless, the success of developmental states depends on their ability to maintain autonomy from private elites while simultaneously developing close ties to them (Evans 1995).

The policies of developmental states mirrored the behavior Gerschenkron and Hirschman argued was needed in order to promote late industrialization. Investments in essential modern infrastructure, such as telecommunications, helped set the stage for industrial growth. Entrepreneurs were induced to make long-term investments that raised national productivity. Subsidies and selective protection against external competition led to the creation of industries like semiconductors, steel, and shipbuilding that private entrepreneurs would never have embarked on without state support. Exports, overall output, and real wages all grew at unprecedented rates. Public investments made rapid rises in education levels possible and health measures, such as infant mortality levels, improved along with education.

4. *Contemporary Issues and Future Directions*

Current thinking about development and the state has been thrown into question from at least three different sources. The recent evolution of the global political economy has brought into question the capability of individual states to shape developmental trajectories. At the same time, the efficacy of the developmental state has been brought into question by the East Asian financial crisis of 1997–8. In an even more fundamental challenge, the validity of traditional strategies of development is increasingly contested. In combination, this questioning suggests a redefinition of the role of the developmental state.

4.1 *Globalization and the Role of the State*

The reorganization of production, and more crucially finance, around global networks, in combination with the increasing hegemony of market-oriented Anglo-Saxon ideology and legal norms, makes traditional industry-focused state strategies more difficult, even when these strategies combine import substitution with export promotion, as in the case of developmental states. Even though global organizations, like the World Trade Organization, continue to depend on the institutional capacities of individual states to implement global governance rules, the leeway that states have in making their own rules to increase local entrepreneurship has been restricted. Even developmental states have felt the effects of globalization.

4.2 *The Crisis of the Developmental State*

The dominant tenor of first reactions to the 1997–8 Asian financial crisis was that either globalization has turned the developmental state into an anachronism or it was a hoax to begin with. More sober reflection produced a different diagnosis. One of the lessons of the crisis was that states cannot afford to relinquish controls over international financial flows before constructing appropriate mechanisms for regulating national financial markets. Abandoning its previous role, not clinging to it, was the developmental state's failing.

This failing did not result simply from the pressures of globalization. It also reflected a change in the politics and policies of the developmental state itself. Having achieved impressive gains in global markets, local corporate elites were less likely to believe that a coherent, capable state bureaucracy was relevant to their success. Global ideology favoring the dismantling of the state's regulatory capability also became more popular within the state apparatus. Even though financial stability and growth were restored with remarkable rapidity, the crisis revealed that, precisely because of its economic success, the state's alliance with private capital was no longer likely to produce the same developmental results. At the same time, the 'accumulation-oriented' definition of development that had formed the basis of this alliance was increasingly criticized.

4.3 *The Contested Definition of Development*

The strategy of the developmental state, like the strategy of import-substituting industrialization before it, was built on the premise that investment in local manufacturing would produce jobs and that the incomes from these jobs would generate widespread increases in well-being. There have always been critics of this view, but recently they have become more vociferous (e.g., Escobar 1995, Sachs 1992). Critiques argue that as manufacturing becomes more capital intensive, manufacturing investment consumes a disproportionate share of the social surplus relative to the

number of jobs that result. Even when the money incomes of some ordinary workers do increase, improved overall well-being is not necessarily the result. Their ownership of more consumer goods does not compensate for the environmental degradation, increasing inequality, and destruction of intangible social and cultural assets that accompany the accumulation of productive capacity. For too large a proportion of the citizens of poor countries, the new global cornucopia of heavily advertised consumer goods remains beyond economic reach but still devalues prior cultural and social satisfactions. While such perspectives, which ignore the benefits of investment in productive capacity, are one-sided, it is still getting harder to defend development policies premised on the idea that the best way to promote well-being is simply to induce entrepreneurs to invest more.

4.4 Redefining the State's 'Developmental' Role

If development is really about well-being rather than about accumulating industrial capital, then what is the role of the state? A 'well-being-centered' redefinition of development implies a more aggressive focus on the state's traditional role in delivering collective goods and services, like health, education, clean air, water, and sewage disposal, and in preserving the collective environment, both natural and cultural. The kinds of state behavior and structures required by this redefined developmental role are surprisingly consistent with early thinking. Hirschman's notion of inducing decision-making among private economic agents becomes an even bigger challenge if the focus is on the provision and preservation of collective goods. Finding ways to convince entrepreneurs that they should invest in clean production techniques or take into account the social impact of investment decisions requires much more skill and capacity than helping them increase their profits through subsidies and protection. The greater magnitude of the challenge makes the emphasis on a capable, coherent state bureaucracy, which is central to thinking about the developmental state, more important than ever.

The biggest single change implied by redefinition is already foreshadowed by the crisis of the developmental state. State-society relations dominated by close ties to industrial elites at the expense of other social groups will provide neither the political will nor the societal collaboration necessary to execute a 'well-being-oriented' strategy of development. A more broadly defined set of state-society relations is imperative. There are some studies of the role of more broadly-based state-society ties in promoting development (e.g., Evans 1996, Heller 1999), but extending and deepening this kind of analysis is the most obvious challenge confronting contemporary work on development and the state.

Development and Urbanization

Economists, sociologists, political scientists, and anthropologists as well as demographers and planners have long theorized a direct connection between

national development, understood economically and/or politically, and the growth of cities. But there is limited consensus about the nature and direction of the relationship, the desirability of analytically linking these processes, and how to define both terms. Reigning ideas have shifted in the face of new theoretical paradigms and as the territorial scope and essential character of markets, states, and cities themselves transform. Unresolved issues include which urban dynamics most articulate with developmental patterns, and how to identify the most appropriate unit of analysis for understanding these articulations.

1. Historical Antecedents

Most scholarship on this subject traces its intellectual origins to writings by nineteenth and early twentieth-century sociologists and economic historians who sought to account for the development of capitalism, the nation-state, and social modernization in early Europe, and who posited a direct and positive role for cities in these fundamental transformations (see *State Formation*; *Modernization*, *Sociological Theories of*; *Capitalism*).

1.1 Cities and Development in the Early Modern World

In early modern Europe cities emerged from and fueled processes of capital accumulation, by virtue of their role as exchange nodes in local, national, and international trade (Pirenne 1936, Weber 1927). Their growth also was tied to the demise of feudal or absolutist orders (Weber 1958) and the rise of the modern nation-state (Tilly 1975). By the late nineteenth century, cities also served as the sites in which the social relations of modernity materialized (Durkheim 1933, Simmel 1950), in turn transforming markets and states.

1.2 Twentieth-century Developments

In the twentieth century when nationalism, war, empire, trade, democracy, and fascism grabbed European scholarly attention, their US counterparts adopted the concern with cities. This was a time when American society demographically tipped its balance to become more urban than rural, and when new waves of postwar black migration combined with renewed streams of international migration to spark interest in the social relations of urban life. Initial research concentrated on the social process and experience within cities, ranging from ghetto life, immigrant social clubs, and gang organization to criminality. Few initially paid attention to the larger political and economic processes that engendered patterns of urbanization in the US, as occurred in Europe; and even fewer tried to link urbanism or urbanization to patterns of national development, understood either politically or economically. It was only when US sociologists began studying cities comparatively and historically, starting in the 1950s, that debates over the relationship between development and urbanization garnered a central place in the social sciences. When the March 1955 (Vol. 60, No. 5) edition of the *American Journal of Sociology* published an entire volume on 'World Urbanism,' the importance of these themes was firmly established.

The desire to examine other parts of the world was partly grounded in a passion for testing ideas drawn from the European-derived grand theoretical narratives of sociology. Practically the only counterfactual cases available for confirming prevailing propositions about the connection between urbanization and developmental progress—whether understood in terms of democratic state formation, capitalist development, and/or 'modern' social values—were the countries of the so-called 'underdeveloped' world of Latin America, East Asia, and Africa. These were countries of the world racked with poverty, limited industrialization, and governed primarily under oligarchic pacts or by despotic or authoritarian governments (see *Authoritarianism*). To the extent that their urbanization patterns also differed across country contexts, scholars were inspired to revisit general claims about development and urbanization, as well as to ascertain how these two processes were articulated in practice.

Working under the influence of the Chicago School, initial scholarship on what were then called Third World cities focused primarily on the folk-urban continuum and urbanization as a social process, including the ways that urbanization produced individualism and severed kinship bases of social organization (see for example Hauser 1957, Redfield 1941, 1953). Over time, interest grew in urbanization as a demographic and spatial process, with scholars examining patterns of population concentration and the growth of cities in a wide variety of comparative and historical contexts (Berry 1973, Hauser and Schnore 1965), occasionally linking them to general propositions about national development. In addition to Hauser and Schnore's seminal *The Study of Urbanization* (1965), the Chicago-based journal *Economic Development and Cultural Change* served as an important outlet for new ideas on the topic.

2. Twentieth-century Dilemmas: Questioning the Nature and Direction of Causality

It was one thing to quantify urban population patterns across time and place (Davis 1969, Hoyt 1962), to identify the extent to which urbanism, as a social

attribute, materialized in different localities around the world (Breese 1966, Mangin 1970), and to elucidate growth processes in these cities (Gugler 1978, McGee 1971). American social scientists were quite good at these tasks, especially the first; and their successes helped catapult the field of demography onto the disciplinary map in the 1960s and 1970s (see for example Goldscheider 1971, Goldstein and Sly 1979). It was quite another to demonstrate a direct relationship between urbanization and patterns of economic development, especially within the confines of the nation-state, the unit that most social scientists were then using for assessing such issues. It was on these latter counts that scholars were least successful, and that longstanding propositions about the positive relationships between urbanization and national development began to generate widespread skepticism.

As Third World cities burgeoned over the 1960s and 1970s, scholars faced the fact that even with high urbanization rates, developmental gains in most of the Third World remained minimal, not just in comparison to the modal patterns established in Europe and the United States, but also as measured in per capita income, GNP, and practically all other standard macroeconomic indicators (Friedmann 1967). With dependency theory taking center stage at about the same period of time, certain attributes of both urbanization and national development were being traced to colonial or mercantile relations that spanned national boundaries rather than to political, social, and economic conditions within the formal confines of the nation-state (see *Dependency Theory*). These transnational relations modified urbanization and development processes, at least when compared to early modern Europe, even as they raised new questions about the best unit of analysis to study the nature and direction of the proposed relationship. Did urbanization husband development, or vice versa; and was it possible that in the late developmental context the relationship between the two sets of processes was more likely to be negative than positive, with one impeding rather than facilitating the other? The answers to these questions shifted over time.

2.1 Development and Urbanization circa 1950: A Positive Synergy

The predominant argument in the 1950s and early 1960s was that the plight of developing nations and their low rates of urbanization owed to their 'backward' social and economic nature, which not only explained why industrialization was minimal, but also why tradition-bound peasants demographically outbalanced 'modern' urban folk. Analytical attention was directed towards how to facilitate one so the other would follow suit, a normative preoccupation pervasive in American social science and quite consistent with US foreign policy goals of the times.

There were disagreements about which domain deserved intervention first. Some urbanists argued that the best way to jump-start Third World development was to shift population and resources out of the countryside and into the city, where industry could expand and modern values flourish (Herrick 1965, Field 1970). Others called for more foreign aid or national investment to buttress urban economies, primarily through industrialization (Richardson 1973), in the hopes that such macroeconomic policies would stimulate employment opportunities and perhaps even produce individuals inculcated with rationality and enough achievement drive to sustain further urban and national gains (see *Industrialization*). Despite policy disagreements, both schools of thought expressed enough faith in the idea of a positive relationship between development and urbanization to keep it alive, albeit embodied in a variety of paradigmatic forms.

Over the 1960s and 1970s, one particularly popular variant was demographic, as those interested in urbanization as a social process looked for linkages between urban growth and national development in fertility patterns as well as family structure and employment. During this period ideas about the demographic transition, at times recast in terms of the 'urban transition' (Friedmann 1975), generated considerable interest among economists and sociologists, who developed expert quantitative skills that sustained a field of research broadly understood as 'population studies.' Those less preoccupied with the social or economic behavior of individuals and more interested in overall patterns of city growth and distribution were more likely to concern themselves with ideas about the proper balance between urban and rural populations (El-Shakhs 1974, Friedmann and Alonso 1964).

During this period, scholars who assumed that the US served as a model of successful economic development paid considerable attention to the extent to which urban systems in developing countries achieved a lognormal rank-size distribution, as opposed to being dominated by one or two large 'primate' cities (Berry 1961), basing their interest on the assumption that rank-size lognormality correlated with economic development. In counterattack, these ideas were criticized as inherently Western-biased, if not drawn directly from the American experience, and thus inapplicable in the Third World (El-Shakhs 1972, McGreevey 1971). While there was no resolution on this contentious issue, in the process the concept of 'over-urbanization' gathered widespread attention, since a city could only be 'too' urbanized if it grew beyond its expected and economically efficient size, which often was calculated on the basis of a rank-size distribution logic.

To the extent that most Third World countries fell into the latter camp, with their cities ballooning in size beyond their fiscal and infrastructural capacities, scholars began to study the internal social and demo-

graphic processes that fueled patterns of over-urbanization, and what Michael Lipton (1977) called 'urban bias,' including rural-urban migration and the national investment decisions that overprivileged a few urban centers at the expense of struggling provincial towns and the impoverished countryside. Still, concerns about city systems died hard, rematerializing in slightly new packaging in the 1980s in the form of arguments about the importance of 'secondary cities' to sustaining national development (Hardoy and Satterwaithe 1986, Rondinelli 1983). This claim, like the rank-size distribution argument, was built on the understanding that (smaller) size and (more equal) distribution of cities mattered; and both arguments confirmed the preoccupation with a relationship between patterns of urbanization and development that had initiated and sustained the field.

But far from merely confirming a connection between cities and national development, these findings laid the foundation for an immanent critique of long-standing claims. Indeed, to the extent that the burgeoning growth of Third World cities was soon seen as an obstacle to economic well-being, there was now evidence that a positive relationship between urbanization and development was effectively reversed on substantive grounds, even if analytically the connection remained. To be sure, there were scholars who conceived of large cities as economically efficient localizers of economies of scale, and they continued to claim a positive relationship between large-scale urbanization and development (Richardson 1973). But by and large, promoters of this idea were arguing against a tide of contrary evidence.

2.2 Development and Urbanization, circa 1975: A Destructive Relationship

The ascendance of ideas about a negative relationship between urbanization and development owed partly to the fact that between 1950 and 1975 conditions in the developing world changed dramatically. This was the period when most Third World cities began to grow enormously, outpacing the capacities of their governments to invest in infrastructure or sustain industrial output in ways that contributed to national development. With large cities peopled by new migrants and un- or underemployed folk with limited education and skills for a newly industrializing economy, they soon were seen as a drain on national coffers. The increasing urban inequality and economic polarization accompanying these trends also sustained urban social movements and overall political coalitions that themselves limited national developmental prospects, by bringing to power governments with restrictions on foreign investment, populist economic policies, and/or protectionist measures that frequently undermined short-term efficiency goals. These social and political problems became so salient in the urban landscape of the developing world that eventually scholars of Third World cities turned their attention directly to them (see Abu-Lughod and Hay 1977, Gugler 1988, Mangin 1970), partially eclipsing the concern with national development. Among the most documented issues were urban housing and employment scarcities, rural-urban migration flows, illegal settlements and urban 'marginality,' and migrant or informal sector politics (Cornelius 1973, Drakakis-Smith 1987, Perlman 1976).

This is not to say that all scholars who looked internally to cities over the 1970s and 1980s failed to examine the larger relationships between urbanization and national development that had consumed their predecessors. Economists at the World Bank and other macroeconomic policymakers loyal to free market ideals continued to study urban economies of scale and the ways urban growth interfaced with industrialization, still seen as the principal route towards prosperity; although they too concerned themselves with questions about housing, illegal settlements, and urban service scarcities more generally (Linn 1983). Likewise, but on an entirely different front, sociologists and political scientists began to examine the national political conditions that made these urban problems so pervasive (Eckstein 1977, Gilbert and Ward 1985, Rabinowitz 1973, Roberts 1978). But this also meant that urban scholars were focusing as much on political as economic developments, linking urbanization patterns to national politics as much as markets (see *Populism*).

When dependency theory kicked in as a dominant paradigm among both resident and foreign scholars of the developing world over the 1970s and 1980s, fewer urbanists began to pose questions about the relations between urbanization and national development unless they were framed within a focus on international economic conditions (Castells and Vélez 1971, Portes and Walton 1981, Walton 1985); and even fewer saw the articulation of urban and national development in positive terms, as had their predecessors. If anything, when urbanization was linked to capital accumulation, the social effects were seen as relatively negative (Armstrong and McGee 1985). By the late 1980s, the main idea in good currency was that capitalist development on a global scale produced and/or reinforced mercantilist relations that fueled the growth of cities, even as they disadvantaged the countryside or the nation as a whole. Scholars focused not just on the ways that unequal, semi-imperial relations between core and periphery brought a few large cities, themselves parasitic with respect to their hinterlands. They also examined the ways these relations produced a form of 'internal colonialism' predicated on extreme income and investment polarization between city and countryside, which further fueled migration, contributed to over-urbanization, and reinforced income and other inequalities within cities themselves (see Timberlake 1985). With world-systems analysts turn-

ing full attention to cities in the 1980s (Smith 1996), claims for a substantively negative relationship between urbanization and sustained or autonomous national development reached new heights of acceptance (see *World Systems Theory*).

2.3 Development and Urbanization, circa 1990: Disarticulated Processes

The growing popularity of world-system theory over the 1980s and 1990s may have strengthened scholars' understandings of the strong connections between urbanization and (under)development; but in the long run it contributed to the analytic disarticulation of cities and nations, thereby casting a mortal blow to studies of relations between these two domains. As scholars joined the world-system bandwagon and bypassed the nation-state as a unit of analysis, few examined national development as analytically distinct from global processes. Those development scholars who did concern themselves with the domestic dynamics of macroeconomic development rarely reserved a place for cities in their analytic frameworks, turning instead to states, classes, and the global economy. The result was that scholars who analyzed Third World cities did so increasingly in the context of global economic conditions, even as most scholars of national development ignored cities by and large.

This analytic disarticulation of urbanization and national development was further fueled by intellectual and political dynamics in the developing world. With many countries in Latin America, Africa, and Asia becoming less democratic and more authoritarian throughout the 1960s and 1970s, their states became stronger and more repressive. These political regimes tended to privilege capital over labor and cities over the countryside, using macroeconomic policy, national investments, and targeted subsidies to accomplish these aims. Resident and foreign observers saw little autonomy for cities, with urban developments mostly dictated by powerful (if not militarized) national forces. This was most evident in the largest cities, home to their nation's most significant industries and investments; but it also was seen as a pattern more generally. The result: in studies of the Third World, urban dynamics were frequently subsumed under national ones. This conceptual sleight of hand may have reinforced views about the direct relationship between city and nation to some extent; but it also chipped away at the analytic distinction between urban and national dynamics. And with these two processes increasingly collapsed into each other, the tendency was to examine one or the other, but not the interactive relationship between the two.

Among the few still fervently examining the direct connections between urbanization and national economic development were neoclassical economists, and World Bank staff and their clients. They worked under the supposition that by facilitating and/or managing cities, national actors could insure productivity, efficiency, and the flow of people and goods sufficiently to maximize overall development. Yet in most of the nonapplied fields, urbanists and developmentalists hardly spoke to one another.

3. A New Articulation (or, Development and Urbanization in the Age of Globalization)

As scholars now widely accept the premise that globalization is a central point of entry for studying changes in the contemporary world, there is a renewed interest in the urbanization-development nexus. But because the units of analysis for theorizing these connections have changed, slightly different claims and different types of research dominate the scholarly agenda. Among them are an increasing preoccupation with large cities, a resurgence of interest in urbanization in advanced countries of the world, and renewed debate about the direction and nature of the relationships between cities, nations, and the global economy

3.1 Globalization and Urbanization

One of the main characteristics of the new scholarship is the fixation with cities of enormous size and importance, frequently labeled world or global cities, whose growth and character owed to the role they play not just within their national borders, but also within global networks of production and consumption (Henderson and Castells 1987, Lo and Yeung 1998, Sassen 1991, 2000). The idea of world cities is not new of course (Friedmann and Wolff 1982); and much current work draws inspiration from earlier writings on overurbanization in Third World cities in which the inflated size and rapid growth of primate cities was linked to unequal relations of exchange between so-called core and peripheral economies. But in the new millennium, world cities are less likely to be seen as fetters on the national development of their host countries, and more likely to be conceptualized as the mechanisms through which global economic integration takes root.

Such views not only challenge past understandings of the destructive impact of global dynamics on cities and nations, they also come with a shift in geographic focus. Over the period 1960–2000 most scholars interested in the urbanization-economic development nexus examined the Third World; but now the US and Europe are back in the center of the conceptual map (King 1990, Sassen 1991), bringing the field full circle in terms of its country origins. The questions being posed also have changed considerably. Given the fact that many of the world cities being studied with

renewed vigor—like New York, London, Tokyo, Paris—are in the most economically advanced nations of the world, fewer scholars care about their potentially negative impact on national economies, since developmental dynamics in these countries are assumed to be impervious. As a result, attention is redirected to urban employment patterns, shifts in sectoral character, and the extent to which these patterns are owed to the globalization of capital and labor (Fainstein et al. 1992, Sassen 1991). There also is renewed interest in the changing 'locations' or economic roles these cities play in a regional, national, or international hierarchy of urban places (see Knox and Taylor 1995). Yet several pressing questions remain about the nature and direction of the relationship between urbanization and globalization.

3.2 Development and Urbanization by way of Globalization

One relatively unexplored issue concerns the impact of globally induced urbanization patterns on aggregate trajectories of economic development, be they understood nationally or on some other scale. On these counts, some headway is being made by those who identify regional dynamics both within and among established nation-states and how they factor into the equation. Saskia Sassen (1991), for example, argues that the globalization of capital and labor flows fuels the growth and economic successes of some cities (e.g., New York) while constraining others (e.g., Detroit), in the process exacerbating regional economic polarization. Taking an entirely different line, contemporary scholars of Europe or even East Asia—where globalization has already increased transnational economic integration in such a way as to form mega-regions with their own supranational governing institutions, and where cities on the receiving end of global investments and labor flows assume greater political and economic significance—are examining the extent to which globally-integrated cities will bypass the nation-state and negotiate directly with one another in larger regional pacts. Both lines of research have direct implications for understanding the dynamics of cities and national development, if only because they underscore the ways that, in an increasingly globalized world, the nation-state either comes under challenge or remains the politically relevant unit for mediating among cities, addressing intra-national regional disparities, and/or coordinating new supranational regional institutions.

To the extent that questions about the interconnected relationships between cities, regions, and nations were once the mainstay of studies of early modern Europe and the Third World, the developmental context where regional analysis reigned supreme (see Friedmann and Alonso 1964, Hardoy and Geisse 1972), scholars can look to the past—and across developmental categories—for insights (Clark 1996). Preliminary results point to a convergence in ideas and research programs, capable of transcending space and time, much like globalization itself, and holding the potential to unite scholars from all parts of the world around a common intellectual project.

Development, Economics of

Economic development is the process through which economies are transformed from ones in which most people have very limited resources and choices to ones in which they have much greater resources and choices. Economic development therefore covers almost all areas of economics, though with modifications to reflect the particular situations of developing countries. Development economics refers to studies of economies with relatively low per capita resources: low- and middle-income economies in Table 1. About 85 percent of humanity currently lives in these economies. Product per capita in low-income economies averages 1.7 percent and in middle-income economies 9.6 percent of averages in high-income economies, with that in Switzerland over 500 times that in Mozambique. Correcting these comparisons for different price structures reduces the variations a lot, but the range still is considerable, with per capita product almost 60 times as high in the United States as in Ethiopia. Human resource indicators (e.g., life expectancies and illiteracy) also are poorer for developing than developed economies, but current differences are much smaller proportionately than are those in product per capita. The question of what causes economies to move from per capita resource levels as in Mozambique and Ethiopia to those as in Switzerland and

Table 1
Population, product per capita, life expectancies at birth, and illiteracy rates by level of development in 1995

Country groups	Population (billions)	Gross national product per capita: United States ($)	Gross national product per capita: Purchasing power parity (United States = 100)	Life expectancy at birth (years)	Adult illiteracy rate (%)
Low-income	3.180	430	1.7–12.1	63	34
Middle-income	1.591	2390	6.6–43.4	68	18
High-income	0.902	24930	42.4–100	77	< 5

the United States is the fundamental question that development economics addresses.

1. *Conceptualization of Development in the Mid-twentieth Century*

Prior to the neoclassical developments in economic analysis of the late nineteenth century, most influential economists, for example, Smith, Ricardo, Marx, were concerned substantially with economic development. In the decades prior to the Second World War, in contrast, most neoclassical economists were not concerned with development, but with topics such as behaviors of firms and households, general equilibrium, and efficiency and, starting in the 1930s, short-run macroeconomic equilibria with aggregate demand shortfalls.

In the immediate post-WWII era, mainstream economics continued to focus on the extension of the neoclassical paradigm and on Keynesian macro short-run disequilibria with virtually no attention to development. Development economics as a subdiscipline branched off from what Samuelson called the 'neoclassical synthesis' of mainstream economics because the development of poorer lands was viewed by development economists as different in essence from concerns that dominated the neoclassical synthesis. Development was seen as involving discontinuous shifts from a stagnant low-income traditional equilibrium ('a low level equilibrium trap' or a 'vicious circle of poverty') to a modern higher-income, changing, and growing economy with increasing average per capita income, poverty alleviation and improvements in human resources. Development was viewed as requiring structural change different in kind from the marginalism of neoclassical economics.

The dominant paradigm of the new/reborn discipline of development economics in the mid-twentieth century was based on key perceptions about the way markets, incentives, and other institutions operated in poor countries. These, in turn, had important policy implications.

1.1 *Key Perceptions about Markets, Incentives, and Other Institutions in View of Development in the Mid-twentieth Century*

1.1.1 Surplus labor and capital shortages. Factor proportions in poor countries implied high labor to capital ratios. Family farms/firms with sharing rules based on average products permitted marginal labor products to fall to zero so that labor was in surplus in large traditional agriculture sectors. Surplus labor presented an advantage because, if it could be moved to industry, large gains in product could be obtained and much of the income generated could be reinvested in further capital accumulation since the 'unlimited supply of labor' keeps real wages low. Physical capital was relatively scarce, so that, in Nurske's (1952, pp. 1–2) words, 'the problem of development is largely … a problem of capital accumulation.' But domestic capital accumulation was limited by a vicious circle: low incomes meant low savings so that investment was low that kept incomes low. Human capital was given little emphasis.

1.1.2 Limited role of domestic markets. Markets had limited efficacy because: (a) large population shares, including traditional peasants and governmental officials, were not responsive to market and other incentives. (b) Markets were not well developed because of large subsistence sectors, costly transportation and communication, and the predominance of mechanisms internal to households and firms for transferring resources across time and space. (c) Markets did not incorporate well information about demand complementarities of investments (e.g., Rosenstein-Rodan 1943) and could not provide the right guidance for investments that would change the basic structure of the economy with more than marginal effects. (d) There were important market failures of the types considered in mainstream economic analyses: technological externalities not transferred through markets (e.g., pollution), increasing returns to scale relative to market sizes, and 'public goods' the use of which are not 'rival' so that more consumption by one individual does not mean that less is

available for another entity (e.g., information). (e) Some major actors in markets—rural moneylenders, landlords, and traders—were 'rapacious profiteers' who 'exploited' the uninformed poor by paying them low product prices and charging them high input and credit prices.

1.1.3 Key role of industrialization. Agriculture dominated employment and production. But the development process was in substantial part industrialization. Productivity-enhancing technologies and positive externalities were primarily available for industry, domestic demand would shift towards industry with increased incomes because of income-inelastic demands for food (Engel's law), surplus labor in agriculture could be shifted to productive uses in industry, savings potentials were much greater in industry, and industrialization was essential for maintaining national autonomy (e.g., Mandelbaum 1945, Rosenstein-Rodan 1943, Singer 1950, Mahalanobis 1955, Lewis 1954, Ranis and Fei 1961).

1.1.4 Limited prospects in international markets. Pessimism prevailed regarding international market prospects, in part because of the market collapses in the 1930s. Prebisch (1950) and Singer (1950) argued that international trade transferred most benefits from increased productivity in poor countries to richer countries, the terms of trade of primary producers decline secularly because demands were income-inelastic for primary commodities and the developed countries had monopoly power in markets for manufactured products, and opportunities for developing countries to expand their manufacturing exports were limited because such markets would not grow quickly and these markets were dominated by monopolistic producers in the high-income countries who had succeeded in establishing protectionist policy-determined barriers to expanded manufacturing imports from developing countries. International capital markets would not provide sufficient investable funds for development and they cause exploitation and crowd out domestic investments.

1.1.5 Policy makers have good information, are disinterested and are effective. Policy makers could identify current and future magnitudes of negative and positive externalities, complementarities among production sectors, and responses of various entities to policies so they could and would design and implement good policies.

1.2 Policy Implications of the View of Development in the Mid-twentieth Century

1.2.1 Capital accumulation. Physical capital accumulation was central, as codified by the Harrod–Domar dynamic equilibrium condition, which in the simplest case is that the rate of growth equals the average saving rate divided by the incremental capital output ratio (ICOR). This relation was used to calculate savings requirements to achieve growth targets given ICORs and to justify efforts to increase savings, including shifting resources from private entities to governments under the assumption that governmental savings rates exceeded private ones, and to obtain foreign savings to supplement domestic savings. When exchange rates became overvalued, foreign capital to purchase critical machinery and equipment became of particular concern, as systematized in the 'two-gap' model of Chenery and Bruno (1962) in which the constraint on growth is either savings or foreign exchange. Human capital accumulation was not central in most analysis partly because of the widespread perception of surplus labor.

1.2.2 Import-substituting industrialization with balanced growth. One major mechanism widely used to shift resources to industry, to protect new domestic industries against foreign competitors, and to increase economic independence was high protection, through tariffs and quotas, on manufacturing imports. This established inducements for 'balanced industrial growth,' with important complementarities for intermediate inputs and for final product demands ('backward and forward linkages').

1.2.3 Policy mix—quantitative, direct public-sector production, planning, and irrelevance of macro balance. The state role was very extensive. The dominant policy mode was *dirigiste*. Efforts to improve markets or to use 'market-friendly' taxes/subsidies were relatively rare. Direct quantitative regulations and allocations, including substantial investment in public-sector production, were common because it was thought that the desired ends could be effected with most certainty through such direct actions by knowledgeable, disinterested policy-makers. Public-sector investments included physical capital and human resource infrastructure and many other subsectors in the 'commanding heights' of the economy so that the state could control directly development.

Planning often was viewed as essential because of market limitations, reinforced by international aid agencies that interpreted plans as essential evidence concerning the seriousness of countries' development efforts. Planning agencies were concerned with investment criteria and choice of techniques for deciding on direct public sector investments and for guiding private investments. 'Shadow' ('scarcity') prices were used to evaluate social cost-benefit ratios or internal rates of return to alternative investments, with un-

skilled labor valued at zero because of surplus labor and foreign exchange valued more highly than official overvalued exchange rates. A considerable literature developed methods for calculating general-equilibrium shadow prices. Multisector planning models were developed and widely used to determine sectoral primary factor requirements, physical capital investments, import substitution possibilities and 'noncompetitive imports' (for which domestic substitutes were not available) for target growth rates. These models generally assumed no substitution among production inputs nor among demands, focused on physical capital, and were quite aggregated with little or no variation in qualities of products. They addressed directly possibilities of supply or demand complementarities. Optimizing versions yielded shadow prices that indicated impacts on objective functions of marginal changes in binding model constraints. Often these shadow prices were not very robust to small changes in the model. Moreover, these models did not incorporate most macroeconomic phenomena, so they did not provide guidance concerning such matters as inflation. Furthermore, most of these planning models ignored or only crudely incorporated most of the major phenomena other than the supply and demand complementarities that underlay the critique of the dependence on markets (Sect. 1.1). Subsequent models improved in some important respects, for example, discontinuities were incorporated into integer programming models and price responses in Johansen-type models (1960) that led to more recent computable general equilibrium (CGE) models (Blitzer et al. 1974). But still many of the limitations noted remained.

Policies to establish macroeconomic balance—a major topic in high-income economies—were rejected as irrelevant. Rao (1952) and others argued that the separation between savings and investment that was critical in Keynesian underemployment analysis was not relevant for developing countries given the dominance of family firms. The Latin American 'structuralists' argued that rigidities precluded economic entities from responding quickly to changes so that orthodox currency devaluation or monetary and fiscal policies would reduce output and employment.

2. *The Dominant Paradigm Concerning Development at the Start of the Twenty-first Century*

Aggregate development experience since WWII in many respects has been very impressive, though with considerable variations across economies. Average growth rates in GDP per capita have been high by historic standards and high for developing relative to developed economies. Other indicators of human welfare, such as life expectancy and schooling, have improved even more impressively. *Prima facie*, such success might be interpreted to ratify the post-WWII development paradigm and associated policies (Sect. 1). But the appropriate comparison should be with what could have been achieved given the conditions of the post-WWII era and appropriate development strategies and policies.

One major change in the last three decades or so of the twentieth century was the rapid expansion of systematic quantitative analyses of development, often based on data and approaches that were not available earlier. Many studies explored the underlying assumptions for the dominant initial post-WWII conceptualization of development. Some were undertaken in relatively visible large-scale comparative projects (e.g., Little et al. 1970, Bhagwati 1978, Krueger 1978, 1983, Taylor 1988, Page et al. 1993). Others have been individual country and microstudies that have investigated more detailed aspects of the development experience using new micro data sets with systematic models (e.g., see references in Chenery and Srinivasan 1988–1989 and Behrman and Srinivasan 1995; some more recent examples are Behrman et al. 1997, 1999, Foster and Rosenzweig 1995, 1996a, 1996b, Jacoby 1995, Jacoby and Skoufias 1997, Pitt and Khandker 1998).

These studies question many of the assumed initial conditions in the post-WWII development paradigm and suggest more nuanced characterizations of others. They suggest: (a) traditional agriculture is relatively efficient and traditional institutions such as sharecropping, contracts tied to multiple transactions, attached farm servants, arranged marriages, and migratory patterns are efficient arrangements given imperfect or absent capital and insurance markets. (b) Substantial increases in savings and physical capital investments rates are not sufficient for development because (i) incentives structures affect strongly ongoing productivity growth and (ii) human resource development related to nowledge acquisition and adaptation is critical. (c) Domestic markets work well for many goods and services and returns to market improvements through infrastructure development, better information, and lessening policy barriers to well-functioning markets are often great. Nevertheless some markets—particularly those related to capital, insurance, and information—are imperfect or missing. (d) Industrialization is not equivalent to development and industrialization strategies that penalize other production sectors may retard development. (e) International markets have presented substantial opportunities for developing countries, with the most successful experiences being for those developing economies (initially primarily in East and Southeast Asia) that expanded rapidly their exports and used international markets to induce ongoing productivity improvements as well as sources of foreign investment. (f) Policymakers have limited information and may be rent-seekers rather than knowledgeable and disinterested.

This re-evaluation of initial conditions has substantial implications for policies. Because of the combination of currently perceived much greater responsiveness, limited information (and information asymmetries) faced by governments, limited governmental implementation capacities, much greater variations in quality of goods and services, much more efficient transmission of certain types of information through unhindered markets, important role of markets in inducing greater efficiency, much greater importance of basic macroeconomic stability, and rapid changes in markets and in technology than assumed in the immediate post-WWII paradigm, there has been a sea change in perceptions of appropriate governmental roles and of the best mix policy mix. A broad new consensus had risen by the early 1990s on the nature of development processes and implications for policies. Components of this consensus include the following.

2.1.1 The basic economic environment must be conducive for investments. The two major components are: (a) a stable macroeconomic environment with non-inflationary monetary policy, fiscal restraint, and international balance (e.g., World Bank 1991, Corbo et al. 1992, Page et al. 1993) and (b) institutions that permit investors to have reasonable expectations of reaping much of the gains from their investments. Domestic macrobalance is important because inflationary taxes advocated by many earlier development economists are inefficient, inequitable, erode confidence in policy and in the prospects for the economy, discourage longer-run productive investments by increasing uncertainty, and are difficult to eliminate. Balance in international economic interchange is important so that critical imports of intermediate and capital goods can be maintained, pressures for increased efficiencies are ongoing through exposure to world markets, and access to international finance and technology is maintained. Institutions include basic property rights, legislative and legal systems that resolve disputes fairly, and various mechanisms to share (but not to eliminate) risks.

2.1.2 Human capital is important, additional to physical capital. In the views of some, investment in human resources is in itself development. For most mainstream development economists, in addition to any direct welfare effects of better human resources, there are important productivity effects. Positive externalities through human resource investments may be considerable, moreover, primarily because of externalities to knowledge and to capacities for individuals to find and to process information. Given gender roles and current market/policy failures, the social returns to human capital often may be relatively high for investments in females (King and Mason 2000).

2.1.3 Responsiveness to incentives created by markets and policies are broad and often substantial. Therefore, it is desirable that markets and policies create incentives for behaviors that are socially desirable and not sufficient, as in the earlier paradigm, that policy makers know shadow prices. Economic entities also adjust many or even all elements of their behaviors in response to changes. Therefore, anticipating full effects of policies or market outcomes on behavior is difficult because of such cross-effects. The impact of new technological options, for example, may increase the value of educated women in marriage markets if gender roles dictate that women play major roles in child education (Behrman et al. 1999).

2.1.4 Information problems are pervasive in a rapidly changing world so incentive-compatible institutions and mechanisms are desirable. Information is imperfect in general, information that policy makers/implementers have often is less and more dated than the information that individuals have who are directly involved in production and consumption of particular goods and services, asymmetrical information creates incentives for opportunistic individual behaviors that are likely to be socially inefficient and inequitable, and markets are relatively efficient in conveying certain types of information. Rather than attempting directly to regulate and monitor many micro activities related to the development process, governments more effectively can support institutions that are relatively effective in inducing desirable behavior. The oft-cited claim that an important aspect of the successful East Asian development experience has been outward orientation, for example, may be viewed in part as a mechanism for encouraging increasing productivity through forcing competition on world markets. Likewise, efforts to make markets work better through open and transparent bidding for governmental contracts, better market integration to lessen monopoly power, introducing voucher systems and decentralization of human resource-related services, eliminating governmental regulations on entry, improving communication and transportation and subsidizing or mandating information that has public goods characteristics all may have important effects in increasing efficiency.

2.1.5 Selective global and directed policy interventions that are 'market friendly' where there are market failures are warranted. Policies should: (a) maintain macroeconomic balance, (b) develop institutions, including property rights and related legal frameworks, so that investors have reasonable expectations of gaining returns from good investments, (c) encourage competition to induce productivity increases through an unbiased international trade system and through eliminating legal barriers and lessening transportation and communication barriers to

greater competition, and (d) use 'market-friendly' interventions that are transparent, rule-based, general and nondiscriminatory such as open auctions, vouchers, subsidies, and taxes to attempt to offset market failures (and directing such policies as directly as possible towards the market failures to limit unintended distortion costs). These considerations imply a critical, but also more selective role for government than in the earlier paradigm. Also involvement in these activities is not necessarily best accomplished by governmental direct production rather than taxes/subsidies and regulations concerning disclosure of private information.

3. *Current Controversies and Possible Future Developments*

Despite substantial current general consensus (Sect. 2), there is neither consensus on every dimension nor on how the paradigm is likely to change.

3.1 *Integration into the International Financial System*

International financial movements have expanded rapidly and can swamp foreign exchange movements from international trade. This may provide useful discipline for governments to keep their policies credible. But this also may result in enormous shocks, perhaps fueled by speculative bubbles, which present great difficulties for even the best of governments. The Asian financial crisis of the late 1990s intensified greatly such concerns. Considerable debate continues about the extent to which such problems can be lessened by greater transparency in developing countries finances, more restrictions on capital movements, appropriate sequencing of liberalization efforts with capital flows liberalized relatively late in the process, new systems to assure that developed country investors bear some of the social costs of disruptions originating in large international capital movements, and greater international insurance through international organizations (with attendant moral hazards of encouraging risky behaviors).

3.2 *Demographic 'Windows of Opportunities' and Aging Populations*

Waves of Malthusian overpopulation fears have featured prominently among noneconomists. But statistical analyses of relations between population growth and economic development do not find important long-run associations. However, recently developing countries are claimed to have transitory (but perhaps lasting several decades) opportunities because aging due to fertility reductions means that they have large working-age populations relative to younger and older populations. Some have attributed a substantial part of the high recent economic growth in some Asian economies to such a 'demographic bonus' associated with higher savings and labor force participation and lower health and education expenditures (Asian Development Bank 1997, Bloom and Williamson 1999). There are controversies about what conditions permit developing economies to exploit successfully demographic windows of opportunity to enhance development, rather than being hindered by faster increases in supplies than in demands for labor. Empirical associations for the 1950–1995 period suggest that the conditions embodied in the consensus that is summarized in Sect. 2 increase probabilities of being able to exploit demographic opportunities. Eventually aging populations will imply increased dependency ratios due to a larger number of aged individuals, which will raise issues about intergenerational transfers for retirees and increased health problems associated with aging. Projections suggest that average ages in most currently developing countries will converge substantially to those of developed economies by 2025, so demographic–development interactions will change further.

3.3 *Poverty Reduction vs. Growth*

The dominant view is that the most effective form of sustained poverty reduction is rapid development that exploits comparative advantages (perhaps including relatively large labor forces), though some safety nets are likely to be desirable for individuals who cannot participate or who suffer dislocations in adjustments towards sustained growth (e.g., Page et al. 1993). But others claim that there are substantial tradeoffs between poverty reduction and the dominant conventional wisdom, at least during transition structural adjustment programs (e.g., the UNICEF critique, calling for 'adjustment with a human face,' Cornia et al. 1987). There are inherent productivity-equity tradeoffs in providing safety nets because a sense of entitlement tends to develop that makes such policies hard to change (e.g., political responses to efforts to eliminate food and transportation subsidies) and because they may dampen incentives for work efforts through implying high effective marginal tax rates. Therefore, there is likely to be an ongoing debate about the extent to which such safety nets should be provided and exactly what forms they should take.

3.4 *Social Cohesion and Social Capital*

There is a growing perception that these are important factors in successful development efforts. If so, then

there may be important policy implications from the perspective of the currently dominant paradigm (Sect. 2) because factors that increase social cohesion and social capital are likely to have social returns beyond private returns and thus be under-rewarded by unhindered markets. Establishing the importance of such factors, however, requires the development of more careful integrated modeling/estimation approaches. Suggestive anecdotes and associations are currently available, but not persuasive systematic studies that lead to confident identification of causality in the presence of behavioral choices and unobserved individual and community characteristics.

3.5 *Paternalism/Maternalism, Individual Choice, and Endogenous Preferences*

In the immediate post-WWII dominant paradigm (Sect. 1) policy makers and analysts acted as if they knew what was best for the poor in developing countries. If the poor were perceived to hold the 'wrong' values (e.g., not working hard enough, wanting too many children, saving too little) it was deemed appropriate to ignore or to try to change their preferences. The current dominant paradigm places greater weight on individual preferences, at least in so far as they are manifested through responses to markets and policies (though limited resources limit the effectiveness of the poorest). There also is recognition of difficulties in making welfare comparisons if preferences are changed. Nevertheless, there are some who appear to wish to impose their values on others regarding, for example, appropriate gender relations. Such concerns raise the analytical question that also has been of increasing interest in general mainstream economics of how to model endogenous preferences and to include them usefully in applied analysis.

3.6 *Association between Economic Participation and Political Participation*

An important component of the current economic development paradigm is much greater recognition of active participation of individuals, which, together with discipline of competitive-like markets, provide checks and balances that limit predatory economic behavior. But is an essential component of successful development also a political system with checks and balances? Some argue that some of the most successful East Asian economic development experiences have been under strong autocratic governments (e.g., Korea under Park, China, Singapore). Others note that strong autocratic governments have not been a sufficient condition for successful economic development (e.g., Myanmar, Cuba, the Philippines under Marcos). This controversy about what forms of political systems lead most effectively to development is likely to be ongoing.

3.7 *Extent of Technological Externalities for Human Resources, Population Control, and Environmental Effects and Remedies for those Externalities*

Assertions are widespread that there are substantial positive externalities of human resources and negative externalities of population growth and economic growth on the environment. Yet empirical evidence regarding magnitudes and natures of such externalities is almost nonexistent, at times *a priori* arguments about what constitutes an externality are confused, and means sometimes advocated to address such externalities do not seem directed well towards the supposed sources of externalities nor do they recognize well the importance of incentives, so they may have substantial distortion costs. There would be high returns to persuasive systematic studies that lead to confident identification of the magnitudes of such externalities in the presence of behavioral choices and unobserved individual and community characteristics (e.g., Foster and Rosenzweig 1995).

4. *Conclusion*

The economics of developing countries was an integrated part of most major streams of economic analysis in the nineteenth and early twentieth centuries. But in the immediate post-World War II period, economic development was widely seen as sufficiently different in degree to be different in kind from mainstream economics for the developed economies. Developing economies were seen as having such imperfect markets and limited responsiveness to markets by private entities that effective development could be best pursued by (supposedly disinterested and very knowledgeable) policy makers using direct quantitative policies guided by planning models to industrialize in part by protecting their economies from the many negative effects of international markets. In the last quarter of the twentieth century, there was a radical shift in the dominant paradigm concerning economic development. This was in part due to a number of new systematic quantitative studies of a range of developing experiences, importantly including the unprecedented growth in a number of East and Southeast Asian economies. The dominant paradigm at the start of the twenty-first century emphasizes that there is considerable responsiveness to opportunities in developing countries so the incentives created by markets and policies may be critical, that development is much more than physical capital

accumulation and industrialization, that human capital and knowledge acquisition may be critical in the development process, that policymakers have limited information and may be rent-seekers, and that a much more nuanced understanding of the nature and response to market failures implies an important but much more limited and incentive-sensitive role for policy. There remain a number of current controversies, such as related to the appropriate degree of integration into global financial markets, the importance of some aspects of social cohesion and social capital, the relation between economic and political participation, and the nature and extent of alleged externalities and other market failures. But for the most part they are considered at least by economists within the framework of this paradigm.

Such a summary of decades of the evolving conceptualization of economic development into a few major paradigms, of course, suppresses considerable heterogeneities of perceptions and approaches among the many economists and policymakers concerned with economic development over the years. But it also captures major dominant features of the evolution of thought on economic development that originally was an integral part of the major approaches to economics, was increasingly separated from main-stream economics in the mid-twentieth century, and then has increasingly converged back with mainstream economics by the start of the twenty-first century. This latter convergence has occurred both because development economics has moved closer to mainstream economics with regard to emphasis on responsiveness to incentives, gains from greater market dependence and limitations of policy interventions and because mainstream economics has moved closer to development economics with regard to such issues as market limitations related to information problems and the broader political, social and cultural context in which economic analysis occurs and policies are made.

Development: Organizational

1. Introduction

Organizational development (OD) is a special interdisciplinary field focused on organizational change. It provides conceptions for understanding the logic of change as well as techniques and tools for managing the change process effectively. The major purpose of OD interventions is to overcome resistance to change and to encourage the willingness of organizational members to participate actively in the change process. As a discipline of social sciences OD has been criticized for lacking a sound theoretical basis and for misconceiving the nature of organizational change as exceptional projects in organizational life.

2. Historical Overview

In classical organization theory, the problem of coping with organizational change was not of much concern. Change basically meant reorganization and the critical activity was to determine the best organizational solution to master new situations. Realizing the new solution, if regarded as a problem at all, was seen as a problem of careful preparation and of giving the right instructions. After a brief period of tolerance, all employees were supposed to work according to the new organizational guidelines.

This traditional model, however, rarely proved to be a success. Organizational members notoriously resisted the new organizational design, unforeseen events rendered the design worthless, the change process came to nothing, etc.

Figure 1
Lewin's triadic episode of organizational change

The typical reaction to these irritations was to blame the plans for having been imperfect and to ask for their refinement. In most cases this actually made the situation even worse; the resistance became stronger, the rejections more sophisticated, etc. Although the problems of organizational change made themselves felt in practice, they did not gain the status of salient question in classical theory.

It was the behavioral sciences, especially the human resources approach, which made organizational change a problem in its own right and developed completely new approaches for its solution.

The impetus to establish organizational change as a field came from empirical studies finding that success in change critically depends on the attitudes of organization members as well as on the general mood towards the new design. This insight originated from studies on 'resistance to change.'

The initiative to study resistance to change, as well as the approaches on how to overcome it, dates back to Lewin (1958). Most salient are his seminal experiments on changing the aversion to specific foods. Group meetings and active involvement of group members proved to be the best way to change food habits. The foundations for what were later to become the 'golden rules' of successful organizational change (Lawrence 1954) have been laid in these studies:

(a) Broad information at an early stage and active participation in the change process.

(b) The group as an important medium (facilitator) for change: Change processes are perceived as less worrying in groups and generally are accepted more easily.

(c) Mutual cooperation among organizational members.

(d) A settling-down period at the end of the change process designed to institutionalize the changes that were carried out.

Lewin (1958, p. 210) later elaborated on these insights and conceived the well-known 'triadic episode' of successful change. The model builds on the idea of homeostasis and suggests a three-step procedure: unfreezing, moving, and refreezing (see Fig. 1).

The most important issue of the model is that organizations need an initial period of irritation in order to break up their habits and routines. Or as Lewin put it, organizations have to become 'unfrozen'; otherwise they are not likely to give up their equi-

librium position and to move to a new level. Changes tend to be short lived if there are no efforts to bring them to permanency. The new patterns, therefore, must be 'frozen,' the system has to settle down again and find a new equilibrium.

3. Organizational Development as a Discipline

Lewin's group experiments and the three-stage model finally boiled down to a special method (Laboratory–Training) designed to cope with behavioral and organizational changes in totally new ways. This new technology of group intervention and observation soon became very popular and built the core of the newly founded National Training Laboratories in Group Development. A series of other approaches emerged and also the facilitation and support of organizational change processes increasingly became a branch for external consultants. All these forces finally led to the birth of a new field, a special discipline in the behavioral sciences, called OD.

Among the other roots of OD, the 'Survey–Feedback' method is one of the most prominent. This approach makes use of attitude surveys and data feedback to facilitate change processes. All organizational members are invited to take part in the change process ('shared power approach'). The intention is to stimulate organizational members' interest in change, that is, to create a motivation to overcome the weaknesses of the present state. Lewin also pioneered this method.

Another, and closely related, historical root was the work of the Tavistock Institute (UK) which is anchored deeply in psychotherapy and group therapy (Bion 1961). The doctor–client consultation framework and the high professional demands which were later put on the change manager originate from this concept. Some prominence was gained from the so-called Tavistock Conferences, that is, leaderless group discussions designed to experience and to explore leadership, authority, and obedience. Tavistock started to transfer the clinical methods to organizational settings in the early 1950s.

Further roots of OD are the approach to job redesign and to the improvement of the quality of working life. Here again, The Tavistock Institute (of Human Relations) played a major role. Frame of reference is the sociotechnical systems approach; that is, a conceptual framework and an action research program which is devoted to meet both individual needs and technical demands (Rice 1958). The emphasis is on changing traditional organizational design towards group-oriented work designs giving organizational members more variety, meaning, and feedback in their work.

Later, the focus of OD was extended significantly. Additional approaches and new issues enriched the field and made it somewhat diverse (Cummings and Worley 2000). At the core of OD, however, still remain change methods and specific interventions at different levels of social systems.

4. Organizational Development: Conception

The field of OD is truly interdisciplinary in both focus and methods. Even though different perspectives exist on what OD is and should be, some overarching characteristics can nevertheless be identified (Cummings and Worley 1993):

(a) *System-wide effort*; that is, OD is being applied to a whole system (company, division, subsidiary, plant, etc.) and addresses comprehensively the change of both structure and behavior. The basic philosophy is that sustainable changes require the involvement of the whole system. Isolated small-scale changes are likely to fail. While OD aims at changing the entire system, the interventions address various levels: the individual, the group, intergroup relations, the whole unit, and interorganizational relations.

(b) *Planned organizational change*; that is, OD conceives change as a planned, systematic effort working on a long-range perspective.

(c) *Based on social sciences* that is, OD methods and procedures are derived from knowledge of various scientific disciplines.

(d) *Full cycle*; that is, OD includes all periods of a change project: its initiation (unfreezing), its realization (moving), and the subsequent stabilization (refreezing).

(e) *Change agent*; that is, OD projects are conducted by external professional consultant facilitators who are trained in the use of sophisticated intervention techniques and clinical methods. It is assumed that organizations often do not know what is wrong and they need professional help in diagnosing the problems and in overcoming the invisible barriers to change.

(f) *Top management support*; that is, commitment of top leadership is considered a precondition of any successful OD project. A commitment is expected in both paying attention to the change problems and giving the OD intervention a sense of urgency.

(g) *Shared power approach*; that is, the OD process is designed to involve all parties affected by the change project and to encourage participants to jointly develop new solutions.

(h) *Dual objectives*; that is, OD projects are intended to reach both organizational effectiveness and fulfillment of individual needs.

From time to time, new themes and fads were included in addition; for example, quality management, learning organization, transformational leadership, organizational culture, strategic vision, intercultural communication. The inclusion of these parts, however, never resulted in a paradigm shift or an essential theoretical revision. The overall framework basically remained the same.

5. Organizational Development Models

Various authors and consultants have developed comprehensive OD programs; among them four models are salient: (a) Survey-guided Development, (b) Process Consultation, (c) Grid Organization Development, and (d) Systemic Intervention.

5.1 The Survey-guided Development

This model is based on a multistep data feedback procedure (Likert 1967, Nadler 1977). After an orientation stage a standardized questionnaire is used to gain a comprehensive picture of the client organization's situation, its major problems, and their causes. The subsequent data feedback is used to determine what changes are required, how they should be reached, and what interventions are appropriate. The data feedback also aims at unfreezing participants and encouraging their willingness to take part in the change process. Follow-up surveys serve to monitor the progress of the OD process and to determine whether the change efforts did work. A somewhat similar abbreviated form of this model is the *Confrontation Meeting* originally developed by Beckhard (1967). Data collection and evaluation are conducted directly and in a condensed form (one day only). A meeting of all those involved is held to identify the major problems of the system. After a joint ranking of the problems the unit develops an action plan and establishes a system of periodical reports on the progress of implementation.

5.2 Process Consultation

This is a nondirective model for supporting the client organization in carrying out change processes, originally developed by Schein (1988). The process consultant helps the client organization to figure out what should be done to improve the situation. A process consultation project typically includes the following stages: Entering and defining the relationship, choice of setting and work methods, data gathering, diagnostic and confrontive interventions (e.g., through the use of feedback or coaching) by the consultant, evaluation of results, and disengagement. Due to its indirect character the results of process consultation are not predictable at the beginning.

5.3 Grid Organization Development

This is a highly standardized intervention program building on one basic conception; that is, an ideal managerial style with high concern for both people and productivity (Blake and Mouton 1969). The development contains six distinct phases: Grid Seminar, teamwork development, intergroup development, developing an ideal model for the whole organization, implementing the model, and examination of the organization's progress toward the plan.

5.4 Systemic Intervention

This is a more recent OD model that builds on family therapy and systems theory. At the core stand paradoxical transactions as invisible barriers to organizational change thereby drawing on the Double Bind Theory of schizophrenia (Watzlawick et al. 1967). The transformation of these ideas into an organizational development approach originally was initiated by the Italian psychotherapist Selvini-Palazzoli and her Milan School. This approach focuses on the hidden rules and games in organizations. In many cases this agenda is pathological in character, its circular reinforcement is likely to consume a lot of the system's energy and to evoke aversions against innovation and change. As a consequence, this approach refrains from any participative change design. Rather, it addresses the hidden agenda and its paradoxical architecture. OD interventions to open the system are conceptualized as a counter paradox (Selvini-Palazzoli 1995). Consultants try to identify the ruling paradox of the pathological system and to dissolve it by implanting counter paradoxes. Systemic interventions mostly result in 'explosions'; that is, the whole architecture of pathological rules breaks apart and unpredictable new patterns emerge.

6. Organizational Development and Beyond

The OD approach in the beginning was received enthusiastically in both theoretical and practical fields but later became increasingly criticized. The most common objection is to the underlying promise of harmony of interests; that is, to meet always both employee needs and the organization's efficiency goals. Critics doubt whether there is always such a win–win solution for interest conflicts. This argument leads into a broader criticism that OD shows a general naïveté towards organizational power structures. It is said that OD can never to be neutral because it always operates within power structures and is likely to become part of micropolitics.

Another objection relates to hidden influences. It is suspected that OD-intervention techniques leave considerable scope for manipulation because 'clients' understand their logic and their implications at best partially. Organizations and their members, therefore, may become objects of uncontrollable influences (Neuberger 1991, McKendall 1993). Also, the financial dependence of the change agents is emphasized. It does not allow them to play the alleged neutral role in the change process. They are paid by corporate

management and, therefore, are expected to pursue the interests of this group.

In addition to these objections a lack of sufficient theoretical foundation has been diagnosed (Beer 1990). The focus is on techniques and instruments but there is no compelling overarching conceptual framework; the empirical evidence is small.

From a practical point of view, OD projects rarely reach the status of a core activity. In most cases, it is considered as an interesting extra-activity, but not as a necessary element of corporate management.

Recently, a new debate on the nature of change came into the foreground of academic and practical interest (Brown and Eisenhardt 1997, Schreyögg and Noss 2000). It goes beyond the criticisms mentioned above and fundamentally challenges the paradigm of organizational change underlying OD models. An in-depth analysis of the OD approach revealed three highly questionable assumptions on the nature of change.

6.1 Organization Change is an Area for Specialists Only

The strong psychological or even psychotherapeutic orientation of OD led to the implicit assumption that organizational change can be achieved by specially trained professionals only. The organization or department is put into the role of a client or even a patient who badly needs a 'doctor' to master the challenge (illness) of change.

This perspective puts managers into a paradoxical situation. They are expected to rationalize and improve procedures and structures, but the important function of putting improved systems into action is said to be an exercise of which they are not capable. Change, however, nowadays is ubiquitous in organizations. It is a challenge for every manager and cannot be reserved for specialists only.

6.2 Organizational Change is a Clear-cut Process

In OD, organizational changes are conceived as clear-cut processes with a clearly defined beginning and end; processes that are separated from the ordinary organizational processes. This view essentially misconceives organizational processes. Problem-solving processes largely overlap and interpenetrate. This is the result of the fact that organizatons are, after all, to be managed in a complex and ambiguous context. Change processes are an integral part of the system's general dynamics; they are not separate entities or events. The definition of a change period is always an artificial construction and does not reflect the (actual) flow of events.

6.3 Organizational Change is an Exception in Organizational Life

In OD change is given a special status, that of an exception. It is conceived of as an extraordinary phase, which is threatening and somewhat chaotic. Changes come close to disturbances likely to undermine the rational order and system of rules. The guiding idea is the stable state of equilibrium. Stability stands for efficiency, rationality, and harmony. Organizational members are assumed to be strongly in favor of order and stability, and to feel helpless and frightened in the face of change. These assumptions fly in the face of nearly all more recent models of *flexible organizations*. Modern organizations are conceived as *inherently restless* and fluid in nature. The most recently discussed conceptions of a *Virtual Organization* or a Modular Organization point in the same direction. All these conceptions fundamentally challenge the view of organizational change as an exceptional state.

7. Outlook

The critique of the basic assumptions showed that a new conceptual orientation is needed which allows for overcoming the episodic view of change and offers a template to understanding change as a *continuous challenge*. The conception of the learning organization seems promising for providing such a reorientation. This concept builds on the idea that organizations operate on the basis of dynamic and not stable elements. The elements constitute and are constituted by communication. Organizational change occurs within streams of learning processes that build the basis of the organization's activities and strategies. By implication, the learning organization no longer experiences the issue of change as an exceptional stage; rather learning and change become common issues in the system's operations. Portraying organizations as self-reflexive learning systems makes it difficult to find reasons why an organization should suddenly cease to learn; that is, stop cognitive enacting, information processing, and knowledge development.

While the basic OD concept of change seems to be questionable, it is not necessary to give up all those well-developed OD methods and experiences. OD methods can be reframed. The mission of OD could be reformulated to help identify communication disturbances and to eliminate learning blockades (Argyris 1985). The purpose of the OD methods would then be to support the processes of learning to learn, and also to guarantee the competency of the system. They would become endogenous system catalysts that can help the ongoing learning processes to function smoothly.

Development: Rural Development Strategies

Discussions of 'development' often confuse two meanings of the word. Development can be understood as the expansion of capitalist forms of production and exchange—i.e., as capitalist development; it can also be understood as an intentional and organized intervention with specified objectives (Cowen and Shenton 1996). These are two quite different meanings and there is no necessary relationship between them. Development interventions *may* be attempts to foster capitalist development, and they *may* (intentionally or not) have the effect of fostering such capitalist development. But many interventions do not have such intentions or effects, and at the very least often change the particular forms taken by capitalist political economy in specific places.

These observations apply equally to discussions of rural development. That is, some discussions have understood rural development as the further unfolding of capitalism in rural areas; others have focused on policy and project interventions in rural areas that aim to foster socio-economic change and human improvement. Among the latter work, some authors have understood such interventions as attempts to deepen rural capitalism (and particular relationships of power and dependency understood to go with it); others have aimed to understand the conditions under which progressive social change might derive from such interventions. As a result, under the broad banner of rural development studies, one encounters work on: theories of peasant economy informed by Chayanov and Marx (e.g., Harriss 1982); policy analyses informed by both dependency (de Janvry 1981) and neoclassical theory (Eicher and Staatz 1984); critiques of rural development discourses drawing on poststructural theory (Ferguson 1990; Escobar 1995); feminist interpretations of gender bias in the institutions and languages of rural development (Deere and Leon de Leal 1987); analyses of the encounters between development professionals and rural people drawing on both actor-oriented sociology (Long and Long 1992) and pragmatist approaches (Chambers 1983); and so on. In short, there is diversity in both the theoretical approaches taken and the substantive topics pursued.

Still, within this broad field of study, one can discern some pattern. First, writing on rural development has often followed broader trends in social theory. Second, theory and practice have informed each other. Policy innovations have often been informed by particular bodies of theory; they have then gone on to generate new bodies of research and theoretical development as scholars begin to reflect critically on these shifts in practice. Third, debates on theory and practice have been informed by broader shifts in the global economy. This reflects the interactive nature of the relationship between rural development as capitalist development and rural development as intervention. This is a relationship in which political economy clearly patterns practice, and where practice not only reproduces the broad structures and effects of capitalist political economy, but can sometimes change them. The remainder of this article tries to capture

some of these interactions. It focuses on rural development over the last three decades of the twentieth century.

1. A Brief History of Rural Development Policy: 1970–2000

While colonial administrations pursued programs to foster rural economic change (Cooper and Packard 1997) both in their colonies as well as in their own countries, the apogee of rural development interventions came in the 1970s with the invention of 'integrated rural development programs' or IRDPs. An important factor in the expansion of rural development programs during the 1970s was the push by the then President of the World Bank, Robert McNamara, radically to redirect the Bank's finance towards poverty alleviation. As poverty—at that time—was deemed a primarily rural phenomenon, IRDPs became one of the principal means through which the Bank increased its poverty lending. In some cases (especially in Latin America), such initiatives came in the wake of programs of land reform and redistribution, and aimed to increase yields on the properties of new post-reform landowners; in other cases, they were targeted at an already existing peasantry.

While these programs had many components, they aimed above all to increase the physical and economic productivity of smallholder productions systems. Agricultural development was therefore a central theme, and IRDPs often disseminated high yielding crop varieties, promoted agrochemical use, provided credit, built irrigation systems, and in general fostered agricultural modernization. Subsidiary components included support to health and education, rural road building, and—occasionally and marginally—efforts to strengthen rural people's social organizations.

In retrospect, many IRDPs were conceived on the basis of insufficient knowledge of rural conditions: they were too large, designed too hastily, and were often hijacked politically (de Janvry 1981). They became highly bureaucratic, overly complex, and often ineffective affairs (Grindle 1986). Worse still, the era of large scale rural development programs also spawned a series of 'development disasters.' Examples here include programs of small farm development and colonization in the Amazon basin (which often led to deforestation and usurpation of lands from indigenous groups), and a range of programs introducing Green Revolution and other modern crop technologies into environments for which they were not appropriate.

It is important to note that the urge for rural development was not only a phenomenon of broadly capitalist economies. Socialist regimes also launched programs, often linked closely to large-scale and state-led efforts to organize collective forms of agricultural production and marketing (e.g., Soviet kolkhozes, Cuban state farms, Tanzanian ujamaa). While the wider policy and political context of these programs clearly differed from that in capitalist economies, in many respects rural development programs in these two broad contexts shared many similarities: the state played a strong and central role in their implementation; agricultural modernization was a primary objective; and the rural economy was seen as a producer of surplus to be transferred for investment (via the state) in industrial and urban activities. In all cases, these programs worked with highly simplified views of rural economy and society: simplifications that were necessary in order to make rural areas legible and manageable by a centralized state (cf. Scott 1998), even though they meant that the programs would inevitably encounter problems and often engender resistance (Scott 1985).

While this mix of routine problems and stunning failures did not necessarily undermine the broader argument for poverty-reducing interventions in rural areas, it did nourish a body of critical writing aimed at trying to understand why it was that such programs had taken the form that they did, and had such mixed results on the ground (see Sect. 2). Parallel to this more analytical writing, a more applied literature has also developed over time, asking many of the same questions, but with different languages and with the primary goal of rethinking appropriate strategies for rural development (see Sect. 3).

2. Theoretical Approaches to Understanding Rural Development

Just as the 1970s were the high point for large-scale rural development programs, so too was the period of the 1970s to mid-1980s one of particularly vibrant intellectual production on rural development. Much of this work was driven by the empirical observation that the great investments made by governments and international agencies in land reform, integrated rural development, and the Green Revolution seemed to have had little impact on rural poverty, nutrition, and welfare—and that in some cases they had indeed had quite negative effects on rural people and their environments.

This was a period when dependency theory, world systems theory, and modes of production theory were very influential in writing on the 'Third World.' Not surprisingly these same theories were marshaled by many to try to explain this limited impact. Alain de Janvry's (1981) landmark study of rural development in Latin America stands out in this context—indeed, it has had intellectual impacts well beyond Latin America. De Janvry argued that in practice rural development and land reform were rarely intended to do much more than further the maintenance and expansion of dependent capitalist economies. In those

cases where they had more radical objectives, he suggested, they were quickly reined in by dominant national and international social forces. De Janvry argued that the underlying logic of Latin American economies was one of 'functional dualism'—a dualism in which a core of capital accumulation benefited from and required the existence of a rural economy that supplied cheap food and cheap temporary labor. Indeed, this argument had wider resonance, paralleling for instance those made by scholars of Southern Africa who insisted that the South African economy required the existence of labor reserves based in rural areas to provide cheap labor to the urban, mining, and industrial economy. Rural development was, in these frameworks, understood primarily as a mechanism through which these functionally dual relationships were maintained.

In Africa, a similarly formative piece was Henry Bernstein's (1978) notion of the 'simple reproduction squeeze' in which African peasantries are enmeshed. Bernstein suggested that peasant economies in Africa were slowly decapitalized by adverse terms of trade, themselves grounded in exploitative social and political relationships. This implied that interventions that did not address these underlying social relationships would have little effect on rural poverty. A significant debate in this early period was that on the question of 'urban bias.' While scholars such as Michael Lipton argued that rural areas were underprivileged largely because policy was biased to urban areas, more critical scholars insisted that any such policy bias was in turn a reflection of more deeply seated, and far more pervasive, sets of sociopolitical relationships that sustained the privileges of classes (rather than cities) and that constituted the primary obstacle to any significant change in rural areas (Corbridge 1982). Work such as that of Bernstein and Byres was emblematic (and formative) of a broader body of work in this period that linked rural development to theories of peasant economy (Harriss 1982). This work hooked up to the broader debates within peasant studies on how to understand the peasant mode of production (a debate crystallized in the creation of the *Journal of Peasant Studies*).

Neoclassical approaches to rural and agricultural development shared many similar concerns to those of political economic analysis (Eicher and Staatz 1984). Questions of peasant economy (in particular agricultural decision making), policy formulation, rural markets, poverty, and food security were thus prominent in this literature. Perhaps the principal difference was that such approaches were less concerned with the social relationships underlying decision-making processes, market transactions, and policy formulation and implementation. Put another way, they were less concerned with questions of social power, and even less with theories of social power. Analytically, this led to analyses framed in terms such as peasant rationality, or market and policy distortion; practically it led to recommendations that in earlier periods laid considerable faith in government as an autonomous and potentially beneficent social force, and in later periods have emphasized the beneficial role that liberalized markets (of diverse types) ought to play in rural development.

In frameworks such as these, the desirability of rural capitalism is not an issue. Indeed, what is deemed a problem with rural development when viewed within more critical frameworks, is deemed its overall purpose when viewed neoclassically. As they emphasize notions of efficiency over issues of equity, empowerment, or rights, neoclassical approaches have increasingly argued that significant parts of the rural population ought leave agriculture, and in many cases rural areas more generally. The contemporary challenge of rural development when viewed this way is therefore to facilitate this outward movement of people, and to foster a more efficient allocation of resources to those producers able to use them most effectively. The empirical support for such a position appears to come from recent research that suggests that many peasantries are already 'disappearing' (Bryceson et al. 2000) even if much of this research would not invoke a neoclassical interpretation to understand such steady disappearance (Bebbington 1999).

Falling somewhere in between such political economic and neoclassical positions, approaches drawing on institutional economics have become more popular in the 1990s, if more so in academic than policy realms (Carter 1997). Such approaches have also emphasized the need to understand rural markets (and household decision making) as embedded in social institutions, and emphasize the extent to which these institutions structure patterns of access to and participation in such markets. The implication is that rural development strategies ought to work on these institutional questions, a lesson not unlike that of political economy approaches. However, institutional economists insist on using the more formal methodological procedures of economics and econometrics to address these questions, and also hold back from assuming that any particular social theory (of power, class, race, or otherwise) can necessarily explain the particular forms of embeddedness of given markets.

Certain sociological and anthropological approaches have also emphasized such institutional questions, though they hold questions of politics and power at the forefront of their analyses; indeed their concern for these questions predates the emergence of such a concern in economic analyses of rural development. While the 1960s saw work on the management of rural development, it was perhaps only in the 1970s and especially the 1980s that a more coherent body of analytical work on the institutional and organizational dimensions of rural development began to emerge (e.g., Esman and Uphoff 1984). Much of this was also inspired by the question: why had land

reforms and rural development programs been so disappointing? Work drawing on Weberian notions of the state began to demonstrate the effects of bureaucratic structure, incentives, and politics on the implementation and outcome of rural development programs (Grindle 1986, Hart et al. 1989). Other work, drawing more on theories of peasant resistance to development suggested that much of the explanation lay in the ways in which rural people subverted institutional interventions designed to foster forms of modernization that people did not desire (Scott 1985).

Though focusing on different parts of the rural development puzzle, taken together, these two approaches helped open up a body of work that has emphasized questions of human agency in rural development. Some of this work, drawing more on notions of resistance, has emphasized the extent to which rural development programs constitute negotiations between state and citizen, and between different notions of modernity (Long and Long 1992, Peet and Watts 1996). Other authors have linked a concern for social power with the goal of devising improved management systems. Much of this work has focused on the roles of particular types of organization in reworking power relationships between rural people, the state, and market, and in simultaneously initiating and managing rural development programs that might be more poverty oriented and responsive than were the IRDPs. Local organizations (Uphoff 1992), nongovernmental organizations (Farrington and Bebbington 1993) and social movements (Peet and Watts 1996) have figured prominently in this work—linking up discussions of development with broader theoretical debates on civil society, power, and identity.

These concerns for questions of power and identity also underlie a more recent line of analysis focusing on questions of discourse in rural development and using poststructural approaches to address ways in which power is embedded in the very ways in which rural development is talked about and conceptualized (Escobar 1995, Ferguson 1990). Such authors have also focused attention on the often-underemphasized theme of culture in rural development: both by addressing how notions of development are now often constitutive of both rural and institutional cultures, and by interrogating the cultural underpinnings of the very concept of rural development. This approach has linked discussions of rural development up with debates in Foucauldian social science, and has been particularly prominent in anthropology, geography and the subfield of political ecology, which has been one of the most vibrant areas of research on rural development in the 1990s (Peet and Watts 1996). While such poststructurally informed work has been criticized analytically (especially for its weakness in addressing issues of agency and of variation) and practically (for its failure to address how the practice of rural development might be made more effective), it has been the most fruitful and dynamic of the subfields of rural development research in the closing years of the century.

Running across these broad theoretical traditions one encounters a series of more substantive foci. One of these has been an ever-increasing attention to issues of gender and rural development, and the frequent exclusion of women from the fruits of rural development, sometimes as a direct result of the forms taken by projects and policies (Boserup 1970, Carney and Watts 1990). Much work on rural development and peasant economy remained largely silent on issues of gender—a silence that became even more untenable the more it became apparent that the rural economy could only be understood by making explicit the shifting roles of and relations between women and men (Deere and Leon de Leal 1987, Carney and Watts 1990). The central importance of women as rural producers has also become ever clearer as periodic out-migration from rural areas continues to increase. A concern for gender issues has cut across a range of theoretical positions: it has appeared in both neoclassical and Marxian analyses of household decision making and bargaining; in more institutionally focused analyses of 'women-in-development' and of women's social movements; and in poststructurally informed analyses of the ways in which rural development discourses create particular notions of gender, and then act upon these.

Given that rural development is closely linked to production, and that much rural production depends directly on natural resources, environmental issues have also been a recurrent theme in analyses of rural development. Perhaps more significantly, many of the 'disasters' of rural development have involved grave and negative impacts on the environment, spawning many critical studies. More generally, analyses of rural development experiences with irrigation, dams, agrochemical use, soil erosion, and high-yielding crop varieties have inspired work that has made critical contributions to the more general discussion of sustainability and sustainable development (Adams 1990, Peet and Watts 1996).

Finally it ought to be noted that, while much of the analytical (and practical) work on rural development has focused on Africa, Asia, and Latin America, there has also been important work conducted in the USA, Europe, and post-reform Soviet Union. Much of this work has drawn on similar theoretical currents, though, arguably, it has been more descriptive than the often quite theoretical work conducted in the 'Third World.' One of the important contributions of this body of 'First World' work, however, has been to raise questions about the longer-term future of rural societies and environments as agricultural production becomes ever less important within national economies, and as the agricultural labor force continues to decline. This work has addressed some of the ways in which rural landscapes change as they move from

being areas of production to areas of reproduction, leisure, and consumption; it has also addressed the acute poverty of those areas (in the developed world) that have simply become unnecessary to the wider economy. Though apparently peculiar to developed-country settings, these issues will become relevant for other regions of the world. For even if small farmer production becomes increasingly uncompetitive in the global economy, rural areas will not disappear. In some cases, they will be populated by some of the most excluded groups in society, unable to find work in a rapidly modernizing economy—in other cases they will be colonized by retirees, commuters, tourists, conservationists, and new enterprises. Such demographic, economic, and social shifts will continue to raise acute questions for the ways in which societies understand themselves, their lifestyles, and their environments, and, indeed, for the different forms that modernity will take in the post-peasant era. Rural development is likely, then, to continue generating important theoretical and empirical debate that will have relevance beyond the purely 'rural.'

3. *Applied Research and Rural Development Strategies*

Alongside these vigorous theoretical debates, a lively and creative body of applied research has also evolved over the last thirty years, dedicated to addressing issues of rural development strategy. While there are some journals dedicated to applied research in which this material can be published, much output remains in institutional publications, working papers, and gray material produced by nongovernmental organizations, nonprofit and international research centers, some university institutes, and development organizations. Though applied in focus, and often undervalued by academia, such documents have often been at least as important as more formal academic publications in pushing forward debates on themes as varied as definitions of poverty, participatory and populist approaches to development, systems analysis in rural areas, indigenous technical knowledge, sustainability, and empowerment. Furthermore, perhaps because much of this work has been conducted from within nongovernmental organizations, it has also raised important questions about relationships between state, market, and civil society in rural development programs, and as a result about the institutional foundations of sustainability.

Of the various themes that have been dealt with in this work, two merit particular attention. The first has been the discussion of rural development administration. A long-standing discussion, this has helped illuminate the different ways in which state, nongovernmental, for profit, and popular organizations might participate in the management and implementation of rural development. An overarching and recurrent theme in such discussions has been how to deal with the complexities and uncertainties that inhere in rural development, and how to design and structure management systems that can best address these complexities without becoming bureaucratic and top-heavy, as so many IRDPs did. One of the general themes to emerge from this sustained inquiry is that increased popular participation must be central to rural development: both in order to handle these complexities, as well as on its own democratizing merits.

The second body of work worthy of note is that which has attempted to understand the logic of rural production, livelihoods, and ecologies in order to elaborate more appropriate forms of rural intervention. In the 1970s, systems-based analyses of agriculture and rural development occupied a prominent place in this applied research. The more that this work made explicit the complexity of these systems, the more it bled into work on popular participation in rural development. The implication, perhaps more implicit than explicit, was that in the face of such complexity, effective management of rural development necessarily had to involve the knowledge of local populations and other local actors. Thus, while earlier statements suggested that the only way in which development interventions could be adequately fine-tuned was through comprehensive *ex ante* systems analysis, later work concluded that such analysis could never be sufficiently comprehensive. Instead, it has suggested the need to shift emphasis from exhaustive *ex ante* analysis to more systematic participation in the process of managing, implementing, and governing rural development.

These reflections from applied research have thus linked discussions of rural development with a far longer-standing concern in activist social science for questions of critical pedagogy, popular education, and empowerment (Freire 1970, Fals-Borda and Rahman 1991). Indeed, beyond the specific themes addressed in such applied work, perhaps more important are the questions of epistemology (and methodology) that it has raised. Applied researchers have, in effect, suggested that practice generates different forms of knowledge from those that emerge from more basic social research. As such they have echoed questions raised by poststructural approaches to rural development (and knowledge more generally) in suggesting that researchers need to be far more modest in the knowledge claims they make, and that the process of generating knowledge about rural development (as theory or as strategy) must be far more inclusive and participatory than it has traditionally been (Blaikie 2000). The relationship between research and practice, and theory and praxis, in rural development is likely to be a hotly debated, and fruitful, theme for many years to come.

Development: Social

If it is true that concepts lack meaning in and of themselves, but rather acquire significance in the context of a set of concepts articulated in what is commonly understood as a theory or a paradigm, then at least as it has been used in the literature the concept of social development is somewhat of an exception. This is true when one compares social development with the notion of economic development, about which there has existed a clear consensus both around a set of powerful theoretical referents (Keynesianism, the neo-classical school, or Marxist radicalism) and around how practical objectives are to be achieved. If the comparison is extended further to encompass political development, the absence of such consensus is mitigated somewhat by the clarity of the goals and objectives to which the concept refers: the construction of the nation state and of democracy. Yet neither of these referents, theoretical nor normative, has played a similar role in the use of the concept of social development.

Social development thus has been a concept with multiple meanings, encompassing at least three connotations developed extensively in the literature pertaining to the social sphere. At its most basic level, social development simply suggests improvement in the conditions and quality of life of the population. Greater levels of wealth, technological advancement, and public policies permit people to live better, to consume more, to feed themselves better, and to get

sick less frequently. This idea of social development is inextricably linked to the idea of economic and material advance of human society. A second approach emerges from considering social development in terms of the distribution of the wealth that societies generate. Here, the economic dimension still constitutes a powerful factor in determining social development, but the latter occupies a space of its own, in the distributive sphere. Finally, a less normative or economistic perspective on social development identifies the latter with the processes of social differentiation and social complexity associated with the capitalist and industrial transformations that gave rise to the modern world.

1. Sketching a Genealogy

In the aftermath of the World War II, and at the height of the period of worldwide decolonization, an important body of literature was produced as a result of concern with economic growth, equity, the establishment of democratic regimes, and the achievement of social order and national autonomy. The basic objective of this literature was to discover appropriate paths through which new nations could advance toward these goals. The term social development originates during this period, and is anchored in an international context characterized by profound transformations of the world order and system of nations.

The notion of social development is as recent as the notion of development itself, and thus stands in contrast to the historical tradition of studies of economic growth and social change carried out primarily in the eighteenth and nineteenth centuries. In the past, attempts to characterize the principal traits of capitalism of that era employed a discourse that relied on different terms. The international system of nations was conceptualized—depending on preferences or discipline—in terms of various binary categorizations: rich and poor countries; industrial or agrarian societies; traditional and modern societies; classic capitalism and late capitalism; or colony and metropolis. Only since the middle of the last century did there emerge an increasing perception that the world was divided in terms of concepts of relative development: of development and underdevelopment. With that shift came the introduction of notions of developing countries. It was during this period as well that researchers elaborated distinctions between center and periphery to understand the insertion of countries into the world economy. This approach was developed subsequently in significant directions by the writings of the Economic Commission on Latin America (ECLA), and contributed to the development of dependency theories (Pinto 1979, Cardoso 1977). Because the concept of social development has its origins above all in the literature produced in, or concerned with, the development of new nations, much of that literature was published in Latin America or in academic and political circles animated by the problems of the great transformation brought about by the economic and political reorganization of the international system of nations. Beginning in the late 1940s, the thinking of ECLA played a notable role in this process. Especially influential were its founding ideas, developed by Raul Prebisch following publication of his classic 1949 article 'Estudio Economico de America Latina.' (See also CEPAL 1989, Gurrieri 1979.)

2. Social Development and Developmentalism

As noted at the outset, it is useful to distinguish social development as a body of concepts and theory as used in academic circles from its prescriptive or normative meaning directed toward action or policy ('planning,' to use the terms of the era). Strictly speaking, there is no theory of social development or similar body of conceptual thinking. The notion of social development formed part of the more general and prevailing idea that economic development was normatively charged. Indeed, this concept of social development originates amid a climate of failure of the assumptions of classical economics regarding social and economic change in late capitalist countries. In particular, it reflected a response to the findings of studies of international trade by such authors as R. Nurkse, R. E. Baldwin, and the Manchester School, or the notion of the 'big push,' rooted in the ideas of H. Ellis (Rosestein-Rodan 1954, Ellis 1961). At the same time, in addition to being a body of concepts articulated in the form of a paradigm, economic and social development was constituted in an ideology known at the time as developmentalism (Hodara 1975). Transforming the objective of development into ideology served to offer a complex system of beliefs that explained social and political arrangements in the world and in society. It thus legitimized and rationalized behaviors and social relations, at the same time that it served as a base for solidaristic and collaborative forms of action motivating individuals to undertake certain kinds of actions. The power of the ideology reflected its capacity to provide meaning to the relationship between circumstances experienced by individuals and those affecting the nation as a whole. Prospects for the eventual improvement of the status of individuals in society could not be separated from the situation and status of the country in the international system.

But if social development had no single meaning from an academic point of view, the elaborations on the concept represent conceptual tributaries of a long tradition of studies and elaborations on social change or social progress. These ideas were central to the thinkers of the nineteenth and early twentieth

centuries, and later would foster formulations of social modernization theory in its structural functionalist versions or in *dependentista* currents.

To a greater extent than the great evolutionary interpretations of Comte, Morgan, or Spencer, or the visions of progress advanced by Condorcet or Saint-Simon, the intellectual currents that situated social change in the context of development were more specific and revived the legacy of a more recent sociological tradition (Nisbet 1966). Especially important was Durkheim's basic concern with the effects of labor and social differentiation on moral density. That relationship was expressed in the tensions of passage from mechanical solidarity to organic solidarity, in the polar structures of community and society of *Gemeinschaft–Gesellschaft*, and in the transformation of small, primitive, traditional, homogenous societies and primary social relations toward their social opposite, as formulated by F. Tönnies, or in the economic sociology of Max Weber on the evolution of the capitalist spirit and the inevitable progress of rationalization and bureaucratization of Western societies; in the process of transformation of authority and autonomization and objectification of the status described by Simmel; or in the sociology rooted in the Marxist tradition and the theorists of conflict. Yet it was Modernization theory, anchored in the work of Parsons, and later in developmentalism, that proved of greatest influence in the analysis of social development in Latin America. Indeed, this is true to the extent that is frequently difficult to distinguish the concept of social development from that of social modernization (see Germani 1963, Moore 1969). In turn, dependency paradigms, particularly in the versions put forth by G. Frank and T. Dos Santos, were centered more in the economic and political spheres than in the realm of social processes.

In its initial formulation, the objective of social development formed part of an optimistic vision of the future of the new nations. Consistent with acceptance of that vision were the two other great goals to be achieved, one at the level of economic development and the other at the level of politics. The perception was that in one way or another, albeit with disjunctures or frictions and with transitory tensions produced by the unequal advance of different dimensions of development, new nations—poor, unequal, repressive, violent, and dependent—would move gradually toward societies characterized by welfare, equity, order, democracy, and autonomy. This evolution was believed likely to follow a path not very different from that of Western societies in Europe and the United States. The literature of the 1960s on social and political modernization was impressive and engaged the talents of diverse students of sociology and political science who shared a common interest in revealing the paths that would permit 'peripheral' societies to overcome their pasts and incorporate themselves into the core (e.g., Almond and Coleman 1960, Lipset 1981, Pye 1962, Deutsch 1963, Almond and Powell 1966). Nevertheless, not all were entirely optimistic, as noted by Huntington (1996). During an initial phase there predominated the view that the objectives of social, political, and economic development were inherently compatible; in a second phase, emphasis was placed on the intrinsically conflictive nature of the three goals; and a third phase was marked by arguments concerning the imperative of generating policies capable of reconciling the goals.

3. *Stages in Latin America*

It is not difficult to distinguish a first phase of the Latin American literature, in which social development was presented as a non-specific set of ideas subordinate to economic development. In the initial writings of ECLA, the terminology 'economic and social development' refers to a single thing. In practice, however, the basic assessment of ECLA stemmed from critical analysis of economic questions and of international trade during the late nineteenth and early twentieth centuries. The criticism of the passive role that classical international trade theory assigned to countries of the periphery was that this effectively denied them a capacity for dynamism and autonomy over the long term (Nurske 1963, Perroux 1958, Baldwin 1956, Barré 1958). Central to this interpretation was the concept of deteriorating terms of trade, which were understood as systematically unfavorable to the periphery. This was seen as the cause of the vulnerability of the productive systems of underdeveloped countries and of the power that traditional groups linked to primary sector exports acquired in those countries. The resulting call for inward-oriented development, based on a push for import-substituting industrialization, productive diversification, and the formation of a modern national entrepreneurial class, was expected to augment national decision-making capacity vis-à-vis the international system. As a natural consequence of these transformations, achievement of several other development goals would be possible: political democratization, cultural independence, and social integration. During this initial phase, social development was understood essentially as improvement in the conditions of life and as a passive dimension of the development process. It is no surprise, then, that the titles of works of the era made reference to 'the social consequences of economic development' or 'social aspects of economic development' rather than to social development *per se*.

Within ECLA itself, the work of J. Medina Echevarria (1955, 1963), of unequivocally Weberian roots, opened important spaces for the consideration of the social as a cause and not merely as a consequence of economic development, particularly with regard to the study of social, cultural, and political prerequisites for economic development and for its emphasis on

linking sociological variables to economic theory. Nevertheless, his ideas developed in parallel to those of the mainstream, and were never incorporated into the core of ECLA thinking.

During a second phase, coinciding roughly with the end of the 1960s and through the 1970s, with the advance of studies in comparative politics and society, doubts began to emerge about the possibility that countries in the periphery would manage to move simultaneously along a path of social, economic, and political development. The notion of compatibility or harmony among these development goals was increasingly questioned. During this phase, research produced in core countries and in other regions of the world had a greater impact on the elaboration of Latin American thought at the same time that ECLA lost its leadership role in thinking about development.

The redefinition of the concept of social development, and above all reconsideration of its role in the general process of development, was influenced by disenchantment with the failure to fulfill expectations. Especially troubling were low levels of economic growth, persistent political instability, the presence of authoritarian regimes, and high levels of indigence and poverty derived from the incapacity to reduce indices of social inequality. The apparent incompatibility of objectives was articulated in the questioning of much of the conventional wisdom about development, in particular with regard to such topics as the relationships between growth and equity (in contrast to the classic thesis of Kuznets; in the controversy over the relationship between democracy and growth (an idea deeply rooted in liberal thought); or about the role of poverty, indigence, and inequality as limits on economic development. The literature on the topic adopted a vision that, if not more pessimistic, advanced at least a more complex and cautious view about the ease of transformation (see Furtado 1996, Olson 1963, Flanigan and Fogelman 1971, Berger 1976, Hewlett 1980, Huntington 1996). At ECLA publication of *El Cambio Social y la Politica de Desarrollo Social en American Latina* (United Nations 1969) reflected renewed attention to the social question, which would become the core of subsequent activities developed by that institution's Division of Social Development.

During a third phase, the temporal boundaries of which are less precise, the term 'social development' became detached from any single current of ideas. In part this was because developmentalist ideology had lost its influence and in part because the confidence deposited in technocratic actions had given way to consideration of alternative logics of an economic, social, and political nature. At least four factors account for these changes. One is the exhaustion of the import-substitution or inward-oriented development model, which proved incapable of sustaining economic growth in the region and inducing the promised social and economic development. Another is the renewed strength of liberal economic orientations that portray the market as the locomotive of history, and that curtail the basic functions of the state expressed in the developmentalist ideology. A third reason is of a different nature, and concerns the sources of discourses about growth. Multilateral financial organizations, and particularly the Inter-American Development Bank and the World Bank, became two of the most important institutions for generating ideas and proposals about the development of peripheral countries, and followed a line consistent with the Washington Consensus and with neo-liberal orientations. Meanwhile, from the United Nations, and in particular from the United Nations Development Program (UNDP), there emerged alternative proposals and the notion of social development. A fourth reason is the competition to which the idea of social development was subjected by a growing array of new themes, concepts, and approaches which broadened and legitimized the inclusion of social goals in development. This competition was reflected in the introduction and increasingly widespread use of such notions as 'sustainable development' and 'human development.'

With regard to the social, there was a contradictory movement of differentiation and fusion. On the one hand, the notion of social development fragmented into multiple sub-goals and in the application of middle-range theories around newly legitimate issues and demands (women, environment, youth, ethnicity, culture, human rights, etc.). On the other hand, the concept of social development—replaced by human development in the UNDP version—implies a return to an integrated vision of the economic and the social. Debates had come full circle, as traditional sets of indicators designed to characterize the evolution of countries once again included economic variables (for example, GDP per capita) alongside social variables (for example, life expectancy at birth). This took place following differentiation between the systems of social indicators and the systems of economic indicators, a distinction that emerged with the 'Scandinavian movement' of the 1960s, and that would be adopted later on by the United Nations Research Institute for Social Development (UNRISD) and ECLA.

C. H. Filgueira

Development: Social-anthropological Aspects

In the years after World War II, development primarily meant economic development: directed change leading to greater agricultural productivity and industrialization. In later years, development moved from a preoccupation with economic growth to considerations of equity, sustainability, quality of life, and popular participation in decision-making. Development is in most cases funded and directed by external donors, governments, and nongovernmental organizations (NGOs).

1. *Development and Anthropology*

In the late 1940s and early 1950s, the US introduced the 'Point Four Program,' which resulted in the employment of several anthropologists, especially in Latin America. Erasmus (1954) provides a good early account of the desirability of taking into account the needs and capabilities of people, versus the perceptions of planners and administrators.

The British Colonial Service employed several anthropologists to help with administration. Gulliver (1985) gives an honest and revealing account of his period in East Africa as a Government Anthropologist, showing that ethnographic research can be used to inform social policy in a manner that made it more appropriate to local needs, and thus more acceptable to local people.

Here we shall be concerned mainly with the period from the early 1970s, when there was a disillusionment with the development policies of the previous two decades, which had been characterized by huge projects and centralized planning and guided by theories of evolutionary modernization and the 'trickle-down effect.' As Hoben (1982, p. 350) wrote, 'the ethnocentric tech-fix orientation of the dominant development paradigm' was challenged. Many indices—the rural quality of life, infant mortality and life expectancy, per capita GNP, food production—had not only failed to improve, but had often fallen. In addition, it was clear the gap between rich and poor—both between and within countries—was rapidly growing. This resulted in major shifts, in the early 1970s, beginning with two of the main donors, the World Bank and the United States Agency for International Development (USAID), redirecting their development projects more specifically at the poor (or even, 'the poorest of the poor'). USAID introduced a series of measures, under its 'New Directions' guidelines, which required that all projects should have a Social Soundness Analysis, to examine the probable consequences of each proposed project for the supposed 'beneficiaries' (or 'the target population,' an infelicitous phrase that is sometimes used).

Not all administrators welcomed these innovations, complaining that they wasted time and were superfluous; few administrators had training in the social and cultural dimensions of development, which they tended to ignore. The World Bank also introduced several sets of guidelines, e.g., for dealing with resettlement, where those resettled are supposed to receive 'land for land,' not a cash compensation. Host governments ('the borrowers'), powerful players on the development stage, have often been slow to implement the guidelines.

With the new emphasis on development for the poor, who were the people who knew anything about the poor? The development 'experts'—economists, lawyers, and administrators—

> were far more accustomed to working with the aggregated data of national accounts then with the nitty gritty, nonquantitative, imprecise, fuzzy and seemingly subjective data of individual farms, household and small rural communities (Horowitz 1999, p. 12).

So anthropologists, who *do* have a good understanding of poor peoples' lives, began to play increasingly significant roles on the development stage.

2. *The Anthropology of Development*

Anthropology is involved with development in two quite distinct ways: (a) the anthropology of development, 'an anthropological analysis of development as a cultural, economic and political process, rather than anthropology in action' (Gardner and Lewis 1996, p. vii); and (b) anthropology in action, or 'development anthropology.' (Cochrane (1971) was one of the first to use this term in print). Grillo (1997, p. 11) summarizes seven main themes in recent work in the anthropology of development. These include: an increased focus on culture and social relations; 'opposition to the marginalization of indigenous peoples and their knowledge'; emphasis on participation and empowerment; 'cynicism about the aims and practices of development'; and 'advocacy of alternative ways of doing both development and anthropology.'

Anthropologists have provided a critical understanding of the nature of development. This is illustrated by Scudder's and Colson's extensive, longitudinal studies of resettlement, among the Gwembe Tonga of Zambia (Scudder 1999), and by analyses of livestock and pastoralism by Baxter, Dyson-Hudson, Horowitz, Little and others (despite nearly one billion dollars having been spent on pastoral projects in East and West Africa, very little has been achieved, mainly because the planners ignored the detailed knowledge that pastoralists have of their environment, and failed to see the logic behind their transhumance). Similarly, numerous detailed investigations of agriculture have included explanations of the significance of household composition, non-farm income, adaptive strategies, decision-making, and mixed farming.

Anthropological analysis has also had a major impact on forestry. The Community Forestry Unit of the Forestry Policy and Planning Division of FAO has been directed by anthropologists (Marilyn Hoskins and Katherine Warner) for an extended period. It has provided global leadership on incorporating gender analysis, conflict management, participatory processes, and other social dimensions of development into natural resource management and policy. Other anthropologists, such as Michael Dove, have had a major influence on the social analysis of forestry.

The need for long-term research has been successfully demonstrated in a few cases, although there is still a long way to go to persuade all major agencies of the value of such studies. Where such studies have been promoted, they have led to clear and effective policy recommendations. Also, anthropologists are increasingly being appointed as team leaders of multidisciplinary teams, in examples of successful interdisciplinary cooperation. Such appointments have sometimes led to different emphases, more sensitive to the local people.

If they are to be truly effective in development, anthropologists should be involved in *all* stages of the project cycle: project identification, project design, project appraisal, project implementation, project monitoring, and post-project evaluation. Normally project appraisal occurs after the donors and host governments have agreed that the project will go ahead. The anthropologist often becomes involved only at the appraisal stage, and is likely to be seen by administrators as a spoiler, threatening timely implementation by pointing out flaws in the original design.

Despite the above examples, it seems that the major donors have been stronger in rhetoric than in action. For example, in the year 2000, the fraction of World Bank spending devoted to rural development and agriculture, the arenas within which anthropologists have been most active, is down to 7 percent from an earlier high of 40 percent. This hardly signals a clear commitment to 'poverty reduction.'

3. *Should Anthropologists be Involved in Development?*

Grillo (1985, p. 28) notes three perspectives on development. First, there are the 'principled rejectionists,' who think that anthropologists should not be involved—period. For a presentation of this approach, see Escobar (1991). Using a Foucauldian style of analysis of discourse, Escobar argues that development, because of the unequal power relations and control of means of production, is hopelessly biased in favor of western donor nations, and that it does not, and cannot, meet the needs and aspirations of the

poor. Escobar tends to treat development as homogeneous, ignoring the vast diversity that occurs. Little and Painter (1995) provide a good summary of Escobar's views, with an effective rebuttal. Arce and Long (2000, p. 23) state that the postmodernists (like Escobar) argue 'that development is no more than a discourse justifying control and surveillance of people's practices by powerful institutions.' See also Ferguson (1990) who concludes that development is 'a puzzle,' after teasing out the implications of a project in Lesotho. Hobart (1993) provides a measured critique of development; an edited collection of essays (Rahnema and Bawtree 1997) provides vigorously antidevelopment views. Second in Grillo's classification are the 'monitorists,' those who study the anthropology of development, but do not wish to be actively involved. The last category is the 'reformers' (or 'conditional reformers') who are prepared to be directly concerned with development policies and projects.

The view from the academy has varied over the years. Until the 1970s, development anthropology tended to be marginalized, or ignored, at major universities. This attitude arose partly from a general conservative view that the proper business of academics was 'pure' research, and that applied work was somehow tainted. But all development anthropology contains some theory, even if it not explicit. In addition, some scholars shared Escobar's views that development was a spurious neocolonialist plot, and to be avoided; these views hardened after the exposure of some very murky, clandestine anthropological collaboration by anthropologists with the US government, in Latin America and in South-East Asia in the 1960s.

By the 1970s, changes began in university anthropology departments, in part as a response to the failures of conventional development practices, and with the realization that anthropologists indeed had contributions to make. There was also a more general awareness that anthropology had an important part to play in dealing with current contemporary problems, including poverty, human rights, landlessness, environmental degradation, and, particularly, inequality of incomes, influence, and power. By now, most university departments have at least one, often several, faculty members who specialize in development, offer courses on the subject, and are engaged in actual development projects. A subsidiary reason for this change may be that development offers a good chance of employment (either at a university or with a development agency)—an important factor in days of a scarcity of academic appointments.

4. *The Role(s) of Anthropology in Development*

Horowitz (1999, p. 14), who has written extensively on this topic, points out the major contributions that anthropologists have made to our understanding of involuntary resettlement, the informal economy, internal differentiation of rural societies by wealth, age, or gender and by a host of other important factors of rural communities.

Hoben (1982, p. 370), writing from his experience as an anthropologist and as a senior administrator with USAID, claims that

> development anthropology has unique perspectives on development planning … it focuses on culturally patterned perceptions, goals, interests, strategies and organization of the intended beneficiaries including elites and administrators, whose cooperation is a prerequisite to change.

Elites function at the national level, where they may have enough power to influence development aid in their favor; they also appear, albeit in more modest guise, at the local level, where again they have the influence to shape the direction of development projects, in order to benefit themselves.

Grillo (1985, pp. 6–7) presents a useful classification of nine types of development anthropology, ranging from fundamental research to revolutionary or liberation anthropology, and shows the possibilities and problems involved when anthropologists become involved with advocacy, or human rights issues, or when they become brokers.

5. *Donors, Hosts, and NGOs*

Both the multilateral agencies—The World Bank, The United Nations Food and Agriculture Organization (FAO), the United Nations Development Fund (UNDP), The Consultative Group on International Agricultural Research (CGIAR)—and the bilateral ones—USAID, the British Department for International Development (DfID), the German GTZ and the significant Scandinavian organizations—are now employing anthropologists in increasing numbers. The World Bank, for example, employed 64 anthropologists in 1995 (Horowitz 1999, p. 10). Michael Cernea, until recently Senior Sociologist at the World Bank, deserves much of the credit for the hiring of anthropologists (Cernea 1991). In addition to the in-house appointments, many anthropologists are hired on short-term contracts as consultants. However, the numbers are not a true reflection of their influence: most anthropologists are in relatively junior positions; many function more as administrators than as anthropologists, although they may be able to use their anthropological backgrounds to influence decisions; and they often in effect become captured by the culture of the institution. Nevertheless, some anthropologists, in some situations, have been influential in changing the emphases of development programs and policies.

The 'host country governments' are generally unenthusiastic about the involvement of anthropologists

in development, preferring rather to see the funds flow, without any hindrance caused by social or environmental concerns. Professional development 'experts,' both in donor organizations and in host government service, tend to see anthropologists as tiresome and romantic figures, who delay development by their ill-considered wish to preserve a local conservative culture. In addition, anthropologists are accused (with some justification) of not understanding the mechanisms and culture of the institution, of having no regard for time, of being unable to write 'useful' reports, and of being poor team players. Having spelled out some main stereotypes held about anthropologists, it should be said that there are many honorable exceptions—professionals from other disciplines who fully understand the potential contribution of anthropology to development, and who strive to promote it. Administrators also tend to distrust the poor, the supposed 'beneficiaries,' who are often seen as superstitious peasants and the main obstacles to change. There is seldom an appreciation of indigenous knowledge, and of the finely tuned strategies employed by local people, simply in order to survive.

NGOs play an increasingly important part in international development, sometimes acting on their own, often acting on behalf of the major donors. Starting as charity or relief agencies, they have rapidly become effective professional development agencies. As part of this change, the NGOs have made much use of anthropologists, many of whom are employed full-time, with others being engaged as consultants for specific projects. NGOs have at times become involved in advocacy, creating a delicate situation in terms of their legal charitable status. At present, there is some tension between the large 'Northern' NGOs, which have until recently dominated the field, and the increasing number of 'Southern' NGOs, which are challenging the older agencies. The latter seldom use anthropologists, both for lack of funds, and, more particularly, because the leaders claim that as local people themselves, they know their own culture, and have no need of outside advice. This may be questionable, when such officials are often separated by virtue of their education and background from the poor people who are the beneficiaries. However, some indigenous groups, such as the Cree Regional Authority of Canada, now routinely hire anthropologists to work with them on land claims and other concerns.

6. *Domains*

Development anthropology has been concerned with a wide range of topics, especially related to management of natural resources—agriculture, livestock and pastoralism, fisheries, forestry, wildlife, irrigation; settlement and migration; rural-urban linkages and markets; ethnicity and the resolution of social conflict; disaster prevention and relief; health and AIDS. In all these areas, the main emphasis has been on the alleviation of poverty, and on making development more effective, more relevant to people's needs, and more sustainable.

Ethical dimensions are always present when a development anthropologist decides which project(s) s/he should be involved in. Resettlement projects, for example, usually cause tremendous damage to the people resettled, including the 'grieving for a lost home' syndrome. But if an anthropologist is involved, their sufferings may be reduced, their concerns publicly aired. Is this adequate justification for taking part?

7. *Participation*

One of the main trends in development is decentralization, whether in the form of democratization, decentralizing or devolution of services and authority, comanagement arrangements, etc. This all increases the scope for local involvement, yet substantial barriers often exist due to gender, class, caste, race, or other variables. One of the enduring challenges for anthropologists is to widen the scope for participation. Coinciding with increased participation there is often increased conflict, with a growing involvement by anthropologists in conflict management.

Much attention has been paid to the need for local people to participate in development projects that affect them, which ideally means that they should be consulted about the design, implementation, and evaluation of projects. Formidable difficulties present themselves, apart from resistance from administrators, many of whom regard participation as a romantic fallacy. Communities are seldom homogeneous, so who is truly representative?

Pottier (1993) presents a collection of papers that 'illustrate a variety of organizational responses to the discourse of participative development.' Contributors favor a 'client-focused, participative philosophy' rather than a top-down western model. They emphasize the managerial capacity of the vulnerable groups, who lack access to and control over resources. Pottier stresses the need for flexibility and sensitivity; 'the social worlds within which development efforts take shape are essentially fluid.' And what is needed is an ethnography of the total project, not just of one group (Pottier 1993, pp. 7, 31).

8. *Training*

In addition to the standard academic training, anthropologists who wish to work in development need an awareness of a wide range of factors, most of which

will best be gained with hands-on experience. Typically, they will need to have, first, a sound knowledge of the region where the development is proposed. Topical/general expertise must be grounded in detailed knowledge of one people and their area. Inevitably, development anthropologists work in many regions, making up in their broad comparative knowledge what they lack in detailed local information. This has led to their being accused, by more conservative antidevelopment anthropologists, of not being qualified to advise on projects outside their own specialized geographical areas.

Second, they will need an appreciation of the major technical aspects, so that at the least they can communicate with the technical specialists.

Training is also desirable for aid administrators, many agencies having organized successful workshops to heighten sensitivity to basic social issues. Government employees also benefit from such training; for example, FAO has arranged a series of workshops to demonstrate to forestry officials why they should take into account the culture and knowledge of local people, before planning any forestry projects. This means dealing with key issues of poverty, gender, land rights, and tree species preferences.

9. *Accomplishments*

What has development anthropology achieved? Although there is a long road ahead, significant contributions have already been made since the 1970s. Regarding development, anthropologists have succeeded, at least partially, in persuading those who direct development at the major agencies that projects will be more likely to attain their goals if they are planned, implemented, monitored, and evaluated with attention to—and, if possible, with the participation of—those local people who are intended to be the beneficiaries. There is a greater awareness of the strengths of local people, of their knowledge, their adaptive capacities, and the diversity and richness of their cultures. More attention is now paid to poverty and inequality, and to the interplay between local level and global factors. Both development planners and anthropologists now have a clearer and more sophisticated idea of how power relations affect people at all levels. Planners have been encouraged to challenge basic assumptions, and to look at alternative approaches. Institutions like the donor agencies are conservative, so the challenges and alternative approaches must be handled with delicacy, so as not to upset the guardians of tradition in the agencies. Anthropology is by now an integral part of development, both in theory and in practice.

Anthropology itself has also been changed, with a widening of the horizons to include not only particular local communities, but looking also at the macro aspects, seeing how global issues reach out and affect the furthest corners of the modern world. More emphasis is placed on modernity, nationalism, ethnicity, power, and, essentially, on class relations.

10. *Future Directions*

It is difficult to predict what lies ahead for development anthropology in the twenty-first century, or for anthropology itself. Periodically, the major anthropological associations organize conferences to discuss (usually gloomily) the future of anthropology, but past pessimistic forecasts have seldom been proved correct. Whatever future the discipline of anthropology has, an emphasis on development will certainly be a major component. '… the cutting edge of scientific anthropology today is the anthropology that is being practiced by persons who are passionately committed to human rights, cultural pluralism and environmentally and socially sustainable development. For anthropology to survive as meaningful discipline, it must focus on the very issues that engage those of us who identify our work as *development* anthropology. Both academic and practical social anthropologists must understand the process of incorporation of agrarian societies into the world of political economy' (Horowitz 1999, p. 11).

It is more difficult to predict what future directions development will take. In the 1990s, there has been a noticeable lack of enthusiasm for development aid, with many national contributions falling to dangerously low levels. Africa, in particular, which has been the recipient of a large proportion of all development aid, has been dismissed by *The Economist* as a hopeless case—because of the seemingly endless series of intractable wars and conflicts, natural disasters, weak administrations, and corruption on a large scale.

In order to achieve their potential, development anthropologists need to sharpen their methodology, aim for greater analytical clarity, be more rigorous, and be more theoretically sophisticated—which entails proceeding along the paths already used and expanding the vision. 'What is needed is a more systematic way to bring these experiences into an empirically informed version of critical theory that advances our understanding of the human species and its diverse wants and needs' (Horowitz 1999).

Arce and Long (2000, pp. 24, 27) advocate an actor-oriented approach, which emphasizes 'the intricate interplay and joint appropriation and transformation of different bodies of knowledge … the critical task of development anthropology is to develop methodologies and theoretical interpretations of different knowledge interfaces inherent in intervention processes and local/global change.' Researchers should adopt a reflexive approach, to include their own encounters with other actors in the development arena.

Finally, Scudder (1999)—probably the most effective contemporary development anthropologist, as far as influencing policy is concerned—draws from his own views and those of 53 other anthropologists to ask the question: 'The emerging global crisis and development anthropology: Can we have an impact?' Scudder concludes by making 'five proactive suggestions as how we can put our knowledge and discipline to work':

(a) identify the key problems that we have the expertise and responsibility to address—for example, among Scudder's respondents, the most important topics were poverty, globalization, and increasing marginalization;

(b) better integrate development into the curriculum of anthropology departments;

(c) 'bring our expertise to the attention of the public and policy makers'; this should include emphasizing the limits as well as the potential of development anthropology;

(d) 'include more generic research that addresses major global problems and the linkages between them';

(e) cooperate with ecologists in public education, and in influencing local, national and international policy makers. Scudder hopes that 'anthropologists—with their peerless awareness of cultural diversity in time and space, and their understanding of how symbols can influence behavior—(can) work with ecologists to translate what we know into a vision for the future.'

Most writers on development anthropology agree that this is an exciting juncture in the world of development, and that despite the formidable problems posed by the nature of development, anthropologists do have much to offer in this field.

D. Brokensha

Development: Socioeconomic Aspects

Introduction and Overview

Although the concept of development first entered the vocabulary of social scientists and policy makers in the 1950s, as we enter the twenty-first century roughly half of the planet's six billion inhabitants remain mired in poverty, lacking access to resources that readers of this encyclopedia would deem basic to human well-being. At the same time that the gap separating rich and poor countries is widening, inequalities are growing within many societies, in North and South alike. Under the circumstances, it is no surprise that economic and social development occupy the attention of social scientists from a number of disciplines, from

anthropology to economics, political science to sociology. Yet despite the intractability of poverty and exclusion—the very circumstances that development is meant to overcome—there remains no consensus concerning precisely what development is or how it should be analyzed. Nor is there agreement about how it might best be achieved in different settings during the twenty-first century, or even whether the concept of development affords a useful lens through which to consider improvements in people's lives. Indeed, at the close of the twentieth century some scholars dismissed 'development' as little more than a discredited remnant of Cold War era policies designed to induce impoverished peoples of the 'Third World' to adopt ways that were often at odds with their interests and with their cultures (Escobar 1995).

Even among social scientists who retain a commitment to development, the term has taken on a variety of meanings, and has motivated inquiries employing vastly different theoretical frameworks. While 'development' may be the concern of macroeconomists modeling the impact of trade liberalization on national growth rates, it may be equally central to ethnographers seeking to reveal linkages between the protection of cultural diversity and the survival of agricultural practices deemed crucial to maintaining biodiversity or to ensuring local production of critical foodstuffs. Despite the semantic overlap, and the likelihood that macroeconomic policies impinge upon the decisions of farmers to plant one crop or another—or to migrate to overcrowded cities that lack the infrastructure to accommodate them—dialogue is at best weak among researchers operating across such broadly different levels of analysis.

Most currents of social scientific research now agree that development refers, ultimately, to improvements in the conditions of life for groups of people experiencing relative deprivation, whether they be located in a particular village, urban metropolis, country, or subnational or transnational region. Efforts to promote development may focus on the entirety of a population, or may be targeted to address needs of specific groups that are deemed especially vulnerable, or whose welfare is perceived as potentially generative of multiplier effects, i.e., whose improved welfare is deemed likely to enhance the life chances of the community as a whole. Thus, peasants, shantytown dwellers, women, or ethnic minorities may merit positions of privilege in considerations of development on grounds that their needs are especially pressing. Similarly, given their potential role in promoting growth or employment, micro-entrepreneurs, managers of competitive firms, or foreign investors may also be central to analyses of development.

Amid continuing disagreement concerning the appropriate scope of analyses of development, there is widespread accord that development concerns trajectories of change, encompassing movement from circumstances of relative hardship and deprivation toward qualitatively improved conditions of life. Those who effect measures to promote development may or may not be the intended beneficiaries of those efforts, but whether development is pursued through interventions by external agents, such as development assistance agencies, or through initiatives of the targeted communities themselves, it is a process that involves social actors. Indeed, to the extent that particular trajectories of economic change are known to correlate strongly with societal characteristics, development increasingly is understood as a set of processes that reflect underlying social dynamics of the territories in which it takes place.

Development implies increasing the volume of available resources, and thus is associated powerfully with economic growth. For many years, widespread scholarly acceptance of the so-called Kuznets curve (Kuznets 1955), according to which inequality expands sharply during initial phases of economic growth and declines steadily upon achievement of substantial industrialization, motivated many development economists to disregard or tacitly advocate economic inequality. More recent research has established a far more complex relationship between growth and distribution, however, suggesting in some instances that a relatively equal distribution of assets is conducive not only to rapid economic growth but also to patterns of growth that reinforce equality (Stallings et al. 2000). Partly in keeping with these findings, and as a result of ethical and pragmatic concern about the plight of impoverished people, at the beginning of the twenty-first century development typically refers not only to economic growth but also to the distribution of income among different segments of the population and, more broadly, to enhancements in quality of life. Thus, alongside the achievement of higher incomes, development is intended to reduce poverty, improve health and nutrition, prolong life expectancy and afford opportunities for education. By some accounts, and for a growing scholarly literature, development encompasses political objectives, such as expanded individual freedoms and greater civic participation, and environmental ones, such as community access to natural resources and protections against ecological degradation.

Of course, these economic, political, and societal goals are not obviously compatible, and as Gereffi and Fonda have noted, '[T]he multi-dimensional nature of development, and the fact that these desired objectives do not necessarily occur together, help to account for some of the … tradeoffs in … development outcomes' (1992). Arguably, this multidimensionality lies at the root of divisions that often limit productive debate about development, but that in some instances, by contrast, have made studies of development especially fertile ground for cross-disciplinary innovation.

The remainder of this article sketches further the evolution of social scientific thinking about development. After tracing movement away from the

conviction that 'all good things would go together' in tandem with economic progress, the article highlights currents of research that illuminate connections between characteristics of social processes and the nature of development outcomes. It concludes by noting promising trends and future challenges for research on development.

1. *From Economy-centered Analyses to Plural Conceptions of Development*

Early twenty-first century preoccupation with the social aspects of development stands in stark contrast to perspectives held widely during the initial decades following World War II. Espousing an underlying idea of development that can be traced as far back in Western thought as Hegel and Marx, who shared a conviction in the inexorable progress of human history toward ever greater levels of perfection, modernization theorists believed that the advanced industrial countries of Western Europe and North America represented the logical end-point toward which the former colonies of Africa, Asia, and Latin America would advance inevitably (Leys 1996, pp. 4–5). Early thinking about development thus posited that properly balanced macroeconomic policies and functioning state institutions would facilitate a relatively seamless evolution of 'backward' nations toward the prosperous and peaceful conditions achieved by economically developed countries.

While the almost universally disappointing experience of postcolonial economies served to undermine the model long ago, confidence in such unilinear progress has disappeared even in the prosperous countries of the North, where deindustrialization and increasing social polarization have eroded the sociopolitical consensus that characterized the period of postwar growth. And despite the often dramatic expansion of industry and rapid urbanization in parts of the former Third World, the economic and political inequalities of the past have not only been slow to disappear but often have actually grown worse in conjunction with these very processes of modernization. These trends have been exacerbated further by growing discrepancies between supply and demand of natural resources needed to assure communities of the ability to satisfy their basic needs.

Dependency theory, the principal alternative to the modernization school as a paradigm for analyzing development, has hardly been proven more prescient. To be sure, the dependency critics were not unjustified in contending that deeply embedded structures of discrimination reinforced the subordinate position of peripheral economies vis-à-vis the so-called core countries. However, they erred in their identification of the particular mechanisms—such as the supposedly deteriorating terms of trade for primary product exporters, emphasized by Raul Prebisch and his followers—through which this process was sustained. Moreover, as evidenced by the significant degrees of industrialization that were achieved in parts of Latin America and Asia, they failed to grasp the degree to which developing economies could advance despite the disadvantageous conditions they confronted (Evans 1979). In particular, dependency analysis was called into question by the considerable success of export-oriented growth in several East Asian countries, which contrasted markedly with the failure of development strategies predicated on isolation from the very global market that *dependentistas* held to be the primary impediment to development in the periphery (Haggard 1990).

Indeed, variations in the development experiences of different parts of the North and South testify to the degree to which the impacts of the international context on particular communities, nations, and regions are contingent on factors that transcend inherited conditions or positions in the world system. Understanding of the strikingly diverse development experiences of apparently similar countries and regions since the 1980s requires analysis of the microfoundations of distinctive trajectories. Structural inequities have by no means disappeared from the scene, but they have taken on new forms, and reflect complexities that are not clarified sufficiently by the sweeping categories of traditional theories of dependency or of the world system.

Moreover, for dependency theorists, as for modernization analyses, development was understood at the level of states and was analyzed through macro-level policies and institutions. The particular societal configurations of developing countries were of little interest to these analyses of developmental impasse, nor were the strategies of social forces or their fate as a result of distinct development trajectories a major concern. As Leys (1996) has pointed out progress, or more frequently stagnation, was deemed a function of underlying structures of interaction operating above and beyond the micro- and meso-level processes that would be of concern to subsequent generations of social scientists concerned with development.

Confidence in the grand theoretical frameworks of modernization and dependency had already weakened by the mid-1970s, when the impact of oil shocks, declining faith in the capacity of economic growth to reach the majority of the world's poor, and debates about ecological limits to growth combined to shift the emphasis in development circles away from large-scale, state-oriented modernization efforts toward localized strategies for meeting the needs of the world's poor (Sutton 1989). The World Bank's 1973 call for targeting development efforts to the 'poorest of the poor' catalyzed a shift in focus away from growth and toward issues of redistribution and equity. Perhaps resigned to the likelihood that significant portions of the globe would remain trapped in low-growth situ-

ations, the concern of policy makers turned to enhancing the well-being of communities that were destined to miss out indefinitely on the postwar vision of modernity and prosperity. This in turn led to increasing emphasis on community participation in development. Whether labeled 'farmer-first,' 'bottom-up,' or 'grassroots' development strategies, the emphasis here was on decentralization, localization, and the satisfaction of basic human needs for food, shelter, health, and security.

Absent expectations of significant increases in wealth, provision of adequate nutrition, sanitation, housing, and health care, and in some instances assurances of minimal incomes and educational opportunities came to be perceived as central objectives of development policies. While such measures as the rate of increase in per capita income retained their traditional appeal for researchers and practitioners, alternative indicators of development gained ever-broader acceptance. The physical quality of life index (PQLI), for example, used by a variety of international agencies to inform their development efforts, sought to measure the overall well-being of particular communities and countries. Incorporating indicators of health, nutrition, and literacy as well as income levels, such measures were acknowledged increasingly as more accurate yardsticks of development than were the more traditional macro-level indicators that focused on economic growth, industrialization, or urbanization.

While the state was sometimes viewed as a potential provider of goods and services required for poverty alleviation, international development agencies increasingly bypassed developing country governments, choosing to rely instead on the mediation of international and local nongovernmental agencies. This trend gained steam during the 1980s, a decade marked by the international debt crisis in Latin America and the implosion of postcolonial states in parts of Africa and elsewhere. Influenced by studies that emphasized the economic distortions effected by rent-seeking elites in command of predatory states (Bates 1981), conventional wisdom increasingly abandoned the notion that central states had the capacity or inclination to ameliorate the hardships faced by most of their populations. Rather, faith was placed in the operation of more-or-less unfettered markets, and in the benefits that market-driven growth could bestow upon societies whose potential for growth had been stymied by inefficient state institutions (Williamson 1993). Accordingly, multilateral institutions and Western governments advocated structural adjustment programs and sharp reductions in the economic role of the state in development countries.

The so-called neo-liberal trend coincided, albeit somewhat awkwardly, with an equally anti-statist notion that development entailed the empowerment of communities and individuals themselves to undertake the development 'project.' The emphasis on local autonomy and grassroots participation provided a useful corrective to top-down development strategies of the past, and engendered significant improvements in efficiency and equity in many settings (Tendler 1997). Yet in most of the periphery, declines in state spending on health, education, and social welfare took a severe toll on living standards, particularly among the poor, as local institutions were given responsibility for tasks without enjoying corresponding increase in their access to resources, or as supply of these public goods was simply transferred from the public to the private sector.

Nor were criticisms of the laissez-faire approach limited to its impact on equity, since a worsening of extreme poverty has been demonstrated to have adverse ecological consequences as well (Martinez Alier 1991). Left solely to the vagaries of the market, limits on pollution, deforestation, soil erosion, and other environmental hazards cannot be ensured. Such considerations emerge as integral to analyses of development that emphasize linkages between the welfare of communities and their access to natural resources. By the end of the 1980s, understanding of these linkages as well as growing scientific and public concern over processes of global environmental change (such as ozone depletion) combined to foster greater emphasis on development strategies that could accommodate the needs of the present generation without jeopardizing the availability of resources for future generations. Much of this work concludes that a high degree of equity and local control over resources are necessary, if not sufficient, preconditions for environmentally sustainable development. In some instances, the argument coincides with an emphasis on empowerment of subordinate groups, ranging from indigenous peoples to women to subsistence farmers, who are portrayed as threatened by a singular focus on economic growth, which is in turn characteristic of the visions of modernity and progress that have provided the justification for much of what we have come to think of as development. It should come as no surprise, then, that proponents of this view often question the desirability of retaining development as a societal objective, and in any event call for 'an alternative modernity,' a modernity fundamentally skeptical of economic growth (e.g., Martinez Alier 1991).

2. *Emerging Trends and Future Challenges*

The need to comprehend the development implications of processes of globalization occasioned a revitalization of development thinking toward the end of the twentieth century. By virtually all accounts, the unprecedented mobility of goods, knowledge, and peoples across national borders, and increasingly transnational flows of capital and information have made the traditional boundaries established by states far more permeable. While some regions, and some

social sectors, appear well situated to benefit from the new circumstances, others face growing hardship, and the boundaries between prosperity and decline often do not coincide with the borders of countries. Research on the changing structure of industries illuminates both the increasingly global scale of economic activity (e.g., Gereffi and Korzeniewicz 1994) and the significance of community dynamics for encouraging cooperative ties conducive to successful adaptation to rapidly changing markets (Piore and Sabel 1984). This literature calls into question the traditional focus on national policies to promote economic growth or to alter prevailing patterns of distribution. Understanding the ways in which different states respond to similar pressures differently (and with varying degrees of success), remains important (Evans 1995), yet state-level analyses of the political economy of development must be supplemented by attention to the ways in which relationships among local and nonstate actors can evolve in such a way as to encourage successful economic adaptation (Doner and Hershberg 1999).

Given strikingly different trajectories of change among apparently similar communities, social scientists have devoted increasing attention to the role of social capital and social institutions in determining prospects of different groups to prosper. Here, the focus has been on the relational dynamics that characterize specific socio-territorial spaces, and that nurture levels of trust without which economic actors cannot work together to insulate themselves from market risks (e.g., Perez Sainz 1996). While a concern with social capital and institutions is shaping a good deal of innovative work in sociology, anthropology, and political science, economists are also advancing influential perspectives on the societal underpinnings of growth. Endogenous growth theorists highlight the mutual connections between rapid economic growth and relatively equal distribution of resources, including such assets as health and education. In this manner, by the end of the twentieth century, equity was increasingly accepted by economists as a foundation of economic growth, and as such has become part of even the most mainstream of development agendas. Similarly, informed by the work of economic historians, researchers in both political science and economics are developing fresh approaches to the study of economic institutions and their relationship to market processes (Williamson 1985).

To the extent that development consists of more than economic growth, and also encompasses movement toward the creation of greater opportunities for political participation, fuller representation of societal interests, and the protection of individual and collective rights, it is crucial to understand how political and economic transformations alter the linkages between state and society in different parts of the world. Whether social actors organize themselves on the basis of class, community, ethnicity, or other principles is of fundamental importance for any comprehensive treatment of development, just as it affects the likelihood for sustaining particular political coalitions, some of which, in turn, appear more likely than others to be able to sustain different strategies of development (e.g., Nelson 1994, Haggard and Kaufman 1995).

The importance of community in considerations of development is underscored by the growing consensus among scholars and practitioners that successful development—in the North as well as in the South—hinges on the strengthening of local institutions, be they community development banks, schools, or health clinics (Ake 1991, Tendler 1997). The importance of neighborhood characteristics—whether for the sociologist studying the experience of growing up in impoverished urban slums, or for the anthropologist concerned with how kinship networks help attenuate the effects of agricultural shortfalls—underscores the degree to which development-related research is concerned with micro-level phenomena. Whether in connection to these sorts of issues or to questions of industrial development and employment (Stallings and Peres 2000), the need to link micro-level processes to the 'macro' level transformations taking place in the global political economy remains an ongoing challenge for students of development in the next decades.

As these comments suggest, many of the topics attracting creative scholarship will continue to reflect challenges that, in hindsight, have been relevant throughout the half century during which development has been the subject of social science inquiry. Yet alongside promising evidence of potential complementarities between economic growth and other indices of well-being, researchers are uncovering disturbing evidence of new forms of immiserizing growth (Kaplinsky 2001). No less daunting are the new forms of exclusion that are emerging, as uneven access to information technologies threatens to reinforce the disadvantaged status of vast segments of the world's population. Perhaps most troubling of all are the development implications for a number of the world's poorest countries, most notably in Sub-Saharan Africa, of the devastation wrought by the AIDS epidemic, the human costs of which are magnified by its likely impact on economic growth for generations to come. It is difficult to conceive of a more striking illustration of the degree to which the economic and social aspects of development are inextricably linked to one another.

Development: Sustainable Agriculture

Sustainable agriculture presents a challenge to students of development. A respect for sustainability requires us to confront the historical, single-minded commitment to increasing output through the extension and intensification of production. The unprecedented support for research that led to the green revolution contributed to a new model of agriculture that was incorporated into a transnationalized agro-industrial system based on specialized production processes. This coincided with the conviction of many members of the scientific and policymaking establishments that the major problem facing the world in the second half of the twentieth century would be meeting the Malthusian challenge by closing the gap between the geometric advance of population and the slower advance of food output.

Since these changes began to be introduced in the 1950s and 1960s, innumerable studies documented the serious disruptive effects that the new cropping systems have had on traditional rural societies and ecosystems around the world. As evidence accumulated about the problems of declining water tables, soil contamination, salinization, social disruption, and growing spatial, economic, and social disparities, serious questions were raised about the environmental sustainability of these new systems. Even more, a series of allied disciplines attempting to integrate indigenous knowledge with scientific advances in our understanding of the ability of local communities to implement effective programs of ecosystem management have demonstrated the potential for increasing output without occasioning the environmental and social devastation observed in commercial monocropping systems.

At the end of the twentieth century, the paradigm conflicts between these knowledge systems grew even stronger as the revolution in biotechnology promised yet another wave of innovations that are being challenged even more vigorously than in the past. Indeed, the risks of mistakes and tragic accidents are greater as the new modifications involve the introduction of genes from one species into another in order to confer a degree of protection against plagues, to develop resistance to natural phenomena, or to increase productivity. The critics argue that these trans-genetic products open the world to an unknown series of challenges that may threaten the very stability

of existing biological or social systems; the damage wreaked by bovine spongiform encelopathy (BSE or mad-cow disease) in Europe is cited as palpable evidence of such potential.

In view of a broadening commitment to the principles of sustainability agreed upon at the UN Conference on Environment and Development in Rio de Janeiro in 1992, attention is turning to the importance of introducing appropriate production models for agriculture. New approaches call for agriculture to be less disruptive of ecosystems and less dependent on nonrenewable sources of energy to maintain soil fertility, control plagues, and power machinery. The changes in agriculture are proceeding on a number of different fronts simultaneously. In the fields, greater attention is turning to techniques that require less disruption of the land itself, by introducing new soil and water management techniques that take advantage of 'zero tillage' so that fertility and moisture are more jealously guarded. Crop rotations and diversified planting programs are reducing the vulnerability of farming regions to massive infestations that are still a serious concern to commercial farmers. On the market side, a more sensitive consumers' movement has dramatically changed the prospects for organic products, which can be certified as being free of inputs in the production process that might pose a threat to either the purchaser or the environment in which they are cultivated. As this movement has grown, people have also become aware of the importance of insuring that peasant producers and field workers are also correctly paid so that their own poverty does not become a source of degradation.

Sustainable agriculture, however, will not be achieved simply by developing new cultivation techniques or introducing more benign inputs to use in highly specialized production systems. From decades of failure of modernization programs that did not deliver their promised welfare packages, we discovered that many of the uprooted rural peoples are capable of providing for their own needs and those of their regional environments, while making valuable contributions to the needs of the larger society of which they are a part. The invaluable research of innumerable ethnobotanists and agroecologists around the world has demonstrated the productive potential that could be unleashed if these communities were allowed to function freely.

Sustainable agriculture cannot succeed if a broader development framework that encourages the initiatives of rural peoples does not accompany it. At present, peasants and indigenous groups are forced into marginality. They lack the resources to function well in the marketplace and the support to realize how important their communal knowledge and experience is for producing crops and managing their environments and their societies. The complex relations between earthly resources, the changing seasons, and cyclical changes such as El Niño are not new problems, but they were generally integrated into a social and political framework that facilitated their management. Today these traditional productive systems and the people are frequently subjected to institutional controls and bureaucratic supervision that impede their implementation. Instead, small-scale specialized production processes force them to produce single-mindedly for the marketplace rather than take advantage of the varieties of processes and products that the natural world has provided.

If development is to proceed, rural communities must be allowed to overcome their marginality and their poverty. This does not require their full integration into a globalized society. Rather it means that they must be freed from the fetters that restrict them from realizing the full potential that their own sociopolitical systems and ecosystems allow. The drive for sustainability involves a three-pronged program for local advance: the development of autonomy and greater self-governance, the pursuit of self-sufficiency in food production as well as in other areas of life, and the development of new productive activities and products that will contribute to their material well-being, incorporating new community members into activities that will generate new sources of income.

Sustainability is not possible as long as the profound inequalities that characterize most societies in developing countries persist. Social and economic polarization are features of societies in decomposition. Institutions that perpetuate inequality contribute the kind of environmental destruction stimulated by unfettered consumption. These same institutions also perpetuate and rationalize the existence of poverty, and force the poor to contribute to environmental degradation. The growing gap also incubates violence while limiting the possibility of conflict resolution.

Only by encouraging the peasants and indigenous groups to create their own mechanisms to overcome poverty will it be possible to move in the direction of sustainability. They must be allowed to assume responsibility for their own social organization and their local institutions must be legitimized. In the current world order, federal governments cannot continue to try to impose centralized forms of administration and governance on all segments of society. In agriculture, the essence of sustainability is the implementation of a wide variety of production systems, carefully adapted to the demands of the environments, the needs of the communities, and the possibilities of the marketplace. National agricultural policies have generally proved too cumbersome to handle the diversity of situations in which rural producers find themselves.

Self-governance, however, is not a sufficient condition for sustainability. Communities also require some minimum guarantee of well being, of products and services that will offer them some security. This is part of the reason why peoples have so steadfastly adhered to the principles of self-sufficiency throughout history; so powerful is this argument that John

Maynard Keynes saw fit to argue in 1933 that 'national self-sufficiency' must be an overarching facet of economic policy, if a country is to be able to have a modicum of control over its fate. Certainly the same principle applies even more so at the community level, where the vulnerability is even greater and 'natural' disasters often affect the poorest groups most harshly.

But providing for one's basic needs through mechanisms of local autonomy and traditional social institutions cannot offer a means to improve material welfare and confront the challenges of the market economy. Productive diversification is a policy thrust that is fundamental for generating the additional resources required for a community to pull itself from marginality. The guidelines for this process must be solidly grounded in a respect for the ecosystems and the primacy of local provision of basic needs. Many a community has faltered or even been dismembered by well-meaning programs of export-promotion that have destroyed local buffers, be they social, political, or productive. In the world of the twenty-first century, where there is a growing concern for the quality of life, many new products can be derived from conservation and ecosystem enhancement activities, such as the sequestration of greenhouse gases or increasing the rate of recharge of important aquifers. Some suggest that ecotourism offers an ideal match between the consumption drives of the urban population and the needs of rural communities. Certainly the move to expand fair trade channels and organic production is ideally suited to the conditions of rural communities seeking to promote development by implement programs of sustainability.

Sustainable agriculture is now recognized as an important underpinning for any development program. It is clear that poverty and environmental destruction rather than the Malthusian specter threaten humanity at the beginning of the twenty-first century. Implementing a program of locally managed rural production that responds to the dual challenges of self-sufficiency and diversification will contribute in important ways to reducing poverty and improving the distribution of income. A key feature of the three principles enumerated here is that they also remove the onus from rural people of depending exclusively on agriculture for their livelihoods. Although it is crucial that cropping patterns and cultivation techniques become as attuned as possible to the demands of local ecosystems, it is also important to realize the importance of actively encouraging rural communities to initiate a broad range of complementary activities that will spread the burden of supporting the community over a broader base of resources and skills, thereby reducing the pressures on the land and on traditional crops that are no longer able to support the nutritional and income needs of the population.

Development Theory in Geography

1. Overview of Post-World War Two Development Geography

Given the obvious significance of topics falling within the spatial problematic, it is surprising that until the last two decades of the twentieth century the contributions of geographers to development theory in the English-speaking world were comparatively limited. A 1960 report by leaders in the field estimated that only two dozen studies had been published on the issue of economic development between 1949 and 1959, and only half of these were on development in 'underdeveloped areas' (Ginsburg 1960, p. ix). Similarly, a 1967 article by D E Keeble showed that between 1955 and 1964, the journal *Economic Geography* published 251 major articles, only ten of which (under 4 percent) were concerned in whole or in part with issues of economic development, while the topic was addressed in only six out of 242 articles (2.5 percent) in the *Annals of the Association of American Geographers* (Keeble 1967, p. 243). A review of research published in *The New Zealand Geographer* cited a similar neglect of development theory (Chapman 1969).

The theories of economic development employed in this early postwar literature were fundamentally those which had been developed in disciplines such as economics, political science, and sociology. In particular, most work by geographers in the 1960s fell more or less explicitly into the category of 'modernization' studies, adopting the view that all countries could and should follow more or less the same course of development as the advanced industrialized capi-

talist countries, passing through 'stages of growth' which lead from premodern, preindustrial, and relatively stagnant societies to societies which are industrial, modern, and dynamic. Geographers gave modernization approaches a spatial bearing through examination of issues such as urbanization patterns (Berry 1961), regional development (Friedmann 1966), and the development of transportation systems (Gould 1960; Taafe et al. 1963), as well as through statistical analyses of the diffusion of modernization indicators (Gould 1964).

By the time development geographers had embraced modernization approaches, however, modernization theories had already been under serious attack for a decade or more by various 'core-periphery theorists'—including structuralist and dependency authors—who placed the claims of modernization theory up against the realities of development in peripheral regions of the global economy such as Latin America, and found the theory wanting. Structuralists found that the historical legacies of colonialism and imperialism—such as technological backwardness, maldistribution of wealth and income, and a large, underemployed rural labor force—made the development of modern industry in the periphery a much more problematic process than modernization theorists had suggested. Dependency authors more explicitly identified the process of development in core industrialized capitalist countries as an obstacle to development in countries of the global periphery, and more radical dependency and underdevelopment perspectives which became popular by the late 1960s went so far as to suggest the impossibility or unlikelihood of capitalist development in the periphery, precisely because of its relations with the core.

These structuralist and dependency perspectives, even though not originally articulated by geographers, helped bring greater attention to geographic differences in patterns of development and to relationships between development processes in different places. This spatial dimension was naturally attractive to many geographers and spurred a significant amount of core–periphery analysis, including theories regarding revolutionary change in Third World urban centers (Armstrong and McGee 1968), general theories of imperialism (Blaut 1970), and critiques of Eurocentrism in geographical research (Connell 1971). By the middle of the 1970s there were a large number of works which adopted either structuralist (e.g., Brookfield 1975) or dependency approaches (e.g., Santos 1974). This burst of core–periphery analyses opened a period in which attention to development issues in geography became much more sustained. Between 1974 and 1983, for example, articles which addressed development issues rose to 16 percent of all articles in *Economic Geography* and 13 percent in the *Annals*, while articles on development in the more recently founded *Antipode* reached almost 40 percent (Corbridge 1986, pp. 4–5).

Even with this more intensive theorization of Third World development and deployment of the spatial problematic, however, development geography remained more a theoretical borrower than a theoretical leader. By the mid-1970s, dependency approaches were already coming under increasing fire from Marxist scholars for fetishizing geographical relations and miscomprehending class issues, and were thus being forced into refinements which could take account of increasing complexity in the 'world-system,' including the possibility of 'dependent development' in what had formerly been peripheral areas. Moreover, the 1970s had seen the emergence within development studies of important work on gender issues, an emphasis which was still missing from work by development geographers.

By the late 1970s and early 1980s, a more fully-fledged turn in the direction of Marxist theory was evident in the work of many development geographers (Slater 1977), while others had taken note of the importance of world-systems theory (Taylor 1981). Eventually, development geographers also paid greater attention to the claims about dependency put forward by the partisans of 'dependent development' approaches (Forbes 1984, Corbridge 1986), and relatively complex arguments about the interaction of 'external' and 'internal' factors began to appear in works on issues such as regional development (Gore 1984) and urbanization (Armstrong and McGee 1985).

Within development theory in general, however, the issues raised by both dependency theory and its Marxist critics had largely faded from view in the 1980s. For neo-classically oriented economists, the dramatic growth of East Asian newly industrialized countries (NICs) in the 1970s and 1980s both undermined claims of blocked development on the periphery and vindicated assertions that unfettered markets performed better than those in which the state intervened. These arguments were countered by the claims of an emerging 'neo-Weberian' school which presented evidence for the important role of the state in guiding the economic growth of the Asian NICs.

In spite of the fact that theorization of Third World states by geographers has been limited (Glassman and Samatar 1997), emphasis on the political and economic role of the state was by no means foreign to development geography. Indeed, by the mid-1980s a number of development geographers had already begun to take up the theme of state activism in the East Asian growth story (Grice and Drakakis-Smith 1985, Browett 1986). Moreover, development geographers also foregrounded the spatial problematic in discussions of the state by highlighting the state's role in creating and maintaining regional disparities within developing countries (Watts 1983, Samatar 1989, Slater 1989).

Work on issues such as gender and development continued to gain little attention in development geography until the end of the 1980s, when more

studies began to emerge (e.g., Momsen and Townsend 1987). These included analyses of the gendering of immigration processes (Radcliffe 1986) and of the gendered environmental outcomes of development (Rocheleau 1987).

By the 1980s and 1990s, geography as a field could no longer be seen as a laggard and had begun to make what were arguably leading contributions to the formulation of theoretical positions surrounding important contemporary development issues. To some extent, this was less a matter of geography as a field catching up with development studies than it was a matter of development studies coming around to some of the issues which are part of the spatial problematic—in particular, geographic expansion of economic processes, human-environment interactions, and difference and spatiality.

2. *Contemporary Themes in Development Geography*

Geographical issues are now at the forefront of much work in development, a matter which can be highlighted by briefly summarizing two broad themes of contemporary research in development geography which are not only important within the discipline but are either already or potentially of leading significance to theory within development studies more generally.

2.1 *The Spatiality and Unevenness of Development*

While modernization approaches had been generally optimistic about the prospects for capitalist development in developing countries, much of the literature by dependency theorists had been highly pessimistic. Since at least the 1980s, however, many development theorists have been inclined towards a more nuanced and contextual approach which recognizes both possibilities for and limitations to capitalist development. In place of the earlier emphasis on either diffusion or blocked development, there is now much greater emphasis on the general geographical expansiveness of capital and the unevenness with which its expansion proceeds. The important theoretical work of David Harvey (1982) has enriched the conceptual foundations for analyses highlighting uneven internationalization of capital—analyses which have been carried forward by a variety of development geographers.

Much work on uneven development by development geographers has focused on uneven development at the national scale, especially uneven economic growth between regions (Watts 1983; Samatar 1989; Slater 1989). The most basic point to emerge from such studies has been that capitalist development—whether or not it is relatively dynamic in a given context—occurs as the result of differential power relations which have concrete spatial expression. These differential power relations lie behind the spatial unevenness of capitalist development and tend to work at odds with efforts to create greater sociospatial equality in the development process. Indeed, in countries which have been relatively successful at 'late' industrialization, the production of disparity is sometimes accelerated rather than slowed.

Directly related to the phenomenon of national unevenness in the development process are issues surrounding urbanization in developing countries. While it is less fashionable now than it once was to speak of 'over-urbanization,' there is still much emphasis on how regional disparities in growth relate to the national pre-eminence of primate urban centers—these often being former centers of colonial administration and/or commercial centers of long standing. Instead of gradual equilibration of growth rates between these centers and outlying regions, capitalist development has generally increased the dominance of primate urban centers. Indeed, it has been suggested by development geographers studying Asia that continued expansion of primate urban centers has led to a historically unique form of extended metropolitan growth which blurs preconceived boundaries between urban and rural, industry and agriculture (McGee 1991). The evolution of such extended metropolitan regions poses unique new problems for urban management and environmental sustainability in Asian countries.

At the same time, the explosive growth of particular urban centers in the context of global economic transformation has led to increasing investigation of the ways uneven development detaches the trajectories of urban centers from their 'hinterlands' while creating global networks of cities through which there is an intensified flow of money, goods, and information (Friedmann 1986). On this view, the spatial unevenness of development increasingly manifests itself as a bifurcation between the major nodes through which capital moves internationally (large urban centers) and much of the rest of the world, with non-urban areas of the developing world being particularly marginalized.

To present the unevenness of capitalist development in this way, however, might be to risk reification of the spatial dimensions of development at the expense of a spatially grounded analysis of social relations. Geographers have attempted to guard against such 'spatial fetishism'—that is, the view that geographical relations have their own independent dynamics, rather than being the spatial expressions of social processes—by foregrounding issues that include class struggles (Herod 1998) and gender relations (Hanson and Pratt 1995) in relationship to particular spatial dynamics. Uneven development thus implies not only uneven development between places but uneven power relations and opportunities for groups of people, dependent upon such characteristics as their class, gender, race or ethnicity, sexual orientation, and age.

Among development geographers, then, much attention has been paid to the spatialization of disparity in the development process. For example, feminist geographers have examined how transformations in Mexico's accumulation process have involved breaking down the hegemony of the family wage-based, male-dominated, and Mexico City-centered labor regime while substituting a lower-wage and geographically more decentralized regime in which women are employed in much larger numbers (Cravey 1998). They have also examined the migration of women to export processing zones which have been the key to economic growth in newly-industrializing countries of South-east Asia and Latin America (Chant and Radcliffe 1992, Chant and McIlwain 1995). Labor geographers have examined the strengths and weaknesses of attempts to create various forms of solidarity between labor and other popular organizations in developed countries such as the USA, and less developed countries such as those of Latin America (Herod 1995, Johns 1998). Authors writing about 'new social movements' and 'popular development' (Brohman 1996) have examined how such movements attempt to forge international linkages ('jumping scale') in order to strengthen their position. Geographers examining state power have noted both how it is transformed by processes such as 'globalization' and how it continues to play a crucial role in relation to various kinds of social struggles through which 'globalization' occurs (Agnew and Corbridge 1995, Webber and Rigby 1996, Dicken 1997). Finally, development geographers who foreground cultural dimensions of the social process have examined issues such as the importance of ethnic networks to economic growth in southern China (Hsing 1998), and struggles surrounding identity among South Asian communities in Tanzania (Nagar 1997).

All of these types of analyses exemplify certain aspects of the spatial problematic—in particular, issues of sociospatial difference in the process of development—and bring an explicitly geographical dimension to social critique. What is either implicit or explicit in such critique is an emphasis on the way general processes, such as capitalist development, can have different types of manifestations in different locations, because of the relationships between different social groups within and across those locations. Thus, the study of development requires balancing an adequately supple general theory with examination of the specifics of development in particular contexts. Theories of capitalist development must be able to explain why the features of capitalism which are posited as general can lead to different kinds of outcomes—e.g., 'late industrialization' in one setting and 'blocked development' in another; stagnant real wages in one setting and rising real wages in another; increasing marginalization of certain women workers in one setting and new opportunities for empowerment of women in another. This theoretically-informed attention to the details of development processes in specific settings is perhaps one of the most important features of work in development geography, and is particularly evident in work taking place around the second major theme of contemporary geographical work, globalization and human/environment interactions.

2.2 Globalization and Human/Environment Interactions

The internationalization of capital has become so extensive that many people in the social sciences speak of 'globalization'—a qualitatively new phenomenon in which national boundaries are increasingly unimportant to the functioning of the global economy. It can be argued that the literature on globalization frequently overstates the unboundedness of capital, but nonetheless there can be little doubt that the growth of international production, trade, finance, and information flows is reshaping global geography in crucial ways. Indeed, it is perhaps globalization as much as any other single phenomenon which seems to have brought geographical perspectives to the fore in the study of development.

Among the phenomena intensified by globalization are increasingly complex issues of environmental change and degradation. Within development geography, an important literature on issues of political ecology has taken up the task of theorizing environmental change in the context of globalization (Peet and Watts 1996). Political ecology can be seen as combining a focus on details of local ecosystems and social structures with attention to global structural forces. In addition, political ecologists have shown a strong interest in what Peet and Watts (1996) term 'liberation ecologies'—varied struggles to transform environmental conditions in developing countries, which are often approached by political ecologists through conceptual frameworks which are post-Marxist and/or poststructuralist, emphasizing the multiclass and frequently community-based forms of local environmental resistance (Rocheleau and Ross 1995). A number of these political ecologists have brought gender into the center of the research agenda, highlighting, for example, the importance of gender-differentiated control over local and household resources to the economic and environmental outcomes of development projects (Carney 1993). More generally, feminist political ecologists have noted how processes of transformation which are occurring in the global economy may have varied effects on women and men in specific localities, depending upon the social position in which they start and the sorts of resources to which they have (or are denied) access (Rocheleau et al. 1996). This may in turn place women at the core of movements to resist environmental degradation connected with development.

Political ecologists have paid special attention to issues of food and agriculture. Michael Watts' study of uneven development and the food crisis in Nigeria (1983) helped bring the issue of food and access to it firmly onto the agenda, and subsequent research by development geographers has continued to analyze access to and control over agricultural resources. Topics examined in relation to such issues of access and control include the impact of contract farming on local food production (Little and Watts 1994) and the impact of new agricultural technologies on poverty and food security (Yapa 1993, 1996).

Globalization is not a process driven solely from above, but must be taken to include attempts to counteract the unevenness of capitalist development with 'globalization from below'—as, for example, with the attempts at international labor and social movement solidarity mentioned earlier. 'Globalization from below' also includes the attempts of local environmental organizations to 'jump scales' and to make their struggles more national or international. This pertains not only to struggles over environmental conditions and control over resources in rural and agrarian communities but to popular struggles over the urban environment (the 'brown agenda'). More generally, development geographers have become increasingly concerned with attempts to build national and international linkages between various types of 'new social movements'—including women's movements and other movements associated with so-called 'identity politics.' These actors are generally seen as the core of a project to promote 'popular development.'

Popular development literature is closely interrelated with approaches which are postMarxist and postcolonial, yet literature on postcoloniality has as yet made less of a mark on development geography than on some other fields. Even so, it has not been absent from discussions. For example, David Slater (1997) has championed postcolonial approaches as an antidote to Eurocentrism, while a variety of scholars have brought postcolonial approaches to analyses of specific development issues. These approaches are part of a broader 'cultural turn' in geography that is still in the process of making its mark within the field.

3. *The Future of Development Geography*

The various but often overlapping and interconnected strands of research identified here—while all exemplifying the spatial problematic in development geography—need not be anchored in any one approach or research agenda which is putatively constitutive of geography as a discipline. Nonetheless, the proliferation of research topics and agendas also brings eventual attempts to synthesize and to identify unifying principles. This task has been undertaken by authors such as John Brohman (1996), who identifies the connecting threads in various attempts to construct alternatives to neoliberal development models, and Philip Porter and Eric Sheppard (1998), who identify a dialectic of unity-in-diversity running through processes of global change and development. Such syntheses must attempt, in particular, to connect the traditions of political economy of development, political ecology, and the emerging poststructuralist and postcolonial approaches to development studies. Indeed, it is at the conjunction of these approaches, particularly as they address various issues surrounding globalization, that much of the most interesting work may well be done. As the twenty-first century opens, the centrality of globalization, uneven development, and popular responses to these processes by diverse groups seems clear; and much of the specific research agenda confronting development geographers will be rgelated to this central problematic. At the same time, the pace and scale of global change itself makes attempts to predict where development theory in geography will head in the future a daunting task.

J. Glassman

Developmental Behavioral Genetics and Education

Behavioral genetics is the study of genetic influences on behavior, and it is subdivided into molecular behavioral genetics and quantitative behavioral gen-

etics (Plomin et al. 1997a). Molecular behavioral genetics studies associations between differences in organisms' deoxyribonucleic acid (DNA) and their behavior. Too little is known on how single genes affect human behavior, however, to draw meaningful conclusions for education.

1. Concepts

1.1 Quantitative Behavioral Genetics

Quantitative behavioral genetics accounts for *individual differences* in behavior in terms of several sources of variability, and it is applied to mental disorders as well as to continuously distributed traits such as IQ that are influenced by many genes. This approach is usually traced back to Galton (1869), who was interested in the origins of excellence. Modern quantitative behavioral genetics partitions the observed or phenotypic variance (the mean squared deviation of individual scores from the sample mean) into (a) additive genetic variance or the additive effects of single genes, (b) gene dominance or the interactive effects of the two homologous genes at the same gene locus, (c) epistasis or the interactive effects of genes at different loci, (d) shared environment, defined as contributing to the similarity of persons reared in the same family independent of their biological relatedness, and (e) nonshared environment, defined as *not* contributing to the similarity of persons reared in the same family. In this context, *environment* refers to the effects of all nongenetic sources of variance, including nongenetic biological variables such as infectious diseases and nutrition.

The importance of these sources of variance is inferred from the correlations between relatives, taking their genetic and environmental similarities into account. For example, the correlation between monozygotic (MZ) *twins* reared apart estimates the combined influence of all genetic sources of variance (broad-sense heritability), whereas twice the correlation between a biological mother and her adopted-away offspring estimates the importance of additive genetic variance (narrow-sense heritability) only. Moreover, the reliable differences between MZ cotwins reared together estimate the importance of the nonshared environment, and the correlation between adoptive siblings estimates the importance of the shared environment. Correlations between different kinds of relatives may be analyzed simultaneously, using structural equation modeling (Neale and Cardon 1992).

1.2 Heritability

An important concept in quantitative behavioral genetics is the *heritability* (h^2) of a trait, defined as the ratio of the genetic variance (V_G) to the phenotypic variance (V_P):

$$h^2 = V_G / V_P$$

For example, if the correlation between the trait levels of MZ twins reared apart is $r = 0.50$, it is concluded that 50 percent of the individual differences in that trait reflect effects of different genes, whereas the other 50 percent reflect effects of nonshared environments, implying that the broad-sense heritability of that trait is $h^2 = 0.50$. Note that correlations between MZ cotwins depend on the genetic variability between twin pairs and on the variability of their environments, implying that the heritability statistic may differ between populations and change across time. For example, if impoverished family environments are improved by education to foster equal opportunities for all children, the average level of performance will rise. But as the previous variability in environments will thereby be reduced, the heritability estimates will also rise. Both seem to have happened in industrialized countries in the latter part of the twentieth century (Flynn 1987, Plomin et al. 1997a).

1.3 Mean Levels Versus Individual Differences

Hence influences on mean levels have to be distinguished from influences on individual differences. Heritability may be high because the environmental conditions in that population are homogeneous, leaving genetic factors to account for the individual differences. That, however, does not imply that the mean level cannot be raised by environmental intervention. Rather, by improving environmental conditions for entire populations, mean levels may be raised in spite of high heritabilities of the individual differences. This is not purely hypothetical: Although IQ is substantially heritable within cohorts, massive gains across cohorts in average IQ have been observed in industrialized countries since World War II (Flynn 1987), reflecting secular changes in environmental conditions. Another example is stature: although being highly heritable within cohorts, average height increased substantially during the twentieth century, probably owing to secular trends in nutrition (Vogel and Motulsky 1997).

1.4 Developmental Behavioral Genetics

This is the study of genetic and environmental influences on individual differences in behavioral development, and it combines a behavior–genetic with a developmental approach. A topic for developmental behavioral genetics that can be studied longitudinally as well as cross-sectionally is how heritability estimates are related to the age of the samples under study.

1.5 Genetic and Environmental Continuity and Change

These concepts refer to the extent that observed stability and change in individual differences reflect stability and change of the effects of genes and environments. As they are inferred from the pattern of concurrent correlations and longitudinal cross-correlations between relatives, they require longitudinal studies. These allow for estimates of (a) genetic and environmental influences at time 1, (b) genetic and environmental influences at time 2, and (c) the genetic and environmental continuities between time 1 and time 2. For example, if the concurrent correlations between MZ twins reared apart are higher than their longitudinal cross-correlations (twin A at time 1 × twin B at time 2, and vice versa), this shows lack of continuity of the effects of genes. Correspondingly, if the concurrent correlations between adoptive siblings are higher than their longitudinal cross-correlations, this shows lack of continuity of the effects of the shared environment.

If heritabilities are high but genetic continuities are low, genes are important but their effects change with age. For example, genes that foster high abilities in childhood may have less beneficial effects in adulthood. It is important to realize that, although persons' DNA usually does not change, the effects of their genes may change across time, hence genetic influence does not imply lack of change. This is obvious for the genetically driven physical changes during puberty, but it has also been shown for individual differences in cognitive development that are more strongly synchronized for monozygotic than for dizygotic (DZ) twins (Wilson 1983).

2. Findings

A meta-analysis of the world literature on family resemblance in IQ by Loehlin (1989) yielded broad-sense heritability estimates of about 0.50 for IQ. Moreover, it suggested moderate effects of the shared environment. That genes have an effect on individual differences in IQ is meanwhile established beyond any reasonable doubt. The evidence concerning genetic and environmental influences on personality traits such as extraversion and conscientiousness also suggests substantial heritabilities (Loehlin 1992). The mechanisms that mediate the effects of genes on behavior are largely unknown, however.

2.1 Heritability Estimates and Age

Loehlin's (1989) estimates for IQ were inferred from a meta-analysis of diverse studies that tested participants at various ages, whereas more fine-grained analyses show that heritability estimates depend on age: In a meta-analysis of 103 cross-sectional twin studies, McCartney et al. (1990) focused on relations between twin age and twin similarity. Whereas older MZ twins were more similar in IQ than younger MZ twins, the opposite was found for DZ twins. This suggests that genes become more influential whereas shared environment becomes less influential across the life span.

This finding is confirmed by longitudinal twin and adoption studies: The Louisville Twin Study followed the cognitive development of MZ and DZ twins from 3 months to 15 years. Whereas the correlations between MZ twins increased from $r = 0.66$ to $r = 0.88$, the correlations between DZ twins decreased from $r = 0.67$ to $r = 0.54$, suggesting growing genetic and diminishing environmental influence from infancy to adolescence (Wilson 1983). In the longitudinal Colorado Adoption Project (Plomin et al. 1997b), the IQ correlation between adoptive parents and their adopted children dropped from $r = 0.20$ at age 3 years to $r = 0.00$ in adolescence, suggesting weak and diminishing shared environmental influence. In contrast, the IQ correlation between biological parents and their own children in control families rose from 0.17 at age 3 years to 0.30 at age 16 years, suggesting narrow-sense heritabilities of 0.60 in adolescence.

2.2 Gene–Environment Covariation

The most reasonable explanation of the growing genetic influence on cognitive abilities across the life span is that the environments that contribute to individual differences in cognitive development become increasingly a function of the individuals' genotypes (Plomin 1994). The older children and adolescents become, the more they create and choose their environments, and they probably do so in ways such that their environments fit their genetically influenced dispositions. For example, more intelligent children tend to be more successful in intellectually demanding tasks and thus tend to persist with them, whereas less intelligent children experience more failure in those tasks and therefore turn to less demanding activities. This is sometimes referred to as a smörgåsbord view of the environment: The technical term for that is *genotype–environment covariation* of the evoked (or reactive) and active variety.

3. Implications for Education

The main implication of developmental behavioral genetics for education is that there are ubiquitous genetically influenced individual differences, as has been shown most convincingly for *intelligence*. General intelligence is problem-solving ability, and it is strongly related to speed and potential of learning. Thus individual differences in learning speed and learning potential are also genetically influenced. Indeed, the *dynamic testing* approach (Grigorenko and Sternberg 1998) focuses directly on the potential to learn.

However, environments are also important. Behavior–genetic research shows that at least some of the variability in behavioral traits reflects variability in environments, and this is only the variability between environments in a particular population at a given time. Most behavioral–genetic research is insensitive to secular changes in environmental conditions that affect entire populations in a similar way as is likely to have occurred for IQ (Flynn 1987). And it is also insensitive to *potential* environmental changes that might be induced by purposeful intervention. The latter is the subject of educational, not behavioral–genetic research.

Hence the prime message from behavioral genetics for education is that the uniqueness of human personality and abilities requires different or even individualized intervention programs. It is unlikely that there is a curriculum that fits all children's needs despite their different abilities and interests. Neither can all children be expected to attain the same level of proficiency, nor can they be expected to learn at the same pace, nor can a given child be expected to attain the same level of expertise in all fields. That, of course, makes education not less important but more demanding.

Moreover, there are two important lessons to be learnt from the principle of gene–environment covariation. First, if environmental variables are associated with behavior, we do not know whether they are the cause of that behavior. The sources of the behavior may as well be genetic, the genes being associated with the environmental variables (Plomin 1994). It needs genetically informative designs such as twin and adoption studies to disentangle these influences. Second, the principle of gene–environment covariation suggests that children should be provided with a variety of microenvironmental contexts to select their preferred niches that fit their inherited dispositions (Wachs 1992). The best learning environment allows children to discover and develop their natural interests, proclivities, and special talents. Behavior–genetic findings indicate that they will do so anyway, and it is probably useful to help them to proceed on their way.

Developmental Psychology

Developmental psychology is a vast and diverse field of psychology. Some developmental psychologists conduct research on conception, the early breaths of life, and the unfolding maturation of infants. Many others focus on children, their steady growth, accumulating cognitive and social skills, and awakening independence. Development of adolescents is equally of interest: the gravity of pubescence, the search for achievement, and the hovering influences of peers and schools. Developmental psychology is also about launching into adulthood, initiating and nurturing mature relationships, propagating families, and pursuing specializations and careers. Recently, some scholars have addressed concerns about settling into midlife, with shifting constraints and redefined opportunities. Finally, there have been long-standing developmental interests in aging throughout late life, a long period in which many changes are more likely to be losses than gains.

After scouring a wide range of textbooks, handbooks, and journals, one's impression may very well be that developmental psychology is about the sum of all of the above—and more. Indeed, it concerns the normative changes that occur during these phases of life, but it is also about the differences and variations in individuals' lives—the diversity of development—as

well as the biological and cultural conditions that occasion unique developments. Given the breadth of the field, however, the published works in developmental psychology are more selective about the issues, theories, and methods to which they attend. For this reason, a simple but broadly accommodating definition of developmental psychology is offered here. Following the definition, a brief analysis of some of the key concepts in developmental psychology is presented. Subsequently, both the emergence (history) and present structure of the field are sketched.

1. *Definition of Developmental Psychology*

A deliberately simple definition is as follows: developmental psychology is the study of psychological phenomena that change at any point in the life span. This seemingly uncontroversial rendition, however, contains several terms that require elaboration, if not clarification. Notably, all of the key terms of the definition—viz., developmental, study, psychological phenomena, change, and life span—may be interpreted differently and perhaps even contested by notable developmental scholars. Accordingly, the field of developmental psychology may actually be described as containing multiple legitimate clusters of developmental psychologies. Although these clusters share some common assumptions, interests, and themes, they differ—sometimes dramatically so—from one another in these and other respects.

2. *Key Concepts of Developmental Psychology*

Unpacking the seemingly simple definition above into its principal terms provides insight into the present status of developmental psychology. In so doing, both the commonalities and the diversities of contemporary developmental psychologies are exposed.

2.1 *Concept of Development*

The fact that there is commonality and diversity in developmental psychology is embodied in the terms development and change. Most contemporary theorists and approaches would subscribe to an underlying developmental perspective, or the notion that an understanding of the present psychological moment (i.e., behavior, belief, knowledge, performance, phenomenon) requires attention to the conditions and processes that led to it. Concurring that developmental psychology directs attention to the sources and courses of psychological phenomena does not imply, however, that there is agreement on whether all (or, if not, which) changes constitute developmental change.

The 'concept of development' refers to the criteria (if any) for differentiating change from development. This concept varies across approaches to developmental psychology. For example, there is disagreement about whether developmental changes can or should be universal (i.e., occurring to all individuals), irreversible (i.e., not naturally reversible or even immune to intervention), qualitative (i.e., stage-like rather than step-like and gradual), or goal directed (related or unrelated to a possible endstate). Legitimate, but contrasting, developmental psychologies rest on dissimilar conceptual assumptions concerning the extent of the difference, if any, between change and development (e.g., Harris 1957). For example, developmental theories that derive inspiration from models of biological maturation may attend principally to early phases of life (through adolescence) and construct theories that emphasize progressive and even universal growth. In contrast, other theories that are inspired by differential influences of proximal contexts, historical periods, and cultural settings are more likely to emphasize multiple developmental directions and perhaps even strong interactions among levels of influences (e.g., biological and cultural). Vivid contrasts in developmental theories may be viewed in a recent collection of chapters devoted to theoretical issues in developmental sciences (see Elder 1998, Gottlieb et al. 1998, Overton 1998, Schweder et al. 1998).

2.2 *Developmental Research*

The study of psychological development refers to the practices and traditions of scholarly research. A wide range of positions on how psychological development can or should be studied is evident. Methods employed in developmental investigations include virtually all those available in the biological, psychological and social sciences. The reason for this is that the phenomena investigated in developmental studies include the full range of processes or performances targeted by other psychologists, but also the (interactive) influences from biological and sociohistorical realms. From the social to the cognitive, from the macro to the micro, methods for investigating developmental change may be adapted from a wide variety of methods for investigating snapshots and profiles of human performance.

Notably, developmental psychologists pursuing research under the aegis of contrasting models or theories may adopt diverging approaches to the collection, analysis, and interpretation of developmental data. Available methods of developmental research include the large categories of experimental and quasi-experimental procedures, individual and profile difference studies, and qualitative techniques. Each of these categories may feature information garnered from standardized tests, experimental tasks, assays, questionnaires, surveys, interviews, textual interpretations, and combinations thereof. In addi-

tion, procedures are available to accommodate a variety of intentions, including a focus on description (what is changing or for whom?), explanation (why is it changing or what causes the change?), and intervention (can the change be remediated or modified?).

Nevertheless, whatever the research question or procedure, all developmental methods have a common paramount concern. Specifically, in developmental research an estimate of chronological age or developmental time is involved. Thus, typically some variation of cross-sectional (i.e., comparison of different age groups at one point in time) or longitudinal (i.e., examining changes in one or more groups across time) designs is implemented. Whatever one's assumptions about the concept of development, generating inferences about developmental change requires attention to more than one slice of the human life span. Thus, underlying the methodological diversity is the shared developmental goal of assessing the 'how' and 'why' of human change. Moreover, the array of methods may be necessary for understanding complex phenomena of individuals developing psychologically in the contexts of biological processes and social-environmental influences. In this respect, developmental methods associated with research in such areas as person and pattern analyses (e.g., Magnusson and Stattin 1998) and life-span change (e.g., Baltes et al. 1998) embody promising research endeavors.

2.3 Psychological Phenomena and Change

What psychological phenomena merit attention from developmental psychologists? The most inclusive view of the focus of developmental psychology permits the phenomena to include the behaviors and events that are measured by any appropriate method or technique. From this view, the principal restriction is that the phenomenon under investigation will be subject to change, at least at some point in the life span. According to developmental scientists, most psychological phenomena reach this criterion: What aspects of personality, affect, social, interactional, self-related beliefs, cognition, knowledge, motor skills, perception, or neurological events are not subject to change? To many developmental scientists, the answer is that virtually all aspects of human (psychological) phenomena undergo some manner of change at some point in the lifespan. Thus, the broadest view would maintain that most psychological phenomena constitute a legitimate focus of developmental psychology. (More narrow views, in which only selected changes are the foci of developmental psychology are supported by conceptual positions as sketched earlier.)

Naturally, specific theories or models of developmental psychology concentrate on different clusters of phenomena, and in some instances these are mutually exclusive. For example, in the middle part of the twentieth century there was much controversy over whether mechanistic (e.g., behavioral) or organismic (e.g., Piagetian) developmental psychologies implemented methods that identified optimal, and perhaps even acceptable, psychological change phenomena (e.g., Reese and Overton 1970). At present, an appropriate emphasis in evaluating whether phenomena are appropriate for developmental research is on whether the measures and observations can be justified from explicit and coherent perspectives on developmental theory and method.

2.4 Period of Change

Life span is the final term from the definition requiring clarification. The simplest interpretation of this term is that interesting and important psychological changes occur throughout life, but numerous challenging and elucidating implications have been derived from this principle (e.g., Baltes et al. 1999). Developmental psychologists focus their theoretical, methodological, and intervention efforts during one or more common phases of the life span, such as childhood, adolescence, midlife, or late life. Historically, many developmental psychologists have emphasized the roughly 15 percent of the typical life span known as infancy and childhood. A smaller but growing cadre of scholars concentrate on changes occurring during the approximately 10 percent of the life span known as adolescence. The remaining 75 percent of the typical life span constitutes the years of adulthood, ranging from young through the middle to the oldest ages. Unsurprisingly, telling the whole tale of development across the life span in any phenomenon—much less all psychological phenomena—is not the goal of life span developmental scientists. From the perspective that much developmentally interesting phenomena occur at all points of the life span, all developmental scholars contribute to a picture that will eventually be more comprehensive and coherent.

3. Emergence and Status of Developmental Psychologies

Seasoned observers of the field of developmental psychology are keenly aware of its formidable array of active theories, methods, and ideas. Recent publications testify to the vitality of the field, whether the focus is on theoretical or systemic issues (e.g., van Geert and Mos 1991), historical scholarship (e.g., Eckardt et al. 1985, Parke et al. 1994), or substantive empirical research on particular processes (e.g., Bornstein and Lamb 1999, Birren and Schaie 1996).

3.1 Historical Notes

As perhaps a sign of a maturing science, the emergence of developmental psychology received considerable

attention in the latter half of the twentieth century. Perplexing more than one observer is the sheer variety of perspectives on human development. Although distinct in several ways, contemporary theoretical systems and age-related divisions of developmental psychology can be linked to historical precedents in the nineteenth and twentieth centuries (e.g., Cairns 1998, Dixon and Lerner 1999). Although several eighteenth century European scholars (e.g., D. Tiedemann, F. A. Carus, and J. N. Tetens) produced prescient age-oriented sciences, the nineteenth century is often viewed as a crucial period in the emergence of developmental psychology. Numerous influences arising during this era have been cited (e.g., Richards 1987), including (a) the rise of evolutionary perspectives in biology (e.g., Darwinism) and other sciences (e.g., geology), (b) the appearance of historical views in philosophy (e.g., Hegel, Marx), (c) social pressures to accommodate education requirements of growing populations of children, and (d) the growth and institutionalization of psychology as an intellectual entity separate from biology and philosophy (e.g., William James). Arguably, the notion that present phenomena may be linked to past and present conditions is a hallmark of the intellectual life of the nineteenth century (Mandelbaum 1971). By the early twentieth century, psychologists were applying this concept of development to behavioral change, and even differentiating their views of development from one another. For example, the distinctions in theoretical perspectives among James Mark Baldwin (e.g., 1895), John Dewey (e.g., Cahan 1994), Sigmund Freud (e.g., Sulloway 1979), G. Stanley Hall (e.g., 1883), William James (e.g., 1890), Jean Piaget (e.g., 1983), Lev S. Vygotsky (e.g., 1929), and John B. Watson (e.g., 1924) are detectable. The theoretical differences are distributed along the dimensions of such generic and long-standing contrasting positions as origin of development (e.g., nature–nurture) and characteristics of developmental change (e.g., continuity–discontinuity). Rooted in differentiable assumptions, contemporary theories and systems of developmental psychology, may be traced to a variety of sources from ancient philosophical, to the fertile nineteenth century, to more recent influences (Cairns 1998, Dixon and Lerner 1999, Parke et al. 1994).

3.2 Present Status

In an initial effort to clarify the extent of divergent perspectives residing in the field of developmental psychology, two prominent and recent handbooks of development in the early and late phases of the life span were examined. The collections boast authors who are widely known specialists, and contain excellent tutorials on important developmental topics. The topics covered in the volume on early life development (edited by Bornstein and Lamb 1999) include the role of (a) cultural contexts, (b) school and community influences, (c) neurobiological aspects, (d) perceptual changes, (e) cognitive theories, (f) language emergence, (g) personality and temperament development, (h) familial relationships, and (i) peer or friendship patterns. There are also chapters on (j) theoretical/historical issues, (k) methodological characteristics, and (l) life span perspectives. A recent collection of reviews of adult development edited by Birren and Schaie (1996) contain a similar range of topics: (a) theoretical overviews, (b) methodological recommendations, (c) biological, neurological, and genetic influences, (d) gender-related differences, (e) cultural and racial perspectives, (f) sensory changes, (g) cognitive and intellectual aging, (h) psychosocial and personality processes, as well as (i) familial, career, and environmental influences.

Although impressively similar in range of topics, among the hundreds of references in each volume are a scant few appearing in both. Apparently, much work remains to be done in portraying the patterns and causes of development across (artificially) divided phases of the life span. Indeed, linking the descriptive patterns will be more manageable than the explanations. Naturally, the why questions in child development are of the sort: What accounts for the predominant patterns of growth and why are there exceptions? In contrast, the why questions in adult development may be summarized as what accounts for the predominant patterns of decline and are there any systematic exceptions?

The variety in contemporary developmental psychology derives in part from the fact that human development as a whole is fascinatingly (but unforgivingly) complex. This observation applies at any point in the life span, but is perhaps exacerbated by the existence of changes throughout life. At the theoretical level, it derives also in part from the fact that the developmental psychologies of the twentieth century have common sources, but often heterogeneous specific philosophical lineages. Different strands of developmental phenomena are captured adequately by select combinations of theories and methods, but no single all-encompassing developmental metatheory has established unparalleled pre-eminence. There are multiple families of developmental theories, multiple systems of developmental psychology. From this pluralistic perspective, each of the systems is more or less adequate in sponsoring theoretical and empirical work.

4. Contemporary Structure of the Field

Developmental psychologists share interests in human psychological change. The enormous variety of topics and perspectives covered by this common interest may be viewed as complementary, but not often overlapping.

4.1 Organizations

In the latter years of the twentieth century, a variety of institutional support mechanisms appeared. These included organizations and societies, journals and regular publications, training and educational sites, professional and career opportunities, and sources of research funding. With respect to societies, organizations are available that reflect interests in general infant and child development (e.g., Society for Research in Child Development), adolescence (e.g., Society for Research on Adolescence), adult development and aging (e.g., Gerontological Society of America), and even all phases of the life span (e.g., International Society for the Study of Behavioral Development). The American Psychological Association sponsors several active and large divisions with developmental agendas (notably, Division 7: Developmental Psychology; Division 20: Adult Development and Aging). In addition to these societies, numerous more focused associations have appeared and prospered. These include the long-standing Jean Piaget Society, a series of Cognitive Aging conferences, and a new child-oriented Cognitive Development Society.

4.2 Significant Publications

Regarding publications, the number of research journals related to developmental psychology has expanded enormously. Prominent examples include *Developmental Psychology*, *Adult Development and Aging*, *Infant Behavior and Development*, *Child Development*, *Journal of Research in Adolescence*, *Journal of Gerontology: Psychological Sciences*, and *International Journal of Behavioral Development*. In addition, several theoretical journals, such as *Human Development* and *Developmental Review*, have been published successfully for many years.

When initially produced, regular publications, such as handbook or advances series, could reasonably seek to cover broad topics such as child psychology or psychology of aging. More recently, however, the number of handbooks has multiplied, and the topics have become more focused as the field has become more specialized. Today, there are handbooks on such specialized topics as infancy research, infant perception, infant mental health, child language, adolescence, parenting, aging and the family, emotion and adult development, and cognitive aging.

What can be concluded about the structure of the field of developmental psychology? Perhaps primarily that, reflecting the rapidly advancing specialization and knowledge generation that occurred during the second half of the twentieth century, it is variegated but well-organized and copiously documented. For virtually every interest area, there are societies that sponsor meetings, agencies that distribute funding, journals that publish empirical and theoretical reports, edited volumes that present recent reviews of research progress, or, in many cases, handbooks or other compendia. If there is a downside to the knowledge advances and the variegated structure that has resulted, it is that there are precious few points of contact among many of the units in the structure of developmental psychology. Piece-by-piece and year-by-year, however, ambitious developmental psychologists are taking on larger strands of the story of life-span human development.

5. Conclusion

Developmental psychology is a vigorous, vast, and not altogether unified field of psychology. Far from being a handicap, however, its theoretical and methodological diversity has resulted in an immense and complex structure of assumptions, interests, and knowledge about human development. Undergirding its many manifestations is a commitment to portray and understand change, psychological change. This interest includes descriptions and explanations of developmental change, but also implementation of procedures whereby suboptimal change may be remediated or successful development may be facilitated. Thus, like many sciences, it has both basic and applied aspects. Like many sciences, it is exceedingly specialized—hopelessly so, if one wishes to capture the whole story of psychological development. Although the gathering momentum appears to move toward further variegation—and not yet toward unification—it also moves toward even greater achievements, even more knowledge. Like most sciences, developmental psychology is far from finished, but the past century has hosted an especially auspicious beginning.

Developmental Psychopathology: Child Psychology Aspects

Developmental psychopathology can be defined in a variety of ways, all having to do with development on the one hand and the resulting set of maladaptive behaviors on the other. Developmental psychopathology focuses on and integrates these two areas, looking at maladaptive processes themselves as well. Underlying much of the study of developmental psychopathology is the principle of predictability. The prediction of maladaptive behavior has been viewed not only as possible, but also as an important feature in the study of psychopathology. With this added feature, we now have a more complete definition: Developmental psychopathology is the study and prediction of maladaptive behaviors and processes across time.

As we can see, the definition of developmental psychopathology involves the merger of two fields of study, that of development and that of psychopathology (see *Developmental Psychology*). Although there is much interest in the etiology of psychopathology, until recently, there has been little research on the development of maladjustment. In part, this was due to the now discredited idea that some adult psychopathologies could not occur in childhood and to the misconception that the adult forms of pathology are the same as those for children. The introduction of a developmental perspective allows for the understanding that the same underlying psychopathology in children and in adults may be seen in very different behaviors. Thus, a developmental perspective is necessary in order to understand psychopathology.

1. *Models of Developmental Psychopathology*

Three models, a *trait model*, a *contextual* or *environmental model*, and an *interactional model* reflect the various views in regard to development and, therefore, to the etiology of psychopathology. Because attachment theory remains central to normal and maladaptive development, it is used as an example in our discussion (see *Attachment Theory: Psychological*). Unfortunately, by describing sharp distinctions, we may draw too tight an image and, as such, may make them caricatures. Nevertheless, it is important to

consider them in this fashion in order to observe their strengths and weaknesses and how they are related to developmental psychopathology.

1.1 Trait or Status Model

The trait or status model is characterized by its simplicity, and holds to the view that a trait of the child at one point in time is likely to predict a trait at a later point in time. This model is not interactive and does not provide for the effects of the environment. In fact, in the most extreme form, the environment is thought to play no role either in effecting its display or in transforming its characteristics. A particular trait may interact with the environment, but the trait is not changed by that interaction.

Traits are not easily open to transformation and can be processes, coping skills, attributes, or tendencies to respond in certain ways. Traits can be innate features, such as temperament or particular genetic codes, or can be acquired through learning or through interactive processes with the environment. However, once a trait is acquired, it remains relatively unaffected by subsequent interactions. The trait model is most useful in many instances, for example, when considering potential genetic or biological causes of subsequent psychopathology. A child who is born with a certain gene or a set of genes is likely to display psychopathology at some later time. This model characterizes some of the research in the genetics of mental illness. Here, the environment, or its interaction with the genes, plays little role in the potential outcome. For example, the work on heritability of schizophrenia supports the use of such a model, as does the lack or presence of certain chemicals on depression.

In each of these cases, the trait model argues that presence of particular genes is likely to affect a particular type of psychopathology. Although a trait model is appealing in its simplicity, there are any number of problems with it; for example, not all people who possess a trait at one point in time are likely to show subsequent psychopathology or the same type of psychopathology. That all children of schizophrenic parents do not themselves become schizophrenic, or that not all monozygotic twins show concordance vis-à-vis schizophrenia, suggests that other variables need to be considered.

This model also is useful when considering traits that are not genetically or biologically based, but based on very early experiences. For example, the attachment model as proposed by John Bowlby and Mary Ainsworth holds that the child's early relationship with its mother, in the first year of life, creates a trait (secure or insecure attachment) which will determine the child's adjustment throughout his or her life. The security of attachment that the child shows at the end of the first year of life is the result of the early interaction between the mother and the child. Once the attachment is established, it acts as a trait affecting the child's subsequent behavior.

Figure 1
Trait model.

Figure 1 presents the trait model. Notice that the interaction of the mother and child at T_1 produces the trait, C_{t1}; in the attachment case, a secure or an insecure child. Although attachment is the consequence of an interaction, once established, it is the trait (C_{t1}) residing in the child that leads to C_{t2}. There is no need to posit a role of the environment except as it initially produces the attachment.

The trait model is widely used in the study of developmental psychopathology; for example, the concept of the vulnerable or invulnerable child. A vulnerable child is defined as one who has some characteristic (trait), acquired early, which makes them vulnerable, even if they show no ongoing problems. Once stress appears, this trait is expressed. As Alan Sroufe has said, 'even when the child changes rather markedly, the shadows underlying that of the earlier adaptation remains [the insecure attachment] and in times of stress, the prototype itself may be clear (Sroufe 1983, p. 74).

On the other hand, the invulnerable child, even when stressed, is less likely to show pathology. Such a model of invulnerability has been used by Norman Garmezy and Michael Rutter (1983) to explain why children raised in highly stressful environments do not all show psychopathology. In the attachment literature, a secure child is more likely to be invulnerable to subsequent stress, whereas an insecure child is more vulnerable to stress.

The trait notion leaves little room for the impact of environment on subsequent developmental growth or dysfunction. Environments play a role in children's development in the opening year of life and continue to do so throughout the life span.

1.2 The Environmental Model

The prototypic environmental model holds that exogenous factors influence development. Two of the many problems in using this model are our difficulty in defining what environments are, and the failure to consider the impact of environments throughout the life span. In fact, the strongest form of the environmental or contextual model argues for the proposition that adaptation to current environment, throughout the life course, is a major influence in our socio-

emotional life. As environments change, so too does the individual. This dynamic and changing view of environments and adaptation is in strong contrast to the earlier models of environments as forces acting on the individual, and acting on the individual only in the early years of life.

In the simplest model, behavior is primarily a function of the environmental forces acting on the organism at any point in time. In such a model, a child does behavior *x* but not behavior *y*, because behavior *x* is positively rewarded by his or her parents and *y* is punished. Notice that, in this model, environmental forces act continuously on the organism, and the behavior emitted is a direct function of this action. Much of our behavior is controlled by an indirect form of environmental pressure. For example, a young child is present when the mother scolds the older sibling for writing on the walls. The younger child, although not directly punished, learns that writing on walls will be punished. Indirect forms of reward and punishment have received little attention, but exert as much environmental influences as direct forms.

There are many other types of environmental pressures. For example, we see an advertisement for a product 'that will make other people love us.' We purchase such a product in the hopes that others will indeed love us. We can reward or punish ourselves by our knowledge of what is correct or incorrect according to the environmental standards that we learn. Poor environmental effects, such as an overdeveloped sense of standards, can lead to high shame and, through it, to other forms of psychopathology.

Because other people make up one important aspect of our environment, the work on the structures of the *social* environment is particularly relevant, and an attempt has been made to expand the numbers of potentially important people in the child's environment beyond the mother. Sociologists and some psychologists, such as Urie Bronfenbrenner, Michael Lewis, and Judy Dunn have argued that other persons, including fathers, siblings, grandparents, and peers, clearly have importance in shaping the child's life. Given these diverse features of environments and the important roles attributed to them, it is surprising that so little systematic work has gone into their study. For the most part, mothers and, to some extent, families, have received the most attention and we, therefore, use them in our examples.

The role of environments in the developmental process has been underplayed because most investigators seek to find the structure and change within the organism itself. Likewise, in the study of psychopathology, even though we recognize that environments can cause disturbance and abnormal behavior, we prefer to treat the person—to increase coping skills or to alter specific behaviors—rather than change the environment. Yet we can imagine the difficulties that are raised when we attempt to alter specific maladaptive behaviors in environments in which such behaviors are adaptive—a point well taken by Thomas Szasz.

Figure 2
Model of change as a function of the environment.

Our belief that the thrust of development resides in the organism rather than in the environment, in large part, raises many problems. At cultural levels, we assume that violence (and its cure) must be met in the individual—a trait model—rather than in the structure of the environment. The murder rate using handguns in the USA is many times higher than in any other Western society. We seek responsibility in the nature of the individual (e.g., XYY males, or the genetics of antisocial behavior), when the alternative of environmental structure is available. In this case, murders may be due more to the culture's nonpunishment of persons or nonrestriction of handguns. The solution to the high murder rate in the USA might be the elimination, through punishment, of the possession of weapons. Thus, we either conclude that Americans are by nature more violent than Europeans or that other Western societies do not allow handguns and therefore have lower murder rates.

Figure 2 presents the general environmental model. The environment (*E*) at t_1, t_2, and t_3 all impact on the child's behavior at each point in time. The child's behavior at C_{t1}, C_{t2}, and C_{t3} appears consistent, and it is, as long as *E* remains consistent. In other words, the continuity in *C* is an epiphenomenon of the continuity of *E* across time. Likewise, the lack of consistency in C reflects the lack of consistency in the environment. The child's behavior changes over t_1 to t_3 as the environment produces change. Even though it appears that *C* is consistent, it is so because *E* is consistent. Consistency and change in *C* are supported by exogenous rather than by endogenous factors.

Other forms of maladaptive behavioral development have a similar problem. Depressed women are assumed to cause concurrent as well as subsequent depression in children. What is not considered is the fact that depressed mothers at t_1 are also likely to be depressed at t_2 or t_3. What role does the mother's depression at these points play in the child's subsequent condition? We can only infer the answer given the limited data available. The question that needs to be asked is: What would happen to the child if the mother was depressed at t_1 but not at t_2 or t_3? This type of question suggests that one way to observe the effect of the environment on the child's subsequent behavior is to observe those situations in which the environment changes.

The environmental model is characterized by the view that the constraints, changes, and consistencies in

children's psychopathology rest not so much with intrinsic structures located in the child as in the nature, structure, and environment of the child.

1.3 The Interactional or Transformational Model

Interactional models vary; Michael Lewis (1990) prefers to call them 'interactional', while Sameroff (1975) calls them 'transactional.' All these models have in common the role of both child and environment in determining the course of development. In these models, the nature of the environment and the traits of the child are needed to explain concurrent as well as subsequent behavior and adjustment. Maladaptive behavior may be misnamed because the behavior may be adaptive to a maladaptive environment. The stability and change in the child need to be viewed as a function of both factors and, as such, the task of any interactive model is to draw us to the study of both features. In our attachment example, the infant who is securely attached, as a function of the responsive environment in the first year, will show competence at a later age as a function of the earlier events as well as the nature of the environment at that later age.

One of the central issues of the developmental theories that are interactive in nature is the question of transformation. Two models of concurrent behavior as a function of traits and environment can be drawn. In the first, both trait and environment interact and produce a new set of behaviors. However, neither the traits nor the environment are altered by the interaction. From a developmental perspective, this is an additive model because new behaviors are derived from old behaviors and their interaction with the environment, but these new behaviors are added to the repertoire of the set of old behaviors. This model is very useful for explaining such diverse psychopathological phenomena as regression and vulnerability. In its most general form, it has been called by Richard Lerner (1986), the goodness-of-fit model.

In the second model, both trait and environment interact, producing a new set of behaviors which transform themselves. From a developmental perspective, this is a transformational model because the old behaviors give rise to new behaviors and the environment itself is altered by the exchange. The variety of interactional or transactional models is considerable.

2. Future Directions

The understanding of these different models of development directly bear on the type of research on developmental psychopathology. It seems reasonable to assume that different forms of psychopathology have different developmental pathways, some fitting one or the other of these models. The task for the future is to articulate which forms of psychopathology are best explained by what models.

Developmental Sciences, History of

Prior to the nineteenth century, most efforts to understand human development were not associated with scientific theories of human development (Dixon

and Lerner 1999). Instead, many models of human development were derived primarily from philosophical, literary, or theological domains. From Aristotle (384–332 BC) through St. Augustine (354–430) to William Shakespeare (1564–1616) and Jean-Jacques Rousseau (1712–78), many important thinkers wrote about the ages or stages of human life, often speculating on their unique needs and purposes. It was not until the eighteenth and the early nineteenth century, however, that these theoretical perspectives were attached to systematic empirical investigations.

The nineteenth century has often been viewed as a formative period in the emergence of scientific models of human development, for example, as in the field of developmental psychology (Baltes 1983, Cairns 1998). A key influence in the development of such models was Darwin's (1959) theory of evolution. For instance, Dixon and Lerner (1999) have argued that historical and evolutionary theories—and particularly Darwinism—provided key intellectual bases for five different theoretical systems in developmental psychology. These systems include, first, the influence of nineteenth-century evolutionary thought on the organismic model; this influence may be traced from the work of G. Stanley Hall, James Mark Baldwin, Pierre Janet, and Arnold Gesell, to the still influential work of Jean Piaget and Heinz Werner. Second, the related psychodynamic model developed in a less direct fashion from the work of Sigmund Freud and Carl Jung to that of Erik Erikson. Third, Wilhelm Preyer and Sir Francis Galton, some of the later aspects of the work of G. S. Hall and John B. Watson, contributed to the development of the mechanistic model. The dialectical model, influenced by G. W. F. Hegel and Karl Marx, was later developed more specifically by Lev S. Vygotsky and Klaus F. Riegel. Contextualism derived from the turn-of-the-century American pragmatic philosophers, most notably William James, Charles Sanders Peirce, John Dewey, and G. H. Mead. Contextualism has evolved—through integration with probabilistic epigenetic ideas (Gottlieb 1997)—to exist now as developmental systems theory (e.g., Ford and Lerner 1992, Gottlieb 1997, Thelen and Smith 1998), for example, as illustrated by developmental contextualism (Lerner 1986).

In addition to the influence of evolutionary theory, several other contributions to the scientific study of human development occurred in the nineteenth century and, as well, in the late part of the eighteenth century. Important contributors include: Dietrich Tiedemann (1748–1803), who, in 1787, produced the first psychological diary of the growth of a young child (see Murchison and Langer 1927); Friedrich August Carus (1770–1808), who endeavored to develop a comprehensive age-oriented science; Carl Gustav Carus (1789–1869), who argued for the application of the developmental method to a broad range of psychological issues (Köhler 1985); Adolphe Quetelet (1796–1874), who produced highly advanced methods to disentangle the multiple influences on the course of human development; and Johann Nikolas Tetens (1736–1807), who argued for natural scientific methods to guide the search for general laws regarding human development from birth to death (Müller-Brettel and Dixon 1990).

In addition, in the nineteenth century numerous 'baby biographies' began to appear. Such ontogenetic observational studies often took the form of diaries written by scientist-parents describing the successive achievements of a child (often their own). For example, Darwin kept such a diary of his infant son's growth during the years 1840–1 (Dixon and Lerner 1999). Many other baby biographies appeared around the turn of the century (e.g., Hall 1891, Sully 1903).

In the early decades of the twentieth century, and continuing through at least the beginning of the 1940s, much of developmental psychology was descriptive and normative. Instrumental in promoting this emphasis was the research of Arnold Gesell (1880–1961). Gesell (e.g., 1946) emphasized that maturationally based changes unfold independent of learning, and his research stressed the need for the careful and systematic cataloguing of growth norms. His work provided the field with useful information about the expected sequence for, and normative times of, the emergence of numerous physical and mental developments in selected groups of infants and children (who were from predominantly European American, middle class families). Conceptually, Gesell's work is related to one side of what has been a continuing debate in the history of developmental psychology: The nature–nurture controversy (Overton 1998). This controversy pertains to a consideration of where the sources of development lie, whether in inborn (or hereditary) mechanisms or in acquired (or learned) processes. By stressing that maturation rather than learning is the prime impetus for developmental change, Gesell (1946) was taking a 'nature', as opposed to a 'nurture', stance. Historically, other terms associated with the nature position are preformationism, nativism, and innateness; some terms associated with the nurture position are learning, conditioning, experience, and socialization.

Although Gesell's (1946) work emphasized the descriptive and normative nature of the field, there was indeed work occurring in other areas of psychology that countered Gesell's emphasis (White 1970). For example, some experimental psychologists stressed the applicability of learning principles to the study of childhood (e.g., Horowitz 1994, Miller and Dollard 1941). One consequence of this activity was to provide evidence that nurture-based learning phenomena, as opposed to nature-based maturational phenomena, could account for some features of children's behavior and development. These learning psychologists emphasized less the facts of development *per se* (e.g., 'What is the age at which an infant sits, stands,

walks, or has a two-word vocabulary?') than the explanation of those facts (e.g., 'What mechanisms—nature or nurture—need to be referred to in order to explain these facts?').

This alternating emphasis between nature and nurture was furthered in the 1940s by events leading up to and including World War II (Lerner 1986). Nazi persecution led many Jewish intellectuals to flee Europe, and many sought refuge and a new start for their careers in the United States. Many of these refugees were able to secure positions in American universities and associated institutions, despite the fact that they often brought with them ideas counter to those that were typical of the American scene (e.g., behaviorism and learning theory). For instance, although Freud himself settled in London (and died there in 1939), many psychoanalytically oriented psychologists, some trained by Freud or his daughter Anna, emigrated to North America (e.g., Peter Blos and Erik Erikson).

One reason that so many psychoanalytically oriented professionals were able to secure faculty positions in America may be related to the fact that the federal government was contributing large amounts of money to universities to support the training of clinical psychologists. Such psychologists were needed to test soldiers for both psychological and physical fitness (Misiak and Sexton 1966). This infusion of psychoanalysis in American academe resulted in the introduction of a nature-based perspective into numerous psychology departments, some of which had been dominated by nurture-based theorists (Gengerelli 1976). Nevertheless, the psychoanalytic orientation represented just one of many different theoretical accounts of human functioning—accounts that stressed either nature or both nature and nurture as sources of behavior and development—that were now making inroads into North American thinking.

For similar reasons, nativistic ideas about perception and learning, introduced by psychologists who believed in the holistic (integrative) aspects of behavior, began to appear more frequently on the North American scene. The gestalt (meaning 'form' or 'shape') views represented by some Europeans (people like Max Wertheimer, Kurt Koffka, Wolfgang Kohler, Kurt Goldstein, and Kurt Lewin) were shown to be pertinent also to areas of concern such as brain functioning, group dynamics, and social problems (Sears 1975). European perspectives relevant to human development also were being introduced. For the most part, these views also emphasized maturational (nature) components and, to some extent, clinical, nonexperimental methods. Werner (e.g., 1948) and Piaget (e.g., 1970) were especially influential.

The outcome of this cross-fertilization of ideas about development was to reinforce, if not redefine, the evolving ideas about development in North America. Any given behavior, pattern of behaviors, or systematic change in behavior could be explained by a number of different theories, and these various theories were advanced by respected advocates often working in the same academic contexts (Gengerelli 1976). Thus, in American departments of psychology, developmentalists were now confronted with a range of perspectives, ones that advanced explanations of development that varied in their reliance on purportedly nature and/or nurture processes.

Indeed, in an early review of the history of developmental science, Bronfenbrenner (1963) noted that from the 1930s to the early 1960s there was a continuing shift away from studies involving the mere collection of data, and a shift toward research concerned with abstract processes and constructs. Some books and essays published during this period epitomized this trend by calling for the study of developmental processes and mechanisms (e.g., Harris 1957). Accordingly, describing the status of the field, Bronfenbrenner (1963) wrote that 'first and foremost, the gathering of data for data's sake seems to have lost favor. The major concern in today's developmental research is clearly with inferred processes and constructs.' For example, this concern with the pluralism of ideas about developmental processes and constructs is exemplified in the now-classic publication, *The Concept of Development*, a collection of chapters pertinent to theoretical and conceptual issues in development that was edited by Harris (1957).

In turn, in a review almost a decade after Bronfenbrenner's analysis, Looft (1972) found a continuation of the trends noted by Bronfenbrenner. Looft's review, like Bronfenbrenner's, was based on an analysis of major handbooks of developmental psychology published from the 1930s to 1972. Looft noted that a shift toward more general concerns about integrating theoretical ideas occurred after World War II, and that the trend continued through 1963 (Bronfenbrenner 1963) to 1972. As a case in point we may note that the editor of the (third) 1970 edition of the *Handbook of Child Psychology*, Mussen (1970), pointed out that: 'The major contemporary empirical and theoretical emphases in the field of developmental psychology, however, seem to be on explanations of the psychological changes that occur, the mechanisms and processes accounting for growth and development.' Mussen's observation may be equally apt today, i.e., the last two decades of the twentieth century served to underscore and extend Mussen's (1970) analysis.

For example, in the fourth edition of the *Handbook of Child Psychology* (Mussen 1983), the first volume was devoted to historical, theoretical, and methodological issues, topics not even juxtaposed in a single section of previous editions. In the most recent (fifth) edition of the *Handbook of Child Psychology* (Damon 1998), the first volume featured developmental theoretical content, including attention to such enduring issues as conceptions of process, how structures function, and how functions are structured over time

(Lerner 1998). Other prominent collections, such as the *Advances in Child Development and Behavior* series (edited by Hayne W. Reese), and the *Life-span Development and Behavior* series (edited by Paul B. Baltes, Orville G. Brim, Jr., David L. Featherman, Marion Perlmutter, and Richard M. Lerner) illustrate similar trends.

The interest in explanations and the conceptual issues pertinent to them generated considerable scholarship during the last three decades of the twentieth century about the different philosophical, or meta theoretical, bases upon which individual development is studied and interpreted (e.g., Lerner 1986, 1998, Overton 1998, Reese and Overton 1970). Following the work of such philosophers as Kuhn (1970) and Pepper (1942), Reese and Overton (1970) identified two major philosophical positions—termed the organismic and the mechanistic models—that provided the basis for many extant assumptions about human development and influenced lower-order theoretical and methodological statements.

The organismic position stresses the qualitative features of developmental change and the active contribution of the organism's processes in these changes. The theories of Piaget (e.g., 1970) and Freud (e.g., 1954) are examples of such organismically oriented approaches. In contrast, the mechanistic position stresses quantitative change and the active contribution of processes lying outside the primary control of the organism (e.g., in the external stimulus environment) as the major source of development. The behavioral analysis theory of Bijou and Baer (1961) is a major example of such mechanistically oriented approaches.

Elaborating on this interest in the philosophical bases of developmental theory, Reese and Overton (1970) initiated a discussion concerning the 'family of theories' associated with models of development. For instance, although there are differences among theories in the organismic family (Freud emphasized emotional development and Piaget emphasized cognitive development), there is greater similarity among the theories within a family (e.g., the common stress on the qualitative, stage-like nature of development) than there is between theories associated with different families (e.g., mechanistically oriented theories would deny the importance, if not the reality, of qualitatively different stages of development).

Since the early 1970s, recognition of the philosophical differences between the family of theories derived from the organismic and the mechanistic models, respectively, resulted in several discussions about the different stances theories from one or another family take in regard to an array of key conceptual issues. Examples are the nature and nurture bases of development (e.g., Lerner 1986, Overton 1998); the quality, openness, and continuity of change (Brim and Kagan 1980); the extent to which theories of development may be inextricably linked to particular content domains (Lerner 1998); the extent to which the developing individual is viewed as a biological, psychological, or sociological entity versus as an integrated aspect of dynamic contexts or systems (e.g., Lerner 1986); the methods that are appropriate to the challenges of studying human development (Baltes et al. 1977); and ultimately, the alternative truth criteria for establishing the 'facts' of development (Overton 1998, Reese and Overton 1970).

From the 1970s to the end of the twentieth century, this awareness of the philosophical bases of developmental theory, method, and data contributed to a consideration of additional models appropriate to the study of psychological development. In part, this consideration developed as a consequence of interest in integrating assumptions associated with theories derived from organismic and mechanistic models (Overton 1998). For instance, Riegel (1976) attempted to apply an historical model of development that included some features of organicism (e.g., active organism) and some features of mechanism (e.g., active environment).

In turn, there was an interest in continual, reciprocal relations between an active organism and its active context (and not in either element *per se*) and with these relations as they exist on all phenomenal levels of analysis. These interests were labeled in different ways in the human development literature. For example, such terms as dialectical (Riegel 1976), transactional (Sameroff 1975), dynamic interactional (Lerner 1986), and person-environment, or holistic, interactional (Magnusson 1996, 1999) have been used. In a similar way, a number of theorists have explored the application of contextual (Rosnow and Georgoudi 1986) and integrative, developmental systems notions about human development (Ford and Lerner 1992, Gottlieb 1997, Magnusson 1996, 1999).

Overton (1998) has explained that these relational theories of human development arose at least in part because of the recognition that differences in approaches to, and interpretations of, behavior, prevalent between World War II and the 1970s, were limited due to their having been framed as Cartesian splits. In addition to the nature-nurture issue the controversies of continuity versus discontinuity, stability vs. instability, and constancy vs. change are cases in point (Lerner 1986). Overton argued that these issues remained controversial precisely because they cast development unnecessarily into a split frame of reference, into a categorical either/or form (Overton 1998). The early formulation and promulgation of such conceptual controversies had the ironic outcome of keeping the field focused on diverse interpretations of behavioral change.

However, more recently, developmental scientists have presented alternatives to such 'split' conceptions. These ideas have stressed the systemic integration, or fusion, of levels of organization ranging from the biological to the sociocultural and historical (e.g.,

Ford and Lerner 1992, Gottlieb 1997, Magnusson 1999, Thelen and Smith 1998). They have encompassed the entire life span (Baltes et al. 1998), and thus have engaged the action of individuals as an active source of their own development (Brandtstädter 1998, Lerner and Busch-Rossnagel 1981).

Indeed, the majority of the chapters in Volume 1 (Lerner 1998) of the above-noted most recent, fifth edition of the *Handbook of Child Psychology* (Damon 1998) reflect such developmental systems notions. By the end of the twentieth century these integrative notions had replaced either mechanistic and reductionistic nature (e.g., sociobiology, behavior genetics) or nurture (e.g., learning or behavior analysis) theories as the preferred frame for research and application in the scientific study of human development (Lerner 1998).

Developmental Sport Psychology

Weiss and Bredemeier (1983) coined the term 'developmental sport psychology' to advocate an appropriate theoretical perspective for studying children's psychosocial experiences through sport. According to Baltes et al. (1977), a developmental theoretical orientation seeks to explain psychosocial and behavioral changes within individuals across the lifespan, as well as differences and similarities in the nature of changes among age groups. Weiss and Bredemeier conducted a content analysis of youth sport research from 1970–81, and found that less than 10 percent of empirical studies employed designs or age selection criteria that considered developmental factors. They strongly encouraged researchers to adopt a developmental perspective to enhance understanding of children's social and psychological outcomes of sport participation.

Adopting a developmental approach means employing designs and methodology that capture the essence of age-related differences in cognitive, affective, or behavioral variables. Weiss and Bredemeier suggested three means by which developmental studies could be designed: (a) select ages of participants based on cognitive or physical developmental criteria; (b) compare age groups at key periods of development; and (c) follow individuals longitudinally on constructs of interest. One could also assess developmental level directly (e.g., cognitive age) and compare individuals who vary in developmental level on the target construct. Since the publication of Weiss and Bredemeier's work (1983), several topics in sport psychology have been investigated using a developmental perspective. The topics focused upon here are observational learning, perceived competence, social influences, and moral development.

1. *Observational Learning*

Observational learning or modeling is a powerful means of transmitting information about attitudes, values, and behaviors. It is not surprising that visual demonstrations are salient for teaching motor skills and influencing psychological responses in youth sport. Because Bandura (1986) specified that attention, retention, production, and motivation processes must be considered for successful modeling, this area is susceptible to a developmental approach (see *Social Cognitive Theory and Clinical Psychology*). Yando et al.'s (1978) developmental theory of modeling emphasized the observer's cognitive-developmental level and motivational system in observational learning of physical and social skills. Cognitive-developmental level includes attention span, memory capacity, rehearsal skills, and physical abilities. Motivational system refers to the intrinsic and extrinsic motives guiding children's attempts to reproduce observed behaviors, such as desire to develop and demonstrate competence, and social and tangible reinforcement. A synthesis of comprehensive reviews of children's observational learning of motor and psychological skills follows (McCullagh and Weiss 2001).

1.1 *Modeling and Motor Performance*

Early research on children's modeling of motor skills adopted a nondevelopmental approach, and focused upon topics such as temporal spacing of demonstrations and model characteristics. Research since the early 1980s employed designs where children were selected based on cognitive-developmental criteria, such as attention and rehearsal capabilities. Results show that a 'show-and-tell model,' one who imparts visual information while verbalizing the task to be completed, was especially helpful for younger children's (8 years or less) successful imitation of motor skills, while older children equally benefited from a visual model or show-and-tell model. These differences were attributed to older children's mature capability for selectively attending to salient task parts and spontaneously engaging in symbolic coding and verbal

rehearsal strategies. Some researchers used kinematic analysis to show that children increasingly match performance form to that demonstrated by the model as a function of observations and practice, with more dramatic increases following trials in which verbal labels are attached to visual stimuli.

1.2 Psychological Effects of Modeling

Peer models maximize similarity between the observer and model, and thus may especially motivate changes in children's psychological responses to activities they perceive as frightening or difficult. Weiss et al. (1998) examined the effect of peer mastery and coping models with children (ages 5–8) who were fearful of swimming. Peer coping and mastery models produced better performance, higher self-efficacy, and lower fear than did control participants. Peer coping models had a stronger effect on self-efficacy than peer mastery models (see *Self-efficacy*). Findings imply that using a peer model along with swim lessons is an effective means of instructing children who are fearful of the water.

Developmental differences in children's use of social comparison are an important consideration in peer modeling of motor and psychological skills. Butler (1989) contends that younger children (less than 8 years) primarily use peers for *observational learning*, while older children use peers for *evaluating one's ability*. It is conceivable that children in the Weiss et al. study primarily used peer models as sources of information for how to perform the skills. Older children who emphasize social comparison over observational learning may respond differently to peer models who demonstrate skills of which they are afraid or see as difficult.

2. Perceptions of Physical Competence

Perceptions of competence refer to evaluation of one's abilities in a particular achievement domain (e.g., athletics) or subdomain (e.g., swimming). Perceived physical competence is a strong correlate of cognitions (e.g., perceived control), affects (e.g., enjoyment), and motivated behaviors. Within Harter's (1978) competence motivation theory, perceived competence is a developmental construct, in that level, accuracy, and sources of perceived competence undergo maturational change. Understanding such changes is important for explaining age-related variations in children's thoughts, feelings, and actions in the physical domain (Weiss and Ferrer-Caja in press).

2.1 Level and Accuracy of Perceived Competence

Research in the academic domain shows an age-related decline in level of perceived competence across middle and late childhood, along with a concomitant increase in the accuracy with which children judge their abilities. Trends in level of perceived physical competence have been mixed, with studies showing a decline, little change, or an increase. In contrast, accuracy of perceived physical competence shows a reliable increase with age. Developmental change in level and accuracy of perceived competence has been attributed to shifts in information sources used to judge one's self-abilities, such as social (e.g., peer comparison), outcome (e.g., performance statistics), and internal (e.g., goal achievement) factors.

2.2 Sources of Perceived Competence

Consistent age-related trends are found for sources of perceived physical competence. Younger children (under age 10) cite adult feedback, game outcome, and sport attraction more frequently than older children and adolescents (ages 10–15), who identify peer evaluation and comparison as more salient sources of judging physical ability. With internalization of a self-reward system and mastery goals, older teenagers (ages 16–18) cite self-referenced criteria as more important than do younger peers, including skill improvement, goal achievement, enjoyment of sport, and internal information (confidence, nervousness). Gender differences in sources of perceived physical competence do not emerge until adolescence (ages 14–18). Females cite social and internal sources as more important than do male cohorts, who prioritize competitive outcomes and speed/ease of learning skills as physical competence sources.

3. Social Influences

Significant adults (parents, coaches) and peers (teammates, nonplaying friends) are central to children's psychological development through sport participation. While parents are primarily responsible for socializing their children into sport at an early age, the child's peer group increases in importance in later childhood and adolescence. Coaches occupy an important role in positively or negatively affecting children's and adolescents' sport experiences, and consequently decisions about whether to continue or drop out from athletic involvement. A rich literature exists on parents' and coaches' influence on youth involved in sport, with peer influence an unfolding area in recent years (Weiss and Ferrer-Caja in press).

3.1 Parents

Parents influence their children's self-perceptions, emotions, and motivation in sport through expressed beliefs, values, expectancies, and behaviors. For example, parents' reported enjoyment of physical ac-

tivity and the degree to which they encourage their child to participate in sport are associated with children's perceived physical competence and attraction toward physical activity. Several studies show that children's perceptions of parents' beliefs about their physical competence are associated with their own self-beliefs, affective responses, and physical activity levels. Still other studies have shown linkages between children's perceptions of parents' beliefs and behaviors with their achievement goal orientations, global self-esteem, and intrinsic motivation.

3.2 Coaches

Several studies implicate the significance of coaches to psychosocial development of children and adolescents. Smith and Smoll (1996) showed that baseball coaches who emphasized praise after successes, encouragement and instruction following errors, and refrained from punishing remarks, were associated with young athletes with more positive profiles. Their athletes reported higher baseball ability, global self-esteem, team cohesion, and enjoyment, as well as lower performance anxiety and dropout rates. These results held regardless of win–loss records.

Coaches' feedback and reinforcement patterns strongly influence adolescent athletes' perceived competence, enjoyment, and motivation. While most results point to a positive relationship between frequency of praise and self-perceptions, emotions, and motivation, Horn (1985) found that greater praise was associated with lower perceived competence and greater criticism with higher perceived competence in adolescent softball players. Horn's analysis showed that coaches' praise was not given contingent to the level of skill demonstrated but rather in a more general way. In contrast, criticism was given in response to specific skill errors, and followed by information on how to improve on subsequent efforts. To bolster this explanation, Horn found that lower skilled players received more praise, while talented players received more criticism and instruction for their efforts. Thus the quality rather than the quantity of praise, instruction, and criticism is a crucial consideration for understanding adult influence on young athletes' psychological development through sport.

3.3 Peers

Sources of physical competence information revealed peer comparison and evaluation to be especially important from later childhood to middle adolescence. Both peer acceptance (being liked by one's classmates or teammates) and close friendship (one-on-one relationship denoted by supportive qualities) are strongly linked to self-beliefs, emotions, motivation, and physical activity behavior during these developmental periods (Weiss and Ferrer-Caja in press). Even as early as middle childhood, children identify being good at sports as an important quality for being popular with one's peers, especially among boys.

Greater attention has been directed toward the developmental importance of children's close sport friendships. Weiss et al. (1996) interviewed children 8 to16 years of age, and uncovered several positive and few negative dimensions of close sport friendships. Younger children (ages 8–12) identified prosocial behavior and physical characteristics as attractive friendship qualities more often than older youth (ages 13–16), who spent more time talking about intimate self-disclosure and positive personality characteristics. Other research has shown that younger children cite companionship and pleasant play more frequently, while older youth rate loyalty, intimacy, similar beliefs and values, and conflict as reflective of sport friendships. Females rated self-esteem enhancement and supportiveness, similar beliefs and values, and loyalty and intimacy higher than males, who rated conflict as occurring more frequently. Close sport friendships and specific friendship qualities (esteem enhancement, companionship) are associated with higher physical self-worth, positive affect, intrinsic motivation, commitment toward sport participation, and physical activity levels.

4. Moral Development

Although we are acquainted with the adage 'sport builds character,' popular media provide more convincing evidence of a negative association between sport participation and ethical behaviors. Widely accepted moral development theories are developmental in nature (e.g., Piaget, Kohlberg), suggesting that individuals proceed through stages of moral reasoning that reflect egocentric, societal, and principled levels (Shields and Bredemeier 1995). Moral reasoning and behaviors should be ultimately linked. Social learning theories suggest that significant others, in particular, exert a strong influence on young athletes' beliefs and behaviors concerning legitimate sport behavior. Structural-developmental theories, in contrast, emphasize the interaction between individual differences in moral reasoning level and the social context in which moral judgments and behaviors are enacted.

4.1 Social Approval and Aggression in Sport

Significant adults and peers model and reinforce beliefs and behaviors that impact upon young athletes' beliefs about the fairness of, and actual use of, aggressive game tactics. For example, adolescent players who selected more violent professional role models received more penalty minutes during games

than did those who chose less violent models. Ice hockey players' perceptions of significant others' attitudes toward illegal violence indicated greater disapproval toward fist-fighting for younger athletes (ages 12–15 years), but approval ratings dramatically shifted for 16–21 year old players. For all age groups, rankings were consistent for significant others' approval of violence: teammates, spectators, self, coach, father, and mother.

Interviews have tapped athletes' perceptions of significant others' approval of legal and illegal violence. Nonplaying peers were viewed as exalting legal and illegal violence during hockey play, with teammates favorable to a lesser degree. Athletes perceived that coaches and fathers approved of legal but hard body-checking, but disapproved of violence prone to penalties. The relation between perceptions of social approval for unsportsmanlike play and moral beliefs and behaviors were examined among fourth–fifth and seventh–eighth grade basketball players. For the younger group, approval of antisocial behaviors by parents, coach, and teammates was associated with lower moral judgment and intention. For older players, perceived approval of unsportsmanlike behaviors by teammates, coach, and parents was associated with lower moral judgment and intent, as well as lower moral reasoning and prosocial behaviors. Mothers for younger players and teammates for older players emerged as the strongest influences on moral variables, lending support for developmental differences in sources of greatest influence.

4.2 Moral Reasoning and Aggression Tendencies

Shields and Bredemeier (1995) established a line of research on moral reasoning and aggression in sport. First, college athletes score lower on daily life and sport moral reasoning than nonathletes. Second, youth (age 12 and older), high school, and college sport participants reason at lower levels for sport than for daily life moral dilemmas. Third, divergence between daily life and sport moral reasoning scores emerge at age 12 and widen as age/competitive level increase. Finally, lower moral reasoning about sport dilemmas is associated with greater legitimacy of and tendencies toward aggressive play. This latter relationship especially holds for male participants at all levels.

Shields and Bredemeier coined the term *game reasoning* to explain the findings of divergence in reasoning about daily life and sport moral dilemmas, athlete–nonathlete moral reasoning differences, and correlations between moral reasoning and legitimacy and expression of aggression. Game reasoning reflects one's viewpoint of sport as set apart emotionally from the broader morality of everyday life, and involves a moral transformation during athletic contests in which an egocentric perspective is considered to be legitimate in the pursuit of winning.

5. Summary and Future Research Directions

Since Weiss and Bredemeier's (1983) paper on the need to adopt a developmental theoretical perspective for studying children in sport, several lines of research were identified. These included observational learning, perceived competence, social influences, and moral development. Still, there is a long way to go. A recent content analysis showed that about 20 percent of more than 600 studies and reviews conducted in 1982–97 on youth sport psychology used a developmental approach. Despite the explosion of studies on children in sport, generally, and the doubled amount of developmental studies, theoretical approaches have still been largely nondevelopmental in nature.

The established lines of research reported here, as well as others, could serve as templates for researchers and educators in the field. Hopefully such efforts will inspire others to follow suit with a series of interrelated investigations that consider developmental factors in psychosocial phenomena, ones that include both between age-group as well as within age-group differences.

If we go back to Baltes et al.'s (1977) definition of a developmental theoretical perspective, the term 'lifespan' was used. While the term 'developmental' has typically referred to infancy through adolescence, the more contemporary view is to consider a lifespan developmental perspective. Research on middle and older adult psychological development through physical activity pales in comparison to youth sport research, and scholars are encouraged to broaden the age groups of their investigations to truly understand 'developmental' sport and exercise psychology.

Dewey, John (1859–1952)

1. Biography

John Dewey was born in Burlington, Vermont, on October 20, 1859. By the time of his death (June 1, 1952 in New York City), he was regarded by many as America's foremost philosopher. During his boyhood and youth in Vermont, Dewey had been an average pupil. In 1864, Dewey's mother moved with her four boys to Northern Virginia to be close to her husband, a quartermaster with the Union army during the civil war. They did not return to Vermont before 1867, and John as a young boy saw the carnage that war brings.

As a student at the University of Vermont in Burlington, he found a mentor, H. A. P. Torrey, who nourished his interest in philosophy. After graduation in 1879, Dewey spent 2 years teaching at the high school at South Oil City in Pennsylvania, and for one year taught at an elementary school in a small town in Vermont. He continued studying philosophy in private tutorial, and in 1882, enrolled at Johns Hopkins University in Baltimore. There, he gravitated quickly to G. S. Morris, a neo-Hegelian. Hegel's ideas had a liberating effect on Dewey's thought. The religious teachings that he was brought up with were transformed into the Hegelian view of cultural institutions as agents of an objective mind that through them shapes the mental life of individuals. Morris let Dewey teach his undergraduate class, secured a fellowship for him, and offered him a position as instructor at the University of Michigan at Ann Arbor where he had moved in 1884, the year of Dewey's Ph.D. exam. During the following decade, Dewey stayed at the University of Michigan (except for 1888, the year spent at the University of Minnesota), where he was promoted to full professor, and wrote articles on psychology and ethics. In 1886, he married Alice Chipman, a strong personality with a secular humanist background. A formative influence—next to Morris' and to that of William James that mainly came by correspondence—was his friendship with G. H. Mead.

The exchange began in Ann Arbor and continued during the decade in Chicago, lasting until Mead's death in 1931. Mead's scholarship in physiology surpassed that of Dewey, and Mead's concept of psychology—based on a view of the organism that is interacting with its environment—was integrated by Dewey into his own transactional theory.

He accepted the offer to head the department of Philosophy, Psychology, and Pedagogy at the University of Chicago in 1894. The city of Chicago, teeming with European immigrants, full of destitute people as well as of people of means and goodwill, appeared to Dewey like one big social experiment. He worked closely with Jane Addams of Hull House, a social settlement; with Ella Flagg Young, District Superintendent of Chicago Schools; and with Francis Parker, principal of the Cook County Teachers' Training School. In 1896, at the request of parents who were willing to pay for most of the school's maintenance, he founded the Laboratory School that quickly became known as the Dewey School. The school's curriculum centered on 'occupations' that engaged pupils' minds and hands in activities such as sewing, weaving, cooking, building, growing corn, etc. A debate society complemented the syllabus for fifth- and sixth-graders. What made the school unique was not so much the emphasis upon the priority of the manual to the conceptual as the attempt to realize the idea of school as a community, in which both teachers and students were stakeholders.

Dewey's book *School and Society* (1899)—probably his most widely read book, with translations into a dozen languages—consists of talks he gave to raise money for the Laboratory School. In 1897, he had published a brief text, *My Pedagogic Creed*, that not only reflects his idea of the Laboratory School but holds much of his later more explicit writing on education in a nutshell.

Dewey's time in Chicago came to an abrupt end in 1904 when the University's president merged the Laboratory School with the Chicago Institute for Teacher Training, dismissing Dewey's school's teachers and his wife, who acted as principal, without prior notice or consultation with Dewey. He resigned immediately and found the position as professor of philosophy at New York's Columbia University that he would hold from 1904 through his retirement in 1930, until his final resignation of all duties in 1939, at age 80.

Courses he had taught in Chicago were published in New York (*How we Think*, 1910; *Human Nature and*

Conduct, 1922), and his major work on philosophy of education, *Democracy and Education* (1916) is a fruit of Dewey's involvement with schools and philosophy of education in Chicago.

In New York, Dewey was engaged with philosophy at Columbia and education at Teachers' College, and quickly he became involved in various political activities, not only as president of the American Association of University Professors and functions in the American Federation of Teachers, but also as leading contributor to *The Republic*, a magazine promoting liberal views, and as president of the People's Lobby and Chairman of the League for Independent Political Action. His travels and consultant activities in Japan (1919), China (1919–1921), Turkey (1924), and Mexico (1926) extended his influence, and a series of lectures on a variety of topics resulted in major publications (Tokyo University 1919: *Reconstruction in Philosophy*; Carus lectures at Columbia 1923: *Experience and Nature*; Gifford lectures in Edinburgh 1929: *The Quest for Certainty*; Terry lectures at Yale 1934: *A Common Faith*).

John and Alice Dewey had six children, three boys, one of whom had died in 1895 on a sojourn in Italy, and three girls. In 1904, on their second trip to Europe, another boy died, and even though the Deweys adopted later, on that same tour, an Italian orphan who was eight years old like their lost son, they never came to accept these deaths.

Alice died after long illness in 1927; John Dewey was married again in 1946, at age 87, to Roberta Grant, and the couple adopted two children. In 1949, when he was 90 years old, Dewey published a book that he had written together with Arthur Bentley, *Knowing and the Known*, a study in epistemology.

2. *Experience the Connecting Agent of Dewey's Life and Work*

One of the more unusual features for a philosopher's biography is the close connection between Dewey's intellectual and actual life.

In politics, he tried his hand at founding a third party, at editing a newspaper devoted to 'thought news,' and at heading the Outlawry of War Movement ('That war be outlawed and declared a crime'). In his fifties and sixties, he traveled widely not only to spread his ideas, but also to help install systems of education in Turkey, Mexico, the Soviet Union; his sojourn in China lasted over two years. At age 78, he chaired the committee to investigate Leon Trotsky (an investigation at Trotsky's own request, in Mexico, into accusations by Stalin's courts in Moscow).

Looking back at 80, he wrote: 'I reached fairly early in the growth of my ideas a belief in the intimate and indissoluble connection of means used and ends reached. I doubt if the force of the idea in the theory of social action would have come home to me without my experience in social and political movements, culminating in events associated with my membership in the Trotsky Inquiry Commission' (Jane Dewey 1939).

As for education, having been a schoolteacher himself and having run the Laboratory School in Chicago, he points to the interaction between thoughts and actions: 'The idea that lay back of my educational undertaking was a rather abstract one of the relation of knowledge and action. My school work translated this into a much more vital form' (Jane Dewey 1939).

In the field of aesthetics and the fine arts, he had worked with Albert C. Barnes, the millionaire collector who befriended him and introduced him to the art of French postimpressionism; Dewey dedicated his book *Art as Experience* (1934) to him.

As for metaphysics, his concept of unity of the ideal and the actual that he named 'God' (*A Common Faith*), appears to have been backed by personal experience. During his sojourn as a young man in South Oil City, he had experienced a mystic oneness with the universe, and he would later declare: 'I've never had any doubts since then, nor any beliefs. To me faith means not worrying … ' (Dykhuizen 1973).

His first years as a young instructor at the University of Michigan in Ann Arbor had impressed on him the actual attainability of a cooperative community and the experience of personal growth within a democratic atmosphere, with encouragement of freedom and individual responsibility, and the immediate acceptance as an adult responsible member of the faculty. This experience may well have contributed to the formulation of his later visionary concept, presented in *The Public and Its Problems* (1927), of democracy as 'the great community.'

He himself summed up the mutual enforcement of idea and action throughout his experience in the autobiographical notes that he added to his daughter Jane's account of his life: 'My belief in the office of intelligence as a continuously reconstructive agency is at least a faithful report of my own life and experience' (Jane Dewey1939).

3. *Contribution*

The upshot of Dewey's work can be described as the subordination of philosophy to life, a contribution to the project of intellectualization of practice. Since intelligence—the assessment of the possibilities inherent in a given situation—is a tool for the solution of practical problems, Dewey referred to his brand of pragmatism as 'instrumentalism': like the wings of a bird and the fins of a fish, human intelligence is an instrument for survival, but unlike the other creatures' physical features, the human mind is capable through the powers of community to promote life's quality

itself, not unlike a process of evolution directed by intelligent action.

One of the most obvious principles in Dewey's philosophy is his exposure of dualisms as artificial alternatives that have become barriers to the kind of intelligence needed to promote the process of experience, e.g., the separation between science and morals appeared scandalous to him, a roadblock on the path to progressive application of intelligence. The method of scientific inquiry developed and employed successfully in modern times provides a model for inquiry into social affairs to the degree that it is an application of reason against that of myth; analogously, intelligence must be applied in the social realm to develop a methodology for the resolution of the problems of men and to facilitate social reconstruction.

His dictum, that philosophers should turn away from the problems of philosophy and instead should turn to the problems of men, is another way of saying that traditional philosophy is concerned with questions that result from views framed in terms of alternatives which do not relate. As he states in an essay, *The Influence of Darwinism on Philosophy* (1909): 'But in fact intellectual progress usually occurs through sheer abandonment of questions together with both of the alternatives they assume—an abandonment that results from their decreasing vitality and a change of urgent interest. We do not solve them: we get over them. Old questions are solved by disappearing, evaporating, while new questions corresponding to the new attitude of endeavor and preference take their place' (Middle Works 1973–1983).

With regard to politics, Dewey maintained that the majority of men and women could and should become active participants in the decision-making processes that govern and shape their lives. He urged the development of a society that facilitates individual growth through participation in community life. Integration of self-realization and the social to form a common good is the major ethical postulate entwined with such an instrumentalization of the political. In *The Public and Its Problems* (1927), Dewey answered an analysis of the political situation in the USA in the years after World War II by Walter Lippmann, *The Phantom Public* (1925). Lippmann, a democratic realist, had shown that self-government and the idea of participatory democracy fell short of the reality of a population largely manipulated by propaganda, and he proposed the establishment of an elite ruling class to identify and serve the public interest. Dewey, while accepting the factuality of Lippman's analysis, did not subscribe to his proposal, but suggested instead the continued pursuit of the idea of a great community, especially through the means of education. His idea of the fullest possible liberation of the potentials of human experience allowed for no other social framework than that of participatory democracy. And for Dewey, the school as the 'church of democracy' is to provide the actual experience for achieving the 'great community' through its model as 'embryonic society.'

Probably, Dewey is known best for his contributions to educational thought. At the core of his philosophy of education is the concept of experience as an ongoing process with no externally identifiable aim. '… education is a constant reorganizing or reconstructing of experience. It has all the time an immediate end, and so far as activity is educative, it reaches that end—the direct transformation of the quality of experience' (*Democracy and Education* 1916, Middle Works 1973–1983). This concept was opposed to teleological concepts of education dominant in countries with an idealistically inclined tradition such as Germany or Japan, and at the same time provided the foundation for an interchange of participatory democracy and education as its exercise in embryonic form.

In *Experience and Education* (1938), Dewey emphasizes the need for a theory of education. Such theory is not a system or an application of static principles. It is entirely subservient to practice and should, in Dewey's words, be 'a light to the eyes and a lamp for the feet'; it might be described as a framework to facilitate a plan of action, or as a set of principles to interpret an experience's educational function.

Dewey elaborates two such principles of experience, that of continuity and that of interaction. He reminds educators to avoid the opposite pitfalls of overindulging children and of subjecting them entirely to external demands. Proponents of progressive education who promoted a child-centered approach had claimed Dewey as provider of the philosophical foundation for their sentiment, and W. H. Kilpatrick, an influential representative of that school, had declared the project method as Dewey's brainchild. But Dewey, while sympathetic to the idea of a participatory approach to education, would not want to see the curriculum content in terms of knowledge and competence buried underneath project-learning for its own sake. Continuity of experience, as he explained in 1938, requested the educator to transfer 'the vested capital of civilization': 'The mature person, to put it in moral terms, has no right to withhold from the young on given occasions whatever capacity for sympathetic understanding his own experience has given him' (*Experience and Education*, Later Works 1981–1991).

In *The Quest for Certainty* (1929), Dewey gives an account of cultural history that exposes the tradition of bad metaphysics in philosophy which seeks to establish a realm of certainty protected from the precariousness of human experience in a world of unavoidable uncertainty. While early religion attempted an alignment with the powers of destiny, philosophy—its inheritor—sought access to knowledge of the immutable, to the certainty provided by everlasting values and principles. Both religion and philosophy distinguished between skills and technical knowledge that eased the circumstances of everyday

existence, and the superior knowledge connected to the higher order of absolute certainty in terms of truth, goodness, and beauty. The sciences that developed in the seventeenth century effectively replaced the qualitative view of nature with one describing it in terms of mathematical relationships. But instead of using that knowledge as an instrument in the service of liberating experience, scientists engaged in a quest for certainty on their own by redescribing reality in scientific terms, as if 'the findings of science are a disclosure of the inherent properties of the ultimate real' (*The Quest for Certainty*, Later Works 1981–1991). Thereby, another dualism was generated: that between scientific procedure with the resulting quantitative description of relationships in nature, and that of the appreciation of qualities and values in experience. Dewey demonstrated how these dualisms dissolve as one turns away from the fixation on certainty in the name of reason and turns instead to intelligence as a means of assessing the possibilities inherent to a situation.

With *The Quest for Certainty*, Dewey aimed at a destruction of the history of philosophy in order to gain plausibility for democracy as the social arrangement with the greatest potentials for the full realization of society's capacities.

In *Art as Experience* (1934), Dewey stresses the continuity of all experience. The aesthetic is that part of experience that is identical with the form that separates an experience from the ongoing flow of ordinary experience. It is of a satisfying quality for its consistent movement toward an intended end, which makes it self-sufficient and lifts it out of the stream of the ordinary, at the same time. An agreeable meal, an intelligent conversation, a talk professionally delivered, a well-conducted concert, a well-played game, etc. all qualify as an experience. As for art, the artist clarifies and intensifies an object's traits in such a way that a new experience results. He does so in a process that requires his attention to the medium he is working with, and the beholder of the finished work appreciates it only to the degree that he goes through the same processes that the artist went through when making the object. By describing art this way, by identifying the aesthetic as part of experience accessible to all, Dewey claims that the removal of the arts from the ordinary lives of the common people, its relegation to museums and to private collections of the wealthy has to be understood as symptomatic of the dualism that separates the aesthetic from the quotidian and is at the roots of the divisions of society.

Like the aesthetic, the religious offers an aspect of consummatory experience. Dewey had hinted in the final chapter of *Reconstruction in Philosophy* (1920) at a 'natural piety' that transcends the denominational and liberates the potentials of religious belief. In 1934, he delivered a series of lectures to extend and clarify his position, which were published under the title *A Common Faith*. He draws a distinction between the religious as disposition and religions as sets of rituals and dogmatic beliefs; he shows the realm of the religious to be the kind of belief that is not in competition with the kind of knowledge achieved through application of research and reason; organized religion, however, has interfered with the progressive expansion of knowledge. Dewey sketches the contour of a natural piety that takes humans to be part of nature and seeks its cooperation not without a just and dignified attitude. Experience of the religious culminates in the unification of the ideal and the actual, i.e. the realization of our most inclusive moral convictions in a given situation, through which an all-pervasive unity may be glimpsed momentarily that aligns human purpose and nature.

Dewey's studies of various fields are all contributions to the foundation of a framework for social life that facilitates the liberation of human potential. Against the separation of experience and dualistic views, he promotes the unifying moments in experience and the resolution of dualism; against concepts of certain truth and the eternal, he emphasizes the contingent and the present in the situation at hand; instead of the closed-down (e.g., Marxist 'law of the laws of history') and shut-off, he points out the continuous and the transactional; against reifications of language and reason, he demonstrates their instrumentality; and instead of leaning to romantic pessimism, he puts a premium on cautious optimism in matters concerning human beings and the universe.

4. *Relevance for Contemporary Social Sciences*

A renewed interest in Dewey is indicated by the number of doctoral dissertations, which doubled during the 1990s from an average seven at US universities in the early years to an average 15 for each of the later years. At the same time, the tone of studies on Dewey appears to have changed. An observation that might be symptomatic: Westbrook (1991) follows Dewey for the most part, but is still critical of his emphasis on education to reach the goal of participatory democracy; Eldridge (1998) attacks Rorty for misreading Dewey on scientific method, Niebuhr for misconstruing Dewey's metaphysics, and Westbrook for prioritizing political action over cultural development.

The explanation of Russel's and Horkheimer's reproach of Dewey's pragmatism as curious misunderstanding has become a common feature in the literature of the nineties; the fierce Marxist–Leninist critique of Dewey's philosophy during the Soviet era is no longer an issue, other than a footnote, and the neo-Thomist repudiation of Dewey's secular philosophy is no longer even mentioned.

At the same time, several tendencies in the development of philosophy have helped facilitate a renewed interest in Dewey's philosophy. The rejection of 'great tales' in French postmodernist philosophy, the promotion of pluralistic views by proponents of

constructivism, have exposed the untenability of philosophy's claim of a relationship with the immutable, for their part. One of the most influential thinkers of the 1980s and 1990s, Richard Rorty, has combined these sentiments and applied them in his reformulation of the contributions of philosophy. His *Philosophy and the Mirror of Nature* (1979) can be read as mirroring Dewey's *Quest for Certainty*. He claims to be 'Deweyan' and comments explicitly on Dewey's writings. While this claim has been disputed by Westbrook (1991) and Eldridge (1998), Rorty's influence on contemporary thought has contributed to a renewed interest in Dewey's work.

There is renewed interest in Dewey's theory of democracy. Westbrook, in his seminal study (1991), has made explicit the relevancy and actuality of the Lippmann–Dewey debate for American democracy at the end of the twentieth century, and the time of that study's publication and its wide reception coincided with a similar appeal for the systematic pursuit of community by a group of philosophers (e.g., M. Dancer) and sociologists (e.g., R. N. Bellah) referred to as 'communitarians.' Perhaps it is indicative of a renewed influence of Dewey's concept of 'great community' that J. Habermas closed a review of the publication in German, after 70 years, of *Quest for Certainty*, expressing the wish: 'He (Dewey) would be the better patron for the Berlin Republic.'

Diabetes: Psychosocial Aspects

Diabetes mellitus is a group of chronic illnesses for which there is no cure, and which requires a complex, life-long, daily regime of management. Diabetes is a demanding chronic illness, behaviorally and psychologically, and psychosocial factors are implicated heavily in all aspects of the disease and its treatment.

1. Diabetes Mellitus

1.1 Background

Diabetes mellitus is characterized by abnormality in the production or utilization of insulin to regulate blood sugar levels. It has a complex etiology and pathogenesis (Mandrup-Poulsen 1998), and affects about five percent of the population, with variation by age, gender, ethnicity, and geographic location. It is grouped crudely into two forms, Type 1 and Type 2, with some rarer forms such as gestational diabetes and maturity onset diabetes of the young. Type 1 diabetes (insulin-dependent diabetes or IDDM) is an autoimmune disease characterized by insulin deficiency, accounting for about 15 percent of diagnoses, typically in people less than 30 years of age. Type 2 diabetes (noninsulin-dependent diabetes or NIDDM) is more complex and is characterized by resistance to insulin-mediated glucose disposal or impaired insulin secretion. It accounts for about 85 percent of diagnoses, typically in people aged 40 or older. The disease has serious long-term consequences caused by elevated blood sugar levels, or hyperglycemia, and can result in blindness, limb amputation, liver failure, and increased risk of stroke and heart disease.

1.2 Management

The diabetic individual must attempt to maintain strict glucose control to avoid low blood sugar levels, or hypoglycemia, which is very aversive, and to minimize long-term complications. Obesity is a major issue in Type 2 diabetes, and management initially focuses on control through diet and exercise, which is usually supplemented with oral medication, and sometimes with insulin, as the disease progresses. Type 1

diabetics, and Type 2 diabetics with little insulin production, must receive insulin through daily self-injection to survive. Treatment also involves dietary change, eating foods containing complex rather than simple sugars and distributing food intake over the day. Regulation of exercise levels and balancing these with food intake is also required to maintain blood sugar levels within a normal range. Management thus involves regular attention to a range of daily self-care tasks, attending to diet, exercise, medication, and blood glucose level monitoring.

Most research into psychosocial factors in diabetes has focused on successful control of blood glucose levels. A major longitudinal study, the Diabetes Control and Complications Trial, established that strict metabolic control can sharply reduce long-term complications from diabetes, and it set standards for glycated hemoglobin levels considered as adequate control. However, strict control is not always achieved as diabetics juggle the demands of the disease against the demands of daily life. This has prompted a move from compliance to adherence (Jenkins 1995) and for educational programs to incorporate local cultural understandings, increase knowledge, motivation and goal-setting, and empower diabetics to self-adjust their regime.

2. *Psychosocial Aspects of Diabetes*

2.1 *Knowledge, Attitudes, and Beliefs*

Understandings of diabetes and attitudes towards it can influence how it is managed. Diabetics with greater knowledge of the disease have been found to deal with issues of glycemic control more appropriately than patients with less knowledge. Knowledge and beliefs about insulin function has also been linked to the pattern of insulin use adopted, and indirectly to control. Hence, knowledge and beliefs are considered important components in diabetic education programs aimed at enhancing adherence. However, their effects on control are generally indirect and mediated by other psychosocial factors.

Comparison of the understandings of diabetes held by patients and health professionals reveal considerable differences between them in responsibility for control and explanations for the disease. Professionals' disease models emphasize pathological and physical aspects whereas patients' models emphasize social aspects and the impact of the disease on their lives, leading to issues of adherence and control being valued differently by these groups.

2.2 *Stress, Coping, and Adjustment*

Stress is widely considered to have effects on diabetes onset and management, but the evidence for this is mixed, and dependent upon the assessment of stress and outcome measures (see *Stress and Health Research*). Cox and Gonder-Frederick (1992) concluded that:

(a) relationships between stress and diabetes are bidirectional, and stress can affect diabetes directly (through hormone release) and indirectly (by disrupting self-care behavior),

(b) with regard to onset, no research has linked stress to onset of Type 2, but there is evidence for increased incidence of stressful life events before Type 1 onset, and

(c) the effects of stress on blood glucose levels after onset are variable. Laboratory studies produce mixed findings and indicate marked individual differences, suggesting that some subgroups are more reactive than others. Field studies generally support a relationship between increased stress and increased blood glucose levels, but differ as to whether this is mediated by self-care behaviors.

Subsequent research provides little evidence for changing these conclusions. Recent research has moved to focus on daily stressors rather than major life events, to use repeated daily records rather than retrospective ratings, and to examine individual variability in stress response. These directions, combined with prospective designs and better controls, may lead to improved models of stress effects in diabetes.

Adjustment to diabetes follows a similar course to other chronic illnesses. Diagnosis can lead to a sense of loss, grieving, and concerns about the future, followed by a period of adaptation to a new life situation and readjustment of goals and life understandings. Successful negotiation of this leads to the development and use of skills to manage the changed situation successfully. Research into diabetic coping strategies is limited and has generally been confined to the postdiagnosis period, and focused on Type 1 diabetes. Most studies demonstrate problem-focused or task-oriented strategies to be better, at least in relation to glycemic control. However, some studies have shown denial or avoidance coping to be adaptive, and this is a continuing area of debate. Gender differences in the use of strategies have also been documented.

2.3 *Social Support*

Social support is a complex construct (see *Social Support and Health*), but generally is found to have positive effects on diabetes management. Research has demonstrated positive effects on adherence and control for both structural support (e.g., family, friends, workers as sources, density of support networks) and for functional support (e.g., diabetes-specific help, communication style, cohesiveness). As much of this research is cross-sectional, directional relationships between support and outcome are not clear. Gender differences have been documented for both level and

type of support and for its relation to outcome. Adolescence has been a particular focus of this research (Burroughs et al. 1997), and has documented the importance of a supportive family, particularly following diagnosis. Functional support, especially involving open, empathic communication within families, is also important for achieving good adherence with adolescents.

Evaluation of interventions designed to enhance support, such as social skills training for diabetics, and diabetic understanding for families, has revealed positive effects on adherence and control. Several trials have demonstrated that group instruction to impart diabetes knowledge and coping skills produces better results than individualized instruction. Support provided through self-help groups (see *Support and Self-help Groups and Health*) or through a mentor (a well-adjusted patient) has been promoted but not researched in the context of diabetes.

2.4 Quality of Life

Diabetes, with daily requirements for self-monitoring and management in order to avoid the short-term consequences of hypoglycemia and the long-term complications associated with hyperglycemia, has a substantial impact on daily life. This has led to considerable interest in diabetic quality of life (QoL), assessed through a wide range of concerns including morale, well-being, depression, and role functioning (see *Chronic Illness: Quality of Life*). The relationship between glycemic control and QoL for Type 2 diabetics is mixed; for Type 1 diabetics, most research finds glycemic control and QoL to be related, cross-sectionally and prospectively. Recent research has also found intensive insulin therapy to be associated with better QoL outcomes, attributed to making management more compatible with the demands of daily living.

Psychiatric morbidity is higher for both Type 1 and Type 2 diabetics than in matched controls, and this is compounded by diabetic complications: those with complications have higher levels of morbidity than those without. Depression has been a specific focus of studies, and prevalence rates between 8 and 27 percent are reported in diabetic patients. Depression appears not to be directly related to glycemic control.

QoL is multidimensional, and only some aspects of it relate to disease-specific outcomes such as control. The development of diabetes-specific measures of QoL (Bradley 1994) provides a means to standardize measurement in this area, and to assess the impact of diabetes on aspects of life other than control.

2.5 Diet and Eating Disorders

Dietary factors are specifically relevant in diabetes: food choice for Type 1 and reducing body weight for Type 2. Limited research here suggests that breaches of dietary self-management show high individual variability, and are associated with reactions to hypoglycemic symptoms and social cues about eating.

Research on dietary issues has focused on younger female diabetics and the relationship between diabetes and eating disorders. Diabetic women are reported to have higher levels of body dissatisfaction and desire for thinness than age-matched healthy controls, and women who omit insulin injections (to lose weight) are found to be more sensitive to external cues to eating. Many reports suggest an increase of eating disorders in Type 1 diabetics, and also an increase of Type 1 diabetes amongst patients with eating disorders. However, recent controlled research does not support this. Intentional insulin admission is, however, potentially indicative of eating disorder in Type 1 patients.

2.6 Sexual Dysfunction

Diabetes is associated with disorders of sexual function, but this varies by gender. Diabetic men report lower levels of erotic drive, sexual arousal, enjoyment, and satisfaction than controls. Up to one-third of diabetic men experience erectile disorder: three times the rate for healthy controls but similar to rates for other chronic diseases. For diabetic women, sexual dysfunction rates appear not to differ substantially from general population rates, although there is limited evidence for loss of libido, enjoyment, and satisfaction. Apart from an association between neurological disorder and erectile dysfunction for men, it appears that psychosocial factors, such as disease acceptance or depression, rather than disease-related factors, such as glycemic control or disease duration, are more predictive of sexual dysfunction, particularly for women (Thomas and LoPiccolo 1994).

3. Future Directions

Psychosocial factors are implicated in almost all aspects of diabetes, but research findings in this area are often inconclusive, fragmented, or limited methodologically. To overcome this, future research should: develop improved theoretical accounts of psychosocial influence; make more systematic use of standard measures such as those described by Bradley (1994); extend research to examine other outcomes alongside glycemic control; conduct more controlled trials and longitudinal studies; and conduct more research, absolutely and comparatively, on the more common Type 2 diabetes.

Dialectical Behavior Therapy

Dialectical behavior therapy (DBT) is a comprehensive cognitive-behavioral treatment program designed for complex difficult-to-treat mental disorders. Originally developed to treat chronically suicidal patients, the treatment evolved into a treatment for suicidal patients who also meet criteria for borderline personality disorder (BPD), and has since been adapted for BPD patients with presenting problems other than suicidal behaviors and for other disorders of emotion regulation. DBT combines the basic strategies of behavior therapy (see *Behavior Therapy: Psychological Perspectives*) with Eastern mindfulness and teaching practices, residing within an overall frame of a dialectical worldview that emphasizes the synthesis of opposites. The fundamental dialectical tension in DBT is between an overarching emphasis on validation and acceptance of the patient on the one hand, with persistent attention to behavioral change on the other. Change strategies in DBT include analysis of maladaptive behavior chains, problem solving techniques, behavioral skills training, management of contingencies (i.e., reinforcers, punishment), cognitive modification, and exposure-based strategies. DBT acceptance procedures consist of mindfulness (e.g., attention to the present moment, assuming a nonjudgmental stance, and focusing on effectiveness) and a variety of validation and stylistic strategies.

Figure 1
A graphical representation of the key concepts in dialectical behavior therapy

1. *Development of DBT*

DBT, developed by Linehan in the early 1980s, grew out of a series of failed attempts to apply the standard cognitive and behavior therapy protocols of the early 1980s to chronically suicidal patients. Difficulties that emerged included the following. (a) Focusing on client change, either by improving motivation or by enhancing skills, was often experienced as invalidating by individuals meeting criteria for BPD and often precipitated withdrawal from therapy, attacks on the therapist, or vacillation between these behaviors. (b) Teaching and strengthening new skills was extraordinarily difficult, if not impossible, within the context of a therapy oriented to reducing the motivation to die. (c) The rigorous control of the therapy agenda needed for skills training did not allow for sufficient attention to be given to motivational issues. (d) New behavioral coping skills were extraordinarily difficult to remember and apply when the patient was in a state of crisis. (e) Borderline individuals often

unwittingly reinforced therapists for iatrogenic treatment (e.g., a client might stop attacking the therapist if the therapist changed the subject away from topics the client was afraid to discuss) and punished them for effective treatment strategies (e.g., a client may respond with a drug overdose when the therapist refuses to recommend hospitalization stays that reinforce suicide threats).

Three modifications to standard behavior therapy were made to take these factors into account. First, strategies that more clearly reflected radical acceptance and validation of clients' current capacities and behavioral functioning were added to the treatment. The synthesis of acceptance and change within the treatment as a whole and within each treatment interaction led to adding the term 'dialectical' to the name of the treatment. This dialectical emphasis brings together in DBT the 'technologies of change' based both on principles of learning and crises theory and the 'technologies of acceptance' (so to speak) drawn from principles of Eastern Zen and Western contemplative practices. Second, the therapy as a whole was split into several different components, each focusing on a specific aspect of treatment. The components in standard outpatient DBT are highly structured individual or group skills training, individual psychotherapy (addressing motivation and skills strengthening), and telephone contact with the individual therapist (addressing application of coping skills). Third, a consultation/team meeting focused specifically on keeping therapists motivated and providing effective treatment was added as a fourth treatment component.

2. *Treatment Stages and Goals*

DBT is designed to treat patients at all levels of severity and complexity of disorders. In stage 1, DBT focuses on patient behaviors that are out of control. The treatment targets in stage 1 are: (a) reducing high-risk suicidal behaviors (parasuicide acts, including suicide attempts, high-risk suicidal ideation, plans, and threats); (b) reducing client and therapist behaviors that interfere with the therapy (e.g., missing, coming late to sessions, telephoning at unreasonable hours or otherwise pushing a therapist's limits, not returning phone calls); (c) reducing behavioral patterns serious enough to substantially interfere with any chance of a reasonable quality of life (e.g., depression and other axis I disorders, homelessness, chronically losing relationships or jobs); and (d) acquisition of sufficient life skills to meet client goals (skills in emotion regulation, interpersonal effectiveness, distress tolerance, self-management, as well as mindfulness). Subsequent to achieving behavioral control, it becomes possible to work on other important goals including (e) focusing on the ability to experience emotions without trauma (stage 2); (f) enhancing self-respect; (g) addressing problematic patterns in living that interfere with goals (stage 3); and (h) resolving feelings of incompleteness and enhancing the capacity for joy (stage 4). In sum, the orientation of the treatment is to first get action under control, then to help the patient to feel better, to resolve problems in living and residual disorder, and to find joy and, for some, a sense of transcendence.

With respect to each goal in treatment, the task of the therapist is first (and many times thereafter) to elicit the client's collaboration in working on the relevant behavior, then to apply the appropriate treatment strategies described below. Treatment in DBT is oriented to current in-session behaviors or problems that have surfaced since the last session, with suicide attempts and other intentional self-injurious acts and life-threatening suicidal ideation, planning, and urges taking precedence over all other topics. Because therapeutic change is usually not linear, progress through the hierarchy of goals is an iterative process.

3. *Treatment Strategies*

DBT addresses all problematic client behaviors and therapy situations in a systematic, problem solving manner. The context of these analyses and of this solution-oriented approach is that of validation of the client's experiences, especially as they relate to the individual's vulnerabilities and sense of desperation. In contrast to many behavioral approaches, at least as described in print, DBT places great emphasis on the therapeutic relationship. In times of crisis, when all else fails, DBT uses the relationship itself to keep the client alive.

Treatment strategies in DBT are divided into four sets: (a) dialectical strategies, (b) core strategies (validation and problem solving), (c) communication strategies (irreverent and reciprocal communication), and (d) case management strategies (consultation to the patient, environmental intervention, supervision/consultation with therapists). There are, as well, a number of specific behavioral treatment protocols covering suicidal behavior, crisis management, therapy-interfering behavior and compliance issues, relationship problem solving, and ancillary treatment issues, including psychotropic medication management. These are more fully described in the treatment manuals (Linehan 1993a, 1993b). Their relationships to each other, and to acceptance and change, are represented in Fig. 1.

Dialectical strategies are woven throughout all treatment interactions. The primary dialectical strategy is the balanced therapeutic stance, the constant attention to combining acceptance with change. The goal is to bring out the opposites, both in therapy and the client's life, and to provide conditions for synthesis. Strategies include extensive use of stories, metaphor,

and paradox; the therapeutic use of ambiguity; viewing therapy, and indeed all of reality, as constant change; cognitive challenging and restructuring techniques; and reinforcement for use of intuitive, nonrational knowledge bases.

Core strategies consist of the balanced application of problem solving and validation strategies. Problem solving is a two-stage process involving, first, an analysis and acceptance of the problem at hand, and second, an attempt to generate, evaluate, and implement alternative solutions which might have been made or could be made in the future in similar problematic situations. Analysis of the client's problem behaviors, including dysfunctional actions, emotions, physiological responses, and thought processes, requires detailed analyses of the chains of events (both responses of the individual and events in the environment) leading up to the problematic responses. This analysis is repeated for every instance of targeted problem behaviors until both therapist and client achieve an understanding of the response patterns involved. The second stage, which is actually interwoven with the first, requires the generation of new, more skillful responses, as well as an analysis of the individual's capabilities and motivation to actually engage in the new behaviors. This process leads into application of change procedures drawn primarily from innovations in behavior therapy and from the cognitive modification techniques of rational-emotive therapy (see *Behavior Psychotherapy: Rational and Emotive*). Management of contingencies in the therapeutic relationship, training in behavioral skills, exposure techniques with response prevention, and cognitive restructuring anchor the behavioral change end of the primary dialectic in DBT.

Validation, which balances and keeps problem solving moving forward, requires the therapist to search for, recognize, and reflect the validity, or sensibility, of the individual's current patterns of behavior. Validation is required in every interaction and is used at any one of six levels: Level 1, listening to the client with interest; Level 2, reflection, paraphrasing, summarizing; Level 3, articulating or 'mind-reading' that which is unstated, such as fears of admitting emotions or thoughts, but without pushing the interpretation on the client; Level 4, validating the client's experience in terms of past experiences or in terms of a disease or brain disorder model; Level 5, validating the client in terms of present and normal functioning (e.g., high emotional arousal disorganizes cognitive functioning in all people); and Level 6, radical genuineness with clients—treating the client–therapist relationship as an authentic and 'real' relationship. In line with this latter prescription of the treatment, the therapist does not treat clients as fragile or unable to solve problems.

In DBT, the therapist balances two communication strategies which represent rather different interpersonal styles. The modal style is the reciprocal strategy, which includes responsiveness to the client's agenda and wishes, warmth, and self-disclosure of both personal information that might be useful to the client as well as immediate reactions to the client's behavior. Reciprocity is balanced by an irreverent communication style: a matter-of-fact or at times slightly outrageous or humorous attitude where the therapist takes the client's underlying assumptions or unnoticed implications of the client's behavior and maximizes or minimizes them, in either an unemotional or overemotional manner to make a point the client might not have considered before. Irreverence 'jumps track,' so to speak, from the client's current pattern of response, thought, or emotion.

There are three strategies designed to guide each therapist during interactions with individuals outside the therapy dyad (case management strategies). The consultation/supervision strategy requires that each DBT therapist meet regularly with a supervisor or consultation team. The idea here is that severely suicidal individuals should not be treated alone. The consultant-to-the-client strategy is the application of the principle that the DBT therapist teaches the client how to interact effectively with the client's environment, rather than teaching the environment how to interact with the client. When absolutely necessary, however, the therapist actively intervenes in the environment to protect the client or to modify situations that the client does not have the power to influence.

4. *Research*

Data suggest that with severely disordered patients meeting criteria for borderline personality disorder, DBT is more effective than treatments applied as usual in the community in reducing targeted problem behaviors (suicide attempts, substance abuse, treatment dropout, use of psychiatric in-patient hospitalization) and improving both general and social functioning (Linehan et al. 1991, 1994). With a less severe population of BPD patients, DBT appears to produce specific improvements in suicidal ideation, depression, and hopelessness, even when compared to a treatment-as-usual condition that also produces clinically significant changes in depression (Koons et al. 2001). Where follow-up data are available, it appears that these results may hold up to one year post-treatment (Linehan et al. 1993). These findings are generally replicated by both randomized clinical trials with better experimental control as well as quasi-experimental effectiveness studies. From available evidence, it appears that DBT is a step toward more effective treatment for multidisordered patients, particularly those with suicidal behavior.

Dialectical Thinking, Psychology of

Dialectical thinking refers to the mental processes of compromising or synthesizing facts, views, and goals of opposing perspectives (Basseches 1984, Moshman 1995, Peng 1997). Only in the late 1970s did the study of dialectical thinking appear in the mainstream psychological literature as a research topic (e.g., Riegel 1973, Basseches 1980, 1984, Kramer 1983), and even at the start of the twenty-first century little is known about the nature of dialectical thinking and its effects on basic reasoning, judgment, and decision-making processes. Still, a variety of work from psychology and philosophy can be seen as bearing on the issue, including thinkers who rooted philosophical systems in dialectical processes. A number of different levels of analysis have been considered—including dialectical dynamics at the societal level, at the level of teacher–student and opposing debaters, and at the intrapsychic level—each offering insights on how opposite positions interact and how they are reconciled, if at all.

1. *Dialectical Thinking as Methods of Reasoning*

Dialectical thinking as a method of reasoning has a long tradition in Western thought. One of the earliest examples of the dialectical method is Plato's *Dialogues*, in which he sought to study truth through discussion in the form of questions and answers. Aristotle also referred to dialectics as a method of reasoning but used it often as a synonym for the science of logic. The first thinkers who distinguished dialectical reasoning from formal logic were Immanuel Kant and G. W. F. Hegel. Kant maintained that logical reasoning is very effective within the confines of science, but 'all the worse for the beyond' (Kant 1781/1965). He believed that there are ways to go beyond things as experienced ('phenomena') and to seek the ultimate reality of things in themselves ('noumena'); this is Kant's transcendental dialectic. Hegel, meanwhile, believed that the evolution of ideas occurs through a dialectical process—that is, a concept (or thesis) gives rise to its opposite (antithesis), and as a result of this contradiction, a third view, the synthesis, arises. The synthesis is at a 'higher' level of truth than the first two views (Hegel 1812/1967). The Hegelian method of reasoning has since become seemingly synonymous with dialectical thinking in Western cultures.

2. *Marx and Engels' Laws of Dialectics*

One of the most influential thinkers of the nineteenth century, Karl Marx opened new vistas of understanding by applying materialistic and dialectical perspectives to the analysis of civilization and cultures. According to Marx and Engels, there are three basic laws of dialectics: (a) the law of the transformation of quantity into quality and vice versa; (b) the law of the interpenetration of opposites; and (c) the law of the negation of the negation (Engels 1872–82/1940, p. 26). Developed in contrast to the Hegelian idealism that envisioned an end to contradiction in achievement of the absolute ideal, Marxist dialectical thought recognizes the permanence of opposition and contradiction in the real material world, and therefore in thought about reality. According to Marx and Engels, the

process of historical development is endless because the synthesis itself becomes a new thesis and is in turn negated by a new antithesis producing a new synthesis, and so on *ad infinitum*.

3. *Dialectical Thinking as a Form of Argument*

Dialectical thinking in contemporary epistemology is defined as a form of argument (Alexy 1989, Habermas 1990, Goldman 1994) that purposely draws out the views of either participant. In formal logical reasoning, an argument is good if the conclusion either follows deductively from the premises, or receives strong evidential support from them, or has only true premises. However, in dialectical argument or discourse where two (or more) speakers successively defend conflicting positions, both citing premises in support of their respective positions, the judgment of the goodness of the argument is a matter of social epistemology and conversational norms (Goldman 1994). In this form of argument, the opposing perspective is invited for the sake of discourse.

4. *Dialectical Thinking as a Psychological Concept*

In the late 1970s and early 1980s, a school of developmental psychologists, frustrated by the limited relevance of Piagetian theories of human development for adult development, started to look for cognitive development beyond Piaget's adolescent 'formal operations' stage. Klaus Riegel, in his 1973 paper on 'Dialectic operations,' pointed out that, 'It has never been shown convincingly that the highest level of operation, i.e., formal operational intelligence, characterizes the thinking of mature adults' (Riegel 1973, p. 363). Riegel believed that adult thoughts, particularly in creative scientific activities, 'are dominated by playful manipulations of contradictions and by conceiving issues integratively which have been torn apart by formal operational thinking.' Accordingly, the final period of human cognitive development and the nature of mature thought are characterized in part by dialectical operations.

A more empirical approach to dialectical thinking was offered by Michael Basseches (1980, 1984), who abstracted 24 cognitive schemata or patterned movements in human thought as basic components of dialectical thinking. These 'dialectical schemata,' as Basseches called them, include steps in dialectical analyses and ways of introducing and maintaining dialectical movement within one's own thought, such as recognition and description of thesis–antithesis–synthesis development, location and description of contradiction, and assertion and description of reciprocal relationships (Basseches 1980). It has been found that such dialectical thinking becomes increasingly important and common in old age (e.g., Basseches 1984, Kramer and Woodruff 1986, Chandler and Boutilier 1992). Middle-aged and older people are more likely to accept contradiction in reality and synthesize contradiction in their thinking than young people (Kramer and Woodruff 1986).

However, some scholars still believe that formal operations can also account for dialectical forms of thought (e.g., Piaget 1980, Kramer 1983). For example, Piaget (1980) argued that there are two types of contradiction: a logical contradiction ('real contradiction') that results from an error in the reasoning process and a natural contradiction ('pseudocontradiction') that results from disequilibrium in one's knowledge. Dialectical synthesis, according to Piaget, is a re-equilibration process of formal operations in dealing with natural contradiction. A conciliatory proposal was made by Kramer, who suggested that formal operations and postformal operations may actually reflect only two different world views, not necessarily two different stages of human cognitive development. Formal operational thought is an analytic world view that emphasizes independence of variables and underlying stability whereas postformal operational thought is a synthetic world view that assumes interdependence of variables and change as basic to reality (Kramer 1983).

5. *Dialectical Thinking as Sources of Individual Differences*

The construct of conceptual or integrative complexity has been used by scholars in many fields of social science to capture individual differences in the complexity of the cognitive rules that people use to process and analyze information (Harvey et al. 1961, Schroder et al. 1967) or situational determinants of complex information processing (Streufert and Streufert 1978, Tetlock 1983, 1985). Levels of integrative complexity in people's thinking vary. For instance, people's reasoning and decision-making processes could be characterized as low differentiation (lack of awareness of alternative ways of viewing problems), high differentiation with low integration (awareness of alternative ways of viewing problems, but no recognition of relations between viewpoints), or high differentiation with high integration (awareness of multiple perspectives on problems and of interrelations among perspectives) (Tetlock 1985). Dialectical thinking should be reflected in higher levels of integrative complexity.

Some psychological work on negotiation, conflict management, and decision making has suggested that integration of different perspectives improves efficiency and outcomes. A coordinative negotiation strategy that attempts to establish collaboration between both sides was found to be more likely to achieve an agreement than a competitive negotiation strategy

(e.g., Tetlock 1985, Pruitt 1981, Pruitt and Carnevale 1993). In a decision-making process, the method of dialectical inquiry (DI) offers a credible counterplan and conducts a structured debate on both plans. Research suggests such an approach may be preferable to simple devil's advocacy (DA) that promotes conflict by criticizing a prevailing plan without offering any counter-plan (e.g., Mason 1969, Mitroff and Mason 1981, Schwenk 1990).

6. *Cultural Foundations of Dialectical Thinking*

Despite the differences among various conceptions of dialectical thinking, they make similar fundamental assumptions. First, they assume contradiction is a temporary state that will be replaced by integrated or synthesized thoughts (even Marx and Engels' constant negation assumes at least temporary integration). Second, they assume that the progress of reasoning is linear, logical, and moving in one direction—from a contradiction to a synthesis. Third, they assume integration or synthesis are at higher levels of cognitive functioning (e.g., Baltes and Staudinger 1993) usually considered to be more sophisticated, creative, and advanced models of thought (e.g., Benack et al. 1989). In the end, most of these approaches are rooted in the laws of formal logic, particularly the law of non-contradiction.

It has long been suspected that certain cultural groups are more dialectical in their reasoning and thinking about the world, knowledge, and human life. Peng (1997) (also Peng and Nisbett 1999, 2000, Peng et al. 2001) has suggested that Chinese folk epistemology (folk beliefs of knowing) emphasizes three interconnected principles—the principle of change (e.g., reality is a process, it does not stand still but is in constant flux), the principle of contradiction (reality is not precise, but is full of contradictions), and the principle of holism (in reality, nothing is isolated but connected, and the whole is more than the sum of its parts). These principles form the foundation of Chinese dialectical thinking, which is seemingly at odds with three basic laws of formal logic: the law of identity (if anything is true, then it is true; thus $A = A$), the law of non-contradiction (no statement can be both true and false; thus $A \neq A$), and the law of the excluded middle (any statement is either true or false; thus (A v B) and (A & B)). Such epistemological differences were found in folklore of Eastern and Western cultures. For example, Chinese folklore contains more dialectical proverbs than does American folklore (Peng 1997, Peng and Nisbett 1999, 2000). Americans as a whole preferred non-dialectical to dialectical proverbs and the Chinese preferred dialectical to nondialectical proverbs when they were presented with samples of commonly used proverbs from Chinese, American, and Yiddish cultures (Peng and Nisbett 1999).

7. *Effects on Reasoning and Judgment*

These epistemological differences of dialectical thinking imply strong cultural differences in reasoning about contradiction. A number of empirical findings have emerged which reveal important cultural differences in dialectical thinking. For instance, in a study of interpersonal conflict resolution, Peng (1997) found that American participants' resolutions of contradictions in everyday life were noncompromising and polarizing. In contrast, Chinese responses were much more dialectical and compromising. Chinese dialectical thinking may also contribute to the fact that Chinese are less likely than Americans to engage in debates and formal argumentation about truth (Becker 1986). Peng (1997) presented two types of arguments—logical and dialectical—on physics and religion to American and Chinese college students and found that, compared with Americans, Chinese participants preferred dialectical arguments. In a direct test of cultural difference on reasoning about contradiction, Peng (1997) used contradictory research reports as stimuli and asked participants to judge the plausibility of each piece of information. He found that American participants followed a *differentiation* approach, such that, when presented with (weak) evidence against the more plausible statement, they actually judged it to be *more* likely than those who saw no contradictory evidence did. Meanwhile, the Chinese participants showed a *compromising* approach. They judged the more plausible statement and the less plausible statement as equally likely when they presented together. In effect, the Chinese behaved as if they believed that both statements might be (somewhat) true.

8. *Conclusion*

Dialectical thinking is an important part of everyday reasoning and judgment. While it has long played a pivotal role in various philosophical discussions, it is only beginning to be understood as a psychological issue. It seems clear that dialectical thinking exists alongside other modes of thought, its use differing over the life course, between individuals and across cultures. Still, psychologists have much left to discover in order to fully understand the psychology of dialectical thinking.

Dialectology

Dialectology, the systematic study of linguistic variation, began as an autonomous discipline in the second half of the nineteenth century and became subsumed as a branch of linguistics in the second half of the twentieth century, though not without difficulty. Today it has worldwide currency and hundreds of active participants engaged in diverse research.

1. *Beginnings*

Its beginning is conventionally dated as 1876, when the German professor Georg Wenker mailed a list of sentences written in standard German to schoolmasters in the north of Germany and asked them to return the sentences to him transcribed into the regional dialect of their school districts. Wenker made further mailings until 1887 by which time he had blanketed the entire nation. He ultimately sent his list to nearly 50000 schoolmasters, and he received completed forms from 45000 of them, The schoolmasters, with few guidelines and no precedents, provided Wenker with thousands of regional variants of all kinds: lexical, pronunciation, phonological, morphological, and syntactic. Overburdened by data, Wenker was forced to limit his analyses to a few variants found in a closely circumscribed area of north and central Germany, which he then painstakingly transcribed by hand onto two sets of maps bound as *Sprachatlas des Deutschen Reichs* and deposited in Marburg and Berlin in 1881 (Wenker 1881).

Thirty years before Wenker, the Finnish polymath Anto Warelius (1821–1904), approached the study of dialect from an entirely different perspective in a scholarly undertaking that remains virtually unknown outside his own country, but which has a prior claim over Wenker as the first truly systematic study. In 1846, Warelius set out on foot from Hamina in southeastern Finland and walked in a northwesterly line, eliciting and transcribing words and expressions from the villagers he encountered across almost 400 km (Rapolo 1969, Chambers 2000).

Warelius remains an obscure figure in the history of dialectology, but this method of eliciting dialect forms in face-to-face interviews with villagers foreshadowed the predominant method used by professional dialectologists for the next 150 years. The influential prece-

dent for the method of direct fieldworker elicitation was set in 1896 by Jules Gilliéron, a Swiss professor at the Sorbonne in Paris, in the dialect survey of France. Gilliéron trained an obscure grocer, Edmond Edmont, in the craft of phonetic transcription, and dispatched him into the French countryside on his bicycle. Edmont has become a legendary figure in dialectology for his unflagging devotion as he pedaled into 639 villages and interviewed 700 *paysans* in less than four years. He sent his transcriptions to Gilliéron in Paris at intervals, where they were incorporated into a cumulative mapping enterprise, and publication of the maps began in 1901 and ended in 1910 with the thirteenth volume of the *Atlas linguistique de France* (ALF). Gilliéron and Edmont's atlas (1901–10) stands as an early consummation of dialect geography and became the influential precedent for future projects for almost a century.

2. Impetus

The motivation for these methodical, large-scale studies in the second half of the nineteenth century is conventionally held to be a reaction to Neogrammarian philology, one of the great intellectual currents of the day. The Neogrammarians demonstrated law-like regularities in the historical descent of modern languages from classical ones. One of their tenets was *Ausnahmslosigkeit der Lautgesetze* 'sound changes are exceptionless.' Such a hypothesis, bold and admirably empirical, invites refutation, and a likely source would come from dialect data gathered from highly differentiated, relatively isolated villages.

The view that the first dialectologists rose to the Neogrammarian challenge has romantic resonance, but it is not strongly supported by facts. Neither Wenker nor Gilliéron nor any of their successors actually marshaled their data for elucidation, revision or refutation of any overriding linguistic principles, Neogrammarian or otherwise. In practice, the main results of their scholarship were descriptive rather than analytical, and their expressed goals aspired to no more. The *Sprachatlas* became the preferred medium for dissemination of results, with linguistic tokens carefully arrayed on geographic representations, usually with commentary on secondary variants which had to be omitted because they would overcrowd the map, and occasionally with isoglosses, lines drawn between locations where different variants tended to occur.

Rather than Neogrammarianism, the main impetus for dialectology as a systematic discipline appears to have been Linnaean taxonomy, another forceful current of nineteenth century intellectual history. Dialect data lends itself quite naturally to the taxonomic bent, with numerous gradations subcategorizable as alloforms of -emic categories roughly analogous to genera and their species.

Though taxonomy dictated the form that dialect studies took, the ultimate impetus has a much deeper source in human nature. History is replete with observations about dialect, going back at least three millennia in the Western tradition to the myth of Babel in *Genesis* 11: 1–9, whereby the Lord punished his ambitious subjects by 'confusing their speech, so that they will not understand what they say to one another.' Since Babel there has been a continuous tradition of astute comment on dialect differences which makes a long prelude to the institution of dialectology as a systematic classificatory enterprise. The English scholar Alexander Ellis remarked in 1875 that 'collecting country words is looked upon as an amusement, not as laying a brick in the temple of science' (quoted by Chambers and Trudgill 1998, p. 15). Ellis's spirit thrives, and is evident today in word columns in newspapers, tourist pamphlets on the local 'twang,' stand-up mimicry in theaters, news features on slang, and in dozens of other ways. The discipline of dialectology appears to be the scholarly manifestation of this natural human curiosity about language variation.

3. Methods

Until recently, dialectology gave primacy to recovering the oldest extant forms of language. This deliberate bias colored its methodology at every point. Fieldworkers chose their subjects as a judgment sample of NORMs, an acronym for a prototype who was nonmobile, older, rural, and (predominantly) male. For instance, Edmont's 700 subjects, all of whom were rural, included only about 200 educated people and 60 women. The NORM prototype was purposeful. Lack of mobility guaranteed that their speech would be characteristic of their village. Harold Orton, director of the Survey of English Dialects (SED), England's nationwide survey on Gilliéronian principles for which data was gathered from 1950 to 1961, said, 'dialect-speakers whose residence in the locality had been interrupted by significant absences were constantly regarded with suspicion' (Orton 1962, 15–16). Old age guaranteed that their speech would reflect a bygone era. Hans Kurath, director of the *Linguistic Atlas of New England* (LANE), part of the Linguistic Atlas of the USA and Canada that was begun in 1931 and still continues, declared that 'since most of the informants … are over 70 and not a few over 80, it would seem that we shall be able to establish the regionalism of the pre-industrial era of New England' (Kurath 1949, p. 27). Rurality eliminated mobile urban dwellers who were likely to be exposed to other dialects and accents (Chambers 2000). Males were targeted because their speech is less class-conscious than women's. As Orton put it, speaking about England, 'In this country, men speak vernacular more frequently, more consistently, and more genuinely than women' (1962, p. 15).

The basic methodology of traditional (Gilliéronian) dialect geography is to send trained fieldworkers to the locations where the subjects live in order to elicit specific items from the subjects guided by a standard questionnaire. The questionnaires are lengthy (Gilliéron's no less than 1500 questions, the SED about 1200, LANE about 700), with questions usually ordered by subject matter (flora and fauna, the barnyard, chores, etc.). Its purpose is to guarantee comparable data from all subjects. The fieldworker is expected to transcribe only the key word or phrase from the subject's response, no matter how long it might be. Labov summarized the method as 'a long question from the interviewer and a short answer from the subject' (Labov 1971, p. 113).

These methods have been subject to criticism from commentators versed in social-science methodology, especially with respect to the reliability of the population sample and the validity of the data (for instance, Pickford 1956). Obviously, NORMs constitute a rarefied minority when the majority population is exactly the converse—mobile, younger, urban, and female (Chambers 1993, p. 134). But criticisms like these largely miss the point about the antiquarian bias that motivates the methods. Raven I. McDavid, a venerated fieldworker on the American project and an articulate apologist, defended the traditional methods with this succinct capitulation: 'There is a deliberate bias in the choice of communities—in the direction of smaller and often isolated places; there is a deliberate bias in the selection of informants, insistence on local roots and a statistically disproportionate sample of the older and less educated; there is a deliberate bias in the choice of items for the questionnaire, in the direction of the old fashioned rural society, the horsedrawn vehicle, the mule-powered plow and homemade bread. All of these biases are essential to the purpose of the investigation, to push the historical records as far back in time as possible' (McDavid 1981, p. 71). Even as he articulated this defence, he inadvertently exposed the limits of the tradition at a time when modern technology had eliminated horsedrawn vehicles and social forces were inexorably diminishing the ranks of the uneducated and, indeed, rural society.

4. *Structuralist Analyses*

With the advent of Saussurean structural linguistics in 1916, language studies took a decisive turn in the direction of synchronic analysis. Taxonomy fell out of favor and intensionality gained adherents, at least in theory. However, dialectology clung to its autonomy, no more moved by structuralism than it had been by Neogrammarianism. Over the years, linguists made several attempts at integrating dialectology into linguistics. For instance, Uriel Weinreich (1954) proposed a level of analysis called the diasystem, which in effect posited a level above the phonemic where 'diaphones' could be segmented into the actual phonemes in two (or more) specific dialect systems by means of interpretive rules. Weinreich speculated that speakers must use something comparable to a diasystem for comprehension when they interact with speakers of other dialects.

Later, with the development of generative frameworks, there were similar attempts at integrating dialectology. For example, Keyser reanalyzed traditional atlas data from the Atlantic coast of the USA by demonstrating that several vowel distinctions found in the painstaking tabulations for dozens of speakers could be generated simply by positing two phonological rules and 'accounting for the formation of new dialect groups through the geographical dissemination of rules' (Keyser 1963, p. 313). Efforts like these gained few adherents, and they remained peripheral to the linguistic mainstream and had little impact on dialect studies.

More successful were the uses of atlas data in elucidating problems of historical linguistics. For instance, Hall (1943) used data collected in the *Sprach- und Sachatlas Italiens und der Südschweiz* ([AIS] Jaberg and Jud 1928–40) to demonstrate the persistence of the old political boundary of the Papal States on patterns of dialect differentiation in twentieth-century central Italy. The purposes of historical linguistics were of course consonant with the intentions of traditional dialectology, although the exploitation of the latter by the former offered much greater potential than was actually realized. It did, nevertheless, establish a vital, if minor, tradition.

5. *Decline and Rebirth*

As post-Saussurean language studies continued to be dominated by synchronic linguistics and entered a period of considerable currency stimulated by the ideas of Noam Chomsky, the failure of dialectology to become integrated caused it to slip ever further into the periphery of language studies. By the middle of the twentieth century, scholarly activities had slowed and become relatively inconspicuous. By 1980, even dialectologists began to realize that reform was necessary. In the first book-length summation of the field, Chambers and Trudgill stated: 'one might well wonder what the future holds for dialect geography. There is no doubt whatever that the financing of research and publishing for large-scale surveys is a great problem, and there is also no doubt that capable and enthusiastic practitioners of the calibre of those who went before are difficult to find; but it seems most likely that both of these facts follow from another fact, namely, that dialect research has taken a new direction … It is probably safe to say that the future of dialect geography depends upon the ability of its practitioners to embrace and incorporate the concerns

and perhaps the methodology of urban dialectology' (Chambers and Trudgill 1980, p. 23).

Many aspects of dialect geography came under criticism when they were noticed at all, including the utility of the *Sprachatlas* as a medium for disseminating results. 'For whom are these expensive volumes designed?' Macaulay asked, and then he said: 'Far from being a visual aid the maps are probably a barrier to grasping the pattern of distribution and it seems very unlikely that anyone nowadays would attempt this kind of mapping. Given the sorting power of computers, basic information is much better stored in a form that is suitable to machine processing than in conventional map form' (Macaulay 1985, p. 180).

With the founders gone, the rearguard reaction to these criticisms was muted. Starting in the mid-1980s, dialectology underwent a renaissance from which it would emerge as a vital and vigorous discipline with greater worldwide currency than ever before and, not coincidentally, greater intellectual depth. The sources were the antidotes identified in the two critiques above: the embracing of powerful new technology and the adaptation of more inclusive research methods.

6. *Computerization*

From its inception, dialectology had been burdened by an overabundance of data. Dialectology aspired to be, in Saussurean terms, a science of *parole*, that is, the study of language as a communal effusion, apprehended in actual speech events, imbued by and indeed mediating what Sapir called 'the apparent lawlessness of social phenomena' (Sapir 1929, p. 166). But the profusion of data proved daunting, and the methods used in classic dialect geography came into being partly as devices for delimiting the effusion and subjugating its lawlessness, by focusing on a narrow, linguistically conservative population, restricting elicitation to a closed set of items, and transcribing only individual tokens from the flow of speech.

The development of tape-recording as a reliable, affordable technology in the 1950s provided a means for making a permanent record of the flow of speech. However, the immediate impact of tape-recording on dialectology was negligible, coming into use merely for recording traditional elicitation sessions and thus serving mainly to provide archival documentation of the practices of McDavid and other fieldworkers. The most innovative of all regional surveys, the *Linguistic Atlas of the Gulf States* (Pederson et al. 1986–92 [LAGS]), directed by Lee Pederson, made a significant advance by recording all its interviews so they could be transcribed later under laboratory conditions. Meanwhile, beyond the formal confines of dialectology, tape-recording was embraced as a liberating medium by a few linguists genuinely interested in studying vernacular speech. In this way, tape-recording stimulated the rise of sociolinguistics, an urban dialectology with methods and goals that bore little resemblance to dialect geography.

More significant technology for the revitalization of dialectology came with the development of computers as reliable data-handling devices in the late 1960s, and especially as affordable and accessible universal processors in the 1980s. As Kretzschmar and colleagues put it: ' … the development of dialect studies, whether geographical or sociolinguistic, has always been hampered by a superfluity of data … Even smaller surveys have had to settle for selective analysis of their data because the wealth of possibilities for analysis overran the editors' time and the human capacity for holding in the mind only so much information at once. Computers can help overcome these problems: they are wonderful tools for quickly sorting and matching pieces of information and for performing complex calculations on the results, and … they are practically unlimited in their ability to store data' (Kretzschmar et al. 1989, p. v). Many dialectologists recognized the computers' potential for relieving the perpetual problem of overabundance. No less important, many scholars recognized the enormous advantages that would accrue from the computerization of the classic databases of the ALF (Heap 1997), SED (Ramisch 1997, Elmer and Rudin 1997), AIS (Goebl 1993), and the others. Generalizations buried in lists and tables for many decades could be disinterred by judicious computation.

7. *Dialectometry*

A significant development directly attributable to computational processing is dialectometry, literally, the 'measure of dialect.' The word *dialectométrie* was coined by Pierre Séguy, director of the *Atlas Linguistique de Gascogne*, one of the regional surveys comprising the *Nouvel Atlas de la France*. Séguy hoped to replace subjective judgments on the occurrence of dialect regions by quantifying the Gascony data in such a way that the regions would be revealed objectively—in effect, they would reveal themselves. In the sixth and final volume of the Gascony atlas (Séguy 1973), Séguy and his associates—*mes élèves-camarades*, he called them—published a set of maps, which linked each of the survey sites to its nearest neighbors by a number representing the percentage by which the two sites differed with respect to the forms elicited there. Séguy conceived the percentages as an index for measuring the 'linguistic distance' between the two places. The analyst, by inspecting the distance indices, could draw inferences about dialect regions based on degrees of similarity and difference.

Though Séguy's methods now look primitive, restricted as they were at the time to univariate comparisons and hand-made cartography, the numerical gradations across the maps rightly impressed many dialectologists as the first approximation of a visual

analogue for the dynamics of dialect gradation in space. Since then, dialectometry has advanced to multivariate statistical programs and computer-generated multidimensional displays that simultaneously compare all sites to one another. Dialectometry has become a generic term for all kinds of statistical dialect geography linked, as Goebl says, by a common goal: 'The preponderant aim of dialectometry consists in discovering, by the numeric combination of many low ranking patterns, higher ranking patterns which have remained hitherto hidden, in order to obtain a systematic insight into the problem of the basilectal management of space by HOMO LOQUENS' (Goebl 1993, p. 277). Practitioners of dialectometry can be found around the world from Japan to Canada. The numerous research programs remain largely uncoordinated and partly incompatible, but in the next decades the consolidation of methods and goals will undoubtedly crystallize into a powerful branch of dialectology unimaginable in the first century of the discipline.

8. *Sociolinguistic Dialectology*

The other revitalizing impulse for dialectology is sociolinguistics, which had its effective beginning in the 1960s with the dissemination of William Labov's fountainhead studies in Martha's Vineyard and New York's Lower East Side (collected in Labov 1972). Linguists began studying language variation with freer data-gathering methods, using larger and more representative subject samples, and they sought to understand its social significance with quantitative, acoustic and statistical analyses. The intellectual forebears of sociolinguistics, far removed from Linnaean taxonomy, were post-structural linguistics and the social sciences.

Dialect geographers, not surprisingly, did not immediately embrace the new currents, and it took a generation schooled primarily in sociolinguistics to recognize that the two disciplines were both, in essence, dialectologies. With hindsight, the rise of sociolinguistics can be viewed as a natural response to global social forces that have arisen since dialectology came into being, including urbanization, mobility of all three kinds—geographical, occupational and social—embourgeoisement, mass education and mass literacy. Those forces shrank the traditional domains of dialect geographers by reducing geographically isolated regions and socially isolated subjects to statistical insignificance in all the developed nations and beyond.

Observations of linguistic variation became refocused on social class, network, age, sex, ethnicity, and other social sub-groups as well as region, and the systematicization of those observations required new sets of independent variables and new methods for tracking them. In the social context that came into existence a century after Warelius and Wenker, the remaking of dialectology as sociolinguistic dialectology was inevitable. As Chambers and Trudgill said, 'A decade or two ago, it might have been possible to think that the common subject matter of dialectology and sociolinguistics counted for next to nothing. Now we know it counts for everything. Dialectology without sociolinguistics at its core is a relic. No serious perspective on dialectology can grant urban research and variation theory less than a central role' (Chambers and Trudgill 1998, p. 188).

One of the historical consequences of dialectology becoming sociolinguistic is that it has become an integral branch of linguistics. Like other branches of linguistics, its seminal works and formative investigations have been impelled and largely defined by specific issues, that is, by the need to develop or refine or refute particular hypotheses. The defining issues include these (discussed in Chambers 1993), among others: (a) How do the changes dialectologists observe in progress reflect the changes that occur in the history of languages? (b) How, if at all, do the grand concepts of the sociology of language—concepts such as diglossia, language shift, heteronomy, linguistic legislation and planning—affect social interaction, or become encoded emblematically in sociolinguistic variants? (c) How do dialect features diffuse throughout regions, and how does such diffusion affect the linguistic behavior of people in the community? (d) What is the adaptive function of dialect and accent? This last question, in particular, can be posed as a kind of ultimate question for all dialect studies.

There is a long tradition that presupposes dialect and accent to be dysfunctional, starting with the Babelian myth. Dialectology in all its methodological and intellectual guises shows that, on the contrary, in every human society linguistic variation prevails and thrives. It is a profoundly human attribute that is essentially irrepressible. The large, open-ended questions of dialectology can only begin to find their answers in fine-grained, minute research into the social significance of linguistic variation. The answers to those questions will ultimately elucidate the human language faculty. With that as its goal, dialectology constitutes a vital branch of modern linguistics.

Diaspora

This article considers the origin and changing use of the notion of diaspora, showing how, despite its specific reference to the history of the Jews, it has now come to be important in understanding many forms of international migration. How modern nation-states respond to the challenges of social and cultural pluralism is discussed. The different types of diaspora and diverse ways in which the concept is now used are also identified.

1. *Origins and Development*

The word 'diaspora' is derived from the Greek word *speiro* (to sow) and the preposition *dia* (over). When applied to humans the ancient Greeks thought of the word as signifying expansion through outward migration and settlement. 'Diaspora' soon acquired a more brutal and catastrophic meaning. In the Greek translation of the Old Testament it was used to describe the forcible dispersion of the Jews. The destruction of the Temple in Jerusalem in 586 BC led to the enslavement and displacement of the key military, civil, and religious leaders of Judah and their exile in Babylon. This fate was held to be predicted in Deuteronomy (28: 58–68) where God had warned that anybody who disobeyed his law would be scattered to all ends of the earth. There they would 'find no peace,' while they would additionally suffer 'an unquiet mind, dim eyes and a failing appetite.' 'Babylon,' then the capital of the Mesopotamian empire, become the code word for Jews (and later for Africans in the New World) signifying a place of loneliness and estrangement, where they were held in captivity.

This catastrophic meaning of diaspora, which may be described as the 'victim tradition,' was one that informed the historical and popular use of the term for nearly two millennia. Gradually, other groups saw themselves as victims of forcible dispersion in a manner similar to the ancient Jews and used the expression 'diaspora' as a self-description of their fate. Armenians, for example, allude to the period 1894–6 when their national movement was violently opposed by the Ottoman Sultan Hamid and some 300,000 Armenians were killed in Turkish Armenia. In 1915–16 'close to one million people' (Melson 1992, p. 146), about half the Armenian nation, were either killed or died of starvation. Armenian scholars and activists have accused the Turkish authorities of genocidal intentions, an interpretation that is generally accepted, though still hotly disputed by the current Turkish government. The subsequent dispersal of the Armenians to the USA, Iran, France, Lebanon, and other countries is now commonly described as a diasporic experience. The brutal Atlantic slave trade for New World Africans, the potato famine for the Irish, and (ironically) the return to Palestine of the Zionist part

of the Jewish diaspora for Palestinians are similarly considered the crucial traumatic events that triggered the creation of these other victim diasporas.

The above examples have an apparent theoretical and experiential coherence. A tragedy perpetrated by a hostile exogenous force generates movement to a number of countries. But because the displacement was forced and the traumatic event so encompassing, collective folk memories are developed, the populations remain psychologically unsettled, and a return movement gains some following. A number of conventional historians would wish to go no further with the idea of diaspora. However, from the 1980s, this relatively well-established meaning began to lose definition at its edges. Many ethnic groups of varying histories defined themselves as 'diasporas,' or were so recognized by scholars or journalists. The decisive intellectual movement for this new pluralism was marked by the launch of a journal called *Diaspora*, issued by the New York office of Oxford University Press in 1991 and edited by a US-based literary scholar of Armenian provenance. His opening manifesto was an impressive call for openness. The journal would be concerned with 'the way in which nations, real but imagined communities, are fabulated, brought into being, made and unmade, in culture and politics, both on the land people call their own and in exile' (Tölölyan 1991, p. 3). By 1998, the journal had published articles centrally identifying 34 ethnic groups as diasporas. Considerably more ethnic groups were more casually referred to as 'diasporas.'

2. *Types of Diaspora*

Natural scholarly caution would invite rejection of this profligacy. Yet, in fact, the pluralists have a good case. The paradigmatic example of the Jews, for example, shows that the communities abroad often arose from voluntary, not forced, movement, while the Babylonian experience can be characterized far more positively—as a place where new creative energies were released and challenging cultural encounters arose over a long period in a largely peaceful setting. Moreover, as has been mentioned, the original Greek meaning of diaspora allowed voluntary movement or even aggressive colonial settlement. Drawing on this etymology it would, for example, be perfectly consistent to allude to the British colonies in New Zealand, Australia, and Canada as comprising part of 'the British diaspora'—of an imperial, rather than victim, type.

In addition to the victim and imperial types, scholars have identified labour, trade, business, professional, religious, cultural, ethno-national, and refugee diasporas, as well as intermediate forms such as incipient, asylum, and 'new' diasporas (Safran 1991, Sheffer 1995, McDowell 1996, Cohen 1997, Van Hear 1998). These subtypes describe the predominant characteristic or characteristics of each diaspora, but cannot represent adequately the full complexity of each group in terms of its history, mixed motivations for emigration, and class diversity. It is apparent, for example, that the 50 million 'Chinese Overseas,' who have only recently been described as a diaspora, include people whose origins lay in semi-free 'coolie labor,' as well as those who migrated as entrepreneurs, traders, and skilled professionals.

Beyond the new pluralism, the key difference between 'diaspora' and more popularly recognized forms of migration is that in the first case cultural, linguistic, religious, historical, and affective ties with the place of origin remain strong. In the second, at least in theory, immigration from 'an old country' involves a one-way ticket, assimilation to the 'new country,' the adoption of a local citizenship and language, and the public acceptance of local ways and customs. As many studies of ethnicity in the USA and elsewhere have shown, in culture and endogamous practices the old ways were more resilient than public ideology proclaimed. Despite this finding, the myth and goal of full integration remain at the heart of the nation-building project and inform the difference between immigration in general and the specific case of diasporic migrant groups.

3. *Responses by Nation-states to Diasporas*

During the period of intense nation-building in the core European, South, and North American states a diasporic consciousness was either not sanctioned or firmly suppressed. The US state's motto '*Ex Pluribus Unum*' provided an example of the prevailing preference for assimilation or the creation of a new national culture. However, under the impact of diverse and accelerating immigration a number of important nation states (Canada, the USA, the Netherlands, Australia, and the UK might be cited) have lost their appetite and perhaps the capacity to assimilate immigrants to a single dominant political culture. By recognizing ideas of multicultural, multifaith, and multiracial societies, their political leaderships have reversed their previous disapprobation of the retention of pre-immigration ethnic identities.

Many social commentators are relaxed about this development and see no incompatibility between a national and an ethnic affiliation. Others, including those from the traditional liberal side of the political spectrum are anxious that the painfully achieved democratic and secular order in societies such as the USA will be undermined by the recognition of diasporas (Dickstein 1993). Even more alarming is the expressed fear that diasporas will become the means to foster religious zealotry, the international drugs trade, political instability, and cross-border terrorism. The involvement of exile groups, like the Tamils, Kurds, Sikhs, or Afghans, in the political life of their homelands or in movements to create nation states, has often created violent conflicts or embarrassing and difficult diplomatic and legal conflicts (Sheffer 1986).

By contrast, Shain (1999) argues that the democratic and liberal ways learnt in a the place of settlement are more likely to spread back into the countries of origin, with benign political effects for all parties.

The attitude of the countries of origin to their diasporic communities abroad has not gained much systematic discussion, though these states are increasingly important players in retaining and amplifying the links between 'home' and 'away.' Historically, countries like China and India have been hostile to their overseas communities, seeing them as painful reminders of colonial days when their labor forces could be captured by labor recruiters or, in the contemporary period, as 'brain-drain' migration. India, China and many other migrant-exporting countries now recognize that their diasporas can provide an important political lobby for advancing their countries' interests (American Jews seeking to influence US attitudes to Israel are cited as a positive example), a bridgehead for economic marketing of the home countries' goods, a means for acquiring transferable skills (for example in information technology) and, above all, a rich source for remittance and investment income. The Philippines has an expertly-run, state-supported set of agencies that promote labor export on a vast scale, help to channel return income, and seek to protect their workers from exploitative employers abroad. A diasporic consciousness is thus often preferred by a particular migrant group, tolerated by many host nation-states, and strongly supported by the country of origin. This is a significant change of policy and practice compared with the situation facing immigrants at the beginning of the twentieth century.

4. *Forms of Diaspora*

In addition to typologizing diasporas by examining their general characteristics, scholars have sought to classify the different 'forms' in which the term has been used, particularly by the different academic disciplines. A generally successful fourfold scheme has been proposed by Vertovec (1997) and modified in Vertovec and Cohen (1999).

The first form, advanced by sociologists and business studies specialists, is 'diaspora as social form,' alluding to the maintenance and development of transnational social organizations and networks, a collective identity, orientations to homeland and particular kinds of economic strategy (Safran 1991, Kotkin 1992, Cohen 1997). The second form is 'diaspora as consciousness.' Cultural studies theorists as well as those working in the fields of ethnic and race relations found in the notion of diaspora a means of breaking free from the 'essentialist' discourse that previously informed the subject matter. Notions of what constituted ethnicity became more fluid, hybrid, and negotiated, and 'diaspora' was a way of mapping how complexity and difference arouse as cultures travelled, interacted, and mutated (Clifford 1992, Brah 1996). The third is 'diaspora as mode of cultural production.' Though closely related to the second, this form is used by anthropologists to show how social and cultural formations, as well as cultural objects, images, and meanings have leaped from their old locales and crossed national lines (Hannerz 1996, Basch et al. 1994). Finally, 'diaspora as political orientation' has been considered by political scientists and international relations theorists. As noted earlier, such specialists concentrate on how the attachment to the politics of homeland can negatively and positively impact on the countries at both ends of the migration chain.

5. *Future of the Concept*

The concept of diaspora has firmly escaped its historical confines in the Jewish experience and at the beginning of the twenty-first century is used in a variety or settings and for a variety of purposes. The enduring logic is that the term conceptually connects home and abroad. The conflicting claims on group loyalties have been given an added emphasis in an age of global networks and the changing role, some would argue the relative decline, of the nation-state as a focus for group identification. 'Diaspora' will remain as an important means of interrogating and exemplifying this tension. It will also provide a useful means of describing the enhanced role for cyclical, transversal, and intermittent international migration.

Beyond this, the future of the term may be imperilled by having been commandeered to serve too many discrepant purposes and its use to describe cognate, yet different, phenomena. The use of 'diaspora' to describe transnational religious communities (as in 'Muslim diaspora') provides one example. In some cases, such as the Jews, Parsis, and Sikhs, religion, ethnicity, minority status, and peoplehood are so closely interpenetrated that the description 'diaspora' is apposite. 'Hindu diaspora' is acceptable, but undervalues the ethnic diversity under the expression 'Hindu.' However, 'Indian diaspora,' which expression is now in common use, misleadingly elides the differences between the three principal faith communities (Hindu, Muslim, and Sikh) and ignores well-organized national minorities (like the Kashmiris), with potentially confusing effects. The idea of a 'Turkish diaspora' presents similar issues. In addressing such problems, there may be some virtue in using the expression 'transnational communities' to characterize a number of different postnational and non-national forms of sociality and association. Examples so categorized can be virtual Internet communities, Christianity, Islam, transnational social movements, and international professional associations. Within the rubric of transnational communities can shelter 'diaspora' as a particular form of ethnically defined community. Some degree of self-restraint may, in

other words, prove necessary if the term is to retain its conceptual purchase.

Dictatorship

The term 'dictatorship' is one of Roman derivation, and originally signified the temporary suspension of constitutional constraints on governmental power and its unlimited transfer to one person. Among the Romans, there was provision for a temporary suppression of citizen rights during times of crises, and the equally temporary transfer of unlimited power, to a person chosen by the Senate and appointed by the Consul. At the end of a specified period—usually six months—the person so endowed, the dictator, surrendered power, and citizen rights were restored. The period of emergency stewardship was then duly reviewed, in accordance with constitutional requirements. During instances of emergency, over three centuries of republican constitutional rule, Rome appointed 88 dictators in conformity with law.

Following the rule of Julius Caesar, who exercised dictatorial powers for an unconstitutional length of time, the institution disintegrated and rulers assumed extraconstitutional powers in permanence. Rather than a traditional dictatorship, such rule took on the properties of what might more appropriately be called 'autocracy,' 'despotism,' or, perhaps, 'tyranny.'

Throughout the Middle Ages and more modern times in Europe, as well as during the institutionalization of dynastic rule in East and South Asia, 'autocracies' tended to be regularized through the agency of hereditary right—providing for succession without recourse to violence. Emperors, kings, and sultans could, and frequently would, allocate powers to 'noble' subordinates through a relatively well-articulated, rule-governed process. At times, as was the case in the rights embodied in the Magna Carta, some substantial rights were accorded subordinates.

1. The Modern Period

With the decline of the Middle Ages, it became increasingly common that adventurers would seize power in emerging city-states and principalities, and rule as despots or benevolent autocrats. The term 'dictatorship' was rarely, if ever, employed to identify such rule until the commencement of the modern period.

In regions such as Latin America, the term came into increasing vogue after the liberation from Spanish colonialism, irrespective of the fact that the ideal, throughout Central and South America—influenced by the North American model—was constitutional democracy and political stability. The basic charters of most of the nations of Central and South America had incorporated broad versions of the civil, political, and economic rights of citizens to the point of extravagance (Davis 1961). Unfortunately, governments in Latin America, throughout the remainder of the nineteenth and the beginning of the twentieth century, regularly came to power through violence and were commonly dislodged by revolution. During a 25 year period, from 1930 to 1955, for example, more than 50 violent, mainly military, revolutions took place in the region—to provide an impressive roster of

'military dictatorships' that ruled for variable periods of time (Lieuwen 1960).

In Africa, military dictatorships became the norm in the decades after the decolonization of European holdings that followed the conclusion of the Second World War. The African military—having a monopoly of coercion at its disposal, and often the only institution having logistical reach over the entire territory—acceded to absolute political power over inhabitants. Control, unconstrained by constitutional limitations, was more frequently than not secured by violence or the threat of violence.

In fact, the term 'dictatorship' (as distinct from terms like '*caudillismo*' used in Latin America) came into increased currency in Europe long before its employment elsewhere. At the commencement of the modern period, it came to be used, for example, to designate what was initially understood to be a temporary assumption of full power by what was called the Directorate under Cromwell in England, and in 1793, by the Committee of Public Safety, during the French Revolution.

After the conclusion of the First World War, the term was invoked to distinguish a pattern of rule by 'dictators' such as Benito Mussolini in Italy, Primo de Rivera in Spain, or Mustafa Kemal in Turkey. Actually, what such dictatorships signaled was a development that was far more portentous than simply the identification of the exercise of political power by a single ruler in any particular country. What was emerging was a singular political system, having a relatively specific syndrome of properties, that can be legitimately identified as 'modern dictatorship' (Talmon 1960).

2. *Modern Dictatorship*

The dislocations that attended the end of the First World War, gave rise to a wave of revolutionary ferment that involved Eastern and Southern Europe (Lee 1987). In Russia, revolutionaries first overthrew the Romanov monarchy, and then the provisional democratic government of Alexander Kerensky, in order to impose, in 1917, a 'dictatorship of the proletariat' under the leadership of V. I. Lenin.

According to the tenets of classical Marxism (the Marxism of Karl Marx and Friedrich Engels, the dictatorship of the proletariat was to be a transitional form of minority rule that marked the distance between 'bourgeois democracy'—what Marxists considered to be, in reality, a 'dictatorship of the bourgeoisie'—and communist democracy (see *Communism*). Lenin assumed full power over the emerging political system that followed the 'proletarian' revolution (see *Revolution*) by legitimizing it through an appeal to an ideological rationale (Furet 1999).

At approximately the same time, in 1922, Benito Mussolini led a collection of revolutionaries against the parliamentary and monarchial government of peninsular Italy (De Felice 1965). Initially what appeared to be a transitional government, calculated to deliver the nation from the crises that followed the First World War, the government of Mussolini quickly took on the features of a modern dictatorship. Through reforms commencing as early as 1925, Mussolini's Fascist regime assumed the properties of permanent minority rule under single-party auspices (De Felice 1968).

Lenin's proletarian dictatorship and Mussolini's Fascism provide a syndrome of traits that specifically characterize modern dictatorship (Johnson 1991). In both cases, a charismatic leader exercises almost total control over followers as well as the national community out of which they emerge. Leadership in both cases is epistemarchic in character. That is to say, leadership, in the absence of popular elections, is legitimatized by the leader's putative possession of an ideology (see *Ideology: Political Aspects*) that is an inerrant guide to policy, satisfying the needs of the collectivity (respectively the proletariat, or the nation). The inerrant ideology informs the belief system of an organization of believers, usually identified as a 'vanguard' of the revolutionary truth. In the course of time, that vanguard becomes the 'unitary party' of the political system—to the exclusion of alternatives. The inerrancy of the ideology and its attendant policy, in turn, is used to justify control over any and all political dissidence (which, under the circumstances, could only be in error) and any initiatives independent of the vanguard leadership (Manoilescu 1941).

In general, modern dictatorships maintain a military adjunct to unitary party rule. In the Bolshevik case that adjunct was the Red Army. In the case of the Fascist revolution, that adjunct was the Blackshirt militia. In the case of Adolf Hitler's National Socialism, that adjunct was the Schutz Staffel While military force remains an ultimate recourse of the system, modern dictatorships tend to be populist in disposition. They seek plebiscitary confirmation through controlled elections. Leadership, in modern dictatorships, because it is characteristically 'charismatic,' enjoys life tenure. The Democratic People's Republic of Korea (North Korea), as a case in point, exemplifies such a system. After the Second World War, Castro's Cuba, and Mao's China constituted illustrative instances. The system under the rule of Gamal I Abd' El-Nasser in Egypt, and Ghana under Kwame Nkrumah took on many of the same features. They took on the properties of a modern dictatorship however much their actual practice failed to fully satisfy the criteria for admission into the class.

In most cases, modern dictatorships, whatever their initial character, took on the features of an emphatic nationalism. Having begun as an ideology predicated on class, Bolshevism, as an instantial case, very quickly made recourse to 'patriotism' to sustain popular commitment. All classes and segments of classes in the

Soviet Union were expected to be supportive of what were unmistakably national purposes, however 'proletarian' they were supposed to be.

Similarly, given the traits exemplified by such a class of polities, they all failed to allow for what parliamentary and constitutional systems understand to be voluntary association, formal opposition, free elections, the separation of legislative, judicial and executive powers, as well as popular freedom of expression and individual movement. In almost all cases, the charter constitutions of such systems change with some regularity (the constitutions of the People's Republic of China, for example, have changed with every change of leadership) and their provisions are subject to unconstrained interpretation (the provisions of the constitution of Fascist Italy, for example, were subject to the regular reinterpretation of Mussolini and the Grand Council of Fascism).

3. Modern Dictatorship and Totalitarianism

By the beginning of the 1930s, a subset of modern dictatorships began to evince characteristics that led political scientists to design them a specific identity: totalitarianisms (see *Totalitarianism*). Possessed of an elaborate security and control infrastructure, supported by a factitious or real consensus, and animated by an irrepressible conviction of their own aggressive moral superiority, such politically repressive systems destroyed millions of innocents, either as a measure of control, or in the pursuit of utopian intention (Horowitz 1997) .

The numbers killed by Stalin, Hitler, Mao, and the Khmer Rouge will probably never be accurately known—but the victims of Marxist–Leninist (see *Marxism/Leninism*) regimes probably exceed one hundred million (Courtois et al. 1999). 'Mild' totalitarianisms—like those of Mussolini's Italy, Chiang Kai-shek's China, or Castro's Cuba—neither particularly homicidal nor genocidal—employ incarceration and exile, together with the characteristic denial of voluntary association and freedom of expression, as means of control.

Whatever the subsequent qualifications on the use of the term 'totalitarianism,' throughout the twentieth century an imprecise subset of modern dictatorships have shared a number of reasonably well-defined traits that qualify them for entry into a specific class of modern political systems (Schapiro 1972, Soper 1985, Gleason 1995). How far into the twenty-first century exemplars of the totalitarian subset of modern dictatorships will persist remains a matter of conjecture.

That such systems can evolve into something like a democratic alternative has been established by the transformation of Chiang Kai-shek's Kuomintang on Taiwan into something very much like a vital democracy. The massive reforms on the mainland of China, that followed the death of Mao Zedong, suggest that such systems have the potential to undergo systemic change. How such change is effected remains uncertain.

Dictatorship in History

Originally, the word dictatorship had a limited and unambiguous meaning in that it defined an extraordinary magistrature of the ancient Roman Empire. During the nineteenth and, particularly, the twentieth century, the meaning of the term has been substantially modified. In contemporary parlance, 'dictatorship' is used to define any means of governing and any type of political regime based upon the *unlimited concentration of power* in the hands of one individual (or of a group of people, a party or institution) holding it for an indeterminate time and exercising it without being

controlled by either the state's institutions or by its citizens.

This article will trace the transformation of the concept of dictatorship within the main instances of government to which it has been applied and with regard to the principal interpretations of the phenomenon, that is, the governmental types defined as dictatorships produced during the twentieth century when the term first became the object of specific historical research and theoretical analysis.

1. Roman Dictatorship

1.1 Origins and Functions

Dictatorship was probably introduced into the constitutional order of the Roman Republic at the beginning of the fifth century BC, soon after the end of the monarchy. Today, the original interpretation of dictatorship as attributed to the survival of the monarchy tradition has been abandoned. A more plausible interpretation is that which sees Roman dictatorship as being derived of an already existing institution in other cities in the province of Latium (Sterling 1965). The role of dictator could be conferred for the performance of various public duties, the most important being that of the defence of the city and of its rule in situations of serious danger, in the case of external war (*belli gerundi causa*) or internal turmoil (*seditionis sedandae causa*). In these circumstances, full civil and military powers (*imperium maximum*) were conferred upon the dictator for a maximum period of six months. The nomination was made by one of the two consuls in office (who could not, however, nominate themselves) upon the request of the senate, which assessed the gravity of the situation. The dictator stepped down at the same time as the consul who had nominated him. All other magistrates were subordinate to the dictator. He himself, however, did not have the power to repeal them nor to pass or repeal laws, modify the constitutional order, or nominate his successor. Once the duty for which he had been nominated to fulfill was completed, even before the passing of six months, the dictator resigned power to the ordinary magistrates.

1.2 The Transformation and End of the Roman Dictator

The dictator remained in force until the third century BC. The last dictator to have maximum civil and military powers was nominated in 216 BC during the second Punic war between Rome and Carthage. When reinstated in the first century BC by L. Cornelius Sulla and later by Julius Caesar during the time of the civil wars that led to the end of the Republic, the dictator's function was radically transformed. The dictatorships of Sulla and Caesar, despite the outward appearance of legality, originated in the force of the army, were conferred for an indeterminate length of time, and were used to eliminate political adversaries and to change the order of the Roman State. Roman dictatorship was legally abolished by Mark Anthony in 44 BC, directly following the death of Caesar (*lex Antonia de dictatura tollenda*) and was not reinstated again during the Empire. The term 'dictator' also was not used for many centuries and was not in any case adopted again until the beginning of contemporary times in order to define new exceptional forms of personal power that appeared in the medieval and modern ages in the form of the 'Podestà' of the Italian communes, the Renaissance 'Signoria' or Oliver Cromwell's 'Protectorate' (see *English Revolution, The*; *Middle Ages, The*; *Renaissance*).

2. From Roman Dictatorship to Modern Dictatorship

2.1 The Model of Roman Dictatorship in the Modern Ages

The term 'dictatorship,' referring exclusively to the Republican magistrature, appeared once again in political writings of modern times such as those by Jean Bodin and Thomas Hobbes, who cited it as an example of the fulfillment of the principle of Reason of State and of absolute sovereignty. Niccolò Machiavelli made a decisive contribution to that which we may term the 'apology conception' of dictatorship, understood as exceptional personal government for the purpose of saving the Republic and defending its liberty against internal and external enemies. The value of dictatorship, according to Machiavelli, was the brevity of its duration. As long as this function should be retained, dictatorship '*fece bene e non danno alla Republica romana*' (*Discourses*, I, 10, 33, 35).

This apologetic conception of dictatorship was again proposed in the seventeenth century with the idealization by democratic thinkers of the Enlightenment of republican public spirit (see *Enlightenment*). Jean-Jacques Rousseau maintained that in periods of danger the democratic state could nominate a 'supreme chief who silences all the laws,' fixing a relatively short period for the fulfillment of this chief's role without the capacity for its being prolonged, because only in this way would it be possible to avoid the transformation of dictatorship into tyranny (Rousseau 1997, p. 138).

2.2 Dictatorship and Revolutionary Power

The term 'dictatorship' re-entered political language at the end of the eighteenth century with the democratic revolutions in America and Europe (see *American Revolution, The*; *French Revolution, The*). In France, following the experience of the Public Health Committee, nominated by the National Convention (1793–5) both a new conception and practical expe-

rience of dictatorship emerged. This was identified by the advent of *revolutionary power* as a form of absolute government, exceptional and temporary, yet personal, which claimed its legitimacy on the basis of the principle of popular sovereignty, the wish to create a new constitutional order and a more just society. After the fall of the Jacobins, François-Noël Babeuf theorized the necessity of dictatorship by a small revolutionary minority in order to seize power by means of insurrection with the aim of realizing a 'society of equals.' After the failure of his insurrectionary attempt (1796) the concept of revolutionary dictatorship was taken up by Filippo Buonarotti, a disciple of Babeuf.

3. *Dictatorship in the Nineteenth Century*

3.1 *'Bonapartism' and 'Caesarism' in Europe*

In the course of the nineteenth century, the term 'dictatorship' was used in its original meaning by the military leaders of the national revolutions. Simon Bolivar proclaimed himself dictator in 1813, and Giuseppe Garibaldi assumed the power of dictator in 1860 during the expedition of the Thousand. The idea of dictatorship was often associated, within nationalism, with the idea of exceptional government for national liberation. Most important, for the history of dictatorship and the transformation of the concept were the new forms of personal regimes founded in Europe by Napoleon Bonaparte (1799–1814) and later by his grandson Luigi Bonaparte, becoming Napoleon III (1851–70). Their dictatorship originated in a *coup d'état*. However, they attempted to legitimize their personal power later with a popular plebiscite and with the transformation of the monarchy without formally reneging on the principles of the French Revolution.

These two experiences of government gave rise to the term 'Bonapartism,' from then on used to define the new type of dictatorship imposed by a *coup d'état*, but claiming a democratic legitimacy by means of plebiscites. The introduction of the term 'Caesarism' was also used in the definition of this new type of dictatorship, in that Julius Caesar was considered the prototype for the modern dictator, emerging victorious after a period of serious social and civic conflict and imposing his personal power using military strength, but also with the support of the masses, presenting himself as the pacifier of the classes, above parties, restorer of stability and of the unity of the State, the incarnation and the interpreter of the national will.

3.2 *Dictatorship in Latin America*

A particular demonstration of a South American version of 'Caesarism' can be found in the presidential dictatorships installed in the majority of the Latin American Republics emerging after independence. These dictators were politicians or military men who elected themselves president and perpetuated their personal power for decades while, nevertheless, paying homage to liberal ideology, allowing for the survival of the constitutional order and, above all, imposing the centralization of state power against the *caudillos*, the local leaders who, in the first years following independence, instituted personal control with the help of the army, the personal fascination with virility, and the support of the indigenous and mestizo populations. Other president-dictators, followers of positivism, justified their dictatorship with the formula 'order and progress' as a necessary means for reinforcing the unity and cohesion of the state, as a pedagogical tool for the education of the people, and as a principal factor in the renovation of society and progress. This new version of the apologetic conception of dictatorship remained one of the principal formulas of populist self-legitimation for the dictators that successively dominated South America (see *Populism*).

3.3 *Apologists for and Critics of Dictatorship*

Other versions of the apologetic conception of dictatorship were elaborated in romantic culture, in Catholic reactionary thought, and in positivism: the dictator was variously exalted as the supreme guide of the people, the interpreter of God's will, or the political genius who actuated the laws of history and of progress. Liberal culture, on the other hand, held that the same possibility of conferring absolute power upon a single individual was incompatible with the concept of the modern state founded upon the liberty of citizens, on the sharing of power and on the principle of majority rule. Duclerc and Pagnerre's *Dictionnaire Politique* of 1848 explicitly refuted the treatment of dictatorship as 'an element of modern politics' because 'invoking dictatorship means invoking violence' and annihilating 'the most sacred principle of democracy, that of majority rule' (see *Crowds in History*; *Liberalism*).

3.4 *The Dictatorship of the Proletariat*

In socialist thinking, the concept of dictatorship as revolutionary power was developed. Louis-Auguste Blanqui theorized the necessity of the dictatorship of a revolutionary minority for the realization of communism. This conception was criticized by Karl Marx and Friedrich Engels because their idea of revolutionary dictatorship had to be the *impersonal power* of the working class. The Paris Commune of 1870 represented for Marx the first concrete attempt at proletarian dictatorship. In that in a society divided into classes every type of state is no other than the dictatorship of the dominant class, according to the idea sketched out by Marx in the *Critique of the Gotha Programme* (1875), 'proletarian dictatorship' was un-

derstood as the organization of the working class at the level of the state following the conquest of power in the transition period from capitalist to communist society.

The concept of 'proletarian dictatorship' was first elaborated with the conquest of power in Russia in 1917 by the Bolshevik Party led by Lenin (see *Communism, History of*). Lenin was a convinced and tenacious advocate of the necessity of dictatorship intended as an unlimited, inflexible, and implacable power in the repression of enemies of the proletariat because, in the absence of this power, the transition from capitalism to socialism would be impossible ('The immediate duties of Soviet power,' April 26, 1918, in Lenin 1971). However, against Marx, Lenin claimed that dictatorship of single individuals, endowed with unlimited power for the realization of the socialist revolution was not in fact incompatible with proletarian dictatorship, exercised by the Bolshevik Party as the vanguard of professional revolutionaries and interpreters of the historical role of the proletariat.

The Leninist conception of dictatorship and its practical activation were criticised by other revolutionary Marxists such as Rosa Luxemburg who claimed that proletarian dictatorship should consist of 'a means of applying democracy, not of its abolition,' and 'the work of the *class*, and not of a small minority of leaders in the name of the class' (Luxemburg 1970 pp. 570–94).

4. The Twentieth Century: A Century of Dictatorships

4.1 The Epidemic of Dictatorship in Europe between the Two World Wars

'In the Victorian era,' wrote Winston Churchill in 1930 in the introduction to one of the first attempts at the historical and theoretical analysis of dictatorship (Forst de Battaglia 1930), 'dictatorship was at once a monstrosity and an anachronism.' The triumph of parliamentary democracy in Europe in the aftermath of World War I was ephemeral. In 1922, the 'crisis of democracy' and the 'crisis of parliamentarism' were already being talked of (Guy-Grand 1922, Schmitt 1923), while with the affirmation of absolute power by the Bolshevik Party in the USSR a new type of dictatorship as a regime by a single party was being affirmed for the first time. The fascination with the Bolshevik experiment excited masses of European workers and prompted the birth of communist parties with the aim of violent conquest of power for the establishment of 'proletarian dictatorship.' Nevertheless, no attempt at communist conquest of power was successful. On the contrary, the fear of Bolshevism generated reaction on the part of the bourgeoisie and the middle classes in many countries which led to the creation of authoritarian, nationalistic, and anti-Bolshevik governments. After 1922, almost every year, more or less durable dictatorial nationalist governments emerged in Italy, Spain, Turkey, Poland, Greece, Portugal, Austria, Germany, the Baltic States, and the Balkans.

4.2 The Model of Fascist Dictatorship

At the end of 1922, with Mussolini's coming to government in Italy (28 October), for the first time a nationalist revolutionary movement organized around a new form of party, the 'party-militia,' conquered power in a country governed by a liberal democracy with the declared object of destroying it. This gave rise to the establishment of a regime that antifascists were the first to call a 'one-party state,' 'totalitarian system,' or 'totalitarianism,' defining a new type of dictatorship founded upon the predominance of a single party, the centralization of power in the hands of the party leader, the imposition of a singular ideology with the aim of realizing the subordination of society to the state by means of control by the singular party and its organizations (Gentile 1995).

Until the middle of the 1920s, fascism, and not Bolshevism, was considered the real threat to parliamentary democracy (Martin 1926). Italian fascism effectively became the model for other nationalist movements that proclaimed their dictatorial vocation, openly opposing the ideals of the French Revolution. At the beginning of the 1930s, Europe was invaded by an 'epidemic of dictatorship' (Sforza 1931). Initially, the dictatorial disease was considered to be exclusive to less developed countries (Cambò 1930). This interpretation was proved wrong after the rise of National Socialist dictatorship in Germany (see *National Socialism and Fascism*). In the second half of the 1930s, however, the 'seduction of fascism' seemed to grow (Drabowitch 1934). During World War II, most of Southern, Central, and Eastern Europe was governed by dictatorial systems.

4.3 Totalitarian States

In the period between the two world wars a new apologetic myth of the dictatorial figure as the 'strong man' who emerges in times of crisis to rescue the State and re-establishes order, discipline, and efficiency was diffused (Séché 1924, Béraud 1933, Massis 1939). At the same time, the first attempts at comparative analysis aimed at elaborating a unitary perspective on the phenomenon of dictatorship were begun. Already, by the second half of the 1920s, several analogies between the dictatorship of Bolshevism and that of fascism came to prominence, later compared also to the dictatorship of National Socialism. The classification of these new types of dictatorship under the category of 'totalitarian states' appeared at the end of

the 1920s and was already consolidated by the 1930s and 1940s when the first comparative analyses of fascist, communist, and national socialist regimes were carried out (see Kohn 1935, Hoover 1937, Sturzo 1938 1972, Borkenau 1939, American Philosophical Society 1940, Neumann 1942, Aron 1946).

These studies analyzed the new form of dictatorship from the point of view of its most original aspects, neatly distinguishing it from both Roman and nineteenth-century dictatorship. These aspects included:

(a) the peculiarities of the original phenomena of dictatorship, attributed to the legacy of war, the embitterment of class war, the radicalization of politics, and the incapacity of the parliamentary system to adapt itself to the tumultuous growth of mass society and to provide an effective solution to social and economic conflicts;

(b) the interest of the masses living through the turmoil of a society undergoing transformation and looking for simple and reassuring solutions by subordinating themselves to the command of a 'strong man' who promised to resolve the crisis with brutal yet efficient methods;

(c) the novelty of contemporary dictatorship as a one-party regime, created by a mass movement that used parliamentary channels, violence, and terror to conquer and maintain power, rendering permanent its own dictatorship and institutionalizing it as a fundamental pillar of a new political system;

(d) the personalities of the dictators brought to power by these parties such as Stalin, Mussolini, and Hitler, that is, 'new men' emerging from anonymity and rising to power solely due to their political capacity, exalted and revered like demigods by their followers and by the masses;

(e) the fanaticism and missionary spirit of the new dictators who endowed their ideology and action with the character of a secular religion;

(f) the use of methods of technological and organizational modernization for the mobilization of the masses and the development of an intense and constant activity of collective indoctrination; and

(g) the ambition of subordinating the collectivity and society to the permanent and capillary control of a single party with the aim of creating a new species of human being.

4.4 The Dictatorial Phenomenon After the End of World War II

In the aftermath of World War II, while parliamentary democracy was being re-established in Italy and Germany, liberal democracy was definitively consolidated in Western Europe and, after 1945, there were no new dictatorships in this part of the continent. From among the nationalist dictatorships emerging from the interwar period, only the Salazar regime in Portugal and that of Franco in Spain remained standing, both of which returned to democracy after the death of the two dictators in the second half of the 1970s. The only new dictatorship was that of the Colonels' regime in Greece (1967–1974).

The phenomenon of dictatorship, nevertheless, enjoyed a new and intensified period of expansion in almost all continents. Only North America and Australia remained uncontaminated by the new dictatorial epidemic. Directly after the end of World War II, East Germany, all of Eastern Europe, and the Balkans were put under the control of the new communist dictatorial regimes, the so-called 'popular democracies' (Fejtö 1969), completely subordinated to the political and military hegemony of Stalin's USSR from which only the communist regimes of Yugoslavia and Albania escaped. From 1949, with the victory of the communist revolution led by Mao in China, the world's most densely populated country became governed by a dictatorial regime with its own characteristics, different to the European communist dictatorships and to those of the USSR. During the 'Cold War,' the communist model, with variations original to each country, inspired the construction of several dictatorial regimes, both civilian and military, in Central America, Asia, and Africa with the help of the two largest communist countries, the USSR and the People's Republic of China, becoming, since the 1950s, rival and antagonistic states both for ideological reasons and for those concerning territorial conflict (see *Chinese Revolutions: Twentieth Century*; *Cuban Revolution, The*; *Vietnamese Revolution, The*).

The common characteristics of the communist dictatorships were (a) the adoption of Marxist-Leninism as their official ideology; (b) the supremacy of the Communist Party as the single and dominant party; (c) the exaltation of the party leader resulting in the institutionalization of the 'cult of personality'; (d) the policed repression of any opposition or dissidence, including the recourse to mass terror; (e) the nationalization and planning of the forces of production and of the economy; (f) the submission to control by the Communist Party of all political and social activities; and (g) the development of a particular form of 'communist patriotism,' centered upon the myth of the historical mission of the proletariat.

During the 'Cold War,' anticommunism was the motive and principal ideological justification for the establishment of right-wing, civilian, and, more often, military dictatorships sustained by the USA. These dictatorships, especially the military ones (Nordlinger 1977), when not based exclusively on terrorist repression and the arbitrary use of power in the interests of the dictator, his family, or acolytes, attempted to relate policed repression to a demagogic politics of nationalist populism all the while linked to programs of modernization and development (see *Modernization and Modernity in History*). In the second half of the twentieth century, dictatorship in the Third World became 'the normal form of govern-

ment' (Roy 1977). Almost all the new states emerging in Africa and Asia after the fall of the colonial empires were governed by dictatorial regimes, generally military with a single party created from above, a charismatic leader, and a populist ideology of national socialism with programs of secularization and modernization. In the second half of the 1970s, in several Islamic countries, religious fundamentalism became the matrix and ideology for new dictatorial governments.

The tendency towards the proliferation of dictatorships came to a halt in the last two decades of the twentieth century (Hamon 1982). The number of dictatorships—or governments considered as such—has notably diminished. In Latin America, parliamentary democracy has been reinstated in the grand majority of states previously governed by dictators. The fall of the USSR brought about also that of the communist regimes of Central and Eastern Europe that it sustained (see *Revolutions of 1989–90 in Eastern Central Europe*). The promotion of human rights has acquired new determination, albeit not always effective, in contesting antidemocratic, repressive, and terrorist governments and in the defeat of the various apologetic conceptions of dictatorship (see *Human Rights, History of*). Nevertheless, it would be too optimistic to use the above to declare the definitive death of dictatorship in the contemporary world and the victory of the democracy of human rights (Hermet 1993).

5. *Contemporary Dictatorship: Problems of Definition and Interpretation*

5.1 *Definitions and Typologies*

Contemporary dictatorships are extremely heterogeneous: civilian or military, personal or collective, conservative or revolutionary, traditionalist or modernizing, bureaucratic or charismatic, authoritarian or totalitarian. Moreover, not only do contemporary dictatorships have nothing in common with their ancient predecessor, apart from the concentration of power, they also differ extensively among themselves according to the geographical, historical, and cultural contexts in which they emerge and owing to the economic, political, and social situations that give rise to them. Furthermore, they differ as regards the social origins of their protagonists as well as the latter's political formation, the modes in which power and methods of action are organized, the ideologies they profess and the aims they propose. Finally, differences exist relative to the historical development of their emergence, the results they have achieved, and the legacies they have left.

Given the variety and complexity of the phenomenon of dictatorship in the twentieth century, it is very difficult to elaborate a general, unitary theory of dictatorship. Several fundamental problems therefore remain unsolved, particularly those which concern the specific nature of contemporary dictatorship with respect to other forms of absolute personal power. There are various definitions and typologies for classifying the numerous forms of unlimited concentration of power appearing during the course of the twentieth century, commonly adopting the term dictatorship albeit with a meaning varying widely from the original (see especially Schmitt 1928, Friedrich and Brzezinski 1956, Neumann 1957). There are some scholars, however, who prefer to use the term dictatorship in reference only to its original meaning, finding the term 'antidemocratic regime' more appropriate for defining the modern forms of unlimited concentration of power, be they authoritarian or totalitarian (Linz 2000). The identification of contemporary dictatorship with antidemocratic regimes is, however, only one aspect of a much more ambiguous relationship between contemporary dictatorship and democracy, understood as the affirmation of the principle of popular sovereignty and mass participation in political life. Contemporary dictatorship in fact 'belongs to the postdemocratic era' (Kohn 1935), that is, it presupposes the democratic process yet nonetheless searches for its own formula of legitimation within the principle of popular or national sovereignty (Duverger 1982).

5.2 *Dictatorship, Tyranny, Despotism*

In contemporary speech, dictatorship is often associated with tyranny or despotism. Terms such as dictator, tyrant, and despot are often used as synonyms or alternated between. The first students of the phenomenon of dictatorship in the interwar period, while maintaining that the concept of dictatorship is linked to the Roman model of an extraordinary, yet constitutional and temporary magistrature, preferred to speak of a 'new age of despots' (Spencer 1927), or of a new '*ère des tyrannies*' (Halèvy 1938). In more recent studies also the term 'tyrant' is preferred over that of dictator for defining the numerous ranks of those holding absolute personal power, dominating, in the second half of the twentieth century—and still in some cases dominating—in many countries of the Third World (Rubin 1987, Chirot 1994). In fact, contemporary dictatorship evokes some of the characteristics of Greek tyranny (Stoppino 1976), but there are also substantial differences. Above all, the origin of contemporary dictatorship is not always illegitimate. For example, Hitler came to power in 1933 through legal channels and many presidents who became dictators in Latin America were legally elected. Furthermore, the majority of modern dictatorships have a very complex structure of organization and exercise of power due to the mass dimension of the societies in which they operate, the methods they adopt, and the aims they propose. All the above makes contemporary

dictatorship substantially new and different to tyranny. Therefore, the thesis that holds that the difference between tyranny and contemporary dictatorship as a form of absolute personal power is not substantive, but regards solely the form, technique, and method of government should be forcefully rejected (Hallgarten 1957).

5.3 Dictatorship and the Dictator

Several scholars consider the figure of the dictator an essential and fundamental element in the definition of dictatorship (Cobban 1939). A large part of the general history of dictatorship consists of collections of biographies that sometimes link, in more or less chronological succession, Greek tyranny and the Roman dictators, Cola of Rienzi and Geralomo Savonarola, Cromwell and Robespierre, the two Napoleons, the 'caudillos' and the authoritarian and totalitarian dictators of the twentieth century (Funck-Brentano 1928, Bainville 1939, Hallgarten 1957). Some scholars maintain that governments in which unlimited power is not concentrated in one individual cannot be defined as dictatorships in the proper sense of the term (Sartori 1971).

The identification of dictatorship with the figure of the dictator is certainly justified in the majority of the cases in history. In almost all contemporary dictatorships, the dominant personality of one man emerged at the outset or was subsequently imposed, often surrounded by a charismatic and sacred fascination with the cult of the personality (Schweitzer 1984). At the same time, dictatorial governments exist without the figure of the dictator, for example, the USSR following Stalin's death and the dictatorial regimes governed by military juntas. Moreover, not even in totalitarian regimes that appear to be internally controlled by the personal power of a dominant and charismatic figure, can the nature and character of the dictatorship as a system of power founded upon the single party be identified in the personage of the dictator (Tucker 1972, Schapiro and Lewis 1970, Gentile 1998).

5.4 Conclusion: General Characteristics of Contemporary Dictatorship

The diversity in the experiences of power defined as dictatorship in the contemporary world, the variety of definitions and typologies and the problems remaining controversial regarding the nature of dictatorship do not, nonetheless, impede us from being able to identify at least some common characteristics enabling the definition of the specificity of the phenomenon of dictatorship in the modern era in their formative or stabilizing phases.

According to the definition given at the beginning of this article, all types of government and regime in which a single person, a group of people, a party, or a military or religious institution (a) conquers the monopoly over political power, by legal or illegal means, and maintains it for an indeterminate length of time; (b) suppresses, reduces, or impedes citizens' enjoyment of their civil or political rights; (c) forbids or represses the activities of dissidents or of the opposition with the use of force and with recourse to terrorist means; (d) excludes *de facto* the possibility of the legal and pacific repeal of the rulers by the ruled even while allowing for electoral consultations and plebiscites to take place, may be included under the category of contemporary dictatorship. Contemporary dictatorship is, thus, the antithesis of democracy understood as a representative political system based upon the division and balance of power, a respect for the personal and public rights of citizens, on freedom of speech and of association, and on the periodic election of the government by the electorate, by means of a free and peaceful political contest and according to legal procedures guaranteed by the constitution.

Differential Aging

Differential aging is a term within lifespan psychology that is intended to communicate the heterogeneity of developmental processes in the later years of adulthood. The concept of differential aging underlies many contemporary theoretical and empirical analyses; however, the introduction of this particular term can be traced back to the work of Thomae in the Bonn Longitudinal Study (Thomae 1979). More recently, investigation of differential aging was a central component of the Berlin Aging Study (BASE), a comprehensive study of over 500 adults between 70 to over 100 years living in Berlin, Germany (Baltes and Mayer 1998).

According to the principle of differential aging, the rate of functional losses and gains over time shows both inter-individual variability and intra-individual variability. Inter-individual variability is shown by the fact that there are differences across individuals in the rate at which changes occur over time. Intra-individual variability is demonstrated by the finding of differences in the rates of change over time within the same individual. The principle of differential aging stands in sharp contrast to the previously held views in developmental psychology that aging is a uniform process of decline, also known as dedifferentiation. Although it is true that death is the inevitable outcome of the aging process, this fact does not rule out the possibility that growth can occur in psychological functions even at the end of life. Plasticity is another component of differential aging, meaning that the potential exists throughout later adulthood for growth and adaptation.

1. *Evidence for Differential Aging*

Support for the concept of differential aging has emerged from a variety of sources within the field of gerontology. One of the strongest arguments used to support differential aging is a meta-analysis of a wide range of empirical studies based on data available through the late 1980s. This analysis yielded evidence of greater variability among older, compared to younger, samples of adults (Nelson and Dannefer 1992). However, without providing explicit tests of the concept of differential aging, many other investigations have led to similar conclusions. The concept of differential aging is becoming a well-established fact

within the field of psychology and aging (Whitbourne 2001). It is no longer unexpected to show heterogeneity across older samples and within areas of functioning in the same individual.

Explanations of differential aging relate to models in lifespan developmental psychology that emphasize the importance of person–context transactions as influences on development (Lerner 1995). Such transactions affect the rate of aging within and across individuals as they are exposed to and select environments that differentially affect their physical, psychological, and social characteristics. Furthermore, rates of aging across and within individuals may reflect exposure to opportunities for prevention and compensation as represented, albeit crudely, by the variable of socioeconomic status. The higher mortality rates of individuals from lower socioeconomic backgrounds may be viewed as a manifestation of these differential opportunities (Lantz et al. 1998). To the extent that higher mortality rates reflect a more rapid acceleration of deleterious changes either directly or indirectly linked to aging, variations among socioeconomic status may be seen as a critical contextual variable within the framework of differential aging.

A concept highly related to differential aging is that of selective optimization with compensation (SOC; Baltes and Baltes 1990). Selection refers to the process of actively or passively reducing the number of goals and domains in which to become involved. The purpose of selection is to conserve energy and motivation for more important goals or to select new goals that will serve particular developmental tasks, such as coming to terms with mortality. Compensation in this model is defined as searching for and using alternate means of reaching a goal once it is no longer possible to use previous methods to achieve that goal. For example, an individual may wish to remain physically active but when limitations occur in mobility, the method of involvement may change accordingly. Optimization is the process of refining the methods and resources needed to reach a goal and thereby achieve success in particular domains. Applications of the SOC model to the processes through which individuals attempt to control and regulate developmental change over the lifespan are providing further elaboration of this model (Heckhausen 1997).

1.1 Application to Physical Aging Processes

The physical aging process is a prime example of the concept of differential aging. Aging of the body occurs across all organ systems, but at different rates within and across individuals. These concepts are expressed in the multiple threshold model (Whitbourne 1996), which postulates a reciprocal relationship between the aging of the systems within the body and the individual's identity or self-conception throughout the years of adulthood. It is known that changes occur within bodily systems at varying rates over time, reflecting both genetic predisposition and the impact of the environment. A threshold is the point at which the individual becomes aware of having experienced an age-related change in an area of functioning. After the threshold is crossed, changes in identity occur as the individual becomes closer to defining the self as 'old.'
