The collection and sharing of information on environmentally relevant aspects of production and consumption are critical components of industrial ecology. Industrial ecology requires firms to more closely cooperate in order to make its promise of increased environmental benefits come true. Therefore, firms need to collect, process, and share data on resource utilization, waste-stream monitoring, and intra and inter-firm component flows. In this respect, existing information systems can be modified to support life-cycle oriented environmental management (Shaft et al. 1997). Thus, many corporate functions will have to deal with environmental issues whereas before they had not; this needs careful planning, top management commitment, and dedicated programs to involve those functions (Dillon 1994).

Consumers, too, need to know about the environmental impact of products and services if they are to value reduced environmental impact in their purchases. Third-party voluntary environmental product labels were introduced as a means of informing consumers accurately on the environmental qualities of products. According to Salzman (1997), such labels have proven not to be effective in influencing consumers' buying behavior, but they may have resulted in reduced environmental impact in different ways, e.g., by stimulating competition among producers for the label and by enabling public and institutional purchasing programs to select labeled products over nonlabeled products.

Not only the information, also the prices need to be right (see *Environmental and Resource Management*). Various studies deal with the questions of whether and how recycling can be economically viable and environmentally beneficial. One of the lessons learnt is the vulnerability of recycling systems to changing costs for collection, transportation, and final disposal of unprocessable wastes. However, recycling schemes can be made more robust if clever solutions are found for collecting goods to be recycled, if those goods are designed such as to meet critical specifications of the recycling system and, if the goods are recycled into something that is marketable (Isaacs and Gupta 1997, Lave et al. 1998).

Taking the industrial ecology perspective may enhance a firm's competitive position through increasing resource efficiency at three levels: within the firm's value chain, within the wider value system, and beyond the value system in a situation of industrial symbiosis (Esty and Porter 1998). The waste exchange network in Kalundborg (Denmark) is one example of industrial symbiosis, the one that developed in the Austrian province of Stryria is another. Schwarz and Steininger (1997) studied why companies participate in the Styrian network. Cost calculations constitute the main reason, both for companies offering wastes as raw materials (increased revenues, reduction of disposal costs) and for companies procuring these wastes (cost reductions). They also studied how the exchanges within the network are governed. Most of the participating companies have entered into long-term contractual agreements or even joint-ownership subsidiaries because of the need to secure the quantity, quality, and price of the wastes to be traded. Alternative governance structures such as integrating waste valorizing activities within the company, or trading waste through spot market arrangements, are considered less efficient, essentially because of higher transactions costs to both the vendor and the seller. There may also exist situations in which taking the industrial ecology perspective does not result in enhanced firm competitiveness, e.g., if the associated cost exceeds the benefits, or if following the suggestions of industrial ecology would lead to undertaking activities that are not valued or permitted in the prevailing economic and institutional frameworks (Esty and Porter 1998).

An example of the latter is the study of Heaton and Banks (1997). They detail how the US statutory system of environmental regulation inhibits technological innovation. 'Perverse incentives' are in place that stimulate firms to use older, more polluting equipment because newer technologies need to meet stricter pollution control levels and hence are more expensive. Additionally, the use of 'best available technology' standards is an impediment to innovation because technology tends to develop at a quicker rate than the adaptation of the definition of what is the 'best' available technology. In such situations, legislative reform is required in order for companies to adopt environmentally more beneficial technologies and practices (see *Environmental Policy: Protection and Regulation*).

3.3 Tools

Most of the tools for industrial ecology are developed to deal with the information problem. Each of these tools has its own body of literature, journals and practitioners, which complicates a comprehensive discussion. Suffices a short characterization of the relationships between the various tools.

Materials flow analysis (MFA) and substance flow analysis (SFA) are basic analytical tools for industrial ecology derived from the principle that matter cannot disappear—what goes in must come out. The life-cycle assessment of products (LCA) extends to these analyses by attempting to quantify the environmental impact of the use of materials and substances in particular product designs. The resulting environmental profile of a product can be used for comparison against competing products or for suggesting ways to improve that particular product design, i.e., design for the environment. The LCA methodology can also be used to justify the eco-labeling of product designs. When applied to production processes, MFA/SFA is helpful to identifying inefficiencies or leaks, which in turn be remedied by process innovations, i.e., cleaner production or pollution prevention. For knowing whether or not any progress has been made one needs environmental performance measures that heavily rely on process data. Both managerial and environmental information systems are likely to contain relevant data. Each of these tools in the 'industrial ecology toolbox' has one or more of four basic functions (Van Berkel et al. 1997):

(a) to enable the identification, quantification and allocation of environmental impacts to (parts of) production processes and product life cycles;

(b) to facilitate the generation of improvement options for products designs, product life cycles, and production processes;

(c) to provide a structured approach for the evaluation of, and priority setting among, environmental impacts and/or environmental improvement options; and

(d) to specify procedures and routines for the development of industrial ecology projects.

An obvious problem with information based tools is that they require considerable amounts of data which are costly to collect, while it remains doubtful whether information would in itself be helpful given the complex trade-offs, ambiguities, and uncertainties in product development. Moreover, it appears that the environmental impact of products is determined to a greater extent by the question of how consumers use a product, than by the product design (Udo de Haes

1997). Finally, to focus on the environmental benefits of one design alternative over another may entirely miss the more fundamental question of whether the functionality or service of that product cannot be delivered by different means (O'Rourke et al. 1996).

3.4 Governance of Materials Flows: New Approaches

Several authors are less convinced that material and energy flows can actually be managed through information, regulation, and prices. For example Harrison (1998) points out that co-operative approaches to environmental protection, such as negotiated agreements, flexible enforcement, voluntary codes and agreements, have been devised because of the difficulty of implementing traditional 'command and control' regulation and market-based incentives. Little is known, however, about their efficacy and efficiency. It might be the case that a rigorous evaluation of such co-operative approaches reveals as much about the specific policy instrument design as about companies' motives and ability to join them.

For some companies in some industries, trends of globalization of trade and competition and flexible specialization shape the scope for strategic decision making on materials use (Bragt et al. 1998, Boons and Baas 1997). Other companies may deliberately choose to follow industrial ecology strategies without regulatory or market incentives commanding them to do so. One example is an outdoor apparel manufacturer that decided to substitute organically for conventionally grown cotton in its garments. Prices and information constituted significant barriers to overcome, but of greater importance was a paradigm shift in the company's management team, which made them accept the risk of a far less competitive cost structure. Because of this paradigm shift, the company was motivated to help existing suppliers adopt, and to look for new suppliers meeting, new quality standards (Chouinard and Brown 1997).

At a more fundamental level, the traditional governance approaches to, and tools of, industrial ecology can be criticized on the underlying assumptions of how firms make decisions (Taylor 1996). Industrial ecology tends to view materials and energy flows as the combined result of natural forces and the aggregate productive and consumptive activities of firms and consumers, whose decisions are primarily guided by direct economic and legal constraints. Within this perspective, Rejeski (1997) points out that too little attention has been given to the service sector and household consumption as mobilizers of materials flows. Beyond this perspective, industrial ecology has hardly begun to consider strategic decision making, inter-firm collusion, the exercise of power, mimetic behavior, cultural preferences, socio-economic institutions, etc., both as additional explanatory factors to understand why materials and energy flows have materialized as they have, and, in some instances, as reasons for the difficulty of changing those materials and energy flows. Systems of production and consumption are not invented, but have developed in a complex way, in which coincidences and unanticipated consequences intertwine with the actions that follow upon the intentions of individuals, organizations, and institutions.

4. Putting Theory into Practice

The practical value of industrial ecology is being explored in two directions. One direction is the application of the principles of industrial ecology at a local level in the development of eco-industrial parks. The other is the exploration of reduced resource intensity of production and consumption at the societal level through dematerialization—which is understood to include product life extension, decarbonization and the substitution of services for products.

4.1 Eco-industrial Parks

An eco-industrial park (EIP) is: 'A community of manufacturing and service businesses seeking enhanced environmental and economic performance through collaboration in managing environmental and resources issues [...]. By working together, the community of businesses seeks a collective benefit that is greater than the sum of the individual benefits each company would realize if it optimized its individual performance only. The goal of an EIP is to improve the economic performance of the participating companies while minimizing their environmental impact' (Lowe 1997, p. 58). The paradigmatic exemplar of an eco-industrial park is the 'industrial symbiosis' between a number of companies in and around the town of Kalundborg (Denmark) that exchange wastes and heat (Fig. 1). The Kalundborg symbiosis was not planned, but has gradually developed from a co-operation between the neighboring industries and the municipality of Kalundborg since the early 1960s (Ehrenfeld and Gertler 1997). Eco-industrial parks can be developed at green-field sites or through the renewal and restructuring of existing industrial parks.

During the 1990s, the concept of eco-industrial park has quickly developed into a planning tool for industrial development in both industrialized and developing countries. Although the example of Kalundborg shows that self-organization is an important factor in the development of industrial ecosystems, several examples exist where university researchers, specialized consultants, and person-

Figure 1
The industrial ecosystem at Kalundborg, Denmark (Source: Ehrenfeld and Gertler 1997, copyright Massachusetts Institute of Technology and Yale University. Reproduced with permission)

nel from economic and environmental development agencies have contributed in helping to develop eco-industrial parks. Several conditions for success have been identified: a clear vision of park's values and performance objectives, careful screening of new companies, methods and information to support companies in seeking by-product trades, flexibility in recruitment strategy, and assurance of continuing support. Challenges and risks that need to be faced include undesired resource dependencies, technological lock-in, leaking of proprietary information, and uneven quality (Lowe 1997)—the same principal-agent problems stemming from the risk of misuse of private information that pertain in any collaborative venture.

4.2 Dematerialization

Dematerialization refers to the 'absolute or relative reduction in the quantity of materials used and/or the quantity of waste generated in the production of a unit of economic output' (Cleveland and Ruth 1998, p. 16). It is considered a crucial strategy for advancing industrial ecology at the societal level. However, the suggestion to develop a service economy that is based on the delivery of function rather than products, intermingles with other debates on dematerialization. For several decades, it has been a central issue in concerns over society's dependency of, and impact on, natural resources. Society's intensity of materials use has strategic, geo-political, and security implications, in addition to environmental significance. Countries strive for some basic level of materials autarchy, especially the US, which may be realized by increasing direct control over, or reducing the level of dependency on, critical resources.

There is a lively debate on the topic of dematerialization. It has even been argued that dematerialization is a natural event in the development of economies —the dematerialization hypothesis. The relevance of this debate for industrial ecology is twofold. First, if it were the case that economies at a certain point in their development do dematerialize, then the need for a radical change in society's metabolism—as advanced by industrial ecology—would be less pressing. Second, the research methods developed for empirical research into the dematerialization thesis can also be used to evaluate to what extent industrial ecology's efforts to make society less material intensive are effective.

Dematerialization is considered the consequence of changing demand for end products in different stages of economic development, because increased demand for services and products with higher added value, results in per capita reduction of materials intensity (Malenbaum 1978). When the market for a particular base material saturates, its use rate as measured in kilograms per unit of gross domestic product declines and at a later stage even its per capita consumption may start to decline (Larson et al. 1986). Sources of per capita dematerialization may originate from process or product innovations, i.e., a more efficient

materials use, from materials substitution and from changing consumer preferences due to higher income levels. The additional dollar is spent on services, higher-value and knowledge-intensive goods, thus reducing the materials intensity of consumption. The resulting declining growth in materials intensity may eventually lead to a decrease of a society's materials intensity.

Several authors have contested the dematerialization thesis. Labys and Waddell (1989) argue that society 'transmaterializes'—through a process of materials substitution—rather than dematerializes. The intensity of materials use in society does follow the typical S-shaped curve of growth, maturity, and decline, but because the collection of data on the use of materials tends to lag behind in the introduction and growth stages, there is the suggestion of, but no real, dematerialization. De Bruyn and Opschoor (1997) propose that periods of dematerialization are followed by periods of 'rematerialization.' This pattern is explained by the evolutionary view of economic growth as a 'punctuated equilibrium' in which periods of stable economic growth are interrupted by clusters of innovations. Whether or not there is dematerialization depends on the relative importance of two rates over time: the rate of economic growth and the rate of efficiency gains in materials use. For dematerialization to occur, it is at least needed that rate of efficiency gains is greater than the rate of economic growth. Since it is likely that during periods of stable economic growth any efficiency gains in productivity are used to increase production (Bunker 1996), an increase of materials intensity will be observed, i.e., rematerialization. Thus, dematerialization may only be observed when there is a major structural or technological change in a society. Still others contest the dematerialization thesis by pointing out that the materials intensity of industrialized countries tends to converge in a narrow range between 16–20 tons of material per capita per year, and that despite structural changes and growth of services in advanced economies, the intensity of materials flows in economies is still growing in absolute terms.

Not only the dematerialization thesis itself has been criticized, so has the proposition that dematerialization would have environmental benefits. If all material eventually dissipates into the environment, then a reduction of materials use need not be beneficial if it is not considered how (in what form, what concentration) that material dissipates into the environment. It might be the case that a more intense use of a material enables a better containment of that material and a reduction of its dissipation rate to the environment

All in all, it must be concluded that at present there is no compelling evidence that society (i.e., the US) is dematerializing. Moreover, knowledge of the extent of, and mechanisms behind, patterns of materials use is scarce and limited to individual materials and specific industries, mostly related to metals (Cleveland and Ruth 1998).

Industrial Geography

Industrial geography is related to but distinct from industrial location. Industrial location is the study of the location decision-making processes of firms and reflects the trade-off between access to natural resources and access to markets. Early work in the field focused on the single location, pricing taking firm (see *Location Theory*) (Weber 1971). Subsequent work incorporated concerns including the nature of the market (see *Spatial Interaction Models*) (Lösch 1954), the economic spill-over effects of firms in the same location (Hoover 1948), and the importance of and variability in pools of labor (see *Spatial Labor Markets*) (Storper and Walker 1989). In contrast with the study of industrial location, this chapter focuses on the historical development of the industrial landscape in the Western world.

1. *The Industrial Geographic Landscape*

What most people see today in the industrial landscape is the sum of multiple periods of economic development. In American and Western European settings, the old mill town is a physical representation of a type of industrial landscape that evolved prior to or in conjunction with the Industrial Revolution (see *Historical Geography*). By beginning with the late eighteenth and early nineteenth centuries, we necessarily leave out a considerable period of the economic history that forms the bedrock of the contemporary industrial landscape. Under feudalism, for example, industrial activity was focused on the manor and the creation of goods for local consumption. Occasional surpluses were produced that were traded in market towns (Rosenberg and Birdzell 1986). With the decline of feudalism and the ascendancy of urban centers of trade and production, the industrial landscape began to emerge in the form of urban workshops. Independent manufacturers were only one source of manufactured goods, however. Merchants were key to early industrialization; they organized not only the markets for manufactured goods, but also production outside the influence of urban guilds. The 'putting out' system of rural manufacturing extended the influence of the industrial landscape significantly beyond urban centers. Rural manufacturing provided a check on urban wages but eventually declined when merchants could no longer guarantee or control output from rural manufacturers (see *Rural Geography*).

Prior to the Industrial Revolution, the production of manufactured goods unfolded within a system of handicraft manufacture under the purview of a master craftsman. One or more journeymen or apprentices assisted an exceedingly clever and dexterous person, the master.

The regulation of this form of production rested with guilds, production organizations that regulated skills and access to skills, and to a much lesser extent access to markets (Landes 1969). By restricting access to skills, craftsmen were able to preserve their markets and ensure public belief in the credibility of their products. Guilds acted as brakes on the expansion of output and thus overproduction. In later periods, guilds also thwarted technological change, a detail that led ultimately to their own demise.

The movement from craft production to the putting out system was an outgrowth of the merchants' increasing control over producers. The expansion of the market and the lack of access to and knowledge of its extensiveness placed artisans at a decided disadvantage. Market reach and knowledge of the tastes and preferences of distant customers was a clear

advantage of merchants who could accumulate demand and periodically fill it (see *Economic Geography*) (Glasmeier 1990).

Putting out, while highly efficient in an era with few economic alternatives, grew less and less viable as an organizing system over time. As workers grew wealthier and additional avenues of income creation became available to them, merchants found it increasingly difficult to control the output and quality of cottage industry goods. During periods of market growth, it became harder to meet new demand as workers began to assert more control over their lives and over their labor process. The need to find an alternative, more controllable system of manufacture became overwhelming as markets grew and demand burgeoned. In Britain, geographic range had essentially been reached and in some cases exceeded. Transport costs became a real impediment.

As control of workers' efforts lessened, and the limits of geographic expansion were reached, a slow but steady transformation took place as machines began to replace human labor, and the organization of labor within specific locales and structures provided the control employers sought. The movement to a factory-based system of manufacture was neither rapid nor complete. The slow demise of the putting out system provides one explanation for the emergence of factories: the need to control labor and the production process. Volumes have been written on this subject, from a wide variety of perspectives and with an equally broad number of emphases. What is important here is the way the movement from a more decentralized to a more centralized system removed control of production from workers laboring in the manufacture of a good, and turned it over to the capitalist. Of additional importance is the recognition that the process of change did not occur in the same way simultaneously in all relevant locations.

The ways in which mechanization unfolded across industrial sectors also are relevant to understanding industrial geography. The reasons for early and rapid mechanization in some sectors and resistance of machine support in others can be reduced to several intervening factors. The nature of the good largely determined its susceptibility to mechanization. This attribute went hand-in-hand with the extent of the market for the good. If the good was high value/low volume and of a luxurious nature, labor costs were relatively insignificant and thus a minimal stimulus to change, unless of course the transition to machines was twinned with a movement toward a broader market and a more widely disseminated good. In this case, market shifts could simply require change in order to hold a longer-term market position. Institutional factors also could serve as impediments to change. The number of possible explanations supporting the lack of investment are certainly sufficient to see that the prospect of a smooth functioning factor market acting as a stimulus for change was inherently contingent on elements other than just the short-term costs of production.

Early centers of industrialization were highly specialized—a result partly of natural resource location as well as of built-up competencies (see *Technology Districts*), the initial impetus of which was often accidental. Trade was essential to the growth of industrialization in place. The formation of institutions and social relationships combined with key developments in technology facilitated and ultimately encouraged trade among regions. Fundamental to the success of trade (see *International Trade: Geographic Aspects*) across long distances was the development of shipping technology that allowed the movement of large volumes of goods in reasonable time. Simultaneously, in order for trade to occur, mechanisms were needed to reduce risk and to finance the time between the manufacture and sale of a good. With the creation of a number of institutional innovations such as the banking, credit, and insurance sectors, industrialization in the late eighteenth and early nineteenth centuries moved beyond local production for local consumption and toward production for trade.

The Industrial Revolution (see *Economic Geography*; *Historical Geography*) marks a critical moment in the formation of the industrial landscape. Essential to the pervasive diffusion of the Industrial Revolution was the ability to harness power sources in order to concentrate economic activities in space. Simultaneously, the development of new technologies led both to an enhanced capacity to organize industrial activity and to the creation of new manufactured goods themselves. Finally, the organization of production within factories allowed the achievement of economies of scale and task specialization across the production process.

Before the beginning of the eighteenth century, the primary source of power used in production was human and animal (Rosenberg and Birdzell 1986). This dependence significantly restricted the size, scale, and location of industrial activity. With the ability to harness inanimate power sources, industrial activity moved toward a larger scale and a greater degree of specialization. First water, then charcoal, and finally coal became the defining power sources of the early Industrial Revolution. The industrial landscape began to spread out as manufacturing became unshackled from water power sources. Timber and charcoal were an intermediate solution; both, however, quickly declined in importance when most of the trees were cut down and charcoal became uneconomic to manufacture. With the discovery of large supplies of coal, production spread further and moved quickly beyond a relatively few industrial centers.

Technological change (see *Technology Districts*) is a critical marker of the evolving industrial landscape. In addition to the ability to utilize inanimate energy sources, a hallmark of the Industrial Revolution was the development of machines that replaced human

action. Metal-cutting and -shaping machines were vital to the formation of an industrial equipment industry. New materials and the understanding of the chemical basis of new materials made possible more complex manufacturing processes and new products. This in turn led to specific spatial concentrations of firms in the same industry, as divisions of labor formed and fanned out in independent enterprises.

2. *The Organization of Industry in the Factory Era*

The organization of capitalist enterprises into factories occurred as both merchants and manufacturers sought to control and coordinate an entire production process (see *Economic Geography*; *Regulation Theory in Geography*). During the craft era, workers exhibited some control over the labor process (declining through time). This had important implications for the volume of output and therefore the size of markets that could be served, the level and source of innovations, and the sources and control of power. The need to harness these capabilities into a more centralized system of command and control had major implications for how industrial systems evolved. According to Lazonick, 'The transition to the era of proprietary capitalism brought the integration of asset ownership with managerial control and with it an internalization of aspects of the craft system. In particular, in order for firms to generate (what were by the standards of the time) high-quality products at low unit costs.' Further, 'firms relied on an ample supply of highly skilled and well-disciplined labor. Senior workers—who eventually came to be known collectively as the aristocracy of labor—not only provided their own skills to the building and operating of machinery, but also recruited junior workers whom they trained and supervised on the shop floor' (1991, p. 25).

The heavy reliance on skilled labor had obvious spatial implications. Firms were more or less bound to a particular place. This dependence on labor is one of the prime determinants of spatially bound production systems (see *Location Theory*; *Economic Geography*), aptly captured by such well-known observers as Marshall (1997). The external economies within such a complex were substantial. Materials, labor, and services (distribution) were sufficiently honed that spatial proximity enabled work in progress to flow through its vertically specialized branches, and to market its output (Lazonick 1991, p. 26). These regional concentrations facilitated high levels of specialization. Consequently, employers' ongoing reliance on skilled labor to organize work on the shop floor diminished the need for business firms to invest in the development of managerial structure and organizational capabilities (Lazonick 1991, p. 26). It also meant that pressures to cut costs were resolved through market transactions rather than through internal restructuring.

The system was self-perpetuating. Because proprietors had access to this complementary system of transactions it was unnecessary to invest in or develop complex managerial structures. Instead, in the early phases of factory industrialization, proprietors tended to own single establishments and rely on the market for the provision of necessary inputs. Firms mostly remained small and new establishments were formed to fill niches. The manufacturing process was inherently labor-intensive and reliant on a cadre of skilled and unskilled workers to manipulate the raw material into final, finished form. The advantages of this supply system, combined with the benefits of a labor force that was self-reproducing, resulted in low fixed costs. Although problems of coordination would eventually become disabling, nonetheless Britain, and other countries including Switzerland, built a globally competitive industry in the early nineteenth century based on just such a system of organization.

What unseated this remarkably flexible system was the emergence of mass production and the manufacture of volumes of products, all of more or less the same quality and capability (see *Regulation Theory in Geography*). In the early era of mass production, the American system became the model to emulate. Unfolding in fits and starts, this system has been characterized as 'the sequential series of operations carried out on successive special-purpose machines that produce interchangeable parts' (Hounshell 1984, p. 15). Implicit in this description was the move away from a dependence on skilled labor, a system based around fragmented and decentralized production, and highly variable, relatively high-cost goods (Hounshell 1984). Costs were not the only concern. Equally important were similarity of parts, interchangeability, and rapid production.

3. *The Emergence of Managerial Capitalism and Factories*

The transition to machine-based, vertically integrated, large-scale industrial manufacturing occurred over a long period of time. There are examples of metal-cutting machines assisting in the rough shaping of parts for final finishing as early as the middle of the eighteenth century. However, it was the middle of the nineteenth century before widespread implementation of this technological and organizational innovation occurred. The movement toward this form of production was neither pervasive nor persistent. There were many obstacles to overcome, not least the construction of the necessary machinery and the resolution of the inherent conflicts presented by machine-based output to established labor relations and hence to the production system itself (Lazonick 1991). Ultimately, the movement toward the American system caused turmoil throughout the entire system as

machine-made parts and large-scale assembly yielded an unprecedented volume of goods. Many problems were associated with the flow of goods, and spilled over into the acquisition of consistent inputs and, equally important, the development of an effective means of distribution. Goods were no longer produced with a proximate market in mind. Indeed, the international supply of foreign markets became an increasingly important part of firm strategy. To produce at large scale necessarily meant distribution at large scale, ushering in the move toward managerial capitalism.

The evolution toward machine-based manufacturing and the ensuing complementary innovations in scale and scope of production, distribution, and management of the modern industrial enterprise arose rather gradually, starting in the 1870s (Chandler 1991). The rise of the multiunit, capital-intensive corporation was the result of three investments. First, production levels had to be large enough to utilize economies of scale and scope of new technological innovations. Second, marketing and distribution capabilities had to be of a scale large enough to sell the goods produced by the new processes of production in the volume in which they were made. Third, a managerial hierarchy was needed to manage and coordinate the operations of large-scale production and distribution and to allocate resources for future production and distribution (Chandler 1991, p. 432). That this new paradigm first took hold primarily in the USA and Germany has much to do with the relatively late industrialization of the two countries compared with Britain, and hence the absence of a pre-existing labor process and managerial system to overcome. In the USA, the shortage of skilled labor placed a premium on developing machine-based alternatives to industrial production. Preceding the Civil War and strongly afterwards, American firms in a wide range of industries pursued mechanical solutions to the expansion of production to achieve economies of scale and serve burgeoning domestic and international markets.

The rise of the managerial corporation brought with it the integration of multiple functions, multiple units, multiple products, and all of the attendant physical and human resources. Although each unit had independent capabilities to execute and manage the enterprise, coordination was offered and accomplished by middle managers who were themselves managed by top officials of the corporation. Quite strikingly, the emergence of this mode of organization and coordination arose rather quickly at the end of the nineteenth and beginning of the twentieth centuries and was most observed in a subset of all industries comprising the US economy. These industries tended to be sectorally concentrated, to consist of firms that were vertically integrated within the same industry group, and to be characterized by high-volume, capital-intensive production processes. In other words, what linked these firms were product characteristics that yielded the need for a uniform managerial structure designed to confront and control problems of production and distribution while benefiting from the potential associated with specific sectoral characteristics.

The sectors and firms most successful in executing the full complement of attributes of the modern corporation were those that benefited from scale and scope linked to standardization of the production process. At the same time, however, there were other prerequisites to effective implementation, particularly relating to market control. To support the huge capital costs required to achieve economies of scale, a relatively few players had to exercise market power. The emergence of oligopolies in such sectors as oil, steel, and heavy machinery went hand-in-hand with the rise of the modern corporation. Control was both seized and achieved through investments in up- and downstream linkages, a capability that most smaller, more consumer-oriented goods producers could not make.

With the emergence of the managerial corporation, firms were now in a position to own and control resources and markets distributed across space (see *Regulation Theory in Geography*). The spatial organization of the national economy evolved from production for local consumption, to regional markets of production and consumption, and finally to national markets and corporate structures of spatially decentralized production systems. The ability to standardize products and produce at mass scale, twinned with the development of national brands and brand recognition, resulted in the creation of huge corporations that controlled vast business assets.

4. *The Rise of Collective Capitalism*

The model of market coordination embodied in managerial capitalism remained an effective organizing system until the 1960s. The lack of cut-throat international competition, and the presence therefore of stable markets, buoyant growth, and rising standards of living, provided hospitable conditions for the cultivation and persistence of the large, vertically integrated corporation (see *Economic Restructuring: Geographic Aspects*; *Regulation Theory in Geography*). The seeds of turmoil that would come to destabilize this system of production, consumption, and market regulation were sown much earlier in the century, however, and lay dormant until after World War II. The challenge to this dominant system arose, ironically, as a new competitor—in this case Japan—coupled long-standing and under-appreciated competency in the production of goods with state-supported (yet private-sector-led) manufacture of new products capable of competing directly in the world's most sophisticated industries and its most developed markets (Conroy 1995). The national pursuit of both import substitution and export-led development policies

provided infant industries with the protection required to achieve economies of scale and hence low overall costs. Accustomed to developing technological competency through technology transfer, the Japanese successfully adopted and adapted major innovations, primarily from the USA, to take the lead in key consumer and producer products over the postwar period.

The emergence of the Japanese as effective competitors in many consumer and producer product markets dates back to before World War II. In the last three decades of the nineteenth century, Japan had begun to develop the competency to produce tradable goods, primarily through the purchase of foreign know-how and technology. By the 1920s, in several key sectors, Japan was second if not first in the world in terms of exports (Glasmeier et al. 1993). Although cut off from international trade in the 1930s, Japan continued to build up its productive capacity until just before the declaration of war. This time the emphasis was placed on heavy and chemical industries.

The emergence of collective capitalism as a distinct mode of organization is both a creature of history and a more modern institutional form. At the end of World War II, Japan had little choice but to pursue an export-led development strategy (McCraw 1986, Samuels 1994). The country lacked resources and had a small land base with a large population. In order to stave off poverty and economic despair, the nation had to develop export competencies in a variety of sectors. For reasons that can only be understood retrospectively, the Japanese did not choose to pursue products that were labor-intensive despite its large labor force; rather, it moved rapidly into capital-intensive production as part of economic recovery in the 1950s.

The second major stimulant in the formation of collective capitalism was in part a holdover of the structure of the national economy that had developed since the beginning of the twentieth century. Japan's economy is comprised of interlocking business organizations that enjoy both vertical and horizontal affiliations. Furthermore, the system of integration reaches down to the level of select blue-collar workers in first-tier firms who are offered lifetime employment in return for a life of dedication to the firm. In this way, guaranteed their jobs, workers willingly accept technological change as a part of labor–management relations.

Although many distinctions are attributable to the Japanese system, of particular importance is the role of the enterprise groups—networks of firms—that form the modern-day extensions of the *zaibatsu*, the family-controlled businesses that led the development of the Japanese economy from the end of the nineteenth century until the occupation after World War II (see *Technology Districts*). These enterprise groups consist of a central business firm around which reside vast numbers of both affiliate and non-affiliate subcontractors. This disintegrated system allows the core firm to enjoy the benefits of vertical integration, especially in terms of financing, technology transfer, and internal markets, without the disadvantages of ownership and bureaucratic control. The core firm is able to ensure quality, quantity, and timely and effective delivery of parts and services due to long-term contracts and investments made by the core firm into subcontracted operations (Lazonick 1991).

The emergence of collective capitalism is essential in understanding the industrial geography of the late twentieth century. Along with recognition of differences in the organization of industry, today there is an increasing interest in how culture helps to shape economic space (see *Economic Geography*). Throughout the life of an industry, different conventions and rules of behavior form the basis for collective action. Organizational behavior and prevailing institutional norms structure the range of possibilities of firms and regions. This interaction forms the industrial landscape. Today's industrial landscape is thus the sum of long-evolving processes, the residue of which is reflected in the structure and formation of business enterprises, industrial clusters, and systems of industrial activity. Contemporary concerns increasingly focus on elucidating the importance of culture as a determinant of corporate behavior (Schoenberger 1997). In this context, culture is defined as the rules and practices, identities and aspirations of individuals at the most intimate level. There is increasing interest in the ways in which culture manifests within people, which in turn shapes firms within regions. In this way, industrial geography is not just the study of a physical place *per se*, but is also an examination of the reservoir of experiences and actions that come to represent actors in a locality and its economy.

Industrial Metabolism

The word 'metabolism' comes from the Greek, meaning to change or transform. The concept in biology describes the combined effect of numerous biochemical reactions that convert the materials in a living cell to provide for its growth and maintenance. While the concept of metabolism is uniformly accepted at the cellular level and for individual organisms, its application to larger systems of living organisms or human societies remains underdeveloped. The term 'industrial metabolism' derives from the notion that industrial economies, like biological organisms or natural ecosystems, can be understood as systems for material transformation with distinct metabolic pathways that evolve over time. Industrial metabolism offers a useful perspective for the study of collective human behavior and its effect on the materials cycles that comprise the workings of the natural environment.

Social analyses have considered industrial production and resource-use statistics as social indicators since the dawn of the Industrial Revolution. In the decades since the 1960s, industrial metabolism has been used as a paradigm to describe the exchange of materials among industrial operations in a way analogous to the description of material and energy balances in natural ecological systems. This metabolic analysis contributes to the formulation of technological, economic, and policy instruments aimed at addressing social environmental concerns. In the context of modern social and political awareness about environmental quality the concept offers an analytical framework that is practically motivated to improve the quality of the natural environment through changes in industrial and social norms.

Industrial metabolism examines the exchange of materials and energy between human society and nature at all spatial scales, applying the same analytical parameters to describe material fluxes within and between natural and human systems. At the largest scale this includes study of anthropogenic contributions to atmospheric concentrations of trace gases and the flow of excess nutrients from agricultural activities to water bodies. At smaller scales, industrial metabolism addresses the use of resources in the human economy through the development of resource-accounting frameworks for political and economic entities as well as life-cycle analyses of the materials used in the manufacture of industrial and consumer products.

Emphasis is placed on following the 'material flow' from its origins (e.g., mined ore) through the industrial processes used for its transformation, to the products that contain it, and finally to its disposal or re-entry into the industrial system. At its most comprehensive, industrial metabolism links to human and ecosystem metabolism, for instance by considering the life cycle of metals and organic chemicals in plant tissue and the human diet. The information is used to construct a 'materials balance' of a system and draw conclusions regarding the actions needed to improve the environmental character of its metabolism. Possible indicated actions might include industrial process change, product substitution, consumer education, government regulation, development of enabling technologies, installation of new resource recovery capacity, and economic incentives by government (see *Global Environmental Change: Human Dimensions*).

To determine existing and potential metabolic pathways, industrial metabolism considers the social dynamics that influence the integrity of the natural environment. To establish quantitative relationships between material flows and social dynamics, industrial metabolism compares indices of industrial production and social consumption to social and demographic variables such as population, gender, age, land use, and economic activity. To aid in the formulation of public policy, industrial metabolism bases its findings in the context of government institutions, economic incentives, and cultural biases that influence the flow of physical resources and their impact on the natural environment.

1. *Natural History of Chemistry*

One main thrust of research in industrial metabolism compares the natural history of the basic biogeochemical reactions observed in planetary evolution and contemporary ecosystems with those employed by

industrial society. By studying the basic chemical processes observed in nature for achieving beneficial transformations of materials, this inquiry seeks to identify industrial processes that minimally perturb global biogeochemical cycles and least interfere with the services provided to humans by nature.

From a historical perspective, the Earth represents an evolved system for recycling materials. Over geological periods the planet has allowed for the biogeochemical feedback necessary to arrive at a state hospitable to human life over the majority of the globe. Characteristic of this evolution is the natural system's ability to find uses for discarded by-products. For instance, at the planetary scale we find the development of organisms using photosynthesis to produce energy. The life-forms employing this process came to dominate a planet rich in atmospheric oxygen, the waste product of previous life. This system attribute, a product of evolution, is also evident over shorter timescales in natural ecosystems. For these systems, scientists describe a complex web of life supported by the wastes from animals and plants, identifying the significance of those wastes as providing the basic nutrients for regeneration.

Industrial metabolism notes that in selected instances the need to find uses for waste products drives the evolution of processes used in human industry. For example, the search for uses for unwanted coal tar led to the birth of the synthetic dye industry at the beginning of the twentieth century in Western Europe. Natural gas, a leading energy source at the end of the twentieth century, was once 'flared' at wellheads before its value was recognized for energy and commercial products from nitrogen fertilizer to synthetic rubber. Chlorine entered the human environment initially as a by-product from the manufacture of sodium chemicals and eventually became the far more marketable product. Following the evolutionary principle evident in natural, as well as human, systems, industrial metabolism seeks to reveal opportunities for using waste materials from contemporary industrial systems (see *Sustainability Transition: Human–Environment Relationship*).

Industrial metabolism stipulates that resource use and waste generation can be avoided if human industry can learn from the design models found in nature and overcome the barriers to replicating natural systems for material transformation in human industry (see *Industrial Ecology*). One of the most basic differences between natural and human-made systems derives from the fact that natural systems are driven by solar energy in its different forms, which contrasts with human energy production as a relatively diffuse spatial source. The intensive use of energy to generate conditions of high pressure and temperature for human production processes further distinguishes human from natural metabolic processes that typically occur under conditions of ambient pressure and temperature. Human-made material transformations also generally follow a series of linear discrete transformations (i.e., unit operations) in contrast to the more continuous processes found in nature. In addition to learning from the design of natural systems, industrial metabolism seeks to identify, and engineer, natural processes to replace commercial ones and thus reduce human resource use and waste generation (see *Greening of Technology and Ecotechnology*).

2. *Resource Accounting*

A complementary thrust of industrial metabolism research explores the actual physical flow of materials within industries and regions. Materials-flow analyses rely on the law of conservation of mass (i.e., no new mass is created or destroyed in a closed system) to provide a complete materials balance equating the quantities identified as inputs with those labeled as outputs. Employing the materials balance principle allows for estimation of material flows in industrial and consumer products as well as in by-products and wastes even when data are missing. The analysis may include material flows apparent to the public, for example in household wastes, as well as the hidden material flows occurring in mines, quarries, power plants, factories, farms, and disposal sites.

Because both large- and small-scale flows have an impact on the environment, industrial metabolism examines bulk materials, typically measured in millions of tons, as well as toxic materials measured in micrograms. Large-scale flows such as hydrocarbon fuels used to supply energy, and fixed nitrogen used for food production, have an impact on global biogeochemical cycles that govern climate and ecosystems. Smaller volume flows that enter the human food chain may pose chronic or acute threats to human health and threaten the biological balance found in natural ecosystems.

The industrial metabolism of any material must be determined within the boundaries of a defined system. Once within system boundaries, flows must also cross an internal boundary in moving from 'nature' to the 'human' domain in order to be included in the account. Geographically based analyses examine the industrial metabolism of material sources and sinks formed by industrial, agricultural, and urban activity, and the surrounding environment. Analysts can also map material flows for individual facilities or entire sectors, provided that they consistently define how to evaluate indirect material flows occurring outside the sector under study. Finally, the material itself may provide the boundary, if the effort calls for improved understanding of its metabolism independent of other associated flows.

Criteria for including materials in the metabolic analysis range from narrowly restrictive to broadly inclusive. Some account only for those material flows associated directly with economic transactions. Other

frameworks include hidden material flows such as mine tailings from metal production, overburden removed to access coal seams, and eroded soil from agricultural land. Still other accounting frameworks tabulate the translocation of dirt and rock for infrastructure such as road building and harbor dredging.

3. Future Development

Several factors motivate contemporary interest in industrial metabolism as a framework for analyzing the environmental impact of human economies. Research aimed at developing operating industrial economies that do not damage the natural environment, benefit from the study of how natural systems are able to operate without permanently depleting natural resources or damaging life-support systems. Resource accounting offers a compact and transparent method to convey environmental information to government officials, resource managers, and industrial operators whose decisions influence environmental quality.

Challenges to industrial metabolism include the need to refine methods for materials-flow analysis to counter limits in the ability of government and industry to monitor all environmentally important materials streams. Far more work needs to be done in the realm of environmental science to establish causative relationships between human emissions and damage to the environment. Finally, the inescapable influence of specific geographical and cultural features on human–environment interactions requires models of individual and collective behavior to describe and improve environmental quality at the local level where humans reside and interact with one another.

Industrial Policy

Industrial policy is an approach to economic policy in which the state gives direct support to particular firms and industries. Since the modern state has a pervasive influence on economic activity, virtually every industry is influenced by its actions. Even general codes typically have a differential impact upon particular firms and industries. There is thus a sense in which every industry is shaped by state action and when the state acts in a deliberate and purposive way to affect the fate of an industry, either on its own behalf or in response to pressures from the industry itself, one can speak of industrial policy in the generic sense of the term. The term might be extended still further to refer to cases where a lead enterprise, and/or an employer association, pursues a strategy for the industry as a whole. But we generally reserve the term for what might be called industrial policy in the large. This is an approach in which particular firms and industrials are supported in pursuit of *national* economic policy goals. Such policy is generally conceived in terms of a broader plan, or strategy, of national economic development. Instruments of support range from tariff protection and import restrictions, tax concessions, subsidies, and targeted services to direct intervention through institutions of the state itself, including the state's own research and development laboratories, state schools and universities and state-owned enterprises. Indeed, industrial policy is a major justification for the state to undertake these activities directly on its own account.

Industrial policy in this larger sense was practiced widely in the early postwar decades, although the term itself seems to date from the 1970s, when this approach to national economic development became the subject of a widespread debate. In more recent decades industrial policy has fallen out of favor, so much so that the term has taken on a pejorative connotation. Its proponents have tended to use various euphemisms and circumlocutions, although one is hard pressed to point to a particular word or phrase that has taken its place. These changes reflect a major shift in the intellectual and political climate of the late postwar period. In some ways, the climate has now shifted back once again in favor of an industrial policy, although one which is understood and practiced very differently from that of the early postwar decades.

In the first few decades after World War II, among the advanced developed countries the leading practitioners of industrial policy were France and Japan. In France, the postwar policy was associated with the Commissariat du Plan (The Planning Commission)

and a process that became known as indicative planning. The term 'indicative' contrasted with the directive planning of Soviet-bloc countries in Eastern Europe and involved a process of consensus-building through discussion and debate within committees organized by the Commissariat. A number of these were industry committees and included representatives of government and administrative agencies as well as business and labor organizations. The idea was to reach a broad-based but also fairly specific consensus on the direction in which each industry should be moving and the kinds of adjustments in industrial organization and state policy that would facilitate that movement. The French state has also been very active in promoting new industries. It invested heavily in information technology, for example, through Honeywell–Bull and, along with other European countries, in Airbus (Cohen 1977, Stoffaes, 1983–84).

In Japan, industrial policy dates back to the nineteenth century and the earliest stages of the country's industrialization. Indeed, it was the state that initiated the development process, itself creating and operating particular production facilities and then subsidizing, but also directing, private enterprise to do so. In the postwar period, policy has operated through the Ministry of International Trade and Industry (MITI). MITI has controlled the flow of all foreign technology and capital into the country and has sought to direct it so as to maximize its contribution not only to economic growth but also to national autonomy and economic independence. It has also sought to direct the evolution of strategically important industrial sectors internally in a detailed way, establishing specific production targets and imposing them upon the industry, dictating output and market share for particular firms, and sometimes even the production methods and organizational structures through which those targets are pursued. Toward this end, it has utilized virtually every instrument available to the state, including direct intervention in the economy to organize industrial cartels (Johnson 1982).

The classic work on industrial policy in the immediate postwar period is Andrew Shonfield's *Modern Capitalism: The Changing Balance of Public and Private Power* (Shonfield 1965). Shonfield saw developments in France and Japan as prototypical of the approach to policy emergent in a more or less explicit and self-conscious form in all advanced industrial countries. Shonfield traces these developments in the major countries of Europe and the USA.

The impetus for—and practice of—industrial policy in the developing world has been a little different. It is generally associated with the process of economic development itself and the conviction that development will not occur spontaneously on its own. In the immediate postwar period, industrial policy was given particular impetus by *dependency theory* (Prebisch 1963). That theory argued that without a conscious and deliberate effort to protect and develop its own industries, the third world would be relegated to a permanent position as supplier of primary products to the industrial world. It led to very high protective tariffs and quantitative restrictions designed to promote import substitution. In automobiles, countries with very large domestic markets, such as Brazil, Mexico, and India, have also imposed local content requirements upon foreign investors. Countries with significant military purchases—China, Turkey, and Korea, for example—have made foreign direct investment in local parts production a condition for purchases of military aircraft. In recent years, the case for industrial policy as a tool for development has been reformulated in terms of theories of learning.

Three strands of thought worked together to create an intellectual climate favorable to industrial policy in the early postwar decades. First, an extensive literature composed of contributions from different scholarly disciplines converged upon the nature of industrial society and the direction in which it was evolving over time. Undoubtedly, the dominant figure in this literature was Karl Marx, but a number of other scholars who were politically antagonistic to Marx and disagreed with him on a variety of specific points nonetheless shared and propagated a similar vision. These included Max Weber, Joseph Schumpeter, Alexander Gerschenkron, John Kenneth Galbraith, and Walter Rostow.

The essential element of this vision was that early capitalism might have been constituted by small entrepreneurial firms which composed an economic system that could be coordinated and directed by the market, but that in late capitalism the economy was coming to be dominated by very large, extremely capital-intensive enterprises. The canonical industries for most of these observers were automobiles, consumer durables, steel, rubber, and plate glass. There were, to be sure, important differences between these various analysts, but the differences in some ways served to underscore the similarities and created the sense that the broad contours of industrial society were unproblematic. This made industrial planning seem unproblematic as well.

Second, these theories of industrial society and late capitalism had the definite implication that markets would be increasingly less effective instruments for managing the economy over time and that some other form of management involving planning and the direct allocation of resources by individual enterprises would take its place. This created ample space for arguments that enterprises themselves would take too narrow a view and that specific government intervention in the national interest would be necessary to achieve an optimal result. It was a small step from this to industrial policy.

The third element of the intellectual climate conducive to industrial policy was Keynesian economics. John Maynard Keynes' *General Theory*, published just before World War II, came to dominate economic

thinking in the postwar period. Essential to the new analytical structure that Keynes created was the assertion that the market would not stabilize the macroeconomy and sustain full employment automatically on its own. Keynes' own explanation for this was that certain key prices, particularly the prices of labor and capital, were rigid and did not respond to competitive forces. This suggested the possibility that prices *in general* were unable to direct the economy and that government action was required in their place.

Keynesianism was absorbed into economics in the USA in a way that sidestepped this particular implication. In what was known as the neoclassical synthesis, the leading American Keynesians combined the new macroeconomics with a view in which markets continued to function effectively to govern the economy at the microeconomic level and to give individuals and industries their direction. They did this, by and large, by accepting the basic macroeconomic conclusion that price variation would not function automatically to maintain full employment, but they did not explore too closely the particular mechanisms that prevented this from happening. Most of their scientific work—for which the leading Keynesian economists later received Nobel prizes—operated within the traditional assumptions of a competitive market economy. Hence this created a predisposition within the discipline to find a way of reconciling the contradictions between macro- and microeconomics along neoclassical lines. But Keynes definitely broke new ground and increased the plausibility of approaches to understanding and managing the economy predicated on the notion that markets could not be counted on even for the management of individual firms and industries.

The disenchantment with industrial policy as an approach to national economic management in recent decades has been part of a broader process of government withdrawal from active involvement in microeconomic activity. It is associated with the political ascendancy of Margaret Thatcher in Great Britain and Ronald Reagan in the USA. But a turn toward the market was already apparent in the USA under the Carter Administration in the 1970s, when the process of deregulation of transport and telecommunications was begun. Among the most aggressive practitioners of industrial policy, the retreat came later and was less complete. In France, for example, policy shifted from promoting 'national champions' in the early postwar decades to a focus on 'lame ducks' in the 1980s, and only retreated further as the budgetary implications of protecting declining industries became overwhelming (Berger 1981). Japan in some sense has never abandoned its commitment to industrial policy.

The demise of industrial policy was, however, not simply political. It also reflected a radical change in those elements of the intellectual climate that had made it attractive and plausible in the earlier period. An important part of that change took place within the discipline of economics and centered on the Keynesian heritage. Keynes was not exactly abandoned: the basic apparatus of macroeconomic analysis that he had created was retained. But the microeconomic foundations were substantially rebuilt; the basic understanding of why the macroeconomy might not be able to maintain a full employment equilibrium was revised in a way that made it less dependent on rigidities in wages and prices (Mankiw 1990). As a consequence, arguments about the ability of prices to regulate and direct the development of individual industries and particular firms became more plausible. The economics profession increasingly came to see government intervention as an interference with the market rather than a remedy for market failure.

At the same time, in the 1980s and 1990s, the texture of the economy shifted dramatically in way that called into question the prevailing assumptions about the underlying nature of industrial society and the direction in which it was moving. The service sector became increasingly important and manufacturing less central. Some very large companies that had seemed permanent fixtures on the industrial landscape experienced serious difficulties and came close to bankruptcy. A few actually disappeared from the industrial scene. Virtually all large firms began to experiment with new organizational forms and managerial approaches that called into question the notion of bureaucratic management. Large companies also began to limit the range of activities in which they were directly engaged: they tended to focus on their 'core competencies' and to purchase ancillary services from subcontractors and external collaborators. New technologies emerged in communication, information processing, and biotechnology whose implications were often surprising and difficult to predict.

These new leading sectors were populated with many small, entrepreneurial companies. As a result, small enterprises in competitive industries suddenly became plausible agents of future development. In the past, small firms had been associated with traditional industries such as garments and shoes, and had thus been viewed as vestiges of the pre-industrial era (Piore 1984, 1994). A similar reversal in the expected pattern of development took place with respect to the role of education. In the early postwar decades, the wage premium for education had declined; thus seeming to confirm an expectation that originated with Marx that the skill requirements of jobs would decrease as industrial development proceeded. In the 1980s and 1990s, the education premium increased, and it began to look like the skill requirements of jobs were actually rising as the economy evolved over time.

It is symptomatic of the changed climate that 'industrial society' as a term used to characterize contemporary civilization has fallen into disuse. It has been replaced in our vocabulary by the older notion of

'capitalism' or by the term 'postindustrial society.' The second term is particularly telling of the emergent intellectual climate: it defines the new era by what it is not, but says virtually nothing about what it is. It thus seems to deny the notion that we have any idea where we are headed. In this sense, it seems to foreclose the possibility of planning upon which the older notion of industrial policy was premised.

The other term replacing 'industrial society,' i.e., 'capitalism,' has a much more definite implication: it points toward the market as the guiding economic institution. Given the dichotomy between markets and hierarchies in which the debate about industrial policy, and industrial organization more broadly, has come to be conducted, the changes in the institutional structures of advanced industrial nations certainly seemed to point in this direction. The market seemed to be the governing institution in coordinating the small entrepreneurial firms which were emerging in new industries as well as coordinating the relationships between the newly streamlined large companies and their outside contractors and collaborators in older sectors of the economy. Central direction and control through industrial policy no longer seemed necessary.

Even as these intellectual currents came to dominate the political and scholarly landscape, a new set of understandings was developing which provided the foundations for industrial policy, albeit of a somewhat different kind than that which prevailed in the early postwar period. Here again one can distinguish between developments within economics as a discipline and trends within social and policy science more broadly.

Within economics itself, the new climate has been shaped by endogenous growth theory and the 'new theory of international trade' which emerged together in the 1980s (Krugman 1992, Romer 1989a, Romer and Rivera-Batiz 1991). Whereas the older theories of growth and trade emphasized comparative advantage and 'natural' or 'innate' differences among countries, the new theories focused on the processes through which competitive advantages were created. They gave a central role to economies of scale and to multiple equilibria, i.e., alternative paths of development all of which are consistent with a country's initial endowment of resources. The new theories thus raised questions about how industries grew to scale and countries shifted from lower level equilibrium growth paths to paths consistent with high incomes and rapid development. The literature focused initially on how this happened 'naturally' in the absence of particular public policies. But it opened an intellectual space for policy. In many ways, it was reminiscent of the older infant industry arguments for protection from international competition.

But the new theories have not led to a revival of interest in policies of this kind, at least within the economics profession itself. Instead, economists have focused on the economies of agglomeration, why firms within an industry tend to locate together in a particular place and how this fosters economies of scale. Another strand in the endogenous growth theory is concerned with the role of research and development activities (Romer 1989b). Why economics has moved in this direction and why the new theories have not led to a reappraisal of the case for free trade is not altogether clear. But one factor has been the politics of the profession itself. Economists as a group have constituted themselves as a political force against protectionism. Paul Krugman, one of the leading figures in both endogenous growth theory and trade, has been particularly ferocious in attacking those who would use the new theories to argue against free trade—whether they operate from within the economics profession or the wider political arena (Krugman 1992).

The second factor that has created a renewed space for industrial policy is the process of globalization itself. In the increasingly large and open international marketplace, individual countries become bit players, more like a single firm than a sovereign entity. It makes less and less sense to think of a national economy as reproducing within itself a complete industrial structure or even as being composed of particular industries. Just as an enterprise is located in a particular part of a particular industry, a country can now think of its industrial locations in this way as well. The institutions governing the emergent trade system have reinforced this analogy. They prohibit protectionism. They also prohibit government subsidies, both direct and in the form of targeted tax breaks. The range of instruments available to governments in promoting particular industries is thus restricted to education, research and development, and internal institutional structures of property rights, incentives, and the like. The menu of possible policies is thus increasingly similar to that of a business enterprise as opposed to a sovereign nation.

The field of management science which is focused on how firms choose their location within the marketplace is called *business strategy*, and as a country, or a region within a country, looks more and more like a firm, industrial policy is readily reconceptualized as a branch of that field. Michael Porter, who is the leading figure in the development of this business strategy both as a field of scholarship and as a domain of management education, has himself developed this analogy in a text, *The Competitive Advantage of Nations*, which is increasingly influential in regional planning and development studies (Porter 1990).

Finally, given the fact that governments are now limited by international treaties in the kinds of policies they can pursue to support particular industries, and forced to think instead in terms of longer range structural developments, the institutional environment in which industries operate must be counted as a central component of the 'new' industrial policy. The interest in, and concern about, institutions as a

determining factor in the fate of particular national economies has been reinforced by the experience in the countries of the former Soviet Bloc and the difficulties they have had in the transition from socialism. This experience has heightened the sense that the market is itself a social creation and does not automatically emerge on its own, simply because it is no longer restricted by hostile government policies and regulations. But it has also brought back to the fore the question of what the limits of the market are.

In thinking about this last question, two analytical constructs have become increasingly central to planners and policy makers: *supply chains* and *industrial districts*. Both constitute structures in which relations among firms involve direct interactions, as opposed to arms-length relationships mediated by the market. The nature of those interactions and the role they play are, however, very different in the two cases.

Supply chains envisage firms as being linked together in a vertical chain of input–output relationships stretching from raw materials at one end to the distribution of the final product to the consumer at the other end (Gereffi and Korseniewicz 1994). But the relationships are so tightly coupled that they require administrative control and interaction and cannot be coordinated by the prices and trade relationships generated by a competitive marketplace. In the past, the relationships along a supply chain required close physical proximity and were often incorporated within a single enterprise. They are now increasingly spread out geographically and involve a series of distinct firms which are independently owned and operated. Such supply chains nonetheless tend to be controlled and directed by firms at a particular, strategic position: assemblers in the automobile industry, for example, or retailers in the clothing industry. Industrial policy, for developing countries, can then be viewed as a strategy for attracting particular parts of the supply chain. The process of development comes to be conceived as one of moving along the chain over time and of gaining, or retaining, control over strategic positions along it. It is a way of thinking about how countries must move to maintain economic prosperity when they no longer have direct control over their costs through protection and subsidies. A particular position on the chain comes to be viewed as a learning opportunity that will enable the country to move upward as its costs rise and it loses its initial advantage to other parts of the world. Policy instruments over which governments retain control, such as education, training and research, and development, are deployed in a strategy conceived in these terms.

The industrial districts constitute agglomerations of independent enterprises that, like the links in a supply chain, interact directly with each other (rather than indirectly in response to price signals generated by a competitive market). But the particular relationships are fluid, the firms are on a more equal footing with respect to power and responsibility, are generally in the same industry and stand at essentially the same place in terms of input–output relation (Schmitz and Nadvi 1999). Examples include the financial districts of New York, London, or Tokyo or the garment districts of Paris, Milan, and New York. The concept of an industrial district originates with Alfred Marshall who studied such districts in late nineteenth/early twentieth century England, and attributed them to external economies of collocation. This industrial form is particularly widespread in central Italy, where it can be found in a range of industries from high fashion clothing and shoes to specialized machinery and motorbikes (Pyke et al. 1990). It has become a focus of both the endogenous growth theory in economics and the strategic planning literature growing out of business strategy. As a fulcrum for industrial policy, it tends to shift the focus radically from the role of the government in shaping the economic environment in which firms operate to the social climate which enables firms to cooperate with each other and to the potential role of government in fostering that climate. In this sense, it opens industrial policy to insights drawn from sociology and anthropology (Putnam 1993).

Industrial Relations and Collective Bargaining

The field of industrial relations generally is defined as the employment relationship and the rules that govern it. In practice, the field tended until the 1980s to be equated with collective means of governing the employment relationship, in particular collective bargaining, CB (which may be defined as the process of negotiation of the terms and conditions of employment between an employing organization and its employees, organized as a group in a trade union or similar body) (see *Employers' Associations*; *Labor Unions*). The emergence of human resource management (HRM) challenged this easy assumption and led to a debate, particularly in the US and the UK, as to whether industrial relations was not only a mere subset of HRM but also one of declining importance as the role of unions was weakening. In the present writer's view, 'industrial relations' is a sufficiently flexible concept to embrace HRM, but for the purposes of this article the term will be delimited to the collective aspects of employment. Even with this limited definition, the field remains a key aspect of the ways in which working life is organized, not least because CB remains well-established in many countries; moreover, different modes of organizing industrial relations have important implications for equality, social justice, and economic performance.

1. *Origins and Intellectual Focus*

The term CB was coined by the British scholar Beatrice Webb in 1891 and developed in her joint work with Sidney Webb, *Industrial Democracy* (first published in 1897). They explained CB in terms of an evolution from a purely individual and temporary agreement between an employer and a worker (what economists now call a spot price), through a 'common rule' established with a group of workers on an informal basis, to a genuine collective bargain which represented a fixed, agreed set of rules between an employer (or possibly a group of employers) and a recognized body, usually a trade union, representing employees. At about the same time, CB was endorsed by the British government as the preferred way of managing the 'labor problem,' a public policy which survived largely intact until 1979. The other major country to see a similar focus on CB was the United States. During the early years of the twentieth century liberal and progressive reformers responded to the severe and often violent labor disputes of the time by arguing that CB provided a more mature way of resolving differences. The term 'industrial relations' first received wide currency through the Commission on Industrial Relations (1912), with the first academic departments using the name being established during the 1920s, when there were several experiments, notably in sectors such as clothing, to develop mutual acceptance between employers and trade unions (Kaufman 1993). The key public endorsement of CB came in the National Labor Relations (Wagner) Act of 1935 which famously declared in its preamble that CB was the best means not only of reducing strikes but also of handling all aspects of industrial conflict.

The key components of this Anglo–American view of CB were the following. First, it was voluntary: employers and unions engaged in it because they recognized the benefits, not because they were required to do so. Second, it assumed that the two parties were adversaries in that they represented the conflicting

interests of profits and wages. This did not imply that they were totally opposed, and indeed the third principle was that CB could provide a system of industrial governance. It would develop agreed rules for settling the key issues of employment such as pay, promotion, and discipline. But ultimately the authors of the rules reflected opposing positions. The fourth principle was that the parties accepted the legitimacy of the other. Finally, the resort to sanctions such as strikes and lockouts was not forbidden, but these were to be weapons of last resort after agreed procedures had been exhausted. It was hoped and expected that CB would develop as the established means of resolving disputes throughout the economy.

Academic analysis developed through the work of such scholars as John T. Dunlop in the US and Allan Flanders in the UK. In his book *Industrial Relations Systems* (1958), Dunlop developed the concept of a web of rules and argued that an industrial relations system comprised actors who establish sets of rules; the system develops a 'ideology,' or common set of ideas defining the role of the actors; and the system is shaped by its economic and social context. Flanders (1970) developed the idea of rules by identifying three weaknesses with the Webbs' model of CB. First, a collective bargain was not an individual bargain writ large but was different in character: it was not actually a bargain at all but was a process for the making of rules. Second, CB is a power relationship between organizations. Third, the Webbs saw bargaining as an economic matter whereas in fact it had a strong political component: it was about the management of the firm and the whole way in which the use of labor was regulated, not about a simple exchange of wages. CB had a 'managerial' as well as a 'market' aspect.

Such work helped to establish industrial relations as a distinct academic field, if not a discipline. A focus on the creation of rules distinguished it from economics, which concentrated simply on the price of labor. Interest in the institutions of work and their inner functioning demarcated it from sociology, which tended to see such institutions as reflections of social class. Industrial relations opened the black boxes of how the price of labor was established and how class relationships were actually organized.

The approach of Dunlop and Flanders also had weaknesses. As British critics argued, the focus on rule-making and formal institutions assumed a natural progression towards 'order' and neglected continuing relationships of power and inequality; there was a permanent conflict over the organization and control of work which insitutionalized CB could manage but not totally regulate (Hyman 1989). Such criticism merged with growing interest from outside conventional industrial relations in the labor process and conflict over the performance of the work task. The absence of such a critique in the US was arguably one reason why industrial relations as a discipline lost some of its vitality in that country and why it was relatively poorly equipped to face the challenge of HRM.

2. *CB Systems*

When seen in international perspective, Anglo–American theory also needs to be extended, for CB has very different 'meanings and functions' in different countries (Bean 1994). In this theory, CB is a private, voluntary process conducted largely within individual firms with the outcome being a collective agreement. Yet in France, for example, the state has been an active agent, key agreements are at national and sectoral rather than company level, the practice of 'extending' agreements to nonsignatories is well-established, and even the idea of a specific agreement signed by all parties has never been established and instead some unions have refused to sign agreements so that CB becomes an arm's length collective relationship rather than a tightly defined process of rule-making and rule-administration. The discussion below focuses mainly on the three countries just mentioned, and also Sweden and Germany, and draws on the accounts in Adams (1995), Bean (1994), Crouch (1993), Ferner and Hyman (1998), and Locke et al. (1995) without further specific reference.

2.1 *Level and Scope of CB*

Clegg (1976) identified key different dimensions of CB. The most important are the level of bargaining (whether it occurs at national or sectoral level or at the level of a whole company or at a lower level within different parts of a company), its scope (the range of issues which it covers), and its extent (the proportion of relevant employees covered by it).

The work of Clegg and of later writers (Sisson 1987) established the main international variations in the conduct of CB. In most European countries the level is national or sectoral. Sweden is the clearest example of a nationally-oriented system. From the 1930s to the 1980s the key negotiation was that between the national employers' organization and the trade union federation of manual workers. Germany after 1945 represents the most developed sector-level arrangements, with unions being organized on clear industrial lines and with collective agreements being made for each industry. In addition, the terms of these agreements are extended to firms in each industry that are not directly parties to them. In countries such as France and Italy, there has been a more variable pattern, with the national level coming to prominence, notably in times of crisis, but with the sectoral level that at which agreements often are negotiated formally.

The scope of agreements in these countries is generally broad, with agreements specifying many of

Table 1
CB coverage (percent of workforce covered)

the key terms and conditions of employment such as wages and holiday entitlements. Often, they are underpinned by laws on minimum holiday entitlements and dismissal.

In the United States, collective agreements generally have an even broader scope, one reason being the limited extent of legal provision. For example, unemployment insurance, which in Europe commonly is covered by statute, has been weak or absent, and during the 1950s contracts began to introduce unemployment protection. A typical American collective agreement often is extremely detailed, with anything not covered explicitly in the contract being left to managerial discretion. As for level, America is largely a country of company agreements. From the 1950s to 1970s some sectors had, in effect, sectoral-level substantive terms, with one company agreement setting the pace for others.

Britain provides a distinctive picture. The scope of agreements has been much narrower than in other countries, with only minimal terms and conditions often being specified. Collective agreements were often procedural, that is, setting out procedures to be followed in cases of dispute, rather than substantive. In contrast to most countries, agreements are not legally enforceable but are merely 'gentlemen's agreements,' binding in honor only. The level of agreements was characterized by the official Donovan Commission of 1968 in terms of 'two systems': the formal system of industry-level agreements, and the effective and informal system in which bargains were struck at the level of the plant or even the individual work group. Britain has long had a uniquely uncoordinated system.

According to Sisson (1987), this reflected the failure of British employers to 'neutralize the work place.' Britain's long industrial history meant that by the early nineteenth century many trades of skilled workers had entrenched customs governing wages and hours of work. Reliance on 'custom and practice' was never rooted out by employers, even when they won apparent victories in open confrontations. This failure has in turn been related to other factors including the unwillingness of the state to support a sustained policy of suppressing unions, employers' own divisions, and the deeply entrenched commitment of employees to customary standards.

The sharpest contrast generally is made with Sweden. The main confrontations in Swedish labor history were at national level, and the key Basic Agreement of 1938 laid down the terms of future bargains, which continued to be at national level. A strong and inclusive employers' organization, underpinned by a relatively homogeneous industrial structure, was able to make a firm agreement with an equally inclusive union organization. Other European countries also faced key historical turning points; naturally, the specific relationships reflected the balance of forces between employers, unions, and the state, but the outcome was generally a multi-employer system that neutralized the work place.

American employers achieved neutralization by means of company-level agreements. These were established rapidly in the wake of the Wagner Act as comprehensive, usually three-year, deals. A key component was their legal enforceability. In most European countries, too, collective agreements are legally enforceable, but this fact often has limited practical salience. It has not prevented French or Italian unions from conducting frequent strikes, and in countries such as Sweden and Germany it is more a reflection of a wider belief in contractual obligations than an independent cause of these countries' generally low strike rates. In the US, by contrast, tight legal rules on legitimate strike action, backed up by employers' willingness in the key years of the late 1930s and the 1940s to put legal principle into practice, rapidly created what labor historians identified as a 'work place rule of law': a system of private justice enshrined in the CB contract, underpinned by public law.

2.2 Extent of Bargaining

The extent of CB requires separate treatment, for it is harder to establish than might appear. Such coverage is not coterminous with union membership, since a contract is likely to cover all workers in a given unit whether or not they are members of the union that negotiated it. In Britain and the US, however, it is reasonably clear who is covered by a collective agreement. America, in particular, uses the language of 'exempt' and 'nonexempt' employees (which was introduced by the Fair Labor Standards Act 1938), with the former (broadly, managerial and supervisory employees) not being covered by CB. Where a collective agreement exists, it will specify clearly the sites and personnel affected. In some other countries, the situation is also clear. In countries such as Sweden, where union membership is very high and embraces many white-collar groups who in America might be classed as exempt, coverage is also extremely high. But in France, for example, a collective agreement is less

clearly defined. Many French unions refused formally to sign contracts since to do so conflicted with communist ideology; they were in practice covered even if they were not signatories. Similarly, it is well known that French union membership is a poor guide to the extent of workers' union affiliation. France, along with Germany, is also a case where collective agreements are commonly extended across a whole sector to cover firms and workers not directly party to them (Traxler 1996).

Traxler (1996) summarizes the best estimates that are available. An extract of his data is in Table 1. As explained above, the gap between union membership and bargaining coverage is very wide in France and virtually zero in the US. It is also worth noting that coverage and membership are much higher in Canada than in the US, despite great similarities between these countries. As Adams (1995) explains, this difference reflects two forces: the intensity of employer opposition to CB and the degree of activity of public policy in containing this opposition.

CB coverage, thus, remains high in many countries. Yet it should also be noted that in countries such as the US and UK it was never complete. There are several reasons. First, managerial and other employees were never within its scope. In America this exclusion was particularly clear. In Britain, it was less so; in particular, managers in the public sector were quite likely to be covered. But in both countries private sector managers were generally excluded. Second, there is the small-firm sector where CB was often seen as inappropriate. Third, many sectors did not develop bargaining institutions. A good example comes from Britain, where Wages Councils were set up in sectors such as clothing and catering, where firms were small and unions weak. These councils were established by law and set wages and conditions. They were seen widely as precursors of CB but only very rarely did bargaining grow out of them. When they were abolished in 1993, they still covered over 10 percent of the country's work force. CB did not grow naturally, and flourished in countries where it was sustained by wider systems of interest representation.

3. *Corporatism*

Established industrial relations concerns with the structure of bargaining were complemented from the 1970s with interest deriving from political science in corporatism (Goldthorpe 1984). Corporatism was defined as a system of interest representation in which peak associations of capital and labor represented their members in dealings with the state, which licensed their activities. The scope and level of CB were taken as an important indicator of the degree of corporatism. Early work saw corporatism as a continuum, with Sweden and also Austria being highly corporatist, countries such as France and the UK being weakly corporatist, and North America and Japan having no meaningful corporatism at all.

The concept of corporatism made two contributions. First, it placed narrowly defined industrial relations systems in a broader social context, and encouraged an explanation of these systems in terms of the role of the state and key periods in the regulation of the labor problem. In the US, for example, state intervention through the Wagner Act reflected employer and union preferences for company-level CB but also reinforced this emphasis and helped to preclude corporatist arrangements. Second, it focused attention on outcomes. Researchers increasingly argued that corporatism shifted labor problems from the industrial to the political sphere: issues of distribution between capital and labor could be handled in the context of welfare transfers and social security benefits, and the need to use the strike as a bargaining weapon was reduced. In addition, corporatism reduced self-seeking behavior: under atomized bargaining, every group seeks its own benefits, even though this will produce inflation that wipes out these benefits. Centralized bargaining can eliminate such tendencies, and lead to a virtuous circle in which low wage pressure produces low inflation which leads to low unemployment, which in turn yields returns to unions so that they moderate wage demands.

This analysis produced academic criticism. Some countries, notably Switzerland and Japan, had many of the alleged benefits of corporatism without being meaningfully corporatist. One response was to widen the concept, although it was also weakened as a result. A second was to argue that economic performance was not linearly related to corporatism. Instead, noncorporatist countries such as the US were argued to perform well, because labor markets functioned in a neoclassical fashion. There was, thus, a U-shaped relationship, with countries with middling degrees of corporatism performing the worst. Yet perhaps the most sweeping criticism was that corporatism was static: it might help to resolve labour problems during low unemployment periods, but it tended to set up structures that were resistant to change and unable to cope with more turbulent times (see Therborn 1992, Crouch 1993). Such criticism was not purely academic but also reflected the agendas of government of the Right elected on programs of market-led reform. This leads into issues of the decentralization of CB, but corporatism was not dead and it retains significant appeal.

4. *Decentralization and Decollectivization*

It was never the case that CB was firmly established in such countries as Britain and America. Coverage was patchy, and in America in particular it came under a

number of challenges, even during its heyday. From the 1980s, however, much more extensive challenges emerged, and these embraced many countries. The challenges embraced all the main dimensions of bargaining. Its level has been lowered, with moves from industry level agreements to the plant level. The scope of bargaining has been reduced, as employers stress direct participation rather than bargaining and aim to move away from what they see as the adversarialism of bargaining towards a more team-oriented approach. And the extent of bargaining has been reduced, as employers retreat completely from collective agreements.

Katz (1993) argues that these trends can be identified in many advanced countries. Sweden is a particularly clear case. The 'Swedish model' was consolidated in the 1950s with centralized national-level bargaining as a key component. This structure, it is important to note, was established at the insistence of employers and not, as the Webbs might have expected, the trade unions; the reason was that employers wished to ensure co-ordination and discipline. The model exhibited tensions as early as the 1960s, including problems of including the growing public sector within it and shop-floor discontent on nonwage issues. The pressures increased during the 1980s as private sector employers, particularly those in the export sector, saw a wage system dominated by principles of equality as too inflexible to reflect their needs. The end of the long period of Social Democrat governments in 1976 also marked the end of unquestioned state support for the structure of bargaining.

Trends were equally clear in Britain. Some large employers began in the 1980s to remove recognition for bargaining purposes from trade unions. Structural change was also important, as the decline of sectors where bargaining was strong, notably manufacturing and coal, was matched by the growth of service industries with little or no tradition of bargaining. The scope of bargaining was also reduced, as employers moved away from traditional custom and practice on issues such as staffing levels to more unilateral regulation. Trends towards the decentralization of bargaining to plant level, which had been in train from the 1970s, continued.

According to Katz, the decentralization of bargaining reflects two main forces. First, there is the changing balance of power between managers and unions, which has allowed management more scope to choose bargaining levels. This is not, however, a sufficient explanation for, in an echo of Flanders' criticism of the Webbs, it is not necessarily the case that unions seek the most centralized level; as Flanders pointed out, CB performs roles for managements as well as workers, and managements may have an interest in neutralizing the work place. Moreover, says Katz, shifts in the balance of power cannot explain trends in Germany, where union power has not greatly weakened and yet where decentralization can be observed. The second factor is the need to handle new forms of work organization such as teamwork. These are implemented at the workplace level and they require agreements to handle them. Thus even in a country like Sweden it has been necessary to develop enterprise and plant bargaining.

Katz's explanation calls for two qualifications. First, it gives insufficient attention to the extent of co-ordination practised within large companies. UK studies have shown that large companies monitor pay rates and staffing levels in their subsidiaries, so that effective control has not been returned to local level. They also assess the overall financial performance of subsidiaries, so that local autonomy can exist within tight confines (Brown et al. 1995). Second, power may have rather more of a role than Katz suggests. Most of the agenda of teamwork is driven by managerial concerns about efficiency, and many of the leading exemplars of teamwork have no collective agreements or ones with limited union influence. It is true that, as many studies on both sides of the Atlantic have shown, HRM initiatives are as common in unionized as in nonunion firms. However, case studies generally indicate that the bargaining power of unions has been reduced. Changes in the level and the scope of bargaining have been closely related. It is also true that managements do not have an inherent interest in decentralized bargaining. However, in the particular context of the 1980s and 1990s, with high unemployment and rapid changes in work practices, managerial power was enhanced and it was possible to use this to press through changes in work practices on a plant by plant basis, with each plant's workers fighting for survival against other plants.

Most importantly, the factors identified by Katz may be offset by other tendencies. Traxler (1996) has questioned how far the extent of bargaining has changed. Echoing many other writers, he suggests that two kinds of system can be identified: the 'exclusive,' where bargaining lacks coordination and usually is at company level, as in Japan, the US, and the UK; and the 'inclusive,' where national or industry levels allow coordination, as in Australia and many European countries. He argues that decentralization is a major feature only in the exclusive cases. As discussed below, this account has been developed by studies of neo-corporatism which stress the continuing value of regulatory institutions. Katz has perhaps over-stressed one tendency, which can be counteracted by others. Yet Traxler may downplay the extent to which the scope, as opposed to the extent, of bargaining has changed. The model of inclusive systems may require development. Crouch (1994), for example, identifies various forms of corporatism. A good example is Australia which, although having an 'inclusive' system, has faced significant market-led pressures. As Hampson (1999) argues, the country's corporatism has always been 'enigmatic' in never fully including employers and in being subject to major pressures to

decentralize bargaining. Although the country's unique structures remain in place, how they work has changed dramatically.

5. *Potential for and Effects of CB*

The debate on decentralization increasingly recognized that bargaining structures cannot be placed on a single continuum. The Nordic countries, for example, are commonly described as being both centralized, in that bargaining is conducted at national and/or industry level, and decentralized, in that the legal regulation of industrial relations is relatively light. Countries' industrial relations systems are best characterized in terms of the articulation between levels (Crouch 1994). The UK and the US have relatively weak articulation, with industry and national level bargaining being limited in scope and with employers' organizations never having had a strong focus at these levels. Several countries have, by contrast, developed linkages between levels. In Germany, collective agreements have covered non-wage issues such as job security and training and have, thus, sought links with changes in work organization which have developed at company level. In countries including Italy, The Netherlands, Spain, and Ireland, variants of centralized co-ordination have re-emerged. Two trends can, thus, be discerned. The first is towards decentralization, but here there is a difference between unplanned decentralization and the co-ordinated approaches in some countries: decentralization does not necessarily mean atomization. Second, there are trends towards national co-ordination. As studies of The Netherlands and Italy in particular suggest, such co-ordination can bring substantive benefits including wage moderation and procedural ones in that processes of wage setting have a predictability and order. Such points echo Therborn's (1992) critique of the concept of corporatism: it had the right idea but tended to apply it through attempts to categorize countries on simple scales whereas corporatism is in fact a multifaceted process, rather than a set of institutions, and is best understood in terms of the historical interactions between employers, unions, and the state.

The concept of neocorporatism has, thus, emerged. It is used to argue, for example, that contrasts between North America (with rapid job generation) and Europe (with rigid corporatist structures giving 'excessive' protection to employees) are too simple: The Netherlands, for example, has created jobs successfully through a mixture of market reforms and revived corporatist arrangements.

Such arguments have taken up implicitly one of Flanders's main points: that CB is not simply a means of setting the price as labor but is also concerned with securing dignity for the worker. CB was a means of establishing an industrial rule of law. This was reflected in fairer systems of discipline and discharge, for example. Studies during the decline of CB have revealed the power of this observation.

First, it has been shown that income inequality is shaped by CB. Inequality is greatest in countries where bargaining is weakest and most decentralized. And the rise in inequality in the countries where this has been sharpest, the US and the UK, reflects the decline of CB institutions. Second, similar results are reported for the gender inequality in pay: this is highest where CB is most decentralized, and some writers argue that the most effective route to gender equality is not specific policies on sex discrimination but effective more general bargaining institutions. Third, there is long-standing evidence that where unions are most established in a workplace, and hence where CB is most developed, there are clear outcomes. These include relatively low rates of absenteeism and quitting, low uses of disciplinary sanctions by employers, and wages that are higher than they otherwise would be (Blanchflower and Freeman 1992).

In short, within a single nation state neocorporatism can bring benefits to capital and labor, while even where it is absent CB has effects on income distribution and the quality of working life. Yet the decline of CB and the absence of any effective alternative has led, particularly in the UK and the US, to arguments about a 'representation gap': without CB, how are employee interests to be identified, organized, and expressed? A challenge for CB is whether it can be renewed sufficiently to offer a meaningful model of industrial government, particularly in white-collar and service-sector contexts where collective representation has been rare. A second is to promote the articulation of levels of CB. In Europe, there are some positive developments in terms of legally mandated employee representation systems, while even in Japan and Korea some quasicorporatist arrangements can be discerned. Fewer such developments are discernible in North America. CB has shown the power to adapt in the past and it may continue to do so in the future.

Industrial Relations, History of

In most developed countries, wages and working conditions, forms of employment, bonuses, and allowances are regulated, either by law or by collective agreements. The latter are themselves bordered by juridical or customary rules which define their beginning, process, and results. Their coherence does not merely reflect the logic of the national institutions and of the economy. It takes into account the social actors themselves and the aggregation of their decisions, which constitute industrial relations systems. They vary throughout the course of history. They also differ amongst North America, Japan, and Europe and within Europe itself. But everywhere these systems have been deeply altered or even challenged since the 1980s.

1. *The Concept of Industrial Relations*

The term 'industrial relations' was born in the USA. It is the product of both changing relations between companies and wage-earners and of academic attempts to instil some order into the turmoil of social change.

1.1 *Commons*

John R. Commons, an economist at the University of Wisconsin (Madison), produced, during the first third of the twentieth century, the first major interpretation of social relations in 'American industrial society.' He argued that US workers were more wage-conscious than class-conscious. If companies became aware of these fundamental tendencies, there was room for contracts between management and trade unions. Conflicts could be avoided, minimized, or solved. Government was welcome to promote economic growth by supporting the contractualization of industrial relations. Commons and his followers stressed the importance of institutions for organizing society. Accordingly, they considered trade unions to be a source of social progress. They privileged collective bargaining as fitted to US exceptionalism and adapted to unionization by trade, not by industry.

Commons and his followers were not pure and simple academics. They actively contributed to the liberalization of US social legislation which developed between 1918 and 1940.

1.2 *Dunlop*

John T. Dunlop, a sociologist at the University of Wisconsin, working between the 1950s and the 1970s, went further in the same direction. He systematized the idea of systems of industrial relations at local, regional, or national levels. Thus he stressed the interdependence between the key elements of industrial relations: for instance, between the definition of a trade union, its representativity, and the nature of a negotiation. This interdependence is characterized not only by a common juridical doctrine, but also by reciprocal strategies carried out by managers and unions. Moreover, rules in industrial relations need to be interpreted by reference to the policies of unions, companies, and trade associations. Social actors create rules and bind each other by such regulations, at least for a specific period of time. Like Commons and his followers, Dunlop and his colleagues worked as experts for public administrations and played a significant part in the evolution of collective bargaining and of legislation till the first oil crisis. Unlike Commons, they moved from the idea of US exceptionalism to its apparent opposite: a possible universal convergence between the national systems of industrial relations. 'Industrialism' would bring about a civilization of

social relations everywhere by generating stable processes of collective bargaining. Meanwhile, Dunlop recognized the plurality of national and continental systems.

2. Three Models in Europe

At the end of the nineteenth century and during the twentieth, Europe developed specific features in its industrial relations systems, which are still in force. Collective bargaining is first and foremost the responsibility of employers' associations and trade unions by trade or sector, coordinated by confederations. Bargaining at company level came later, is growing, but remains under the aegis of federations. A distinction is made between collective bargaining, which deals mostly with wages and working time, and participation of wage-earners, which includes work conditions, welfare, and the adaptation of a broader collective agreement to a firm; also, more recently, information on the firm's strategy and its impact on employment. In Germany, participation extends to codetermination, introduced under the Weimar Republic and generalized in the aftermath of World War II, by laws passed in 1951–2. Governments are involved in the national regulation of industrial relations. Intra-European variety may be reduced to three types of patterns. The patterns are quite different on other continents.

2.1 The UK and the Republic of Ireland

This is the oldest industrial relations system. Trade unions are closely related to trades and collective bargaining is basically at the level of the firm or the workshop. Conversely, strikes are frequent at this level, yet they do not foster political radicalization. Labour legislation is light. Politics and society tend to privilege the freedom of action of employers and unions.

2.2 Central and Northern Europe

This group comprises Germany, Austria, Switzerland, and the Scandinavian nations. It is characterized by a trend towards uniqueness in several forms: uniqueness of employers' associations—powerful, structured, obeyed; uniqueness of trade unions—strong and connected to political power; uniqueness of social conflicts—abiding in written or implicit rules. Collective bargaining is centralized by branch. So are strikes, limited to the period of negotiation. In these countries government intervenes by legislating on industrial relations. However, employers and unions have moved to restrict its interference. The Netherlands and Belgium may be included in this group, although both have a plurality of trade unions.

2.3 The Latin Countries

This group covers France, Italy, Spain, Portugal. The keyword here is pluralism: pluralism of conflicts, with a significant percentage of preventive strikes and of wildcat strikes; pluralism of trade unions, with a pole of socialist origin, another of Christian origin, and one which calls itself autonomous or independent; pluralism of political influences among wage-earners. In addition, there is limited authority and even, for many years, pluralism of employers' organizations themselves. Collective bargaining long proceeded only at the national level (for one branch or for the general economy), except at the end of local strikes. Bargaining at company level became a more regular practice in the mid-1950s or even later. Government regulates a variety of issues, except in Italy.

3. North America and Japan

3.1 North America

The US labor movement long featured a pluralism of organisations (in fact till 1955), and employers were as reluctant as elsewhere to negotiate with unions. Things changed with the New Deal. The 1935 Wagner Act, however deeply modified by the 1947 Taft–Hartley Act, made collective bargaining a right for employees, but a union had to be accredited by the vote of a majority of them as the sole counterpart of management in collective bargaining. Law deemed collective bargaining to progress 'in good faith,' i.e., to aim at an agreement. Thanks to the sitdown strikes of the mid-1930s, bargaining spread all over the USA and its contents broadened. The areas of bargaining are now wages, working hours, and work conditions. They may include other matters which have consequences for these elements. The closed-shop clause has been declared illegal. As for Canada, it generally followed the US trends.

3.2 Japan

Up to Japan's defeat at the end of World War II, collective bargaining was exceptional in Japanese companies and would materialize only at the end of strikes. Practices and legislation changed in the late 1940s, under the influence of Japanese liberals and US occupying forces. Collective bargaining became a constitutional right for wage-earners. A company has to bargain with any union which asks for it, and even with any group of employees which does not constitute a union, provided it can express a common will. The employer must present counterproposals to the demands of the employees and negotiate 'loyally.' The contents of collective bargaining are extremely broad. A wave of strikes enabled both the spread of unions and of collective bargaining in postwar Japan. How-

ever, radical unions were finally defeated; worker activism and protest gave way to management victory in the 1960s and 1970s. Company unions took the upper hand in pursuit of economic affluence. Collective bargaining became a type of cooperation with management, and often quite an influential one. This evolution laid the foundations for a corporate-centered society.

In North America and in Japan, when there is no union in the workplace or no agreement is reached, the rights of the employee may be in fact minimal and management keeps its unilateral powers.

4. Recent Changes

4.1 The End of an Era

Many authors consider the stages reached by national industrial relations systems after World War II to have been parts of social settlements built after the strains of the international economic depression of the 1930s and of the wars of the early 1940s, paving the way for a new era of growth. When growth decelerated in the time of oil crises in the 1970s, when national tariff barriers were lowered, and neoliberal ideas made a spectacular headway in the West, industrial relations systems came under attack. At the same period in a number of countries, though not all, membership of unions started to decline. The breakdown of the population changed from a majority of blue-collar workers to an increasing proportion of white-collar employees, in keeping with a growing proportion of women at work and a shift from industry to services. Unemployment simultaneously rose.

4.2 A Shift in Industrial Relations

On a world scale, trade unions entered an era of concessions to employers in terms of wages. The flexibility of work conditions grew. Mechanisms of social protection weakened. Companies moved to a greater individualization of wages, careers, even contracts, and to a more intense involvement of each employee in the workplace. Integration quite often became their motto. Japan was the last country to undergo this new trend and to try and adjust to the challenge. In many countries militancy and the yearly number of strikes and strikers declined. Yet both large companies and governments stressed the importance of collective bargaining to accompany such far-reaching changes and to stabilize the emerging global competitive order. In some countries ways were found to integrate small and medium-sized enterprises in industrial relations systems. Outside the USA the reduction of working time became a target for collective bargaining and legislation. In each country some of the trade unions began to adapt and modernize their strategies and structures. Some were able to regain members in new working groups. But altogether their societal position has not yet been stabilized and the balance between individual and collective has been altered in significant aspects, in favor of the former.

5. Current Debates

5.1 The Impact of New Practices on the Paradigm

These changes in industrial relations themselves have caused new debates among scholars about Dunlop's paradigm. The development of framework agreements, of agreements on discussion methods, of agreements setting a policy and targets rather than rights, in short of agreements which are not contracts, is quite different from the explicit forms and the strict obligations characterizing most of collective bargaining in the USA during the 1950s and the 1960s. Collective actors appear less neatly defined, more unstable, and the representativity of unions is under redefinition in some countries. In short, actors may become more defined by action itself. A number of scholars argue that such developments do not invalidate Dunlop's paradigm, as it is based on autonomous actors able to create rules and to keep their word.

5.2 Recurrent Critiques

Simultaneously older critiques of the paradigm find a greater audience. A number of authors have stressed the importance of unorganized conflict, expressed by absenteeism and turnover. They also stress that the US model of the social conflict as a simple form of adjusting industrial rules may reduce its dimensions and that trade unions are not everywhere limited to the provision of personal services to wage-earners. These authors doubt the possibility of a convergence of national industrial relations systems, despite the development of multinational companies and of continental economic unions. Is it still so easy to say that these systems are functional to industrialization? Are the frontiers of these systems clearly defined, as they indeed produce part of their economic or technological 'context' themselves? Are they not less stable than their earliest analysts implied? What are the multiple sources of their dynamics? Therefore, research on industrial relations is coming back on the agenda of social sciences, as well as of organizations and of individuals.

Industrial Society/Post-industrial Society: History of the Concept

As the proportion of occupations engaged in manufacturing industry declines, to be replaced by work in those sectors of the economy called generally 'services,' social observers have tried to understand the wider changes involved. While much has thereby been learned about the character of society after the decline of industry (i.e., 'post-industrial society'), continuing extensive change makes it difficult to reach firm conclusions.

1. The Theory of Economic Sectors

An awareness that the rise of mechanized manufacturing would have implications for social life going far beyond the production of goods itself had been one of the central ideas stimulating the emergence of sociology as an intellectual discipline during the mid-nineteenth century. Before the growth of industry, social life had been governed primarily by the routines and social relationships of agriculture and landholding. Industry brought a vast range of new occupations; new concentrations of population changed the character of cities; and relations between the owners of capital and those who worked for them replaced relationships based on land tenure as the basic structure of power and inequality.

Central to the change had been the gradual shift of population from agricultural to industrial work. By the mid-twentieth century, however, it was becoming clear that, in those areas which had industrialized first, particularly Great Britain, this process would peak and be replaced by a new change. A number of observers, notably the British economic geographer Colin Clark (1940), had noted a rise in various occupations which 'were not concerned with the production of goods.' They called these 'service' occupations and developed a model of three sectors of the economy, which also embodied evolutionary assumptions about the order of change: a primary sector, in which people extracted useful material from nature (agriculture and mining), was succeeded by a secondary one, in which people fashioned the material so extracted into goods (manufacturing and construction activities); which was in turn to be succeeded by a tertiary sector, in which people made use of the goods produced (services). That distinction of three sectors entered common parlance and became one of the main means by which economies were analyzed and change over time predicted.

For a number of years the most industrialized countries (UK, USA, and some cases on continental Europe) continued to experience growth of both industrial and services sectors (at the expense of agriculture) but from the 1970s it became clear, first in the USA, then in the whole of Western Europe and later Japan, that employment in the secondary sector had joined the primary in a secular decline and that virtually all net employment growth was coming from the tertiary sector. This led to predictions that, as the proportion of the workforce employed in industry declined, there would be extensive social change across many areas of life, possibly as marked as that involved in industrialization itself. The idea of post-industrial society—not just post-industrial employment—was born.

1.1 Subdivisions of the Services Sector

At the same time, various economists, geographers, and sociologists were becoming aware of the inadequacy of the tripartite division of sectors. The services sector was not really defined at all by the idea of using the products of industry, but was just a residuum, made up of everything that could not be allocated to the other two sectors. A number of writers attempted further analysis of the activities that were being included in the services sector. Katzovien (1970) suggested distinguishing between services complementary to industry, 'new' services such as the welfare state and leisure, and 'old,' mainly domestic, services. Singer (1971) made a similar proposal, but replaced the distinction between old and new by one between 'collective' and 'personal'. Most contributions sought

to continue the evolutionary idea of a gradual move away from nature, though Katzovien's reference to 'old' services indicates some doubts about the simplicity of this.

The German sociologist Joachim Singelmann (1978) produced a useful synthesis of the debate with a six-sector model. The primary and secondary sectors remained as in Clark's model, but the tertiary was restricted to those activities concerned with the movement of manufactured products: transport, distribution, and all sales activities. A fourth sector identified services organizing and financing productive activities (banking, other financial services, and all other business services). The fifth sector followed Singer in distinguishing 'collective' services, those activities which had little at all to do with goods, but comprised direct inter-personal services of a social and community kind, such as health and education. This left for a sixth sector Singer's 'personal' services, including leisure and domestic services.

Since Singelmann's contribution at the end of the 1970s, there has been little further progress in the construction of models of sectors, though both the theory of and empirical support for the model were considerably advanced by the Spanish sociologist Manuel Castells (2000). Most popular and political, as well as much economic, discussion still uses the basic three-sector model. However, most national and international statistical services now collect data on occupations which permit identification of five and often six sectors. Also, theories of post-industrial society draw on the idea of the different sectors in order to complete their models of the character of that society.

1.2 Problems in the Analysis of Sectors

This task is made difficult by considerable differences among these sectors. Observers who assume that the characteristics of some extend to all, will make mistakes, as in the frequent assumption (discussed in Sect. 2.1) that services employ predominantly educated labor forces. By far the largest single component, in many countries now larger than manufacturing as an employer, is the social and community services sector. This certainly does employ a particularly high proportion of educated, scientifically trained workers, and is often taken as paradigmatic of post-industrial society (e.g., Daniel Bell's 1974 particularly influential account). However, in the majority of countries, this sector depends rather heavily on public investment and employment. Today this seems to have peaked, as public spending and the role of the public sector are undergoing some decline in most parts of the world.

A second sector which also employs highly educated labor, business services, is growing extremely rapidly. However, it remains very small and, as Singelmann pointed out, often comprises just an out-sourcing of activities which could be part of manufacturing enterprises. This raises an important methodological problem in the study of post-industrial society. Occupations are usually classified according to the predominant activity of the organization for which a person works. Thus, an accountant working for an aircraft-manufacturing firm will be classified as employed in the manufacturing sector; an accountant working for an accountancy firm will be classified as employed in the business services sector. Indeed, if the aircraft-manufacturing firm stops employing its own accountants and subcontracts to specialized accountancy firms, the occupational statistics will show a shift from manufacturing to business services—a move towards post-industrialism—though in fact no change at all will have taken place in work activities.

Should some firms be making decisions to out-source ancillary services while others are doing the opposite and in-housing previously subcontracted work, there would be no overall effect on employment patterns. However, since at least the 1980s, there has been in a number of advanced economies a major trend for large firms to out-source ancillary activities and concentrate on what they define as their core business. There is also evidence that this tendency has been stronger in some countries (e.g., USA) than others (e.g., Germany). While these changes and differences are sociologically important in a number of ways, they have the effect of exaggerating the wider significance for the pattern of human activity of the trend to post-industrial society.

The two remaining services sectors are arguably not really post-industrial at all, as Katzovien's (1970) distinction between new and old services suggested. Although the distributive sector includes some advanced activities in telecommunications, much of it, and much of its recent job growth, involves ancillary services not only to industrial, but also to pre-industrial, society: transporting goods and persons, selling things in shops. The personal services sector constitutes mainly 'servant' activities, a large number of which are certainly preindustrial.

More recently, the growth of information technology and economic globalization have further complicated the question of identifying and distinguishing sectors (see the detailed account in Castells 1996). The use of computers in very many areas of production has confused the once strong distinction between manufacturing and many services employments. Further, the most advanced firms use the internet to fragment and recombine production and distribution activities using disaggregated subcontracted production units. This changes completely the idea of an employing organization located primarily in a certain range of activities, which is central to the idea of occupations and even sectors. In globalized firms, these activities will be located across different parts of the world, with manufacturing components of the task being based in some countries and various associated services in

others. The analysis of economic sectors and change within them needs to develop further. Nevertheless, the theory of post-industrial society has made considerable progress on the basis of the knowledge so far available.

2. *Theories of Post-industrial Society*

The strength of the concept of post-industrial society depends on its being able to identify broader social changes propelled by the initial shift in occupational structure. The leading theorists have tried to do this.

2.1 *Education and Class in Post-industrial Society*

In particular, both the American Daniel Bell (1974) and the Frenchman Alain Touraine (1969), the leading initial theorists, expected a rise in the educational levels of the work force; for Bell, the university-based scientist working for public service would be the emblematic figure of post-industrial society, in the same way that the production-line worker had been the emblematic figure of industrial society and the peasant digging the land that of preindustrial. In this they were partly right; the typical formal educational levels of persons working in many services activities are considerably higher than those in manufacturing. However, as noted, this is true of only some sectors: business, and personal and community services; not distribution and personal services (Castells 1996, Crouch 1999).

Bell and Touraine entertained opposite expectations of class structure. For the former, the decline of the industrial proletariat, a declining importance of material as opposed to intellectual capital, and the overall rise in education standards would see the emergence of a more classless society. Touraine, however, did not expect capitalist management to respond creatively to the new intellectual capacities of the work force. He therefore predicted intensified class conflict as the intellectual capacities of the work force grew. Both have been wrong. Bell was right in expecting that the decline of manual manufacturing work would produce a decline in class organization. However, he was unable in 1974 to anticipate the extraordinary resurgence of financial capital and shareholder power which would follow the global liberalization of capital markets and their association with new information technology to acquire an historically unique flexibility and mobility.

Bell also exaggerated the extent to which the new occupations would be educated ones and did not predict the growth of the many new low-paid jobs, particularly in distributive and personal services, which have been an intrinsic part of the rise of post-industrial society, and the widening gap that would exist between the skilled and unskilled parts of its diversified work force. To the extent that the USA is the country which most embodies trends towards postindustrialism, it shows its society to be one of sharper inequalities than the industrial society of the midtwentieth century (Crouch 1999, Chaps. 5 and 13). Touranaie was mistaken in that the new highly educated section of the work force did not in general become an alienated, disaffected class, but were absorbed alongside or within the ranks of management. However, professional workers in public services—a significant proportion of the highly educated work force—have in many countries often acted as Touraine predicted. This became particularly important from the 1990s onwards, as governments, business interests, and taxpayers began to resent the fiscal cost of public services, and governments began to privatize them.

Not only models of class, but concepts of occupational hierarchy in general, change with post-industrialism and yet sociologists, government statisticians, and political debate still use the images that derive from the factory as the paradigmatic work place: a small group of managers and professional experts; a number of more or less routine office workers; and large numbers of manual workers with various grades of skill. Hardly any services enterprises have that appearance. On the other hand, the different services sectors all produce very different structures. For example, a typical business services or social and community services organization will have a small group of managers, a large staff of professionals, and a small number of routine nonmanual and possibly manual staff; while a typical distributive or personal services firm might have a small core of managers and a large work force engaged in relatively low-skilled tasks that cannot be identified easily as manual or nonmanual.

To date, there have been few attempts to provide a viable paradigm for the occupational hierarchies that would be typical of post-industrial society, nor successful class models based on these. The most successful so far has been that of the Danish sociologist Esping-Andersen (1993), who does so by relating the transition from industrial to post-industrial society to that from the Fordist to post-Fordist economy. This contrasts the familiar industrial and Fordist class model based on bureaucratic rank and the distinction between manual and nonmanual work with a post-Fordist, service model based on differences of scientific and professional skills. However, this involves certain oversimplifications. In particular, it ignores the fact that several sectors of manufacturing have also been identified as 'post-Fordist,' while many organizations providing services exhibit the bureaucracies seen as typically Fordist.

2.2 *Gender in Post-industrial Society*

Strangely, neither Bell nor Touraine anticipated what has been perhaps the most significant social change

involved with the passage to post-industrial society. All service sectors, however they differ among themselves, usually have far larger proportions of female employees than manufacturing industry (Crouch 1999 Chap. 4). There are some exceptions to this, in eastern Europe and parts of Asia, but in the industrial heartland of North America, Western Europe and Japan, manufacturing industry employs very few women. This is not the case of services sectors, especially social and community services, where the majority of workers are usually female. Usually women occupy the junior roles within these organizations. More recent contributions, particularly those of Esping-Andersen (1993, 1999) have brought this to the centre of their analysis.

The major increase in female labor-force participation, which has been experienced in the most advanced economies since the 1970s, is almost entirely due to the shift from industrial to services employment; very rarely has there been an increase in women working in manufacturing. A central characteristic of post-industrial society, justifying the argument that post-industrialism marks a fundamental social change, is therefore a major shift in gender relations.

2.3 Post-industrialism and Post-materialism

It is tempting to relate the idea of post-industrialism to that of postmaterialism. This concept originated in the work of certain US psychologists (Herzberg 1966, Maslow 1970), who believed they could identify a hierarchy of human needs. People had certain basic needs—primarily for food and shelter—which had to be satisfied before they could move on to more sophisticated ones, ending with the so-called non-material needs, such as culture and leisure pursuits. This was taken up by the political scientist Roland Inglehart (1977, 1990, 1997) in a number of works which have tried to identify differences in political aspirations and voting behavior among successive generations in Western societies as these moved into high levels of affluence and presumed material satiety.

This thesis can be criticized at a number of points beyond current concerns, but there is a clear parallel between it and that of the move from industrial to post-industrial society. This is, however, at least in part a misleading parallel. The shift away from employment in production industries towards services does not necessarily imply a similar shift in consumption. The decline in manufacturing employment partly reflects the major improvements that have taken place in productivity in manufacturing and the greater difficult of securing productivity improvements in service delivery. To some extent, it also represents a shift in goods production towards the newly industrializing countries, which goods are then imported into the post-industrial countries. Finally, Singelmann's (1978) arguments that the sectoral shift is sometimes only an artifact of changing corporate strategies on out-sourcing further limits the extent to which changing occupational patterns can be related to consumption.

3. The Future of Post-industrialism

The changes involved in the emergence of post-industrial society have not yet reached a point of rest. As noted above, globalization and the growth of information technology are continuing to have important effects on occupational and economic structures. Globalization involves the growth of extremely large corporations which have activities ranging across several sectors and which locate different parts of these activities in different parts of the world. These moves are an element of what has become the overwhelming demand of firms: flexibility. This has been made their central operational priority by a combination of the uncertainty of markets in the post-Keynesian economy and the new centrality of stock exchanges. Maximizing shareholder value has become the overriding objective of firms and this means a capacity to switch activities rapidly. If a firm's managers see its main chance for maximizing profits in excelling at a particular kind of activity (say, running hotels), they bend all their efforts to acquiring expertise and reputation in that activity. If, however, their main aim is to maximize shareholder value, they must be prepared rapidly to move out of running hotels into something different if share values are advancing more rapidly in the latter.

Having flexibility of this kind goes beyond the process mentioned above, whereby corporations retain a core business but sub-contract ancillary activities. Having the idea of a core business itself becomes a rigidity. The most advanced firms are trying to subcontract more or less everything except a strategic headquarters decision-making capacity. Virtually all other tasks are out-sourced to small firms, self-employed workers or franchise holders. As noted, information technology can be of great assistance to them in the complex organization tasks which this involves. This development is only beginning and it may find its own limitations in problems of ensuring quality control, integrating activities, and motivating work forces. However, to the extent that it does develop, it implies such a degree of organizational fragmentation that the allocation of work activities to anything as static as economic sectors becomes extremely difficult. Economic and occupational changes are continuing at such a rate that social science is finding it very hard to conceptualize the kind of society they are producing. The last word has certainly not been written on what social form follows industrial society.

Industrial Sociology

Industrial sociology denotes the systematic study of the cultural and historical forces that foster the development of manufactories, and the diverse organizational structures, infrastructures, and market structures with which this development is associated. Researchers also analyze the correlates of and consequences, for a society, (a) of the systems of distribution, stratification, administration, and education and (b) of cultural, legal, political, and social institutions that evolve to accompany industrialization. Finally, investigators tend to specialize in studies of microscopic phenomena (like work settings), mesophenomena (like industries, unions, and interest groups), and macrophenomena (like national public policies, business cycles, and international trade relationships).

Industrial sociology has its intellectual headwaters in both the Enlightenment and in the Enlightenment's own origins in fifteenth and sixteenth century natural law. The most relevant legacy of these bodies of thought was the Western tradition according to which 'liberty,' 'individualism,' and 'egalitarianism' could be balanced by 'justice,' and widespread beliefs that liberty could be equated with private property in the enumerations of individuals' rights. The efforts, in England and in America's constitutional convention, to reconcile individualism and liberty with equality, justice, and the common good became, in their sum, the most fundamental of the conundra to which industrial sociologists have addressed themselves in both historical and comparative terms in modern and then in contemporary times (Kerr et al. 1994, Polanyi 1957, Taylor 1960).

The first intellectual effort to reduce these complex ideas into a coherent statement about a society's trade, commerce, and sociopolitical organization came in the writings of Adam Smith, a Scottish professor of moral philosophy. Smith's Enlightenment comprehended: (a) the shift from mercantilism to free trade, and to what soon would be called capitalism; (b) the increasingly higher degrees of specialized labor mobilized by property owners free to deploy their property without government fetters; and (c) the belief that an economy's markets would ultimately serve consumers, though the term, 'economy' in the national sense, was barely used until the 1890s.

These theses have been among the contested subjects of the continuing investigations of industrial sociologists in their efforts to determine the characters, in macrocosmic terms, of the interdependencies of capitalism with democracy, although micro-(organizational phenomena) and mesolevel studies (stratification and public policies) have become more dominant.

Smith and other eighteenth century liberals believed that *laissez-faire* policies, i.e., market-driven economies, would be productive of: (a) equitable returns to investors, workers, and managers; and (b) large sums of returns paid to the factors of production, and to public and private agents who serve them, a sum that would constitute a nation's wealth, later to be measured as a nation's gross national and gross domestic products.

Note here that market forces were admired as producers of both equity and efficiency; in more general terms, the 'common good,' would be the sum of the values generated by self-serving men who

pursued their individual interests (in returns on their capital) and of self-serving persons, otherwise, who are free and well advised to gather and assess information on their opportunities, pursue relevant training avenues, and possess traits of temperament and such commitments to 'virtue,' as would make them attractive to employers.

It has been industrial sociologists' tasks to conduct research into every part of every choice regarding public and private activities strongly implied in the foregoing text and to study the evolving correlates and consequences of these choices by employers, workers, and consumers from the late eighteenth century until industrial sociology began to fragment into specialized segments in the 1960s.

Smith, himself, offered two insightful observations supporting some doubts, at least about the efficiencies he imputed to market forces. First, in a telling discussion of the workings of a pin factory, he extolled the virtues of 'mass production' over hand-crafted pins: a highly rational-specialized (and oppressively tedious) division of labor that afforded what we later came to call 'economies of scale.' This argument became and remains part of the key defense of hugh and complex corporations, but friendly critics point out that 'scales' may be pursued beyond diminishing returns and will simultaneously raise the costly barriers to entry of would-be competitors to challenge dominant, i.e., 'oligopolistic,' firms jealous of their market shares and thus aggressive in their use of their pricing power.

Smith's second reservation was that he doubted whether his 'unseen hand'—price competition—would consistently discipline producers: 'whenever two or more men of commerce meet,' he fretted, 'there is born a conspiracy' to set prices, multilaterally, at the expense of customers; these doubts have been honored by most social scientists who study industry structures.

Finally, in his discussion of the deadening effect of endlessly repetitive and highly specialized tasks in the pin factory, he offered a notion that Marx three-quarters of a century later, elaborated famously into his theory of 'alienated labor,' a theory of workers' interests that sharply flavored both microanalytic studies of organizations and mesostudies of social stability in the US, especially from the late 1920s to the mid-1970s.

As we will see, Smith's paradigm, or 'model' still admired (if not closely read) by many of today's 'Liberals' (i.e., conservatives), has been the subject of sufficient additional research on markets' operations ('industry structures,' opportunity structures, pricing strategies, worker turnover, 'informal' work group behavior, and 'mal-distribution' of income) to lead many industrial sociologists to offer alternative scenarios of the impacts of industrial capitalism; the results show clearly that Smith's and others' *laissez-faire* model can fail to describe capitalism accurately, most conspicuously when 'market imperfections' (e.g., 'rigged markets') together with 'market failures' (recessions and depressions) generally tend to stimulate popular demands for ameliorative regulatory activities, often displacing organized 'class warfare.' Limitations on faith in markets' disciplinary capacities have led to differences in the structures among capitalist economies and in the amount of regulatory activity that is popularly demanded of central governments.

With this background we can move (a) to the conundrum—that dedication to equality and individual liberty (cum property) will very likely lead to inequalities, as some free persons prosper, far more than others, and thus lead economic winners to search for rationalizations that will foster sufficiently widespread sentiments, in a democracy, that inequalities are 'legitimate,' and beliefs that a social system can thus be reasonably stable if citizens are at least equal in political and social, but not necessarily so in economic terms; and (b) to the correlates of the resulting tensions.

1. *The Evolution and Progress of Industrial Sociology*

Smith's thesis was fleshed out by Smith's contemporaries, Henri St. Simon and the latter's one-time student, Auguste Comte, in France; their disagreements have left industrial sociologists with somewhat contradictory perspectives, still with us, for studying macro- and microcosmic industrial phenomena.

St. Simon celebrated the French Revolution by extolling the application of science to all social organizations, a 'rational system' approach, in which merit-by-examination would replace aristocratic birthright in claims to the legitimate exercise of authority over others. Comte, however, pursued a 'natural system' perspective, according to which applications of reason (read science) should be significantly tempered by sensitivity to popular participation, to 'spontaneous' voluntarism—e.g., religious devotions and family formation—and to society's traditions; St. Simon's work has strongly flavored the treatment of bureaux-bureaucracies from Max Weber at the turn of the twentieth century, to Blau and Meyer (1987).

Comte's work was recaptured, 1930–70, in innumerable studies of workers' 'informal groups,' by the founders of the long enduring 'human relations' movement, founded by Elton Mayo and Chester Barnard (both business practitioners) with support from social psychologists, during the 1930s, all at the Harvard Business School; both were critical of F. W. Taylor's 'scientific management'—'one best way of designing jobs'—and of what they called economists' 'rabble hypothesis' regarding workers' putatively individualistic and exclusive interests in wages (Barnard 1956, 1958, Roethlisberger and Dickson 1937). The differentiations of modern macro- and

microsociologists of industry were accordingly most clearly marked, in the early 1960s, in extraordinarily lively debates (Machlup 1967) over the virtues of 'managerialism' (human relations) over 'marginalism' (the more atomistic-individualistic model of workers' material interests) in economists' theory of the firm.

When rationalistic business leaders and their social science colleagues move from factory-level studies to macropolicy issues, however, they admire markets as prototypical natural systems; contrariwise, modern liberal observers shift from their natural system view of organizations (favoring collective bargaining, for example) to the rationalist position (favoring government initiatives to shape economic forces) at the macroanalytical level.

The modern social sciences came into their own late in the nineteenth and early twentieth centuries with the institutional, cultural, and psychological analyses, in France by Emile Durkheim, in the German-speaking world by Max Weber and Sigmund Freud, and in Italy by Vilfredo Pareto and Roberto Michels; these figures influenced industrial sociologists just as they did other social scientists. A little earlier Karl Marx offered an admiring assessment of capitalists' systems, for which Smith had become a founding theoretician, but saw only class conflicts inherent in capitalism' 'production relationships.' Observant of the Marxian contribution, the early theoreticians offered systematic studies (a) of the role of labor's traditions in shaping economic achievements; (b) of the self-seeking roles of elites regarding public policy; (c) of the character of modern economic organizations—*bureaux* or bureaucracies —and; (d) in Freud's case, a full-blown theory of, among other things, personality developments, modal personality structures, and a theory of differential responses to authority among different persons that he identified with child rearing customs, a theory that inspired a number of analysts to identify industrial systems with deferred gratification and even with the repression of natural impulses.

Collectively, these writers contributed to both St. Simons 'rational system' and Comte's 'natural system.' In their midst, Herbert Spencer (in England) and Charles Sumner (at Yale University) applied Charles Darwin's theory of natural selection to whole human societies—'Social Darwinism' (Hofstadter 1944). The results, grist for macro- and mesoscosmic-industrial sociologists, were complexes of ideas about (a) justice and income distribution; (b) the legitimacy of the authority of employers; and (c) the ways in which labor-management conflicts could be defused (and unions avoided) by therapeutic counseling, urged by the Harvard Business School researchers who were inspired by their studies of work groups at the General Electric Company's Hawthorne works; (d) and finally, about the ways in which bureaucratic organizations could be fine-tuned by efforts to expand workers' 'zones of indifference' toward managers' initiatives, i.e., in ways that would enhance leaders' capacities to safeguard their claims to legitimacy, while minimizing what Chester Barnard (1938) termed 'the pathologies [or dysfunctions] of systems of status [differentiations].'

This intellectual ferment encouraged macroindustrial sociologists to look more closely at the sources of stabilities of institutions in and the durability of the 'partnership' of capitalism with democracy; those interested in those macro- and mesoquestions turned increasingly to the work of legal historians with interests in the conundrum, noted earlier, of the problematical Enlightenment linkages of liberty, property ownership, and individualism, on the one hand, to equality, and justice on the other.

These legal and institutional historians, led by John R. Commons and the so-called Wisconsin School, traced the 'legal foundations of capitalism' and focused on the corporate person, and the full array of rights, as bundles of private property, that these *persona ficta* were accorded by the Supreme Court in the Dartmouth College case in 1819 (Commons 1968) and many later decisions.

The more micro-oriented industrial sociologists embraced the concept of corporate persons and their legal attributes, but focused on natural persons, workers especially, in their informal associations with each other in work groups that were often seen to be subversive of employers' goals by their inclination to set production quotas, as at the Hawthorne Works. Managers' own restrictions of output, to their embarrassment, were documented by the writers in the Commons School, M. Josephson, among them.

For most of the period since the early 1930s, industrial sociologists have thus been segmented; one group has been interested in macrosocial structures, stratification, 'webs of rules' (Dunlop), collective bargaining, and ameliorative public policies to deal with market failures, and other relevant ameliorative programs. These programs include 'welfare state'-type interventions on behalf of citizens that these analysts conceived *not* to be 'unfit,' as in Charles Sumner's Darwinian perspective, but victims of the chill winds of markets that were sometimes far more tempered, on their own behalf by large, sector-dominant corporations than by market forces.

The micro-oriented industrial sociologists, human relationists, came into their own, however, during World War II—while unions were neutralized by wage and price controls and by rationing; these investigators offered help in motivating workers to be productive in pursuit of military victory overseas, while union leaders and critics of business leaders' 'manipulation of workers' backed off as they were neutralized by restrictive public policies.

The last of the prewar influences on macroindustrial sociologists were the findings of A. A. Berle and Gardner Means (1938) and by the Congress's Temporary National Economic Committee that the 'fittest' corporate persons in America's markets, like those in

West Europe (Brady 1943) gained their powerful places by taming their markets with the help of the price-setting leaders of the dominant firms in steel, aluminum, glass, rubber, heavy electrical equipment, autos, and appliances—the core, at the time, of the American economy—and by rugged nonprice competition rather than 'destructive' cost-cutting price competition.

2. *Industrial Sociology in the Post-World War II Era*

During the post-World War II period, industrial sociologists, long attentive to the oligopolistic character of the 'core economy,' became interested in the 'peripheral economy' and the differences between the favorable circumstances of blue collarites whose unions capitalized on the postwar economic booms, assisted by Cold War defense expenditures in the manufacturing sector, while the economy's service sector, dominated by retailing, finance (unorganized and with lower wage jobs) and their managers, began to swell. Not a small part of this growing population was linked to the expansion of 'staff' workers, called 'white collar overhead,' in large manufacturing corporations, whose earnings and benefits reflected the gains of their unionized peers.

The first investigations indicated an intensification of the 'bureaucratization' of corporations with consequent concerns about a new, 'industrial serfdom' (growing numbers of blue and white collarites tied to well-heeled employers who had used benefit programs—e.g., healthcare—to attract workers during wartime wage controls) making for a well-situated 'core' population vis-a-vis a peripheral and expanding low wage sector. Sensing they were indeed better off, the first group weathered stagnant incomes, 1970–93, with little protest, while Lyndon Johnson's 'war against poverty' in the late 1960s had already served to focus the attention of 'have nots' more on their educational deficiencies than on their 'relative deprivations.'

In the early 1960s economists urged that better educated persons accounted for a significant portion of the rates of economic growth in North America and Western Europe and that the returns to education were attributable to their putative productivity, the productivity having been measured, tautologically, from their earnings. This human capital theory (Becker 1964) gained no support in a less crude study, i.e., of direct measures of actual productivity and education (Berg 1970), but the theory squared well with some studies of 'status attainment,' in which the dollar returns to occupations are combined with their prestige value to create indexes and then scales of achievement. These status attainment studies took on a life of their own, outside industrial sociologists' purview and, with the aid of emerging computing capacities to process masses of data, helped the field of stratification to become and continue to be one of the most active self-standing areas of sociological research.

Of the major lines of postwar investigation, during the late 1950s and into the 1970s, the work of an interuniversity consortium, 'Industrialization and Industrial Man,' was extraordinarily influential, in scholarly terms, in seeking to sort out the elements of the conundrum adumbrated at the beginning of this article.

The consortium was immensely productive—well over 50 monographs and volumes alone in studies over two decades—in identifying, in comparative terms, the convergence and divergences in the industrialization processes in North America, West Europe, and the USSR, touching on the organization, education, and management of human resources, on industrial relations, and on roles of the cultures, traditions, political arrangements, welfare policies, and infrastructures of the nations under review. The work of the consortium was a high water mark in industrial sociology; its contributors addressed virtually all the permutations and combinations of institutional, cultural, legal, political and managerial arrangements and their individually distinctive contributions to democratic and capitalist ways of governance and production, respectively. A final report (Dunlop et al. 1975) and afterstatements (Kerr et al. 1973) are invaluable resources. Among the most seminal of the individual contributors, in a study of authority in industrial corporations, was R. Bendix (1956).

The increase in price competition, 1970–99, meantime, has had the effect of tempering the proportion of corporations in all industrialized economies once able to manage their competitive environments and, with that, a celebrated balance of power—big business, big labor, and big government, a 'pax Americana,' began to become ineffective (Galbraith 1952). Industrial sociologists, who recognized the stabilizing effects of an 'unstable triad,' also recognized the decline in unions' influence with substantial reductions in unions' membership ranks, starting in the 1960s and, by the 1970s, the raise of single interest groups of sundry types, as well, with the conspicuous loss of the political and economic commerce among big unions, big government, and big corporations, i.e., the tempering of corporations' industrial market power by 'countervailing powers.' Industrial sociologists literally lost a subset of phenomena—both power plays and policy confrontations that were built into the shifting 'two-on-one' *detentes*, on critical issues, that countervailing powers facilitated. The Pax American augmented America's vaunted pluralism, a structure now undermined by proliferations of interest groups.

With the waning of community power studies, well developed before and immediately after World War II, like stratification research and the 'politics of late stage capitalism,' industrial sociologists saw their field

further narrowed as price competition forced a change of interests away from workers' satisfaction and morale among microresearchers and the emergence, instead, of opportunities for increasing productivity and profit by 'downsizing,' 'outsourcing,' and 'off shoring,' as methods for dealing with costs.

Productivity, meantime, has indeed increased, as foreign imports threatened the jobs of some and layoffs have disciplined others; the human relations tradition among microindustrial sociologists has given way to studies of 're-engineering' and other reforms. Business leaders have been made increasingly aware, since the 1980s, that merger movements, for example, feed on corporations' stock values which can be enhanced by selling off segments of the acquired 'targets' and 'downsizing' what remains in order to increase productivity which is measured by a formulation in which the dollar values of output are divided by the number of persons employed; stock values reflect this narrowly bizarre mensurational technique, as corporations prepare themselves to become, themselves, commodities, alongside their products. The most recent study of this new order of phenomena has recently been offered by Cappelli (1999), though the 'externalizing' of work to 'temps' and contract workers is basically an extension of cycles of 'centralization' and 'decentralization' in big industries, 1950–90.

It should be noted that the essential collapse of the human relations school, except for 'sensitivity programs' focused on sexual harassment and race relations, did not even change very much the character of American industry. The reform movements, inspired initially by the human relationists, rarely had enduring effects in most industries, as the data fairly clearly show in a mid-1970s empirical assessment (Berg 1978).

While the linkages of capitalism to democracy are no longer the focus of the attentions of other than industrial sociologists, in the meantime, their other interests have been productively pursued under the headings 'world systems,' political sociology; African American studies; gender studies; stratification (as noted); organizations, work and occupations; and, with renewed interest, economic sociology. The latter was imaginatively limned, early on, by Smelser (1959, 1963).

Other concerns, still pursued essentially as industrial-sociological topics, include labor markets (Berg 1979), industrial relations (Locke et al. 1995, Kerr et al. 1994), and industrial democracy in many publications by W. G. Runciman, in England. The apparent contradictions between the savings and consumption propensities in America, favoring consumption, have been revisited by D. Bell in a new afterward to an5 earlier masterpiece (1978, 1996). Finally, the shift toward capitalist systems and away from 'command economies,' after the Cold War has been helpfully explored by Yergin and Stanislaw (1998). These notable efforts suggest that industrial sociology will be quickened by the so-called global economy, which is not an economy in any useful sense of the term, but a semiorganized congeries of national economies. The emergence of a new world system could well be the occasion for the mobilization of the macro-, meso-, and microanalytical 'triple threat' strategies of industrial sociologists' timely offerings.

Two significant circumstances, beyond those hinted, suggest a revitalization of industrial sociological interests. First, the rapid recoveries (sparked in some measure, by American, German, and by British and other corporate bargain hunters) of the economies that were severely troubled in 1997–99; these developments had helped their highest and their middle classes, but less than half of the other populations (Japan excepted) of the 'Asian Tigers.' The rapid recent recoveries have thus masked the plights of millions upon millions of workers in each of the many Asian economies; the question, now, of a balance of capitalism with democracy is thus not a meaningful one. The situation is not unlike that of the great powers, in the 1920s and the 1950s, vis-à-vis the rest of the world; the 'global economy's' national members' stability, based on growth, cannot be so easily assured, and the resulting dynamics may well be new grist for industrial sociologists' traditional mills.

I. Berg

Industrialization

Industrialization is the process of applying mechanical, chemical, and electrical sciences to reorganize production with inanimate sources of energy. A technological criterion of industrialization by no means entails technological determinism. On the contrary, comparative studies of industrialization have served as a key field for social investigators to highlight the influence of culture, political contingency, and the timing of local development in relation to world history. Cross-national comparisons of industrialization have undermined unilinear models that had predicted that the international sharing of technology would lead to convergence in the social institutions of manufacture.

1. Key Features

Processes of industrialization across diverse kinds of capitalist societies as well as across state-dominated societies with central planning, such as the former Soviet Union, have shared essential similarities. Initially industrialization is marked by massive transfers of labor out of agriculture and into factories that have concentrations of capital equipment. Increases in the productivity of the labor devoted to manufacture come to balance increases in demand for goods, however, and employment in the service sector increases more rapidly than in manufacture after initial industrialization. In the leading industrial societies of Europe, East Asia, and North America, consequently, employment growth during the second half of the twentieth century was concentrated in services, professions, and finance. Even in industrialized countries that are net exporters of manufactures, including Germany and France, the absolute number of workers in manufacturing has been in decline since the 1970s. Some of the most dynamic national economies, including those of the USA and the UK, have become net importers of manufactured goods and net exporters of know-how and of services derived from the use of technology. Insofar as industry is identified by the application of scientific know-how and of inanimate sources of energy, however, it is misleading to speak of a process of 'deindustrialization' in these expanding and comparatively prosperous economies. Concentrations of smoke-stack industry are likely to continue shifting their location around the globe. There is little to suggest that a particular kind of industry comprises a transhistorical requisite for economic preeminence.

Processes of industrialization have universally produced key changes in culture. As the sociologist Reinhard Bendix emphasized, the concentration of workers in factories has everywhere triggered the elaboration of novel ideologies to legitimate the employers' exercise of authority. The mobilization of resources for industrialization also entails innovative definitions of responsibilities and rights over the factors of production, including guidelines for finance or capital allocation and for monitoring workers' health in some measure. Ownership of resources by the state alters only the details of these regulatory challenges. In all settings industrialization has demanded new statutory frameworks for governing the flow of labor across nations, cities, and firms. Industrialization triggers the development of procedures for identifying intellectual discoveries and for singling out their creators for reward, whether in the form of patents and copyrights or through other kinds of social privilege.

Despite these profound similarities in industrialization, scholars guard against exaggerating its concomitants and against identifying industrialization with modernity. The mechanization of some forms of production has called forward more of its opposite, traditional hand work. In nineteenth-century UK, for example, production in centralized facilities with steam power created great demand for the inputs of artisanal trades, including tools and equipment. Mechanization of the simpler branches of enterprise, such as spinning, stimulated home crafts that proved more difficult to mechanize, such as weaving. Factories in Europe, East Asia, and elsewhere have relied upon and invigorated traditional kinship networks to secure better supplies of reliable labor. The growth of factory systems that employed whole families in relatively closed communities sometimes cut down on geographical mobility of labor and reinforced the influence of male family heads who supervised the labor process and recruitment. Especially in contrast to craft work by independent producers for putting-out merchants, therefore, industrialization can intensify the authority of family heads or the subordination of women.

In late nineteenth-century Europe, when employers located factory work in rural areas to reduce wage costs, industrialization also stemmed migration to cities. Rural factories generated supplemental income for families of small land-holders who would have been unable to sustain themselves in the countryside with only agriculture or handiwork. Industrialization in some settings is compatible with the growth of domestic employment using electric-powered looms, grinders, and other home equipment. Most recently, headway in telecommunications and computer linkages has enabled professional workers in finance and science to work from home or to reside in rural communities. Depending on context, therefore, industrialization may run counter to such putatively modern patterns as geographical mobility, centralization of production, personal independence from family authority, and urbanization.

2. *Historical Origins*

The first historical instance of industrialization, sometimes termed an 'industrial revolution,' occurred in the UK from approximately 1760 to 1830. The country's coal output rose tenfold in this period, due in part to the installation of steam-driven water pumps in mines. Pig iron production increased sixteenfold, and many enterprises, including the celebrated cotton mills, introduced steam-powered equipment. No consensus has emerged about the primary causes of the UK industrial revolution. Some historians, adapting Marx's suggestions, have focused on how property relations in the English countryside accelerated improvements in agricultural productivity and thereby released workers for manufacturing. Imperial UK's location in the world economy is also a plausible key, particularly because the country's cotton firms relied on demand from captive colonial markets to cushion the risks of investing in costly machinery. The development of a broadly shared middle-class culture of consumption in the UK increased domestic demand for industrial products. Apart from these explanations centered on macroeconomic conditions, some investigators spotlight the most immediate factors favoring technical innovation. A disproportionate number of the technological pioneers in business belonged to Protestant denominations that sacralized the application of science in everyday life. The UK was unique for having a style of practical education that diffused knowledge of mechanics and engineering among the common people. A widespread popular science and motivation to apply it contributed to the incessant simple improvements in machine design that characterized early mechanization.

Yet explanations of industrialization that highlight the supply of the inputs of labor, technology, and know-how on one side, as well as demand for the product outputs on the other side, can prove inattentive to what lies between: the social institutions of industrial work itself. What led entrepreneurs to centralize work in mechanized factories? Unlike merchants who gave work out to domestic workers, factory employers could directly accelerate throughput to meet shorter delivery deadlines, increase the obligatory hours of work, regulate and reorganize work procedures to ensure quality or flexibility, and prevent competitors from gaining knowledge of innovative changes in products or technology hidden behind their factory walls. Early industrialization was driven perhaps as much by employers' need to control the process of labor as by a need to save on labor in the market. On the eve of industrialization the commercial development of domestic putting-out industries across many regions of Europe supported demographic expansion by making early marriage and new family formation economically more feasible for young adults. In these environments of rapid population growth, employers lacked compelling incentives to invest in centralized machine production purely for the sake of economizing on labor.

Indeed, manufacturers and engineers in Britain's initial lead sectors of industrialization rarely justified new technology by the savings in labor effort. They claimed that such classic inventions as the Crompton spinning mule and the use of chlorine in bleaching works increased turnover and thereby reduced the outlays on supplies and land per unit produced. The management goal, as a textile mill proprietor put it, was to 'produce the goods on time.' Not unexpectedly, therefore, variation in regional economic variables—such as the level of commercialization of household crafts, artisanal specialization, and labor supplies—correlated very inexactly with variation in

the transition to factory systems. Many regions at the forefront of dynamic networks of commerce and putting-out systems by 1750, such as East Anglia, were largely bypassed in the early Industrial Revolution. They show that industrialization did not represent the logical culmination of trade, capital accumulation, the separation of labor from independent means of subsistence, and formation of a nonagricultural work force. Entrepreneurial interest in commanding the production process played a role of its own.

3. *Profit and Investment in Technology*

Industrial development highlights the key economic tensions of capitalist societies. The inputs of technology and labor at the worksite have a quantifiable market value, but the conduct of manufacture itself depends only on their qualitative use values. Put another way, investors and economic planners follow the exchange values of the resources committed to manufacture and of the outputs distributed in the market, but commercial success depends on the separate moment of utilizing the concrete resources and employees at the worksite. Capitalist societies vary in how much their systems of finance and management focus on the need to upgrade technology at the worksite from only a short-term pecuniary perspective, and how much the technical drive to improve productivity steers investment in its own right. National economies that have experienced unusual industrial expansion, such as Germany's in the late nineteenth century, have sometimes pumped more funding into research and technology than prudent financial logic alone might have justified. In the classic case of the successful development of nineteenth-century German cotton textiles, for instance, investment surged at moments when earnings were ebbing and uncertain, but when the interest in upgrading equipment and the use of labor was keen. The example of Japan's slow growth in the last decade of the twentieth century suggests that in some settings, however, it is possible to overspend on research or on capital-intensive technology.

When producers invest in new industrial methods, they call upon their cultural conceptions of the capitalist economy to navigate the uncertain waters. In particular, their orientation to profit intertwines with popular conceptions of labor as an abstract, quantifiable resource in the workplace. Nineteenth-century manufacturers in the UK comprise a classic example of employers who believed the quantifiable increments of labor they appropriated from workers were delivered as if embodied in the workers' produce. British manufacturers accordingly viewed profit as the gain that resulted from buying labor products and other tangible articles at low prices and from reselling them higher. In the British cotton trade, for instance, manufacturers focused on cornering cheap raw materials, even if inferior grade inputs retarded improvements in labor productivity. Given their focus on profit from the sphere of exchange, British manufacturers purchased innovative equipment in the nineteenth century if they could foresee relatively immediate payoffs in trading in the current environment. Their contemporaries in Germany imagined that employers appropriated labor in the form of *Arbeitskraft*, 'labor power.' German manufacturers accordingly viewed profit as the result of the efficient conversion of this labor capacity into an output at the point of production. Industrial employers in Germany invested more heavily in new technology and in reorganizing work than did their counterparts in similar economic settings in Britain.

Practices for upholding relations of trust among firms have offered advantages in industrial development even when they contradict short-term profit seeking. In Japan, for example, corporations in the late twentieth century purchased assembly parts from suppliers through long-term relations that carried diffuse mutual responsibilities. So long as a customary supplier strode to boost its performance, corporations bought its components even when the price or quality fell below that offered by an emerging competitor. Models of individually rational economic behavior would expect corporations to switch to the best or least expensive provider in short order. Yet the longer-term purchasing commitment may paradoxically foster technological improvements in industries as wholes by increasing confidence that products issuing from renewed investment find secure buyers. The habitual Japanese purchasing system created effective organization for industrial innovation by ensuring an appropriate time horizon for carrying out research and design, by putting incremental but not lethal pressure on suppliers to upgrade their results, and above all by generating diffuse obligations to uphold quality and service beyond the letter of a formal contract.

4. *Contingencies in Industrial Organization*

Karl Marx, perhaps the most famed theorist of industrialization, inferred a single path of factory organization based on cumulative investments in machine technology. He expected that advanced firms would mass produce standard wares and simplify tasks expected of workers to reduce continually labor inputs per product manufactured. The assembly line made famous by the US auto maker Henry Ford, as well as the state-run firms of socialist regimes, attempted to embody a similarly rigid logic. Yet examinations of historical diversity in manufacture have undermined the assumption that industrial development necessarily depends on maximizing the production of uniform goods. Industrial districts such as Solingen and Neuchâtel in the nineteenth century, and Bologna and Palo Alto in the twentieth century, have prospered

by exporting short runs of custom products. The hundreds of small cutlery firms in Solingen, for example, obtained crude blades from mechanical forges and on purchasers' demand custom finished them with steam-powered grindstones into literally thousands of types of cutlery. By 1914 Solingen had outstripped foreign competitors by focusing as much on variety in design as on cost minimization. This alternate course of development, called flexible specialization, comprises a salient strategy today for manufacturers in the mature economies. Producers who bear high wage costs can compete in the world market by rapidly adapting technology to add value to products through innovative or specialized design, often with the aid of computers.

Whether flexible specialization works effectively as an industrial strategy under capitalism depends on political events and on the infrastructure of public institutions, not purely on economic conditions. Firms that remain modest in size seem more adept at adjusting technology to changes in the needs of market niches. Much of the employment growth and dynamism in mature economies is consequently focused in small-scale enterprises. Yet these smaller organizations typically lack sizable pools of funding for research into fundamentally new kinds of technology, and they risk stagnation if they vary products only minutely. For enterprises to share the costs of basic advances in technology, flexible specialization typically calls for a complement of cooperative research centers, universities with ties to business, or other institutes for promoting local technological improvement. The creation of these supporting institutions can grow out of municipal campaigns for local entrepreneurs, out of guild programs for promotion of the trade, and out of scientific provisions by central states. Flexible specialization also requires safeguards against sweatshop wage reductions, so workers have reason to invest in their own skills and to contribute their ingenuity to the adaptation of equipment in changing markets. Labor relations supporting this path of industrialization may emerge unintentionally out of struggle between labor and capital at key political junctures. In the cutlery trade of Solingen, for instance, employers were 'forced into their luck' by powerful unions in the 1870s that successfully pushed for codified procedures to divide productivity gains between workers and employers.

An accelerating need for firms to deploy fundamentally new scientific discoveries has further undermined the accustomed models of factory work. Frederick Winslow Taylor and other managers at the beginning of the twentieth century believed that the division of work into fixed elementary tasks should take primacy in industrial organization. By contrast, corporations embedded in fast-changing scientific communities today find their primary challenge is to decide on responses to events and to speed collective learning of sophisticated skills. The tasks in nineteenth-century manufacture could be carried out separately and their outputs added up to assemble a product. Contemporary industry, by contrast, often finds that work processes are more interactional than additive and that the challenge is to encourage mutual adjustments among work groups as they address qualitatively new assignments. Firms of relatively modest size dependent on continual scientific change have therefore encouraged collegial and participatory work styles rather than hierarchical and bureaucratic forms. Yet no single method for organizing industry is becoming dominant. Large multinational corporations that lean more heavily toward bureaucratic organization tie much of the global economy together, and the top 10 dozen of them account for perhaps one-quarter of the world's production. The intensification of global exchange has opened new opportunities for mass production, because it widens economies of scale for making durable goods as well as for offering marketing and services. The diverse kinds of industrial organization are not simple historical alternatives, but call on each other in mutual exchange.

5. *The State and Industrial Change*

With the relative decline of state barriers to trade, and with the increasing salience of an international division of labor, processes of industrialization scarcely represent local or national trajectories of change. They are formed by the position of local production in the changing industrial networks of the globe. Entry into an industrial subsector such as elementary computer chips may bring high rewards and global leadership in one global setting yet represent a tributary, dead end path in the next. In some eras of international development the state has emerged as a critical actor for identifying prospective lead sectors and for facilitating their penetration by local firms. In the late twentieth century the governments of Japan, Korea, and Taiwan were prominent among those that guided local industry into more rewarding stations in the global hierarchy of labor. States successful at sponsoring relative industrial advance in the late twentieth century maintained their autonomy from narrowly self-interested business groups by building an organization of career bureaucrats who were both recruited and remunerated by meritocratic standards. Yet developmental states also benefited from the close-knit social networks between these state officials and entrepreneurs. Unofficial social ties, based in part on comradery among elite university graduates, encouraged the circulation of information about the business and technical environment as well as effective negotiation and implementation of strategic goals.

In Japan, for instance, the state's amalgam of bureaucratic autonomy and informal social connections to economic decision-makers was key to its triumphal stewardship of the domestic computer

industry. The central state not only offered tax incentives for domestic computer design while discouraging imports. It also used the in-depth knowledge of the industrial players it acquired to allocate patent information and funds for shrewdly chosen research projects. It set up a sound cluster of competing firms within each segment of the computer market. Japan's office for economic policy distributed the findings of research cooperatives to individual firms for competitive product development, and it defended firms against excessive price-cutting so they could devote resources to further research. Sponsorship of technological risk-taking among competing firms, as in Japan, is currently more successful than public investment in a single champion firm. As part of global historical development, however, comparative industrial advance cannot be linked to a particular kind of state policy across all eras of development. Indeed, in eras when the most promising pathways toward technological development in an industrial sector may be unchartable, or when their pursuit depends on transnational scientific collaboration, the nation state may become ineffective at organizing development. The very success of local industries at one stage of development creates subsequent challenges for government policy makers. For success is apt to vault leading local firms into multinational corporations whose decision makers have less interest in national development as such because they take their investments across the globe as the foundation for strategy.

6. *Diversity and Discontinuity*

The concept of industrialization, an inheritance from nineteenth-century social science, originally carried evolutionary connotations of long-term, cumulative progress. But processes of industrialization vary fundamentally by the kind of control over labor that entrepreneurs seek in a particular epoch, by the location of an enterprise in the swiftly changing global division of labor, and by the variety of technology exploited. In neither the mature nor the newly developing regions of the world economy do industrial achievements today necessarily descend from the same economic and technological logic as that of the first Industrial Revolution. Investigators can appreciate the diversity in processes of industrialization if they discard the assumptions of sequential advance or of continuity in development that once governed modern social thought.

Industrialization, Typologies and History of

1. *The Process of Industrialization*

Industry is distinct from agriculture, forestry, fishing, mining, quarrying, transportation, finance, trade, and the myriad of services that make up separable but classifiable tasks performed by the workforces of modern economies. Throughout history men and women manufactured commodities for use or for trade and sale. No society has operated without producing some range and levels of industrial output. Industrialization refers, however, to economic change that is recent and different in scale and scope from the manufacture of artifacts. As a socioeconomic process, industrialization includes a rapid transformation in the significance of manufacturing activity in relation to all other forms of production and work undertaken within national (or local) economies.

Economists, historians, and sociologists have measured and compared industrialization in statistical form as it appeared in national accounts and evolved historically for a large number of countries. Their data shows that, as industrialization proceeds, shares of workforces employed in and national outputs emanating from agriculture and other primary forms of production decline, and the shares of employment and output that are classified as industrial increase. Output and employment emanating from the third macro

sector of national production, services, goes up or down in relative terms. Services include all forms of non-commodity output that are sold (and/or supplied) either to consumers (for instance as health care) or utilized as 'inputs' (e.g., distribution, legal advice, accountancy, etc.) in order to sustain both manufacturing and primary forms of production. Clearly as and when industry grows more rapidly than other forms of commodity output then the allocation of services changes towards manufacturing and away from farming, fishing, forestry, and mining (Kuznets 1965).

For sustained development there is no substitute for industrialization, which can also be measured as the reallocation of a nation's stock of capital (embodied in the form of buildings, machines, equipment, tools, infrastructure, communications, and distribution networks) away from primary and towards industrial production. But macro data is more likely to be available for the foreign trade of nations which allows observers to measure the progress of industrialization over the long run in the form of predictable shifts in the composition of a country's exports and imports. Sales of domestically produced manufactured exports normally grow in significance and purchases of foreign manufactures diminishes as a share of total imports (Jones 1988).

Economic data has been classified in heuristic ways and has been disaggregated into numerous activities and functions in order to expose the extent, pattern, and pace of industrialization over time across regions and among countries. These essentially taxonomic exercises help to define and make concrete a process that has proceeded on a global scale for centuries. They expose national variations from more general or regional patterns and contribute to the understanding of major economic variables that historically have fostered or restrained industrialization in various parts of the world (Kuznets 1965).

Industrialization has been an important process for the welfare of humankind because the reallocation of labor, capital, and other national resources towards industry has usually been accompanied by technological and organizational change, which led to higher levels of output per person hour; rising living standards; population growth; urbanization; cultural changes; and shifts in the balance of power among nations. Thus, industrialization can also be defined in social, cultural, and political terms, and sociology depicts the history of industrial societies in terms of a set of interconnected characteristics, hegemonic values, and legal systems, represented as functional for the development of modern industry.

How, when, and why particular societies moved from pre-industrial to industrial norms, motivations, status, family systems, and modern institutions that characterize industrial society remains difficult to explain. Sociological theories elaborate upon the type of *changes* required in individual behavior and social institutions for the modern industry to succeed. They contrast 'traditionalistic patterns of action' that are defined as ascriptive, multidimensional, communitarian, familial, and authoritarian with the types of individualistic, achievement-orientated, mobile, entrepreneurial attitudes and behavior that became dominant in cultures as industrialization took hold. This approach depends upon the vocabularies and concepts drawn from sociology, psychology, and cultural anthropology, and on analyses inspired by Max Weber that continue to be preoccupied with value systems (derived ultimately from religions) that have 'motivated' the 'drive to industrialize' in different national and cultural settings (Parsons 1971).

Unfortunately, historical records are not clear on whether social changes precede or accompany industrialization. Until the late twentieth century, sociological approaches to industrialization have, moreover, been more concerned with its disruptive, dislocative, and potentially negative consequences for families, communities, villages, and regions, than with its nature, origins, and positive effects on living standards. Read as a social process, industrialization often leads to differentiation flowing from the division of labor, class formation, and uneven regional development. As industry diffuses from country to country, it becomes associated with diminishing returns, de-industrialization, unemployment, and the economic decline of some nations. Pessimistic writings about industrialization are often derived from Marx. Fortunately modern sociological understanding of industrialization combines several traditions and schools of theory with historical enquiry and a more process-centred global perspective which has exposed how complex, multifaceted, and variable the process of industrialization has become since Marx, Comte, Durkheim, and other canonical social scientists wrote their critiques.

2. *The British Industrial Revolution and the Diffusion of Modern Industry*

Modern industry, concentrated in particular regions and towns, housed in factories, organized in corporations and firms, and using machinery and inanimate forms of energy evolved gradually. That evolution has preoccupied generations of economic and social historians who have explained why industry became dominant in some national economies before others and analyzed major forces that carried industrial sectors forward from one stage to another. Their writings are heavily concentrated upon the epoch which opens with the beginnings of the British Industrial Revolution in the mid-eighteenth century and closes with World War I. Latterly, historical literatures have emerged dealing with proto-industrialization in Europe and Asia before the First Industrial Revolution and with late industrialization characteristic

of Russia, Eastern Europe, East Asia, and Latin America. The bibliography of literature on the histories of firms, industries, manufacturing sectors located in villages, towns, regions, countries, continents includes entire libraries of monographs, essays, and articles. The volume of research covering millennia of time and every conceivable set of spatial arrangements defies summary. Thus the task for historians (and social scientists) and the aim of this essay is to review the theories, patterns, and typologies that have been imposed upon this mass of otherwise incomprehensible local and historical detail (O'Brien 1998).

Shortly after 1945, when the causes of the wealth of nations emerged to dominate the agenda for the social sciences, historians began to formulate models to make sense of Europe's precocious industrial development. At that time the most accessible heuristic device was to refer continental industrialization to a paradigm case, the British Industrial Revolution, as it supposedly proceeded from the 1750s to the 1840s. On the assumption that Britain's lead could be ascribed to the early diffusion of superior industrial technology, it followed that the economic history of Europe could be understood as the spread of techniques of production and new forms of industrial and commercial organization from the first industrial nation to more backward economies on the mainland. In this perspective, British methods constituted not merely initial but best practice with universal application. Diffusion then became a major concept and the central problem for European economic history, at least for the nineteenth century, was to explain Britain's early start and the rate at which other European economies adopted British ways (Landes 1969).

Yet European statesmen, businessmen, and other contemporary observers rarely perceived of their national goals in terms of a race to catch up with Britain. Indeed many expressed doubts about the 'British way' and historians of European economies have not allowed their accounts of the industrialization of economies on the mainland to be dominated by a model inspired largely by Anglo-American perceptions and experience. Diffusion is now perceived as a complex process of creative adaptation rather than a mere emulation. The transfer of technology only succeeds when a matrix of related capacities into which machinery can fit has been built up and is receptive to change (Berg and Bruland 1998). Once in place, European firms and technologies spawned their own problems, solutions, and national trajectories for future innovation (Mokyr 1990).

Furthermore, late twentieth century historical research has restored perceptions of the British Industrial Revolution as a drawn-out process in which the upswings in national income and industrial production of the eighteenth century are no longer represented as 'discontinuities' let alone 'take offs.' Britain's technological lead has emerged as less novel, diffused slowly, and eventually succeeded because it rested upon the evolution of a commercialized economy throughout the British Empire over several generations before the American and French Revolutions (Crafts 1985). Comparative historical research which now brings Asian as well as European economies into the frame has also elaborated upon foundations of Britain's early start which were specific to that well-endowed offshore island. For example, the relatively high level of energy consumed per capita and per worker, obviously reflected abundant and accessible supplies of cheap coal (Wrigley 1988). Located at the hub of a rapidly growing Atlantic economy, when waterborne transport was the cheapest way to conduct commerce, a small island was more likely to reap larger gains from oceanic trade than continental rivals. That locational advantage was, moreover, safeguarded and extended by extraordinarily high levels of public investment in sea power which over the long run lowered transaction costs for British merchants, provided favored access to imperial and to foreign markets, and weakened the economies of Britain's Iberian, Dutch, and French rivals. Writing long after Trafalgar (where the Royal Navy finally won the centuries-old battle for the Atlantic) and sanctified by an ideology of liberalism, British historians tended to overlook the role of the Royal Navy in securing for British business 'disproportionate' shares of world trade, shipping, shipbuilding, and commercial services (O'Brien and Quinnault 1993).

Thus the First Industrial revolution can be represented as something of a special and less of a paradigm case for the economic history of Europe (Mokyr 1985).

3. *Regions, Towns and Proto-industrialization*

Industrialization was a regional process. Modern industry certainly did not spread randomly over national maps but 'clustered' within defined geographical boundaries. Insights are gained by observing the factors and circumstances which prompted industry to locate, grow, and decay in some regions rather than others; and in some places before others (Pollard 1981). Clearly the geographical matrix for the analysis of economic change must be specified in terms of what the historian is trying to explain, and the rise and decline of regions forms an important component of national economic histories. Where and when markets for commodities and factors of production are bounded in space, regional, rather than national or multinational, economies constitute the obvious units for study.

Research into European regions of proto-industrialization over three centuries before 1800 promises to create the evidence required for a typology which might help historians explain the long-term evolution of major branches of manufacturing (particularly

textiles, but also leather goods, finished metal wares, clocks and watches, and furniture) into mechanized factory industries over the nineteenth and twentieth centuries (Musgrave 1999). However, no single model has emerged to account for the complex range of cases that historians have uncovered of tendencies for industries to concentrate geographically, to specialize, and to engage in long-distance external and internal trade. Histories of proto-industrialization usually elaborate upon a set of initial conditions which contributed to the availability and willingness of local workers (males, females, and children) to turn from dependence upon agriculture to become involved (either part- or full-time) in manufacturing. Their accounts include: infertile land, inheritance systems, size of farms, communal rights to land, the cost of alternative supplies of food, the productivity of local agricultures, regional specialization, and competition within agriculture. Populations living close to subsistence levels, on relatively small holdings, and afflicted by high densities of labor to cultivable land were often among the first to embrace opportunities to supplement family incomes provided by industrial work, but so did landless and seasonally underemployed laborers from richer and more commercialized agricultural areas (Kriedte et al. 1981).

But mercantile organization and capital were also required and they usually emanated from towns. Towns housed the majority of educated and innovative people. Productive knowledge was more readily diffused across economies where populations became spatially concentrated into 'networks' or 'hierarchies' of cities and towns. The development of towns improved the efficiency of labor markets, promoted the commercialization of agriculture, and replaced barter with monetary transactions. Europe's maritime cities established imperial outposts overseas which fostered international trade and specialization (de Vries 1984).

By the eighteenth century, the map of industrial Europe could be colored into fairly well defined regions of proto-industrialization, specialized upon the production of textiles, clothing, boots and shoes, clocks and watches, tools, weapons, furniture, household utensils, and pottery. Several of these urbanized regions had survived and adapted to competition over long periods of time. Others had recently emerged as loci of concentrated production. All these industries faced limits to improvements in labor productivity through further refinements to the division of labor or from organizational improvements to the putting-out system.

Over the nineteenth century and as mechanical innovations came on stream and markets widened through innovations in transport, the long-term development of these regions had endowed them with several advantages for transitions to factory systems of production. For example, their sales outlets had been long established; they contained supplies of labor experienced in manufacturing for distance markets; capital and managerial skills were available from urban merchants and all kinds of other external economies flowed from the prior concentrations of industry in the hinterlands of towns. Local agricultures had long demonstrated their capacity to respond to the demands of industrial populations for food and raw materials (Braudel 1981–4).

Yet despite, and sometimes because of, these favorable historical traditions, many advanced regions of proto-industrialization did not move rapidly forward to embrace new techniques of production and modes of organization. In some cases traditions proved to be more of a hindrance than help or several regions lacked some essential ingredients for mechanization, such as supplies of cheap energy or engineering skills.

Research into proto-industrialization constitutes a program with explanatory potential, but it only covers certain sectors of modern industry. Producers' goods (iron, steel, ships, transport equipment, bricks, glass, and minerals) as well as some important consumer goods (such as flour, beer, and soap) were not manufactured under conditions that even approximate to a putting-out system. Furthermore, if the program is to fulfill its promise we still need to know rather more about the varieties and adaptabilities of organizational forms that are encompassed under the heading of proto-industrialization and far more about the causes of success and failure, both before and, *above all*, during the transition to the factory system (Cipolla 1973–4).

4. *Patterns and Typologies of European Industrialization*

Largely because he conceived of European industrialization as a process of diversity rather than uniformity, Gerschenkron produced a heuristic model which focused research upon variations in the *way* European economies passed through a decisive stage of accelerated industrial growth, or the 'great spurt.' In his view, Britain forged ahead because conditions for 'spontaneous industrialization' developed early—and the problem for 'relatively backward economies' on the mainland was to find effective substitutes for missing (British) prerequisites. Thus delays exhibited by continental economies in their endeavors to catch up with Britain are imputed to a range of 'prerequisites' for successful industrialization available to those who transformed the British economy (but in shorter supply elsewhere in Europe), and also to the time they took to develop substitutes for their cultural, institutional, and technological deficiencies (Gerschenkron 1962).

Gerschenkron (like Rostow before him) neglected natural endowments and the role of the state for the British Industrial Revolution, and he concentrated

upon other elements of industrialization which he hypothesized would vary systematically with the timing and degree of backwardness exhibited by 'follower' countries, as they passed through a clear discontinuity in the growth rate of industrial production (Rostow 1965).

Gerschenkron predicted that when historians examined the build-up of modern industry in Europe, country by country, they would observe that the more backward or late the economy when it began that process, the more rapid would be the rate of acceleration in the growth of industrial production, and the more pronounced would be its reliance on capital as distinct from consumer goods. He anticipated that among 'latecomers' new industrial enterprises would emerge as technically sophisticated and capital intensive, larger in scale and more prone to monopoly. Such enterprises would rely to a great degree upon external sources (banks and the state) for both investible funds and entrepreneurial initiatives. For their markets and supplies of cheap inputs they would depend far less than their British counterparts had upon rising productivity in domestic agricultures. Historical research (inspired by his hypothesis) has not merely widened the sample to include potentially deviant cases from the Austrian Empire, the Balkans, and Scandinavia, but has deepened knowledge of British, Dutch, French, Italian, and even Russian industrialization in ways that appear inimical to the survival of Gerschenkron's typology as a usable heuristic device to generalize about European, let alone Asian, industrialization (Sylla and Toniolo 1991).

The theoretical and statistical problems involved in delineating phases of trend acceleration seem to be insurmountable and as historians turned away from imperfect and partial indices of industrial and national production to investigate the regional and urban proto-industrial foundations of modern industry, the drama of 'take-offs,' 'spurts,' and 'discontinuities' in macroeconomic history has faded from view.

Expectations that historical records might reveal distinctively national patterns of industrial organization cannot be tested because the data required to quantify and systematically compare the prevalence of larger-scale, more capital intensive, and monopolistic firms across countries cannot be constructed. Furthermore, typologies which juxtapose continental deviations against a 'stylized' version of British industrialization now look anachronistic. Late twentieth century research on British industrial organization reveals variance in scale, capital intensity, and departures from competitive norms across industries throughout the First Industrial Revolution (Floud and McCloskey 1994). Variations in plant size, competitiveness, and factor intensity are not systematically correlated to backwardness, but are related to legal conditions for incorporation, the development of capital markets, changing technology, and above all to product mix. Long-term changes in the composition of manufacturing output do not expose any systematic or predictable shifts from the production of consumer to capital goods or vice versa (Pollard 1990).

Nevertheless, transitions from simple to complex processes of manufacturing activity are normally orderly. Thus the initial mechanization and standardization of several consumer-goods industries tended to be located within well-defined regions of specialization, utilizing the investible funds, skilled labor, and entrepreneurial talents available in established proto-industrial regions. Factories emerged on a small scale with relatively low capital–labor ratios to engage in the linear transformation of raw materials into familiar products sold on well-established markets. In many cases resources could be mobilized from within the traditional economy in order to replace imported manufactures or the products of handicraft industry. As manufacturing expanded, as the agricultural sector embarked on mechanization and farmed with chemicals, and as transport networks began to cover national terrains, demand and supply constraints on the expansion of domestic capital goods sectors gradually diminished. At that stage a 'second wave' of industrialization carried economies forward (Mathias and Davis 1990–8).

Deviations from a path dependent process of diversification from simple to complex systems of manufacturing occurred, but are explicable in terms of country size, natural endowments, comparative advantages within an evolving world economy, direct foreign investment, and state policies. Typologies of European industrialization which pay insufficient attention to geography and foreign trade miss essential elements of the process. Europe developed over the nineteenth and twentieth centuries as a continent of large and small political units, with a skewed distribution of natural resources. As possibilities for foreign trade expanded, that promoted different patterns of industrial growth from country to country (Aldcroft and Sutcliffe 1999). For example, at comparable levels of per capita income very few European economies achieved anything like Britain's comparative advantage in the export of manufactures. As late as 1913 the shares of 'manufactured commodities' to total exports varied from under 10 percent for Greece, Denmark, Norway, and Portugal to over 75 percent for Britain, Belgium, Switzerland, and Germany, with the rest of Europe somewhere in between. Systematic comparisons of trade data across countries and studies of long-term trends in the composition of net imports (exports minus imports) for major manufactured commodities offers historians prospects for the statistical delineation and comprehension of the patterns of industrialization undertaken by different European economies before and after 1914 (Bairoch 1976).

General propositions about the role of banks have also proved difficult to force into the form of generalizations. Modern research on financial intermediation

has fruitfully shifted attention towards the problem of analyzing responses by banks to industrialization as it proceeded in particular national and regional contexts. Cameron summarized the results of international comparisons by admitting he lacked criteria to measure their success or efficiency. Although he was prepared to laud the contribution of banks in Scotland and Sweden and to deplore their sparseness in France—an economy which apparently managed to achieve respectable levels of per capita income and industrial output without much help from its banks (Cameron 1967). For Germany, (once the paradigm example for the positive role of banks) there is now a debated hypothesis that the overpraised Kreditbanken misallocated capital and slowed up overall growth (Fremdling and Tilly 1976). In the Czech Crownlands (Bohemia, Moravia, and Upper Silesia) risk-averse banks did little except supply a modicum of working capital. After 1873 Austrian banks 'lost most of their interest in industrial enterprises for years to come.' For Hungary it was not banks but 'unencumbered access to the Austrian capital market' that appears crucial to the beginning of industrialization (Good 1984). Norwegian commercial banks showed little initiative and failed to play any leading role in the process of economic growth. In general it is difficult to find cases where banks clearly played the progressive and entrepreneurial role in national industrialization (Teichova et al. 1997). In analyzing connexions between the state and industrialization Gerschenkron suggested that before 1914 several European governments supplied substitutes for deficiencies in private enterprise, private capital markets, and household demand. Although his observation seems plausible and is based upon historical examples (drawn largely from Russia and Eastern Europe), statistically it has remained untestable because the scale and intensity of governmental intrusion into an otherwise market-led spontaneous process cannot be measured (Gerschenkron 1962). One macroeconomic indicator—the ratio of public consumption to gross national expenditure—shows no tendency to vary in any systematic way across countries (O'Brien 1994).

Instead economic historians have moved on to classify and to attempt to evaluate potential effects on private industrial investment (domestic and foreign) flowing from the different fiscal, tariff, monetary, and exchange rate policies pursued by European governments over the nineteenth and twentieth centuries, and for this topic there is a bibliography of sophisticated studies which apply macroeconomic theory to history (cited in O'Brien 1994).

Nevertheless to confine investigations into the direct and indirect role of governments to their macroeconomic policies would be to neglect the core functions performed by states to promote industrialization, namely the creation and reform of laws and institutions which underpinned the operation and spread of markets for commodities and factors of production. Such markets operated within a framework of rules which regulated cooperation and competition among individuals and enterprises engaged in economic activities. One of the central traditions of 'old' economic history was to study the laws, regulations, property rights, and enforcement procedures which molded and constrained economic behavior over those long spans of history before the era of the French Revolution, when 'inefficient' sets of institutions are perceived to have held European economies inside their production possibility boundaries. That program (associated with the German historical school) has been revived with the aid of theories and a vocabulary borrowed from modern economics (Hoselitz 1961). Neo-liberal institutional economics has been applied to the history of early modern Europe and suggests that frameworks for the operation of commodity and factor markets emerged in some societies (Holland and England) long before others (Spain and Russia) (North and Thomas 1973).

Clearly it remains important to understand how governments constrained the progress of industrialization by defining and enforcing inefficient systems of rules and property rights. The general problem resides in comparing legal frameworks for economic competition and cooperation across countries, in analyzing alterations to laws and property rights over time, and in systematically linking specified variations in law to economic growth. Although the research programme is concentrated on the early modern period when states established (or failed to establish) conditions for subsequent specialization and the widening of markets in the eighteenth and nineteenth centuries, its relevance to a latter era of the 'Second Industrial Revolution' (which witnessed the rise of new industries, such as chemicals, electricity, and motorized transportation, and the concomitant appearance of 'big government' to regulate the operations of corporations, unions, and financial intermediaries) is also clear (Mathias and Pollard 1989). Historians have work to do and are still some way from theorizing or generalizing about connexions between states and industrialization (Tilly 1990).

5. *Conclusions*

A long line of distinguished social scientists and historians (including St. Simon, Schmoller, Weber, Bloch, and Braudel) have offered students of European economic history, theories, concepts, approaches, and typologies designed to help them organize, clarify, and generalize from the vast accumulation of knowledge now in print about the history of European industries. At present when the British Industrial Revolution has re-emerged as a special case, the potential for histories, of European industrialization constructed around the concept of technological diffusion has been degraded (Landes 1969).

From philosophers of the Enlightenment, through Marx to the German historical school, scholars of European industrial development have found it difficult to organize their analyses without recourse to stages of growth. Rostow's stage theory certainly provided a memorable vocabulary but his schema is not considered to be a particularly illuminating way to write industrial history (Rostow 1965). Conceptually, the whole notion of a sharp discontinuity no longer attracts historians of economic growth, inclined to analyze that process with biological rather than aeronautical metaphors (like take-offs) and to explain accelerations (if, when, and where they might be measured) as the product of fortuitous political events, or basically as the final outcome of a protracted process of institutional change and the prior accumulation of physical and human capital (Braudel 1981–4).

Gerschenkron's typology inspired generations of scholars and survives as the best frame of reference for economic historians concerned to place their research within wider and potentially deeper perspectives that emanate from comparisons across Europe. But more often than not, the heuristic value of typologies seems to reside in the organization of evidence that simply fails to fit the country or case into a pattern (Sylla and Toniolo 1991). Meanwhile, and as research upon economies, regions, towns, industries, firms, and factors of production proliferates, no scholar with Gerschenkron's awesome learning and capacity for generalization has emerged to reconstruct an alternative typology which might serve to draw the long history of industrialization into a European frame of reference (Senghaas 1982).

That is why the majority of economic historians continue to pursue research within the framework of nation states and to offer their scholarship as a basis for comparative history. Indeed that program is exemplified by most textbooks in the field, which tend to be surveys of foreign scholarship arranged country by country, industry by industry, input by input. Readers of these analytically sophisticated books in economic history are implicitly asked to make intellectual leaps from national histories moving through long centuries of industrialization to comparative history unfolding across Europe. They will certainly find scholarly and detailed elaborations on 'connexions' between techniques of production, transport facilities, types of financial intermediation and state policies, foreign trade, urbanization, institutions, legal systems, cultures, on the one hand; and the pace and pattern of industrialization, on the other. Alas, their connexions can rarely be specified, investigated, and quantified in ways that might suggest how observed variations across regions and countries in the manifold factors promoting or restraining industrialization through time might be 'tested' for significance.

Meanwhile (and after two generations of postwar research on the economic histories of Africa, the Near East, South East and South East Asia) another metanarrative concerned with the 'Great Divergence' or why Europe industrialized ahead of economies located on other continents is beginning to generate syntheses, generalizations, and exciting controversies for historians to pursue (Landes 1998, Frank 1998, Pomeranz 2000).

Industrial–Organizational Psychology: Science and Practice

1. *What is I–O Psychology?*

The objective of this article is to describe the breadth of topics studied by industrial–organizational (I–O) psychologists, with an emphasis on what I–O psychologists do to improve organizational effectiveness. I–O psychology is an applied branch of psychology dealing with people's attitudes, behavior, cognition, and emotions at work. More specifically, it is the science of collecting, analyzing, and using data to help organizations make better decisions about the selection, utilization, and management of workers. Non-academic I–O psychologists may work for private consulting firms, large private firms, or government agencies (including the military). Regardless of the setting, the I–O psychologist most frequently operates in an advisory capacity, conducting research that leads to the implementation of a new human resource technology or organizational strategy, or evaluating the impact of an ongoing one. For example, an I–O psychologist may design a new work simulation for selecting customer service representatives, conduct an employee attitude survey to determine the primary determinants of turnover, or evaluate the effectiveness of a management development training program. In the USA, a graduate degree (master's or PhD) is typically required to be considered an I–O psychologist. In other countries, such as those in Western Europe, practitioners often hold master's degrees, while researchers and professors hold PhDs. There are over 100 graduate programs in the USA that offer specialized degrees in I–O, and approximately 30 more in Australia, Canada, and Europe.

2. *A Brief History of I–O Psychology*

The notion that organizational efficiency can be improved by classifying workers and matching tasks to worker attributes can be traced in time back through the writings of Adam Smith, John Locke, Thomas Hobbes to Plato and Aristotle (see Katzell and Austin 1992). Yet, at the beginning of the twentieth century, there was no formal discipline resembling what is now known as industrial–organizational psychology. In 1903, W. L. Bryan gave his presidential address to the American Psychological Association, in which he encouraged psychologists to examine the activities and functions of everyday life. Given the centrality of work to everyday life, this can be construed as a formal call for the application of psychology to industry. Interestingly, in the published version of this address, Bryan referenced an earlier speech in which he called for more research on *individual* psychology. However, Bryan mistakenly wrote *industrial* psychology and did not catch his mistake. Thus, the first instance of the term industrial psychology is as a typographical error (Muchinsky 1997).

The German Psychologist Hugo Munsterberg is considered by many to be the father of industrial psychology (Katzell and Austin 1992). His 1913 book addressed the application of psychological methods to practical problems in industry, including selecting workers, improving worker safety, designing work

environments, and using psychology in sales. Concurrently, industrial engineers Frederick Taylor and Frank Gilbreth advocated job design, training, and selection programs to improve the productivity and efficiency of employees. By the early 1920s, principles for the selection of employees developed to a point that remains constructive to this day. For example, Freyd (1923) presented the following five assumptions of personnel selection: (a) people have measurable abilities, skills, and habits that are relatively stable; (b) people differ in these abilities and these differences should be the basis for decisions about jobs—all other things being equal, those with higher levels of abilities relevant to a job can be expected to perform better than those with less ability; (c) relative differences in ability remain relatively constant even after training or experience; (d) different jobs require different ability—effective selection requires matching abilities required by a job to abilities held by individuals; (e) abilities can be measured and used to rank-order job candidates. Freyd also spoke of the need to conduct job analyses and validate instruments used for selection.

Beginning in the 1930s, the field of industrial psychology broadened with the advent of the so-called human relations movement. Charges of the exploitation of workers by Taylor gave rise to the need to understand and support workers' psychological needs. Instrumental in this shift was a series of studies conducted at the Western Electric plant in Hawthorne, Illinois between 1924 and 1932. Although much of the original data were lost, never reported, or, in fact, ran contrary to the phenomenon that bore the town's name, the studies gave rise to the so-called 'Hawthorne Effect' (Rice 1982). The Hawthorne Effect, that research participants will perform better simply because of the attention paid to their behavior, probably never occurred, and has never been intentionally replicated. Nonetheless, through the 1940s and 1950s, it provided a strong impetus to the human relations movement in industry by convincing organizations that improving job conditions and attending to worker needs would increase worker motivation and productivity.

Through the 1950s and 1960s, greater numbers of researchers were being trained in I–O. Psychology as a whole was dominated by principles of behaviorism, and stimulus–response paradigms affected theory development in I–O. Given these two influences, there arose a number of behaviorally based taxonomies or theories of leadership (Stogdill 1963), motivation (e.g., Herzberg 1968, McGregor 1960), group behavior (Lewin 1951, Cartwright and Zander 1968), worker attributes (Fleishman 1965, 1972, McCormick et al. 1969), performance appraisal (Smith and Kendall 1963), and training (Gagne 1962). While cognitive influences on behavior and performance have slowly begun to influence theory and practice since the late 1980s, a number of these theories have held up reasonably well over the years.

3. *What Does an I–O Psychologist Do?*

As may be inferred from the prior discussion, the field traditionally has been divided into two broad subdisciplines: industrial and organizational psychology.

3.1 *Industrial Psychology*

Topics traditionally considered with the domain of industrial psychology include (a) the evaluation of representative tasks and requirements of jobs, (b) the assessment of individual attributes and skills, and (c) the process of matching individuals to jobs, given (a) and (b). Specific topics generally classified under industrial psychology include: job analysis and job evaluation, recruitment, test development and validation, personnel selection and placement, training and development, and performance appraisal and performance management. Through these processes, an organization comes to understand the core attributes of jobs, identify potential applicants inside and outside the organization, build selection and screening methods that optimize its ability to find the best available applicant, train new workers to proficiency, and monitor and evaluate performance to ensure employee development and satisfactory performance on the job.

Since 1980, the field of industrial psychology has undergone a period of unification driven by the assumption that successful hiring and placement decisions can be made based on a fairly narrow set of worker characteristics (called knowledge, skills, abilities, and other personnel characteristics, or KSAOs). From 1965 to 1980, much of the research and practice surrounding personnel selection was influenced by the Civil Rights Act of 1964 in the USA. The Civil Rights Act made it illegal to discriminate on the basis of race, gender, religion, or national origin, unless done as a business necessity. Through a series of later court decisions, business necessity was interpreted as job relevant which in turn meant that the organization charged with discrimination must provide logical or statistical evidence (through test validation) that performance on the challenged test was related to job performance. The Civil Rights Act has been humorously referred to as the full employment act for I–O psychologists, but it ultimately led to the reinforcement of a long-held tenet that the determinants of job performance are situationally (i.e., organizationally) specific and that job analysis, test development, and test validation are required each time a new selection system is implemented.

Unification began in the mid to late 1970s following the popularization of meta-analysis as a tool for aggregating the results from multiple studies (see *Meta-analysis: Overview*). Meta-analysis, or validity generalization in the vernacular of selection researchers, applies common statistics (e.g., mean and

standard deviations) to the outcomes of multiple studies, rather than to the responses of subjects in single studies. Further, by estimating and removing the impact of extraneous sources of error such as sampling error or differences across studies in test reliability, a meta-analysis or validity generalization study may lead to the conclusion that a particular type of test predicts job performance regardless of the setting or type of job (Schmidt and Hunter 1977). This indeed was the conclusion reached by two I–O psychologists, Schmidt and Hunter, who developed modern validity generalization techniques and conducted multiple large scale meta-analyses on common employment tests (e.g., Schmidt et al. 1986). While debate continues on both their methodology and sweeping conclusions, they had a significant impact on moving the field away from a doctrine of situational specificity and toward one that is beginning to recognize common attributes or worker requirements across jobs as well as a common model of job performance across jobs.

I–O psychologists at the beginning of the twenty-first century might intervene in an organization much as they would have 30, 50, or even 70 years ago: using an analysis of common or critical tasks and requisite KSAOs to construct a selection test battery, performance appraisal, or training program. Popular selection methods include interviews, paper-and-pencil tests, or work samples. However, the movement towards unification has also resulted in emerging models or taxonomies of job requirements, job performance, and worker characteristics that offer promise for streamlining these processes and enabling I–O psychologists to focus on other strategies for improving organizational effectiveness. For example, John Campbell (1990) has proposed a multidimensional model of job performance applicable to most, if not all, jobs. Campbell suggests that performance in any job is a function of three determinants: declarative (or factual) knowledge, procedural knowledge (operative skill or know-how), and motivation. Further, job performance can be described by all or a subset of eight higher-order factors: job specific task proficiency (e.g., a carpenter must be able to join two pieces of wood), non job-specific task proficiency (e.g., cleaning a work site), written and oral communication, demonstrating effort, maintaining personal discipline, facilitating peer and team performance, supervision/leadership, and management/administration. Borman and Motowidlo(1993) further categorized successful job performance into two behavioral classes: task-related activities and what they term contextual behavior—activities such as regularly coming to work on time, helping others, or demonstrating organizational citizenship. To evaluate performance in most jobs, I–O psychologists can derive assessment instruments rooted in these eight factors and involving multiple technologies such as objective performance metrics or subjective performance evaluations (e.g., ratings by supervisors or customers; see *Performance Evaluation in Work Settings*).

Arising from the meta-analytic work of Schmidt and Hunter and others, emerging evidence suggests that adequate (though not optimal) selection systems can be built using a simple combination of a general intelligence test and a measure of personality (Behling 1998). Cognitive ability is an excellent predictor of performance in most, if not all jobs. More intelligent people learn to perform the job better than do less intelligent persons and typically perform better after training (Ree and Earles 1992). Certain fundamental personality traits, particularly conscientiousness and emotional stability, have been consistently reported to add significant incremental variance in the prediction of job performance, both in the USA (Barrick and Mount 1991) and Europe (Salgado 1997). Considering the taxonomies of Campbell (1990) and Borman and Motowidlo (1993), it is not difficult to imagine a generalized selection system in which cognitive ability measures are used to predict the acquisition of the declarative knowledge and procedural knowledge necessary to perform task-related activities, and personality measures are used to assess motivational determinants of citizenship and certain nontask-specific performance dimensions (e.g., facilitating team performance).

Even the process of job analysis—the foundation for decisions about test development, performance appraisal, and training design—is becoming streamlined and driven by a single taxonomy (see *Job Analysis and Work Roles, Psychology of*). With the aid of a team of I–O psychologists (Peterson et al. 1995), the US government has developed O*NET, a comprehensive source of occupational information available to employers, job seekers, trainers, and analysts. For a database of over 1,000 job titles. O*Net contains data that include training and experience requirements, worker characteristics (abilities, values, and work styles), worker requirements (e.g., technical or problem-solving skills), and occupational-specific information (e.g., labor market forecasts). Though not yet fully developed or publicly accessible, O*NET promises to be a valuable resource for identifying selection criteria, planning staffing requirements, and educating individuals seeking employment opportunities.

3.2 Organizational Psychology

Organizational psychology is the second broad subdiscipline recognized with I–O psychology. Topics traditionally considered within the domain of organizational psychology include: (a) internal states of individuals related to jobs (e.g., work motivation, job satisfaction, and organizational commitment); (b) determinants of effective interpersonal interactions

within organizations (e.g., leadership, group behavior, and team performance); and (c) the design of work, organizational structures, and organizational systems that facilitate individual and organizational effectiveness. As can be seen from this topic list, the potential impact of organizational psychology is far broader than industrial psychology, ranging from values, emotions, and cognitions within a person through the dynamics of interpersonal communication (in groups, teams, or leader/member dyads) to systemwide interventions such as the creation of a continuous learning environment (see *Organizational Behavior, Psychology of*).

As a field of study, it is easy to relate the field of organizational psychology to the experiences of most persons. Why does someone love or hate his or her job? Are satisfied workers better job performers? How does job stress undermine job performance and does job stress spill over into home life? What makes someone an effective leader? Why are some tasks intrinsically interesting and others boring? How can some organizations consistently sustain employee growth and firm performance? While the questions asked by organizational psychologists feel familiar, it is harder to capture or describe the methods used by organizational psychologists to improve organizational effectiveness. Very often, interventions are systemwide, their casual impact on measurable outcomes are not readily apparent. For example an I–O psychologist may conduct an attitude survey to study reasons for high turnover among entry-level workers, then recommend an array of system changes including employee flextime, new compensation plans, self-managed work teams, and additional communication training for managers. Given seemingly random fluctuations in product demand, the overall economy, competitors' strategies, and available labor pools, the relationship between the I–O intervention and reduced turnover may be difficult to isolate.

One area of organizational research that has produced consistently positive findings (and successful interventions) is the goal-setting theory of work motivation. While goal setting cannot account for all motivated behavior, as first articulated by Locke (1968), goal-setting theory simply states that employees work harder and perform better with a goal than without. Moreover, more difficult and more specific goals result in higher motivation (and better performance) than easier or less specific goals; thus social workers who set a goal of helping 50 clients per-month will perform better than if they had set a goal of 25 clients or simply 'trying their best.' Goal-setting theory has been supported by considerable field and lab research, and holds valuable practical implications for managers. Managers can motivate employees by helping them set specific goals and by gaining commitment to goal attainment.

While I–O psychologists have been able to provide valuable tools to managers and leaders such as goal setting and group decision-making strategies, the determination of what makes someone an effective leader has proven elusive. Researchers in the 1940s sought to define physical, intellectual, or personality traits of successful leaders. After failing to come to consensus on leader traits, researchers in the 1950s focused on what leaders did, seeking to find a set of effective leader behaviors (see Stogdill 1963). Fiedler (1967) was the first researcher to advocate a contingency approach—what leader behaviors were the most effective depended on the situation (often defined in terms of task difficulty, characteristics of followers, and/or forms of environmental uncertainty or strain). While most modern leadership theories can be characterized as contingency models, there is little agreement as to what is the best approach.

As organizations move into the twenty-first century, the nature of work and characteristics of the workforce appear to be changing rapidly and already are greatly affecting the research of organizational psychologists. Consider the implementation of computers and technology. Not only does the automation of work change worker requirements (e.g., telephone workers who once carried bundles of wire up poles now program fiber optic relay changes on the computer), but hold implications for where work is done (e.g., telecommuting), how information is shared (e.g., the use of video conferencing and e-mail), and even who or what piece of equipment is considered part of a team (e.g., should a robot be invited to an autoworker's retirement party?).

Demographic population shifts have resulted in a workforce that, compared to 30 years ago, is older, more ethnically diverse, and more likely to be female. Not surprisingly, distinctions between work and nonwork settings are blurring, and I–O psychologists are being asked to help organizations manage the impact of diversity, work–life balance, and the introduction of new technology on member satisfaction and productivity (Igbaria and Tan 1998, Lobel 1999). Examples of this type of work include evaluating the cost effectiveness of providing an onsite daycare or exercise facility, training managers to interact effectively with members of diverse ethnic groups, or surveying members for indicators of lower organizational commitment given perceived violations of psychological contracts by the organization (Morrison and Robinson 1997).

It is fair to criticize the overall impact of I–O research on the selection and management of workers. For example, organizations in the USA use unstructured interviews for selection, and organizations in some European countries routinely use handwriting analysis, despite considerable evidence by I–O researchers that neither method is reliable or valid. However, I–O psychologists are continually seeking new ways to reach and educate organizations regarding effective management practices. As we have seen in this article, as new methods are found for

bridging the gap between science and practice, I–O psychologists are prepared with generalized principles of human performance, and ever-expanding research on the dynamics of the attitudes, cognitions, and behaviors of individuals in organizations.

Inequality

The most straightforward definition of inequality is 'differences among people in their command over social and economic resources.' To be useful, however, one must go further and specify inequality: (a) of what, (b) among whom, and (c) how summarized. Furthermore, interest in 'inequality' is often prompted by a concern with 'inequity,' which can be defined as 'morally or ethically unjustifiable differences among people in their command over resources.' Although measurement of inequality often cannot avoid the problem of choosing which differences among people are of greatest concern, and that choice inevitably involves some values, in principle the discussion of inequality concerns issues of fact. In general, it is useful to distinguish as clearly as possible between analytic or descriptive statements about social in-

equality—i.e., how society *is*—and statements about inequity which involve moral evaluations of how society *should be*.

1. Inequality of What?

Although analysts of inequality would often like to discuss inequality of well-being, utility, or happiness, such differences among people in their internal psychological satisfactions must typically be inferred from observable inequalities in social and economic resources. Academic disciplines also tend to specialize somewhat in their focus. While political scientists emphasize the inequality of political power, social inequality in prestige and status is the domain of sociologists. Economists typically limit their analysis to the inequality of income or wealth or consumption. However, there has been a notable broadening of economic perspectives to the inequality of capabilities or economic functionings (see Sen 1985, 1992).

Inequalities in power, status, income, or wealth clearly interact, but these are also analytically distinguishable dimensions of inequality, which are not necessarily perfectly correlated. Furthermore, whatever the dimensions of inequality considered, many analysts would think it important to distinguish between inequality of opportunity (i.e., inequality in the sets of potential choices open to individuals) and inequality of result (i.e., inequality in the specific outcomes actually observed).

The appropriateness of a distinction between inequality of opportunity and inequality of outcome often depends on the time frame of analysis. In access to housing, for example, at any given point of time there will be some persons who are homeless and some who are adequately, or perhaps munificently, housed. These outcomes will depend partially on the choices that were available in earlier periods of time to each individual and on the events they have experienced. In the housing example, an analyst who stressed inequality of opportunity would want to know how many people ever had the opportunity to buy a home, and the income to keep up payments, while an emphasis on inequality of outcome would simply focus on the percentage of current homeowners.

The distinction between inequality of opportunity and of outcome is particularly important for intergenerational issues. In a multigenerational context the inequality of outcomes experienced by a given generation of parents will largely determine the opportunities which their children's generation face. By unconscious socialization and imitation, or by conscious choice of child-rearing practices, time allocation, schooling, and material bequest, parents pass social, cultural, human, and financial capital on to their children—but they can only do so to the extent that they have acquired such assets themselves. Inequality of outcome among parents, and the choices made by them, therefore condition the inequality of opportunity experienced by their children.

In the analysis of inequality, there is a great deal of complexity (and potential for ambiguity) in the empirical operationalization of broad concepts like power, status, income, or wealth. In general, it is important to distinguish between stocks (the total resources available at a point in time) and flows (the change in resources over time). Although the case can also be comparably made for social and political resources like power or status, inequalities in economic resources offer a particularly clear example.

Wealth differs from income precisely in the stock/flow distinction. Wealth is the total stock of economic resources—total potential consumption—that an individual has at a point in time. The classic Hicksian definition of income, on the other hand, is the maximum amount that a person could consume during a period of time and still be as well off at the end of the period as at the beginning. Measurement of wealth therefore requires specification of the date of measurement while income measurement is always for a specific period of time.

In practice, the accounting period over which one measures income flows is far from innocuous. Analysts have to choose whether it is lifetime, annual, or shorter period (e.g., monthly) income that should be measured. The underlying reason for studying inequality should determine the appropriate period over which to measure income flows, but the choice will influence measures of inequality. Over any individual's lifetime, some changes in income will follow a predictable pattern (for example, when workers get raises based on seniority), while others (such as the income losses caused by illness or unemployment) may be less predictable. If income is measured over a longer interval of time, periods of low and high income will be averaged, implying less measured inequality among income recipients.

The most common measure of economic resources used in analysis of economic inequality is annual money income, which includes cash earnings, rental interest and dividend income, and cash transfers from government. Money income can be calculated before or after tax, and in countries with progressive income tax systems the choice makes a significant difference to measured inequality. However, in a complex modern economy, it is also common to find complex cases in which the calculation of annual money income is not straightforward. For example, the cash flow of self-employed individuals or entrepreneurs typically has to be adjusted to reflect the depreciation of the capital they use in production. Since stock options and capital gains are very important for upper income groups, calculation of the level of income inequality is sensitive to whether income is calculated to include only the value of stock options actually exercised in the current period, or to include the value of unrealized capital gains.

Furthermore, a full definition of 'income' would include the value of nonmarketed goods and services received, as well as money income. In countries in which much of the population is agricultural, the value of food produced and consumed within the household may be a large fraction of total income. Individuals also receive a benefit from leisure time enjoyed, the goods and services which (like child care) are produced in the household, and the services of owner-occupied houses. They may also benefit from services (like medical care or education) provided by government agencies. Arguably, the value of these benefits should be added to cash income.

In addition, individuals who live in larger households benefit from a greater ability to share resources (e.g., due to household 'economies of scale,' a couple with a household income of $40,000 is better off than two individuals who each have $20,000 and must live separately). If the objective is to measure inequality in economic well-being, some account should be taken of living arrangements. Economists have therefore argued that 'equivalent income,' which adjusts income for household size, is the best measure to use in the analysis of inequality in economic well-being.

The complexities in measuring 'income' are a reminder that in measuring inequality, 'the devil is in the details.' Although 'income' is a complex concept, income inequality is only part of economic inequality more broadly conceived. Moreover, since institutions change over time and differ across countries, comparisons of inequality can often be sensitive to these measurement issues—and in the analysis of inequality, comparative statements on time trends or differences among societies are the major issue of interest.

2. *Inequality Among Whom?*

Because assessing the extent of inequality involves a comparison of resources, it is crucial to be clear about whose resources are being compared—and which resources. An analyst who looks only at inequality in family or household income is ignoring the fact that families and households differ significantly in size. On the other hand, if an analyst were to look only at the distribution of money income directly received by individual persons, the fact that many people (e.g., young children, unpaid spouses) have zero cash income of their own would tend to exaggerate measured inequality.

Because individuals without income of their own typically reside in households in which other family members do have cash income, the effective degree of sharing of income within households is crucial to inequality measurement. However, this is difficult to observe in practice, and it is often convenient for researchers to assume that all persons within a household have the same level of effective income (Phipps and Burton 1995 demonstrate that alternative assumptions can make a big difference to perceived poverty). Similarly, it is common to assume that all members of a given household have the same socioeconomic status. Effectively, such procedures amount to assuming away inequality within groups of people (in this example, coresident household members) and concentrating attention on inequality between groups.

Table 1
A comparison of inequality in two hypothetical societies

	Men			Women		
Arcadia	4	6	8	2	4	6
Bucolia	0	6	12	6	6	6

Assuming equality within groups can be problematic (e.g., much feminist scholarship has challenged the presumption of within-family equality in consumption, status, and power). Furthermore, the larger the group is, the harder it generally becomes to maintain the presumption of within-group equality. There is much social interest in the extent of inequality between broad groups of people (e.g., occupational groups, regions, racial or ethnic groups, age cohorts, etc.). In some instances, between-group comparisons are driven by an underlying theoretical framework which defines categories of interest (e.g., bourgeoisie/proletariat). However, when within-group inequality is large relative to that between groups (as in income comparisons between age groups, where inequality among individuals of the same age is far greater than the differences in average income between people of different ages), comparisons of average group characteristics may suggest unwarranted stereotyping.

Furthermore, the term 'inequality' can be used in two subtly different conceptual senses. In some discussions—discrimination is an example—'inequality' is used to refer to differences between particular individuals or groups (e.g., person A is not equal to person B). In other instances, 'inequality' refers to differences among people in general (e.g., in country A there is more inequality than in country B). These usages need to be distinguished, since pairwise and group inequalities do not necessarily imply aggregate inequality differences. Table 1 presents a numerical example of men and women in 'Arcadia' and 'Bucolia' to make the point.

Is there more inequality in Arcadia than in Bucolia, or less? Would eliminating between group inequality imply an end to inequality? Inequality among groups of people is illustrated by comparison of men and women in Arcadia and Bucolia. In Arcadia, women have a lower average income (4) than men (6), while in Bucolia the average is the same (6). However, the equality of male and female average income in Bucolia does not imply equality of individual incomes. Inequalities in average income between groups also do not imply individual inequalities (in Arcadia, for

example, two-thirds of men can be matched with women with exactly the same income while in Bucolia only one match can be found).

To answer the seemingly simple question of whether, overall, there is more inequality in Arcadia than in Bucolia, or less, one must compare the entire distribution of outcomes. Although there is a large middle class in Bucolia (two-thirds of the inhabitants have the same outcome (6)), there are also greater extremes (from 0 to 12). In Arcadia, middle-class incomes are more differentiated, but the extremes are not as widely separated. Hence, answering the seemingly simple question whether there is more or less inequality requires finding a way to summarize the number and size of differences in outcomes among all individuals.

3. *Inequality—How Summarized?*

The example of Arcadia and Bucolia has been simplified by the presentation of only one outcome, among a small number of individuals. In actuality, modern societies have millions of inhabitants who differ on a wide number of dimensions. There are, therefore, a very large number of potential comparisons. Even if one restricts attention to a single variable, like income, it is not a simple matter to summarize the extent of inequality.

One approach to inequality measurement is to order the population from worst off to best off, divide them into groups of equal size and calculate the share of total resources flowing to each group. (If five groups are used, the result is the calculation of five 'quintile' shares of total resources.) If, for all low income groups, this calculation always produces the answer that the less well off get a larger share of total income in country A, then it is easy to say that country A has less inequality. However, in the Arcadia/Bucolia comparison, the poorest sixth of Bucolia get a smaller share (zero compared to 6.6 percent), at the same time as the second poorest sixth of Bucolia get a larger share (16.6 percent compared to 13.2 percent). Which country has more inequality? If one wishes to know whether there is more inequality in country A than in country B, or whether there is more inequality at time A than at time B, inequality must be summarized in a single number.

The most popular index summarizing the extent of inequality within society is probably the Gini index. Mathematically, the index is calculated as the average differential (in absolute value) between any two people in society, as in Eqn. (1).

$$G = \frac{1}{2\,\bar{y}\cdot n\cdot(n-1)}\cdot\sum_{i}^{n}\cdot\sum_{j}^{n}|y_i - y_j| \qquad (1)$$

The Gini index also has a convenient graphical interpretation. When individuals are ordered from poorest to richest, Fig. 1 graphs the relationship between the cumulative percentage of income received on the horizontal axis, and the cumulative percentage of population on the vertical axis—the result is known as a 'Lorenz curve.' If everyone in society had the same income—perfect equality—then the Lorenz curve would be the straight line OY. If one person in society had all the income and the rest had nothing—perfect inequality—the Lorenz curve would lie along the horizontal axis for almost all its length.

Actual societies are somewhere between perfect equality and perfect inequality and as an example Fig. 1 graphs the Lorenz curve for Sweden and the USA. A convenient feature of the Gini index is that it is equal to the ratio of the area between the Lorenz curve and the line of perfect equality (area A in Fig. 1) and the triangle OPY. (In the early 1990s, the Gini index of equivalent after-tax money income of Sweden was 0.222, substantially less than the Gini for the USA of 0.371; see Osberg and Xu 2000.)

As Fig. 1 indicates, the Lorenz curve for Sweden lies entirely inside the Lorenz curve for the USA. The verbal interpretation of such a case is that the poorest x percent of individuals in Sweden always have a larger share of total income than the poorest x percent in the USA—whatever the value of x. If this is true, it is straightforward to say that there is less inequality in Sweden than in the USA. However, when Lorenz curves cross, comparisons between societies become sensitive to which part of the income distribution is of greater interest.

The dashed line in Fig. 1 is drawn to represent 'Bucolia,' in which the bottom sixth of individuals get nothing, the middle two-thirds share equally two thirds of total income, and the top sixth get the remaining third of total income. The Lorenz curve for this hypothetical society crosses the Lorenz curve for both Sweden and the USA. The poorest sixth of individuals in this hypothetical society get a smaller share of national income than they would in actual Sweden or USA, while the second and third poorest sixths get substantially more. In hypothetical 'Bucolia' the bottom half of the income distribution gets 33 percent of total income. In the real world of 1994, in the USA the bottom half of the income distribution received, after taxes and transfers, is about 24.8 percent of total equivalent income (for full details of methodology and data see Osberg 2000). Which is the more unequal?

When Lorenz curves cross, it matters which part of the income distribution one thinks to be most important. If one thought that the most important aspect of inequality was the share of income received by the very poorest, then Bucolia should be counted more unequal than Sweden or the USA. However, the Gini index for Bucolia is 0.139—well below that in either Sweden or the USA. If inequalities among 'most people'—i.e., those in the middle part of the income distribution—are thought to be the most important

Figure 1
Relationship between cumulative percentages of income and population

issue, then the low Gini index in Bucolia is the appropriate measure. In Bucolia, two-thirds of people have exactly the same income, and by this criterion one would count Bucolia as considerably more equal than either the USA or Sweden. However, if inequality between the poorest and everyone else is thought to be the important issue, one would disagree with the Gini ranking. When Lorenz curves cross, a different ranking of inequality may be obtained, depending on which part of the distribution is of greater concern. In this case, a single index number for inequality may be insufficient.

The Gini index is not the only possible single index in widespread use, and the choice of index to use depends upon which aspect of inequality is of greatest importance. Theil's index of inequality can be calculated as in Eqn. (2) and has the attractive property that it can be decomposed, so that an analyst can say how much of total inequality is due to inequality within social groups and how much is due to inequality between groups. Also, because it is based on the average proportion of mean income received by individuals, it responds strongly to changes in the dollar incomes received by low income individuals.

$$R = \frac{1}{n}\sum_i \frac{Y_i}{\bar{Y}} \log \frac{Y_i}{\bar{Y}} \tag{2}$$

The Coefficient of Variation is another decomposable index of aggregate inequality, which is derived from the standard deviation of income, as in Eqns. (3) and (4). It also has the property of decomposability (unlike the Gini index, in general) but since it is based on the average squared deviation, it is most responsive to changes in income among the more affluent.

$$Var(Y) = \frac{\sum_{i=1}^{n}(Y_i - \bar{Y})^2}{n} \tag{3}$$

$$CV = \frac{\sqrt{Var(Y)}}{\bar{Y}} \tag{4}$$

The literature on inequality (ably summarized in Silber 1999) has broadly agreed on a set of criteria that an acceptable index of inequality should satisfy. The principle of transfers argues that if a transfer of income is made from a richer person to a poorer person, an acceptable inequality index should always decline. The anonymity principle states that an index of inequality should depend only on the relative sizes of incomes and be invariant with respect to the identities of those occupying each position in the income hierarchy. The properties of scale invariance and population invariance require an index to be the same if all incomes are measured in different units or if identical populations are added together. These properties are not possessed by some possible measures (summarizing inequality by the 90:10 ratio of the top 10 percent's average income to that of the bottom 10 percent would, for example, not satisfy the principle of transfers, since transfers from richer to poorer in the middle part of the distribution would not affect the index).

In some cases, measurement of inequality is unambiguous—if the Lorenz curve for one country lies entirely inside that of another, all acceptable inequality indices will give the same ranking. However, as Atkinson (1970) observed many years ago, it is common in the real world to observe crossing of the Lorenz curve of two populations. In this case, when choosing an index of inequality the analyst is implicitly also choosing to emphasize inequality in a particular part of the distribution.

In some instances, it is possible to reduce inequality in several dimensions of life to a common denominator—for example, a good deal of work has been done in establishing the monetary value of access to different public services (such as education or health care). However, it is also reasonable to suppose that individuals differ in dimensions (e.g., income and life expectancy) that cannot easily be made equivalent. In this case, unless the dimensions of inequality are perfectly correlated, the assessment of aggregate inequality will depend on the relative weight to be assigned to each aspect of inequality and the correlation and shape of each variable's distribution.

4. Summary

If there were only two types of people, who differed only on one easily measured dimension, then inequality would be a fairly simple concept—the difference between 'the rich' and 'the poor.' In practice, however, there are multiple dimensions to inequality, and multiple differences between people. As soon, for example, as one adds a 'middle class,' inequality could be seen as either the differences between the rich and the poor, or the differences between the poor and the middle class or those between the middle class and the affluent. Key concepts like income, status, or power are also ambiguous and difficult to measure, in practice.

Furthermore, as Atkinson (1998), Brandolini (1998), and Osberg (2000) have demonstrated, although there have been clear trends in inequality in some countries in recent decades, there is no universal trend in all countries. Household income depends on household composition (i.e., on the processes determining formation, dissolution, and size of households); on the total market income of all household members from capital (which is influenced by inheritance patterns and taxation); as well as on individual incomes from labor (which depends on trends in both hourly wages and the distribution of work hours across employees, and on the correlation of male and female earnings within households); on the transfer incomes for which household members are eligible; and on the household's treatment by the tax system. Trends in the inequality of household income depend on changes in all these variables, some of which are heavily influenced by the public policies of governments, but some of which depend more on shifts in culture and society (both of which vary by country). National differences in culture and politics, and the vagaries of the evolution of such differences, thus have many channels of influence—and no segment of the income distribution is insulated from the impact of political decisions and public policy. It is not, therefore, really surprising to find a diversity of national experiences—as Brandolini (1998, p. 38) puts it: 'Neatly defined and unambiguous trends are unlikely to result from this multiplicity of factors.'

There is, therefore, a good deal of complexity in the concept of 'inequality.' This complexity does not imply either that measurement of inequality is impossible or that a measure can be found that will justify any hypothesis. However, recognition of the complexity of inequality measurement does imply that analysts should test explicitly whether, in a particular instance, all plausible measures of inequality agree. If there is ambiguity in inequality rankings, analysts should be prepared to be clear about which aspect of inequality is of greatest importance.

Inequality: Comparative Aspects

Inequality is defined here as sanctioned differential access to valued things, experiences, and conditions in human societies. Comparative aspects are similarities and differences found among systems of inequality as a result of comparing societies in all of their variety: through time (developmentally) and space (cross-culturally), in societies small and large, homogeneous and complex, prehistoric, historic and contemporary, throughout the world.

1. *Social Inequality*

Social inequality has been debated from the time of Aristotle and Plato to Rousseau, Karl Marx, Max Weber and innumerable contemporary authors (Beteille 1987). The classic triumvirate, 'class' (economic order), 'status' (honor) and 'party' (power) are widely cited as its essential dimensions, with power—the ability to prevail over others—as the virtual independent variable. Powerful people are privileged; powerless people are rarely so, and then only under sponsorship of the powerful. Their perspectives on inequality reflect their places in the system: those who look from below see and experience a different world than those whose gaze and experience is from above, and the latter are the ones in a position to define and explain the system, as well as enforce it.

This entry draws on understandings of social inequality obtained, primarily by anthropologists, through cross-cultural and cross-temporal research focused on peoples who have been otherwise largely ignored: those commonly labeled, if noticed at all, as primitive, aboriginal, tribal, native, indigenous, heathen, nomadic, peasants, untouchables, colonials, minorities, ethnics, immigrants, refugees—in short, those rendered vulnerable for whatever reason, or unreason.

2. *Egalitarian (Unranked) Societies*

Dominance and differential evaluation exist in every society, but in some—those often loosely described as 'egalitarian'—are limited to elemental roles found in all societies: those of family, sex/gender, age/seniority, specific activities or skills, and cherished or stigmatized personal characteristics. If additional inequalities occur they are more symbolic than material or political. Inequalities in such societies have received increasing attention from ethnographers and archaeologists in recent years (Flanagan 1989).

These are small, mobile bands of kinsmen with households as the basic social and economic units. Theirs are subsistence economies derived by foraging wild species, without privileged or curtailed access to resources or the means to obtain them. They share their economic pursuits and rewards, without expectation of specific returns, in what has been termed 'generalized reciprocity' (Sahlins 1968). Requisite knowledge and skills are present in every household, extra-familial authority or occupational roles are rare or absent, and sexual division of labor is complementary with little or no differential evaluation.

2.1 *Assertively Egalitarian Societies*

Even in 'egalitarian' societies, equality of power, possessions and prestige is in jeopardy. The *Hadza* of Tanzania, are foragers who consume the products of a successful foray before embarking on another. This, Woodburn (1982) describes as an 'immediate return system.' He characterizes societies with such economies as 'assertively egalitarian' in that their members characteristically resist and sanction attempts to exert authority or consume resources without sharing.

2.2 *Relatively Egalitarian Societies*

By contrast, foraging economies in which long-term collective investments of resources are employed (e.g. construction and maintenance of corrals for game drives), Woodburn terms 'delayed-return systems': the return on investment of labor is delayed rather than immediate. Although they are egalitarian to an extent found among few non-foragers, and are therefore 'relatively egalitarian,' they entail authority and accumulation untenable in immediate-return societies as a result of the need for coordination of delayed-return

activities and preservation of products for use during periods of delay.

All societies whose economies and organization are more complex than those of 'assertively egalitarian' foragers have delayed-return systems. Those with economies and social systems more complex than those of 'relatively egalitarian' foragers, are inegalitarian or 'rank societies' (Fried 1967).

3. *Inegalitarian (Rank) Societies*

Inegalitarian societies are those wherein members are individually, or more often collectively, hierarchically ordered in access to valued things, conditions and experiences. All societies discussed below are in this sense inegalitarian. This presentation here moves from those of relatively 'small scale' (small in numbers and relatively homogenous), to increasingly 'large scale' (large in population and socially complex). This sequence reflects and extends the strong correlation which exists between scale and inequality.

3.1 *Affluent Foragers and Farmers: Transition to Assertive Inequality*

Some cultural anthropologists and many archaeologists have turned to supplementing largely static extant typologies, with analyses of transitions, especially those from unranked to, and within, rank societies (Price and Gebauer 1995, Kirch and Marshall 1992).

Rank society emerges when circumstances permit some members to acquire privileged or, in the extreme, exclusive access to essential resources. This has traditionally been attributed to the invention of domestication—primarily of plant species, hence agriculture—and the resulting opportunity for some to control land and command the labor of landless others to till and guard it. Similar conditions obtain for pastoralists' control of their herds.

It has long been recognized that some foraging societies share with early farmers the inequalities characteristic of agricultural and pastoral peoples (Koyama and Thomas 1981). The most widely cited example is the peoples of the US northwest coast, who developed maritime economies devoid of domesticated species, combined with complex and highly inegalitarian social structure (Lightfoot 1992). This seeming anomaly is explained by the annual runs of salmon which, accompanied by technologies of preservation and storage, provides a food supply as predictable and productive as any domestic crop or herd. Inequality results from opportunities for some to control the best fishing sites and equipment, and to mobilize personnel to exploit them. This system entails ranked kin groups (clans) and their chiefs. The latter accumulate goods provided by their clansmen for subsequent ceremonial, status-enhancing distributions to rival chiefs and clans—the storied potlatch.

Other examples of such systems are found primarily in horticultural societies, which employ two distinct kinds of leadership role and social organization: big man and chief (Sahlins 1968).

3.2 *Big Men, Big Women*

The simpler of the two structures is 'big man' (rarely 'big woman') society. The big man's role is an informal, acquired, or achieved status. Through personal charisma and persuasion he recruits a volunteer following whose number contribute valued goods to a fund which he will ceremonially distribute to a competing big man and his followers (as in a potlatch). Recipients thereby incur a debt to be paid off, and if possible exceeded, in a reciprocal distribution. The magnitude of the distribution is the measure of a big man's stature, while his followers receive credit (and when next he is on the receiving end, goods) proportional to their contributions.

3.3 *Chiefs*

A chief differs from a big man in that his is an office, ascribed to him as a result of his paramount position in his clan. Fellow clansmen are his obligatory supporters and he their hereditary headman. As chief, he must behave in a chiefly manner, ever responsible and generous to his clan. His behavior follows from his role; the opposite of the big man, whose role follows from his behavior.

Big man organization may evolve into chieftainship when big men find that kinsmen are more reliable supporters than others and therefore preferentially, and eventually exclusively, recruit them. As kinship becomes the *de facto* principle of organization, the followers of a charismatic big man may become in effect, and ultimately in fact, clansmen of their paramount kinsman, and he their chief.

3.4 *Chiefs to Kings, Kinship to Class: Transition to Complex Society*

The offices of both chiefs and kings are ascribed on the basis of kinship with their predecessors. But they differ fundamentally: the relevance of kinship for the king stops with his coronation; for the chief, investiture is only the beginning. The king becomes sovereign over all within his domain, beholden to no one; the chief is paramount only among his kinsmen, and as kinsman

is beholden to them as they are to him. The king rules, accumulates, and consumes; the chief proposes, coordinates, accumulates, and redistributes.

Kingship thus represents the demise of kinship as the basis for social structure, replaced by economic stratification: ownership of productive resources including land, territory as the dimension of governance, authority and force as its method, and depersonalization as a result of dramatic increases in scale. There appear for the first time, ranked economic classes and cultural categories.

As reciprocity is the economic hallmark of unranked society, and accumulation for conspicuous redistribution is the hallmark of big-man and chiefly organization, accumulation for conspicuous consumption is a hallmark of kingship and the state.

4. *Stratification*

Contemporary nation states are socioeconomically stratified in a variety of complex ways, their populations distributed along continuums of differential access to necessities and rewards. These distributions are often perceived as comprising distinctive, ranked categories—social strata—of people similarly positioned.

An issue to which comparative analysis has made major contributions, is the nature and function of stratification: does it primarily serve to select the best qualified for the most important roles in society by offering them the highest rewards, or does it serve mainly to withhold opportunities from vulnerable segments of society, thus assuring that there will be people with no choice but to perform cheaply and tractably the necessary tasks shunned by others? Caste in India, and US race/ethnic relations, are examples which support the latter interpretation (Berreman 1960), as is the status of Nepalese and Brazilian immigrant labor in Japan (Yamanaka 2000).

4.1 *Dimensions of Stratification*

Power is key to stratification, but class and status are closely linked to it; the three vary together. Stratification systems differ in significant ways, the analysis of which is facilitated by comparison along three axes of inequality. One defines the nature of the ranking, contrasting status strata, ('honor and privilege') at one pole, and class strata (the 'economic order'), at the other. A second axis describes the locus of characteristics which determine an individual's status, contrasting those regarded as intrinsic to individuals (ascribed), with those regarded as extrinsic (acquired or achieved). A third addresses the composition of strata: whether they comprise named, organized, acting groups, or analytically discernible but unorganized categories. Variations along these axes, together with the cultural explanations that rationalize each system, constitute the significant differences among them.

4.2 *Acquired Economic Status: Categories as 'Classes,' Groups as 'Sodalities'*

Acquired status is based on possessions and privileges, its inequalities defined by economic factors (income, net worth) and their accompanying lifestyles (patterns of consumption, education, occupation). These are classes, of which it is useful to contrast: (a) those comprising objectively discernible categories, useful to an analytic observer, but amorphous, unorganized and not necessarily recognized even by those who comprise them; and (b) those which comprise groups, publicly recognized, members aware of their shared situation and its sources, organized, acting in their common interests. Marx recognized this distinction when he described the first as 'groups in themselves,' and the second as 'groups for themselves.'

Ranked economic *categories* are here designated simply classes. Ranked, economically based *groups*, such as labor unions and professional associations, are designated associations or sodalities.

4.3 *Feudalism and Estates: Groups with Ascribed Economic Status*

Feudal systems are complex agricultural societies comprising hierarchical relations among landed nobility, various levels of commoners and rural peasants. Because patron–client relationships with respect to land, are a defining characteristic, such systems fall well within the 'economic order.' They therefore constitute systems of class stratification (Stavenhagen 1975). But these are classes with a difference, for they are explicitly ranked, with specified rights and obligations. So long as a person belongs to a given category, he or she shares its rank. However, mechanisms exist—usually economic—by which an individual may, with difficulty, move to another category thereby acquiring its rank. Status is thus intrinsic to the category but not to the individual. Such named, bounded and jurally defined categories can be labeled estates, to distinguish them from classes.

4.4 *Ascribed Honor: Caste, 'Race,' and Ethnicity*

Ascribed statuses of honor are distinguished by the fact that rank is assigned on the basis of membership in differentially privileged and esteemed groups or categories rather than on the basis of activities or possessions. They are also distinguished by the fact that, as a result of ascription, those who share them constitute publicly recognized, self-acknowledged

groups. Often they are culturally distinct, cohesive—sometimes corporate—groups *for* themselves. Weber called them status groups. Four types will be contrasted below: 'caste/race,' 'ethnicity,' 'sex/gender,' and age/seniority.

4.4.1 Caste/race. Status assigned to culturally distinct, socially segregated categories of people on the basis of shared and differentially evaluated characteristics claimed to be innate, is unalterable. 'Race,' as it is socially constructed in the US and 'caste' (*jati*), as it is constructed in India, are classic examples. Castes are localized, internally organized, endogamous, and often corporate, groups ranked according to conceptions of ritual purity. Most low ranking castes lay claim to higher status than that accorded them—claims that are routinely ignored or brutally quashed by high castes. Attempts to validate their claims entail status emulation: adoption of high caste rituals and behaviors, a process familiar in Indian social science as *Sanskritization* (Srinivas 1966). They are exceedingly rarely successful, and then only if backed by unprecedented power.

Stigmatized 'races' in the US differ from low castes of India in that they are nationwide social categories rather than localized groups, but they share with low castes their birth-ascribed subjection to disparagement, discrimination, and exploitation, rationalized by accusations of intrinsic worthlessness. Similarly disparaged 'outcaste' groups have included the *Burakumin* of Japan and *Hutu* of Rwanda and Burundi. All respond to their oppression with resentment and resistance. The only consensus on inequality in these systems is the pragmatic one of who has the power, under what circumstances and with what effect it will be used. When this consensus is breached, the systems are often vigorously challenged. These fundamental similarities are here deemed to be sufficiently significant to justify the combined term 'caste/race,' except where their differences are at issue.

4.4.2 Ethnicity. Ethnicity, or ethnic group, are terms for ascribed identity bestowed on groups or categories defined by their distinctive cultural attributes such as language and religion. They are frequently, but not necessarily, ranked within their societies. If ranked, their status is not wholly ascriptive for, while the ethnic group's ranking is ascribed, the defining attributes of its individual members are acquired through shared socialization—learning—and what is learned can be rejected or forgotten. Therefore, as in the case of estates, rank is intrinsic to the group but extrinsic to individuals, so that individual mobility within the system is possible. If circumstances permit, people can acquire or construct other ethnicities, other statuses (Barth 1969).

4.4.3 Sex/gender. Sex is a usually birth ascribed and immutable category of difference, which in all societies serves as a basis for division of labor, and in most complex societies is a basis for inequalities. Gender is the social construction of its nature and significance. Many societies define other genders as well, among them the *berdache* 'men–women' of several American Indian societies and the 'manly hearted women' of some of them, Polynesian *fa'a fahini* ('in the manner of women'), and India's 'third sex,' the *hijara*. These, and gay, lesbian, bisexual, and trans-sexual genders, of Euro–US and other complex societies, are but some of the diverse gender roles worldwide. Some are stigmatized, but as many are not and occupy conventional or exceptional roles in their societies.

The relative status of the sexes in human societies has been long debated. Universal female subordination is often taken for granted. To challenge this one has only to look across the full range of human societies, including especially those which resemble the ones in which 99.9 percent of our ancestors, through time, have lived (Leacock 1978). Among more complex and inegalitarian societies, one must consider those whose systems of descent, inheritance and post-marital residence follow the female line. The highest incidence of such systems are found in Southeast Asia and Melanesia, among horticultural peoples in which women own the land, do the lion's share of cultivation of staple crops, and enjoy a high-to-superior degree of autonomy, authority, and respect.

Gender status correlates positively not only with the prominence of its role in descent, residence, and horticulture, but its contribution to the household or kin group economy, whether foraging, horticulture, agriculture, pastoralism, wage labor, or professions. In complex societies it correlates most highly with the economic contribution made from outside of the household or 'domestic sphere' (Caulfield 1981).

In discussing gender inequalities it must not be overlooked that, while every society has distinctive female and male cultures, the genders are largely socialized in the intimacy of family and kin of both sexes, sharing class, ethnic, caste/race statuses, and environments. They are therefore familiar with one another to an extent that people of other ranked identities are not. However, the extent to which such experiences contribute to respect and empathy cannot be predicted from the fact of contact. As studies of US 'race' relations have demonstrated, contact does not necessarily reduce prejudice, and may exacerbate it by seeming to confirm stereotypes, unless it occurs in status-equal circumstances.

US women have long been discriminated against, while sharing class and ethnic status with male family members. In India, women share the ritual and economic status of their male caste fellows, while being subordinated to males. Circumscription of women in activities outside the household is an

important symbol of high caste rank. *Sanskritization*, caste status striving, entails increasing subordination of women (Berreman 1993).

4.4.4 Age/seniority. Age categories and cultures, like those of gender, are ascribed, socially constructed, familiar to all, and highly variable. As a basis for inequality, age and seniority are at their minimum in unranked societies. Societies organized in lineal kin groups or clans often place great importance on seniority, as the first born in a senior (most often male) lineage becomes the paramount.

A number of societies, the most thoroughly reported of which are East African cattle herders, are organized into ranked, age-based groups, more often male than female, whose members share distinctive ritual, economic, military, or other privileges and responsibilities.

Comparative studies of age in other kinds of societies include Mead's classic *Coming of Age in Samoa* (1928), which challenged the universality of adolescence as a period of trauma, and Henry's *Personality and Ageing* (1973), which argued that individuals are regarded as persons to the degree that they possess symbols of attachment to their social system, and that in the US such symbols (gainful employment, license to drive) are often withdrawn from the elderly leading to the experience of diminished personhood, resulting in social suffering, hostility and depression. This is precisely the kind and consequence of denial of full humanity inflicted by racism, casteism, ethnic and gender discrimination.

5. *Colonialism: International Hegemony*

Relationships between colonizer and colonized are among the most powerful of the world's structures of domination and exploitation (Asad 1973). In its classic context, colonialism has referred to nations and peoples annexed for their natural, manufactured or human resources by one of the 'great,' usually European, maritime, powers. Subsequently the concept has been directed to other contexts, as in 'third world colonialism' (hegemony over developing nations, often by their erstwhile colonizers), and 'internal colonialism' (domination of minorities within developed nations, e.g. African Americans, Palestinians in Israel).

By analogy, 'academic colonialism' refers to the dominant role well-funded researchers from 'advanced' nations play in 'developing' nations, while local scholars are scantily funded if at all. It is most damaging and resented when indigenous scholars are evaluated by the standards and fashions of colonial countries, ratified by foreign degrees, and by publication in foreign journals, in colonial languages. Social and behavioral scientists, perhaps more often than others, may find themselves strangers in their own academies and virtual pariahs in world scholarship (Saberwal 1967).

6. *Full Circle: Modern Egalitarian Societies?*

Egalitarian social systems require egalitarian economies. Both have been on the agenda of utopian communities and ideal societies studied by social and behavioral scientists: Soviet and Chinese communes, Israeli Kibbitzum, socialist societies, and anarchist communities (Barclay 1982), American 'counter-cultural' communities of the1960s–1970s and various egalitarian cults. Many live in small, self-contained communities, combining interdependence and individual/familial autonomy, bound by ties of kinship (usually fictive), sharing ideology and communal activities, while avoiding in so far as possible participation in the complex society, economy, and politics of the world system. They often pursue subsistence economies through cooperation, sharing and reciprocity, their production for use rather than profit, abjuring private property, accumulation of wealth, hierarchies of authority or privilege, and status symbols. That is, they reproduce the social and economic practices of small-scale, 'assertively' or 'relatively' egalitarian societies, with which human societies began and for so very long survived. Prehistoric, recent, and current exemplars have virtually all succumbed to appetites, blandishments, and requirements of stratified, state organized, producer–consumer society.

Bodley closed *Victims of Progress* (1975) with the observation that small-scale, egalitarian culture 'is gone—after a very long and successful tenure,' and it seems that the presently dominant, stratified 'culture of consumption … too, will disappear … but after a very brief and preposterous career.' He was probably right, but hope, courage, and determination do spring eternal and could prevail.

Infancy and Childhood: Emotional Development

Emotion is a familiar but psychologically complex human experience. Consequently, the growth of emotion integrates diverse developmental processes in infancy and childhood, including psychobiological growth, perceptual processes, emotional and social understanding, self-awareness and self-understanding, and the growth of self-regulation. The study of emotional development has also been stimulated by basic questions concerning the nature of emotion itself, and its role in behavior and development. This article explores the issues that have contributed to considerable research interest in emotional growth early in life.

1. *The Nature of Emotional Development*

Emotions color the life experience of people of all ages. For infants and children, emotions have especially powerful motivational consequences because emotional understanding is rudimentary, capacities for emotion self-regulation are limited, and the young child's engagement or withdrawal from events is primarily emotional in quality. Emotional development is central to understanding the growth of social competence, intellectual achievement, self-understanding, and the earliest origins of mental health or psychopathology because of the importance of emotion to the organization and regulation of early behavior (Lewis and Haviland-Jones 2000). Emotional development provides a window into the psychological growth of the child as, from infancy to late childhood, emotions become integrated into the broader fabric of behavioral competence, become objects of thought and analysis, can be strategically expressed or concealed in social situations, are shaped by the child's experience of significant relationships, motivate prosocial as well as aggressive tendencies, become part of self-understanding (especially in feelings of guilt and pride), and color the individuality of personality growth.

1.1 *Emotions and Development*

Emotional development was vigorously studied earlier in the twentieth century, and has recently received renewed attention after a period of dormant interest. There are several ways that the contemporary study of emotional development differs from traditional approaches rooted in psychoanalytic or Piagetian theories. First, emotions are regarded as centrally important to understanding development in infancy and childhood, rather than as a peripheral or disruptive facet of early growth. Second, emotional development offers a uniquely integrative perspective on human development. Understanding emotional growth requires synthesizing biological perspectives on development (including neurobiological growth, temperamental individuality, and neuroendocrine functioning) with social perspectives (including relational and family influences, and the child's developing understanding of cultural norms). Third, emotions are

viewed as having constructive as well as disorganizing features. Although emotions are capable of undermining effective functioning (which accounts for current scientific interest in the growth of emotion regulation), developmental researchers also emphasize how emotions motivate and organize social interaction, underlie the quality of early social relationships, shape self-understanding, and provide incentives for developing new skills and capabilities. This is consistent with a new appreciation for the constructive, organizational role of emotions in other areas of psychological study.

Contemporary study of emotional development in infancy and childhood is also motivated by clinical concerns—most notably, a growing realization of the early emergence of emotionally related disorders in young children, including depression, anxiety disorders, and behavioral and conduct problems. Thus the study of emotional development is informed by developmental psychopathological studies of the origins of these disorders in troubled parent–child relationships, temperamental vulnerability, environmental and genetic risk, and individual capacities for emotional self-regulation. This research further underscores the complex, integrative quality of emotional growth, and the various risks that exist for emotional dysfunction as well as alternative avenues to prevention and remediation.

Developmental research on emotions has required a broad range of methodologies. These include fine-grained analysis of videotaped facial expressions, naturalistic observations of social interaction at home or school, conversations with young children about their comprehension of emotional events, detailed study of the responses of children to emotionally evocative laboratory vignettes, parent-report approaches, and psychobiological measures of heart rate, cortisol, or cerebral asymmetry during emotionally arousing situations. Developmental scientists are increasingly integrating these methodological strategies in broadly based longitudinal studies that enable them to study the emergence of emotional capacities over time and in the context of family processes, psychobiological maturation, and other influences.

1.2 What is Emotion?

Contemporary study of the functions of emotion in behavior and development is accompanied by debate over the nature of emotion itself. Two broad perspectives can be distinguished. The structuralist perspective defines emotion in terms of discrete emotional states, each with unique patterns of subjective feeling, cognitive appraisal, physiological arousal, and facial expression (Izard 1991). These emotion components are tightly interconnected and are deeply rooted in human evolution because of their relevance to reproductive success (e.g., feelings of anger involve visceral, perceptual, subjective, and expressive components relevant to self-defense). This view is consistent with the everyday tendency to distinguish basic emotions like anger, fear, sadness, and joy as readily dissociable states.

More recently, however, functionalist perspectives on emotional development have questioned whether emotional life is so discretely packaged and have offered an alternative view (Saarni et al. 1998). In this perspective, emotion is defined in terms of the quality of the transactions between the person and the environment on matters of significance to the individual. In this regard, what defines an emotion is not a network of internal subjective, physiological, and other components, but rather the constellation of a person's goals, appraisals, action tendencies, and other capacities in relation to environmental inventives, obstacles, and opportunities. As a result, emotional experience is not confined to a predefined set of emotion categories, but can encompass the rich variety of subtly nuanced emotional blends characteristic of everyday experience, as well as the breadth of how emotion is conceptualized in diverse sociocultural groups based on how specific person–environment transactions are conceived.

A functionalist approach is also well suited to developmental analysis. One way that emotions develop, for example, is in how the generalized arousal conditions of early infancy mature into the more specific, organized, and refined emotional states apparent in older children and adults. Young infants do not necessarily experience or express emotions in ways that fit into the discrete emotion categories of English speakers, but appear instead to experience more diffuse affective systems that become progressively better differentiated as a result of early social experiences and socialization, cognitive growth, and psychobiological maturation. Studying this developmental process requires methodological creativity and breadth, as functionalist theorists suggest. Rather than relying exclusively on facial expressions as primary indicators of underlying subjectivity, for example, developmental researchers increasingly index emotion multimodally, integrating facial, vocal, and other behavioral indicators into an organizational interpretation in relation to the child's interaction with environmental opportunities and challenges.

2. What is Emotional Development the Development of?

The primary challenge of developmental analysis is understanding why developmental changes in emotion occur, and how emotional growth is associated with concurrent advances in social, cognitive, linguistic, and physical development. Exploring the various components of emotional development reveals how

emotional experience integrates significant aspects of psychological development in infancy and childhood.

2.1 Psychobiological Growth

Emotions are biologically basic features of human functioning. They are predicated on richly interconnected brain structures and hormonal influences that organize the interplay of activation and regulation that constitutes emotional reactions. The young infant's capacity to exhibit distress, fear, surprise, happiness, and rage reflects the early functioning of these biologically deep-rooted psychobiological systems. Emotional development is based, therefore, on neurophysiological, neuroendocrine, and other biological processes that change rapidly in infancy and childhood (LeDoux 1996, Panksepp 1998). For example, the developing stability of sympathetic and parasympathetic nervous system functioning in infancy helps to account for the growing predictability, manageability, and environmental responsiveness of the infant's emotional responding. Later in childhood, as higher brain regions (especially in the frontal neocortex) progressively mature and become integrated with early developing regions of the limbic system and other subcortical structures, emotional life becomes increasingly characterized by more acute emotion appraisals, complex emotional blends, and growing capacities for emotional self-regulation. Because an apparently simple emotional reaction is actually a surprisingly complex psychobiological event, developmental changes in multiple brain regions, hormonal functioning, and neurotransmitter regulation are involved in emotional growth.

2.2 Perceiving and Responding to Emotions in Others

Throughout life, emotions are evoked by one's perception of emotion in others. Infants are capable of discerning the emotional meaning in an adult's facial and vocal expressions before the end of the first year, and there is evidence that they respond resonantly to the sound of another infant's crying even earlier. Moreover, by the end of the first year, infants not only attend to the emotional expressions of adults but also incorporate the meaning of these expressions into their understanding of the adult's behavior. This phenomenon is called 'social referencing,' and it is analogous to how people enlist the emotional expressions of others into their assessment of their circumstances (Feinman 1992, Saarni et al. 1998). In a comparable manner, when a one year old encounters an unfamiliar person or object, the sight of a trusted adult's reassuring smile or terrified look (especially if it is accompanied by appropriate vocalizations and other behavior) significantly influences the child's approach or withdrawal tendencies. It appears that the infant 'reads' appropriately the meaning of the adult's emotional expression and its referential relevance to the unfamiliar event.

In the years that follow, advances in emotional understanding significantly expand the young child's capacity to respond appropriately and insightfully to the perception of emotion in others. By the end of the second year, for example, toddlers are more consciously aware of the subjectivity of emotional experience (i.e., another person can feel differently than oneself) and of the causes for others' emotions. This is often manifested when young children are observed comforting a distressed adult or peer, teasing a sibling, during pretend play, or even in humor (Denham 1998).

In early childhood, moreover, genuinely empathic responses to another's distress can be observed. Initially, young children respond with concerned attention to the sight and sound of another's distress, but empathic responses increase in sophistication and scope in the years following. Early empathy is not reliably accompanied by prosocial initiatives toward the distressed person because empathic arousal is a motivationally complex experience for young children (Zahn-Waxler and Radke-Yarrow 1990). Young preschoolers have been observed to laugh, tease, become distressed, and even hit a distressed parent, for example, as well as offering comfort. With increasing age and greater understanding of their own efficacy as prosocial agents, empathy becomes somewhat more regularly associated with helping others.

2.3 Emotional Understanding

The advances in emotional understanding accompanying conceptual growth enable children to better understand others' emotions, and also their own. Consistent with growth in their naive 'theory of mind,' for example, two to three year olds appreciate how emotion is associated with the satisfaction or frustration of desires (which vary for different people), and four to five year olds understand the more complex associations between emotion and thoughts, beliefs, and expectations (Bartsch and Wellman 1995). The latter is important because it contributes to the growing realization that emotions can be based on false beliefs or appearances (a peer anticipating a delicious dessert that is actually missing from her lunch bag), and that outward emotional appearance does not necessarily reveal underlying emotional reality.

In middle childhood, children begin to understand the dynamics of emotional experience, such as how emotional intensity gradually dissipates over time, how specific emotions are related to specific antecedent causes, and how a person's unique background, experiences, and personality can yield unique emotional reactions. By late childhood, children begin to

appreciate how multiple emotions can be simultaneously evoked by a single event, such as feeling happy and afraid when performing before a group (Saarni et al. 1998). Despite these conceptual advances, important features of emotional understanding do not emerge significantly until adolescence, such as an awareness of the psychological causes of emotion in relational experience, the experience of ambivalence or emotional conflict, and a grasp of complex emotional states (e.g., poignancy).

2.4 Emotion, Self-Awareness, and Self-Understanding

Emotional development is complexly tied to the growth of self-awareness and self-understanding in infancy and childhood. Prior to a dawning awareness of the self as a psychological entity, for example, a young child's emotional repertoire does not include self-referent emotions such as pride, guilt, shame, and embarrassment. Late in the second and during the third years of life, however, as young preschoolers reveal increasing psychological self-awareness (e.g., calling self by name, insisting on 'doing it myself'), these self-referent emotions begin to appear (Tangney and Fischer 1995). As young children begin to see the self as an object of analysis by others, and also by oneself, the simple joy of success becomes pride in achievement, and in response to conspicuous attention young children increasingly respond with gaze aversion, smiling, and other signs of embarrassment.

Emotional reactions to the self are significantly shaped by the reactions of others to the child. The development of self-referent emotions is advanced not only by growing psychological self-awareness but also by the young child's increasing understanding of behavioral standards and the ability to apply those standards to an evaluation of personal behavior (Kochanska and Thompson 1997). Guilt derives, for example, from an awareness of how personal behavior has departed from an acceptable standard. Parental reactions are crucial to the young child's dawning awareness and application of these standards of conduct, and indeed the earliest expressions of self-referent emotions commonly occur in contexts where young children can explicitly perceive, or anticipate, parental reactions to their accomplishments or misconduct. With increasing age, children appropriate parental standards that become the child's own internalized expectations for conduct. Thus the manner in which parents convey, reinforce, and attach emotional and relational significance to a young child's achievements or misbehavior is an important influence on the child's emotional life, and developing self-esteem and self-concept.

This underscores the complexity of the association between self-understanding and the growth of self-referent emotions. A dawning psychological self-awareness is necessary before self-referent emotions become part of a young child's emotional repertoire. Once these emotions are possible, however, the circumstances in which they are elicited and their relational consequences are significant for further growth in self-concept and self-understanding.

2.5 Emotion and Emotional Displays

One consequence of young children's developing understanding of the difference between belief and reality is the growing realization that emotional expressions may not accurately reveal underlying emotional reality. This awareness emerges at the same time that children discover the social expectations governing emotional expressions. A person is supposed to show delight when opening a gift in the presence of the gift-giver, for example, even if the gift is undesirable. This and other emotional 'display rules' governing the expression of emotions in social situations proscribe how emotions are used to avoid hurting others' feelings, protect self-esteem, and preserve relationships.

Young children do not understand display rules, but they can be observed using them as young as age four. Not until middle childhood do children grasp the nature and purposes of emotional display rules, but once they do so they can enlist them in their interactions with family members, peers, and others (Saarni 1999). As they do so, children also begin to appreciate the privacy of emotional experience: emotions need not necessarily be conveyed to others if one can manage emotional experience and its expression.

2.6 The Development of Emotion Regulation

One of the important differences between infants and adolescents is in their capacities for emotion regulation. Emotion regulation is distinct from emotional display rules because although the latter regulate the *expression* of emotion, the former manages emotional *experience*. People have many reasons for managing their emotions: to feel better under stress, elicit support from others, act courageously, resist bullying, enhance motivation, think better, and for many other reasons. Although the goals underlying emotion regulatory efforts are easily understood in very young children, these goals become increasingly complex and nuanced in the more complex social situations of older children. Competent emotion regulation may be observed, for example, when a child loudly protests a peer's provocations when adults are nearby, but quietly tolerates the bully when adults are absent. Moreover, in conditions of risk for developmental psychopathology, the goals underlying a child's emotion regulatory efforts may be complex, mutually inconsistent, and thus, in some senses, self-defeating (Thompson 1994).

In infancy, emotions are primarily regulated by others, especially parents. Parents manage a baby's

emotions by directly intervening to soothe the child, and also by regulating the emotional demands of familiar settings like home or child care (often in accord with their perceptions of the child's temperament), altering how the child construes an emotional arousing situation (such as by smiling reassuringly when a friendly, but unfamiliar, adult approaches the child), and later by actively coaching young children on expectations or strategies of emotion management. More broadly, the security that young children derive from their emotional attachments to caregivers is an important resource for emotion regulation because of the confidence it inspires that events will not be uncontrollable and that the adult will intervene helpfully when necessary (Cassidy 1994). Emotion regulation is fostered by others, in other words, not only by their immediate interventions but also by the reassurance provided by the child's relationship with a caring adult.

From an early age, however, young children are also developing rudimentary skills for managing their own emotional experience (Thompson 1994). This can be observed initially in the comfort-seeking of a distressed infant or toddler, but skills of emotion self-regulation expand considerably in early childhood. Young children can be observed making active efforts to avoid or ignore emotionally arousing events, changing or substituting goals that have been frustrated, redirecting activity or attention, using distraction, engaging in encouraging or reassuring self-talk, obtaining further information about the situation, or enlisting other simple behavioral strategies. In the years that follow, moreover, older children become increasingly proficient at enlisting psychologically more sophisticated strategies of emotion regulation, such as using emotion-blunting ideation, redefining the situation (or attributions for behavior), or acting in a manner inconsistent with felt emotion. The growth of strategies for emotion self-regulation occurs in concert with the development of emotion understanding and children's increasing psychological self-awareness, and contributes to developing social competence with peers and adults.

3. *Relational Influences on Emotional Development*

Emotions are not just the outward expression of an internal experience, but are deeply influenced by the social contexts in which they occur. Emotional development illustrates how early in life, intrinsically human and biologically fundamental response processes take shape in a social context.

Social influences on emotional development are especially apparent in children's close relationships with caregivers and other adults. Many things happen in their relationships with adults that guide the course of children's emotional growth (Thompson 1998). Early in life, the responsiveness of caregivers to a baby's emotions influences the frequency, persistence, and intensity of the infant's emotional signaling, as well as the baby's developing confidence in the adult's helpful assistance. The adult's emotional expressions influence the child's vicarious emotional and behavioral responses to events, in a phenomenon earlier described as social referencing. Parental behavior is often also a catalyst for empathic responding, especially when parents fix the attention of offspring on another's distress and carefully explain the causes of that person's feelings. As earlier noted, the behavioral standards that parents convey in their responses to good behavior and misbehavior shape the earliest experiences of pride, guilt, shame, and embarrassment, as well as developing self-concept and self-esteem. More broadly, the simple conversations shared by parents and their young offspring about the day's events help to color and socialize emotional understanding by how the parent describes and explains emotional experiences, attributes motives and emotions to people, and interprets the emotional events they have shared (Dunn 1994). Among the many things children learn from these conversations are the sociocultural rules governing emotional expressions in social situations. Finally, adults in close relationships are influential as they directly manage the emotional arousal of young children, and as they coach (and model) the child's use of personal strategies for emotion self-regulation.

Beyond these specific influences, the broader quality of the parent–child relationship provides a context of security and confidence, or of insecurity and uncertainty, that colors emotional growth and the development of emotion self-regulation (Cassidy 1994). In the security or insecurity of the parent–child attachment relationship that is inaugurated in infancy and maintained throughout childhood, young children experience reassurance that emotions are constructive, enlivening, and manageable facets of life experience through the support of others, or instead learn that emotions are potentially overwhelming and undermining events that are faced alone.

Because of the importance of these relational influences, the 'emotional climate' of the home is a significant influence on early emotional development (Gottman et al. 1997). The emotional climate is significantly shaped by sociocultural values, for example, that guide how emotions are socialized and how children learn to interpret their emotional experiences. In more extreme conditions, unfortunately, the home climate is characterized by the emotional turmoil created by marital dysfunction, parent–child interactions defined by coercion or abuse, or the adult's affective problems. In these circumstances, caregivers not only fail to be sources of emotional support for the child but they contribute to emotional demands that most young children find difficult to manage and which are, for many, potentially overwhelming (e.g.,

Cummings and Davies 1994). As a consequence, children are themselves at risk for emotional disturbance resulting from their inability to cope with the emotional demands they face, their enmeshment in the emotional turmoil of their caregivers, their heightened sensitivity to cues of emotional arousal around them, and their exposure to a compelling model of emotional dysfunction in the adults they live with (Garber and Dodge 1991). Sadly, studies of such children illustrate further the importance of close relationships to healthy emotional growth.

In more constructive family environments, by contrast, parents contribute to the child's growing ability to understand and enlist emotions constructively in social relationships, and enjoy emotional experience personally. In other words, they contribute to the growth of emotional competence (Saarni 1999).

4. *Future Directions*

This discussion reflects two themes that will guide future research on emotional development. The first concerns children's developing representations of emotional experience, especially as they predict children's responses to emotionally arousing events. How do children understand emotion and its influence upon them, and how does this affect their efforts to manage emotion and respond adaptively to situations that evoke emotion? How do these representations change with age and in concert with changes in other representational abilities? The second, and related theme, concerns the emotional dimensions of developmental psychopathology. How are relational influences, self-awareness, and other developmental processes relevant to emotional growth pertinent to how children cope with anxiety disorders, depression, conduct problems, and other emotion-related forms of psychopathology? Future research on both questions will advance normative understanding of emotional development, and its applications to clinical and other practical issues.

Infant and Child Development, Theories of

From infancy through childhood, and across the adult and aged years, individuals develop, showing systematic and successive changes over time (Baltes 1987). These changes are interdependent with variations in

people's families, communities, societies, cultures, and physical ecologies. Changes within one level of organization, for example, developmental changes in personality or cognition within the child, are reciprocally related to developmental changes within other levels, for example, involving changes in caregiving patterns or spousal relationships within the family (e.g., Lerner 1998).

Moreover, the reciprocal changes among levels of organization are both products and producers of the reciprocal changes within levels. For example, over time, parents' 'styles' of behavior and of rearing influence children's personality and cognitive functioning and development; in turn, the interactions between personality and cognition constitute an emergent 'characteristic' of human individuality that affects parental behaviors and styles and the quality of family life (e.g., Lewis 1997).

These interrelations illustrate the integration of changes within and among the multiple levels of organization comprising the ecology of human life (Bronfenbrenner 1979). Human development within this ecology involves organized and successive changes —that is, systematic changes—in the structure and function of interlevel relations over time (Ford and Lerner 1992). In other words, the human development system involves the integration, or 'fusion' (Tobach and Greenberg 1984), of changing relations among the multiple levels of organization that comprise the ecology of human behavior and development. These levels range from biology through culture and history (Bronfenbrenner 1979, Elder et al. 1993, Gottlieb 1997, Riegel 1975). Indeed, the embeddedness of all levels of the system within history provides a temporal component to human development (Elder et al. 1993); makes the potential for change a defining feature of human development (Baltes 1987); and as such assures that relative plasticity (i.e., the potential for systematic change across ontogeny) characterizes development across the human life span (Lerner 1998).

Given that human development is the outcome of changes in this developmental system, then, for individual ontogeny, the essential process of development involves changing relations between developing people and their changing context (Lerner 1998). Similarly, for any unit of analysis with the system (e.g., for the family, studied over its life cycle, or the classroom, studied over the course of a school year), the same developmental process exists. That is, development involves changing relations between that unit and variables from the other levels of organization within the human development system. Accordingly, the concept of development is a relational one: Development is a concept denoting systemic changes —that is, organized, successive, multilevel, and integrated changes—across the course of life of an individual (or other unit of analysis).

A focus on process, particularly on the process involved in the changing relations between individuals and their contexts, is at the cutting edge of contemporary developmental theory and, as such, is the predominant conceptual frame for research in the study of child development (Lerner 1998). These conceptual and empirical orientations represent the essential approaches within the preponderant majority of theoretically derived scholarship in the contemporary study of human development.

1. *The Evolution of Theories of Infant and Child Development*

The integrative, relational emphasis in current theoretical models of child development stands in contrast to the focuses of theories that predominated in developmental psychology in earlier periods (Cairns 1998). These theories often involved causal splits between nature and nurture (Overton 1998). On the one hand, these theories emphasized predetermined and biological (organismic) bases of development (that is, either genetic or maturational sources of change). Examples are attachment theory (e.g., Bowlby 1969), which stressed the importance for infant and child development of evolutionarily based, early-life interactions between the newborn and the mother; ethological theory (e.g., Lorenz 1965), which emphasized the role of purported instincts in establishing motor and emotional behavior patterns in development (e.g., as occurs when a precocial bird, such as a duck, follows—and forms an alleged immutable social bond, termed 'imprinting'—with the first moving object it sees after its birth); and behavioral genetics (e.g., Plomin 2000), which stresses that, to the extent that genetic differences between people account for the variance in trait distributions (e.g., in regard to interindividual differences in scores for characteristics such as temperament or intelligence), that trait is caused, within the person, by heredity (see *Behavioral Genetics, Psychological Perspectives on*).

On the other hand, some theories that subscribed to a causal split between nature and nurture looked to the environment as the source of behavior and development. Through a mechanistic reductionism (e.g., to the purported stimulus–response connections that comprised all behavior), these theories attempted to account for all changes in people's functioning across life. Examples include the theory of Bijou and Baer (1961), which stressed the application of classical and operant conditioning principles to child development; and the early social learning theories of Bandura and Walters (1959), which emphasized the observation and imitation of models as a basis for the social learning of behaviors displayed by developing children.

Other theories stressed more of an interaction between organismic and environmental sources of development. For instance, Piaget (1970) proposed a developmental theory of cognition, one wherein the

child's knowledge progressed through a series of universal, invariantly ordered, and qualitatively distinct stages that, progressively, involved the elaboration of internal and reversible cognitive operations (or actions). Cognitive development was thought to be propelled by an attempt by individuals to create a balance (an 'equilibrium') between (a) their efforts to change the environment to fit existing knowledge, and (b) their making changes in cognition (accommodating) to match the environment.

In turn, psychoanalytic theorists, such as Sigmund Freud (1954), stressed the importance of instinctual forces or energies (i.e., 'libido') and inborn (nativistic) personality structures (the 'id') in the stages of emotional (or 'psychosexual') development that he proposed as universally applicable to all people. Similarly, neopsychoanalytic theorists, such as Anna Freud (1969) and Erikson (1968), emphasized the role of emergent personality structures (i.e., the 'ego') in the maturationally based stages of emotional development they proposed. While both psychoanalytic and neopsychoanalytic theorists stressed the role of instinctual or maturational contributions to development, they believed that the environment could either change the rate of development across stages or, in extreme cases, arrest emotional development (a situation termed a 'fixation'; Freud 1954).

Nevertheless, despite these differences in emphases on nature, nurture, or the interaction between the two, there remained in the discipline a presupposition that there were two distinct sources of development, that is, that there was a theoretical split between variables associated with heredity and those associated with the context. In other words, there was a belief that the individual and the environment were able to be separated, not only in a conceptual sense but also in the sense of empirical reality. As such, it was the role of theory to explain the contributions of these two separate domains of reality to human development (Overton 1998).

2. *Dimensions of Contemporary Theories*

The stress in contemporary theories, however, is on a 'healing' of the nature–nurture split (Gottlieb 1997), and on accounting for how the integrated developmental system functions, that is for understanding probabilistic epigenesis. Gottlieb (1997 p. 90) defined this process as being 'characterized by an increase of complexity or organization—that is, the emergence of new structural and functional properties and competencies—at all levels of analysis (molecular, subcellular, cellular, organismic) as a consequence of horizontal and vertical coactions among its parts, including organism–environment coactions.'

As such, the forefront of contemporary developmental theory and research is represented by theories of process, of how structures function, and how functions are structured over time (Lerner 1998). For example, most contemporary research about child development is associated with theoretical ideas stressing that the dynamics of individual-context relations provide the bases of behavior and developmental change (Ford and Lerner 1992, Gottlieb 1997). Examples from the literatures of infant and child development include the study of infant motor development (Thelen and Smith 1994), skill development in childhood (Fischer and Bidell 1998), and parent–child relations and parenting during infancy and childhood (Collins et al. 2000).

Thus, in emphasizing that systematic and successive change (i.e., development) is associated with alterations in the dynamic relations among structures from multiple levels of organization, the scope of contemporary developmental theory and research is not limited by (or, perhaps better, confounded by an inextricable association with) a unidimensional portrayal of the developing person (e.g., the person seen from the vantage point of only cognitions, or emotions, or stimulus–response connections, or genetic imperatives; e.g., see Piaget 1970, Freud 1954, Bijou and Baer 1961, Plomin 2000, respectively). Rather, the power of the contemporary stress on processes of dynamic person–context relations is the 'design criteria' imposed on research, method, and application pertinent to the study of any content area or dimension of the developing person. This power is constituted by four interrelated assumptive dimensions of contemporary theories of child development (Lerner 1998). Accordingly, it is useful to discuss these dimensions in order to illuminate the key theoretical and methodological (e.g., research design and measurement) issues pertinent to understanding how biological, psychological, and contextual processes combine to promote behavior and development across the life span.

3. *Change and Relative Plasticity*

Contemporary theories stress that the focus of developmental understanding must be on systemic change (Ford and Lerner 1992). This focus is required because of the belief that the potential for change exists across the life span (e.g., Baltes 1987). Although it is also assumed that systemic change is not limitless (e.g., it is constrained by both past developments and by contemporary contextual conditions), contemporary theories stress that relative plasticity exists across life—although the magnitude of this plasticity may vary across ontogeny (Lerner 1998).

There are important implications of relative plasticity for the application of developmental science. For instance, the presence of relative plasticity legitimates a proactive search across the life span for charac-

teristics of people and of their contexts that, together, can influence the design of policies and programs promoting positive development (Birkel et al. 1989).

4. *Relationism and the Integration of Levels of Organization*

Contemporary theories stress that the bases for change, and for both plasticity and constraints in development, lie in the relations that exist among the multiple levels of organization that comprise the substance of human life (Ford and Lerner 1992, Schneirla 1957). Different models of these levels have been proposed. For instance, Riegel (1975) argued that these levels ranged from the inner biological level, through the individual/psychological level and the proximal social relational level (e.g., involving dyads, peer groups, and nuclear families), to the sociocultural level (including key macro-institutions such as educational, public policy, governmental, and economic systems) and the natural and designed physical ecologies of human development. In turn, Bronfenbrenner (1979) noted that there were instances of the social ecology of human development (such as the home or day care) within which infants and children interacted directly (he termed such settings 'microsystem'). In addition, Bronfenbrenner (1979) noted that there were connections among these microsystems (an ecological level he termed the 'mesosystem') and there were portions of the ecology (such as parents' workplaces) within which children did not interact but that, nevertheless, affected their behavior and development. Finally, he indicated that there was a higher order level of the ecology (the 'macrosystem') that, by being the 'seat' of broad cultural institutions and social policies, influenced all other levels of the ecology of human development.

Despite the terminological differences among these theorists, all were interested in the role of the context of human development and how fused, dynamic, or systemic relations between these levels and the child provided the basis of human development. All these theorists believed that these levels are structurally and functionally integrated with the developing individual, thus requiring a systems view of the levels involved in child development (Ford and Lerner 1992, Sameroff 1983, Thelen and Smith, 1994).

Developmental contextualism (Lerner 1998) is one instance of such a developmental systems perspective. Developmental contextualism promotes a relational unit of analysis as a requisite for developmental study: Variables associated with any level of organization exist (are structured) in relation to variables from other levels; the qualitative and quantitative dimensions of the function of any variable are shaped as well by the relations that variable has with ones from other levels. Unilevel units of analysis (or the components of, or elements in, a relation) are not an adequate target of developmental analysis; rather, the relation itself—the interlevel linkage—should be the focus of such analysis (Lerner 1998, Riegel 1975).

Relationism and integration have a clear implication for unilevel theories of development. At best, such theories are severely limited, and inevitably provide a nonveridical depiction of development, due to their focus on what are essentially main effects embedded in higher order interactions (e.g., see Wahlsten 1990). At worst, such theories are neither valid nor useful. Accordingly neither biogenic theories (e.g., genetic reductionistic conceptions such as behavioral genetics or sociobiology; Freedman 1979, Plomin 2000), psychogenic theories (e.g., behavioristic or functional analysis models; Bijou and Baer 1961), nor sociogenic theories (e.g., 'social mold' conceptions of socialization; e.g., Homans 1961) provide adequate theoretical frames for understanding human development). Simply, neither nature nor nurture theories provide adequate conceptualizations of human development (cf. Hirsch 1970). For instance, theories that stress critical periods of development (e.g., Bowlby 1969, Erikson 1968, Lorenz 1965), that is, periods of ontogeny constrained by biology (e.g., by genetics or by maturation), are seen from the perspective of theories that stress relationism and integration as conceptually flawed (and empirically counterfactual).

Moreover, many nature–nurture interaction theories also fall short in this regard; theories of this type often treat nature and nurture variables as separable entities, and view their connection in manners analogous to the interaction term in an analysis of variance (e.g., Bijou and Baer 1961, Erikson 1968, Plomin 2000, Wahlsten 1990). The cutting edge of contemporary theory moves beyond the simplistic division of sources of development into nature-related and nurture-related variables or processes; instead the multiple levels of organization that exist within the ecology of human development are seen as part of an inextricably fused developmental system.

5. *Historical Embeddedness and Temporality*

The relational units of analysis of concern in contemporary theories are understood as change units. The change component of these units derives from the ideas that all of the above-noted levels of organization involved in human development are embedded in history, that is, they are integrated with historical change (Elder et al. 1993). Relationism and integration mean that no level of organization functions as a consequence of its own, isolated activity. Each level functions as a consequence of its fusion (its structural integration) with other levels (Tobach and Greenberg 1984). History—change over time—is incessant and continuous, and it is a level of organization that is fused with all other levels. This linkage means that change is a necessary, an inevitable, feature of

variables from all levels of organization (Baltes 1987); in addition, this linkage means that the structure, as well as the function, of variables changes over time.

Indeed, at the biological level of organization one prime set of structural changes across history is subsumed under the concept of evolution (Gould 1977, Lewontin et al. 1984); of course, the concept of evolution can be applied also to functional changes (Darwin 1872, Gottlieb 1997). In turn, at more macro levels of organization many of the historically linked changes in social and cultural institutions or products are evaluated in the context of discussions of the concept of progress (Nisbet 1980). The continuity of change that constitutes history can lead to both intraindividual (or, more generally, intralevel) continuity or discontinuity in development—depending on the rate, scope, and particular substantive component of the developmental system at which change is measured (Brim and Kagan 1980). Thus, continuity at one level of analysis may be coupled with discontinuity at another level; quantitative continuity or discontinuity may be coupled with qualitative continuity or discontinuity within and across levels; and continuity or discontinuity can exist in regard to both the processes involved in (or the 'explanations' of) developmental change and in the features, depictions, or outcomes (i.e., the 'descriptions') of these processes (Cairns and Hood 1983).

Of course, not all people will change in the same way. One person may show rapid change, whereas another may change more slowly. Still another person may not change at all. Such differences in patterns of within-person change can occur in regard to any particular substantive area of development (e.g., intelligence, personality, or emotions). As a consequence, between any two or more times in life, and for any domain of development, there may be differences between people in how they change. In other words, there may be between-person differences (i.e., interindividual differences) in within-person change (i.e., in intraindividual change). When such between-person differences arise they are termed 'instability.' If, however, there are not such between-person differences present between two or more points in time, then stability is present. Baltes and Nesselroade (1973) have explained that in the study of human development across the life span one may find any combination of continuity–discontinuity (within person constancy or change) and stability–instability (between-people differences—in their respective patterns of intraindividual change. In other words, continuity–discontinuity is a dimension of intraindividual change and is distinct from, and independent of, stability–instability—which involves between-person change, and is, therefore, a group, and not an individual, concept (Baltes and Nesselroade 1973).

In sum, since historical change is continuous, temporality is infused in all levels of organization. This infusion may be associated with different patterns of continuity and discontinuity across individuals. The potential array of such patterns has implications for understanding the importance of human diversity.

6. *The Limits of Generalizability, Diversity, and Individual Differences*

The temporality of the changing relations among levels of organization means that changes that are seen within one historical period (or time of measurement), and/or with one set of instances of variables from the multiple levels of the ecology of human development, may not be seen at other points in time (Baltes et al. 1977, Bronfenbrenner 1979). What is seen in one data set is only an instance of what does or what could exist. Accordingly, contemporary theories focus on diversity —of people, of relations, of settings, and of times of measurement (Lerner 1998).

Individual differences within and across all levels of organization are seen as having core, substantive significance in the understanding of human development (Baltes 1987). Diversity is the exemplary illustration of the presence of relative plasticity in human development (Lerner 1998). Diversity is also the best evidence that exists of the potential for change in the states and conditions of human life (Brim and Kagan 1980).

Moreover, the individual structural and functional characteristics of children constitute an important source of their development (Lerner 1998). The individuality of each child promotes variation in the fusions he or she has with the levels of organization within which the child is embedded. For instance, the distinct actions or physical features of children promote differential actions (or reactions) in others toward them (Lerner 1998). These differential actions, which constitute feedback to the child, shape at least in part further change in his or her characteristics of individuality (Schneirla 1957). For example, the changing match, congruence, or goodness of fit between the developmental characteristics of children and of their context provide a basis for consonance or dissonance in their ecological milieu; the dynamic nature of this interaction constitutes a source of variation in positive and negative outcomes of developmental change (Thomas and Chess 1977).

The major assumptive dimensions of contemporary theories of child development—systematic change and relative plasticity, relationism and integration, embeddedness and temporality, generalizability limits and diverstiy—are very much intertwined facts of a common paradigmatic core. And, as is also the case with the levels of organization that are integrated to form the substance of developmental change, the assumptive dimensions form the corpus of superordinate developmental systems views of human development (Ford and Lerner 1992), for example,

developmental contextualism. As is the case with the several defining features of the life span developmental perspective, which—according to Baltes (1987)—need to be considered as an integrated whole, the assumptive dimensions of contemporary developmental theories need to be appreciated simultaneously. Such appreciation is required to understand the breadth, scope, and implications for research and application of this 'family' of conceptual frameworks.

7. *Conclusions*

Contemporary theories of child development and the research associated with it take an integrative approach to the multiple levels of organization presumed to comprise the nature of human life; that is, 'fused' (Tobach and Greenberg 1984) relations among biological, psychological, and social and physical contextual levels comprise the process of developmental change in human life. Rather than approach variables from these levels of analysis in either a reductionistic or in a parallel-processing approach, theories, such as developmental contextualism (Lerner 1998), rest on the idea that variables from these levels of analysis are dynamically interactive—they are reciprocally influential over the course of human ontogeny.

It is such ideas that shape an increasing proportion of the empirical work in the study of child development, especially those instances that reflect longitudinal, change-sensitive, multilevel, integrated, and dynamic approaches to the study of child–context relations. Only through such research will adequate understanding be developed of the bases and import of the multiple pathways that comprise the life span.

In turn, theoretical views such as developmental contextualism do not just provide an agenda for a developmental, dynamic, and systems approach to research about child development. Such theory also allows us to envision the possibility of promoting positive developmental trajectories in children (Lerner 1998). We may actualize this vision if we remain assiduously committed to a developmental systems orientation; if we recognize the 'double-edged sword' nature of plasticity that derives from the functioning of this system; and if we therefore create, through policies and programs, a social context that promotes positive development across the life course. Such a context would provide a social network encompassing the familial, community, institutional, and cultural components of the ecology that impacts people's behavior and development across their life.

Ultimately, then, there is great potential 'practical' (applied) value for developmental theories (Lewin 1943). Indeed, at the beginning of the twenty-first century there is growing recognition that traditional and artificial distinctions between science and service, and between knowledge generation and knowledge application and practice, need to be reconceptualized if society is to successfully address the harrowing developmental sequels of the social, economic, and geopolitical legacies of the twentieth century (Lerner et al. 2000). Scholars, practitioners, and policy makers are increasingly recognizing the important role that developmental science can play in stemming the tide of insults to the quality of life caused by poverty, premature births, school failure, child abuse, crime, adolescent pregnancy, substance abuse, unemployment, welfare dependency, discrimination, ethnic conflict, and inadequate health and social resources.

Successful application of the theory, substantive knowledge, and methodology of developmental science to the promotion of human capital will be determined by the extent to which research findings can be effectively related to problems of daily living (Lerner et al. 2000). Research designs that examine topics of immediate social concern, that consider both normative and atypical developmental pathways as means of promoting and enhancing human welfare, that take into account the contextual nature of development and employ ecologically valid means of assessing functioning, and that are sensitive to the ethical dimensions of action research are required if science is to make a difference in the lives of community members, young and old. Without such research, the knowledge produced by developmental scientists risks being ignored or misused by practitioners, educators, the public, policy makers, and other potential consumers. With such theory-derived research, developed by combining the assets of our scholarly and research traditions with the strengths of educators, practitioners, and policy makers serving the community, such collaborations can demonstrate that a science devoted to using its scholarship to improve the life chances of all people is of inestimable value to civil society.

Infant and Child Mortality: Central and Eastern Europe

1. Historical Outlook

At the beginning of the twentieth century, Central and Eastern Europe was handicapped compared with the West in terms of delayed socioeconomic development. Higher mortality rates for infants and children reflected this situation. While infant deaths per 1,000 live births in western and northern European countries ranged from 80 (Norway) to 150 (Belgium), Central Europe had levels exceeding 200: Czech lands, comprising the current Czech Republic, 225, Slovakia 207, Hungary 213, and Austria 216. The infant mortality

rate was equally high in Germany (199). In addition to delayed socioeconomic development, additional factors contributed to this unfavorable pattern—notably lifestyles, techniques of childrearing (breastfeeding, weaning, wet-nursing), and the status of children (Chesnais 1992). Eastern European countries had similarly elevated levels. In Romania, one-fifth of the children died before their first birthday. A slightly lower infant mortality rate was reported in Bulgaria (161) and Poland (163). In Russia, the areas with a predominantly ethnic Russian population had a rate of 298 infant deaths per 1,000 live births, in contrast to 188 in the other ethnic groups. A desperate situation in infant mortality was primarily attributed to the general socioeconomic underdevelopment of the country, habits and traditions associated with a predominantly rural culture, and an overall lack of knowledge about sanitary and health care. Infant mortality rates in urban and rural areas were virtually the same. The infant mortality rate in Russia tended to be much higher in the Orthodox population (263) than in the Catholic (151), Lutheran (161), and Judaic (116) populations. The observed differentials according to religious affiliation have been explained by different patterns of infant feeding (Zakharov 1994).

A long-term trend of decline in infant mortality in Europe started at the end of the nineteenth century, but Romania, Bulgaria, Albania, and Russia lagged behind. The decline was interrupted by peaks due to the two world wars. In Russia, the evolution was, in addition, disturbed by upheavals related to civil war (1918–22), famines (1921, 1933, and 1946), and forced collectivization. This unfavorable situation in infant mortality patterns of Central and Eastern European countries remained unchanged until after the end of World War II.

After World War II, Eastern Europe (now called Central and Eastern Europe) appeared as a new political region. This socialist bloc displayed strong inequalities in demographic behavior, economic indicators and social structures. In 1950, the infant mortality rate varied from 64 per 1,000 live births in the current Czech Republic to more than 100 in Romania, Bulgaria, and the former Soviet Union. In Western Europe the risk of infant death ranged from 21 (Sweden) to 55 (Federal Republic of Germany) at that time. During the communist regime in Eastern Europe, the effort toward massive schooling and rapid coverage of the entire population with basic health services reduced the greatest contrasts among the socialist countries as well as within individual countries. The downward shift in infant mortality rate was more pronounced for less economically advanced countries, and this led toward greater homogeneity. The progress was particularly strong during the 1950s when predominantly organizational measures led to decreases in infant mortality, as well as in maternal mortality (Štembera 1993). Since the 1960s, Western countries experienced a significant drop in infant mortality accompanied by an even stronger decrease in neonatal mortality and mortality of low-birth-weight babies. In contrast to Western countries, where special care policies were developed for high-risk pregnancies, uniform prenatal care was stressed in former socialist countries on the presumption that social risk differentials were nonexistent. The health-extensive approach based on a large-size medical staff with only basic training could not compete with a health-intensive system that involved specialized training and sophisticated equipment. As a consequence, infant mortality rates stagnated or deteriorated in all Eastern European countries. Data on infant mortality were not published in the USSR from 1974 to 1987 because of this increase.

2. *Current Trends*

During the postsocialist social and economic transition, such uniformity has been broken and previous inequalities have emerged again. In most former republics of the Soviet Union (FSU), the recorded infant mortality rate has increased (Blum and Avdeev 1994), partly due to the introduction (primarily in the Baltic States) of the standard WHO definition of a live birth. Infant mortality has decreased only slightly in the transition period in the Czech Republic, Slovenia, Slovakia, Hungary, and Poland. Recently (1996, 1997), an improvement has been observed in Estonia and Lithuania. With a 1999 infant mortality rate of less than five per 1,000, the Czech Republic and Slovenia are the closest to Western European standards.

2.1 *Age-specific Patterns*

The risk of infant death currently depends primarily on intrauterine development, and the role played by post-neonatal mortality is minimal (for children older than 27 completed days). The reduction and frequency of high-risk pregnancies determine the level of infant mortality. There are particularly strong differentials across countries in mortality in the early neonatal period (less than seven completed days), particularly for very low birth-weight babies (less than 1,500 g). At about 12 deaths per 1000 live-born children, the infant mortality rate in 1996 was twice as high in Poland as in the Czech Republic, due primarily to extremely high risks in the early neonatal period and/or low birth weight.

2.2 *Medical Causes of Infant Deaths*

Congenital anomalies and perinatal conditions are the most frequent causes of death in infants under the age of one year. The variation of infant mortality rate between these countries varies by a factor of three for congenital anomalies and by a factor of five for perinatal conditions. The lowest rates are in Slovenia and the highest in Latvia. Romania and Moldova are

in a rather exceptional situation in that infections and respiratory diseases are significant causes of infant mortality in the post neonatal period in addition to the previously mentioned groups.

2.3 Demographic and Social Factors in Infant Mortality

Demographic variables such as the mother's age and birth order have J-shaped profiles in conventional studies of infant mortality patterns. Differentials according to age and birth order are more pronounced in the Czech Republic, Hungary, and Poland than in Belgium, for example. The increase in the infant mortality rate is particularly striking after the age of 35 and for birth orders four and more. According to a special study for the Czech Republic from the period of 1986–92 (Rychtaříková 1999), the negative impact of higher birth order can also be seen in the interaction with mother's age (Table 1). The results concerning

relative risks (controlled for birth weight, duration of gestation, sex, mother's education, and marital status) suggest that to have an additional child at an 'inappropriate' age is risky. Thus, to have a second child at an age less than 20, to have a third child in the age group 20–24, or to have a third or fourth child at age 25–29 implies an elevated death risk for the child. Birth order also has social implications, because a higher relative risk of infant death is observed for children of a higher birth order even when the child has a normal birth weight (2,500g or more).

Two Central European countries (the Czech Republic and Hungary) have a gradient of age-specific infant mortality rates according to marital status similar to that of Belgium (Table 2). Lower values are experienced by children born to married women than to single, divorced, or widowed mothers (Rychtaříková 1995). In Belgium, differences in pregnancy outcomes are smaller between married and single mothers than in both these Central European countries. However, the pattern is inverted when the outcomes according to marital status are combined with low birth weight. Infants weighing less than 2,500 g have a better chance of survival when born to a single mother than when the mother is married (Syrovátkar and Rychtaříková 1984). A higher frequency of low birth weight in single mothers results in a higher crude (nonadjusted) infant mortality rate.

The impact of the education of mothers as a determinant of infant mortality could be questionable in an egalitarian society with weak social-class differentiation, and where health care and social opportunities are accessible to everyone. However, education is also a proxy for socioeconomic status and lifestyle. When birth weight is disregarded, the infant mortality rate decreases when the mother's educational level increases, as illustrated in Table 3. This pattern is also valid for children born in normal birth-weight categories. For lower birth weight (less than 2,500 g), a similar inversion occurred in the Czech Republic in 1988 and 1992. In this weight class, children born to mothers with no more than a basic education had the lowest infant risk of death. This phenomenon has also been documented in the US Afro-American population (Wilcox and Russel 1990).

During the period of postsocialist transition, children in formerly socialist countries have been more affected by the increase in poverty than other traditionally vulnerable population groups, such as the elderly. A number of countries also show some evidence of increasing child maltreatment, including the detrimental use of child labor. In Central and Southeastern Europe, unemployment and losses in family benefits have penalized families with children; in the successor republics of the FSU countries, an additional factor has been the dramatic rise in wage inequality. Also reflecting the effect of unfavorable social settings is the excess postneonatal mortality in Romania, Moldova, Ukraine, and Bulgaria (Fig. 1(a)). When child mortality rates at ages 1–4 and 15–19 years are correlated, most FSU countries show increased risks for teenagers. With the weakening of

Figure 1
(a) Mortality rates of infants below age 1 year in 1995;
(b) child mortality rates in 1995

social controls, new threats have arisen—drinking, smoking, drug abuse, sexually transmitted diseases, accidents, poisonings, and violence. The reappearance of diseases of poverty, including tuberculosis, has been reported among children. Historical inequalities observed at the beginning of this century are re-emerging today because of currently growing contrasts between former socialist countries in infant and child survival, including mother's health. In 1995, the maternal mortality rate ranged from about five maternal deaths per 1,000,000 live births in Central Europe (except Hungary) to more than 40 in Russia, Moldova, and Romania. Factors known as risky for pregnancy or infant/child survival have been significant in FSU countries, as well as in Romania and Bulgaria, where the ratio of legal abortions to live births—as well as the share of births to mothers below age 20—is high as compared with Central Europe. All countries in transition have poor access to health services and screening. The responsibility for monitoring children has been shifting from schools to parents. The system of family support has been eroded considerably during the period of transition. The observed deterioration of public health and family support systems has been disproportional, as has the development of infant/child mortality. Currently, four different regions are emerging in child health and infant mortality, namely, Central Europe, Southeastern Europe, the Baltic countries, and the other successor countries to the former Soviet Union.

Infant and Child Mortality in Industrialized Countries

In most industrialized countries, about five out of 1,000 newborn children will die before their first birthday. A similar risk level will not be reached again before age 60. The first year of life has a very high risk of death, especially when compared to the 10 or 15 years that follow. At those ages mortality is very low, namely less than 0.5 deaths per 1,000 children between the first and fifth birthday, and below 0.2 deaths between the ages of five and 15. Infant mortality (during the first year) and child mortality (during the four following years) are quite different from each other. Infant mortality essentially results from circumstances during pregnancy and delivery, as well as from congenital anomalies, while child mortality depends on several causes, among which accidents become increasingly prominent.

1. A Century of Continuous Improvement in the Struggle Against Infant Mortality

Infant mortality is measured by the infant mortality rate, which is usually computed by dividing the number of infant deaths (i.e., deaths before the first birthday) observed during a calendar year by the total number of live births during the same year. If the total number of births fluctuates widely, it may be necessary to distinguish infant deaths among births of the index year from those of births from the previous year, and to divide each one by the corresponding total number of live births.

At the beginning of the twentieth century, only a few countries had infant mortality rates below 150 deaths per 1,000 live births. Present rates are often between four and five deaths per 1,000. This is 25 to 30 times lower, and is due to important improvements during the late twentieth century. At the beginning of the twenty-first century we may hope for, not the disappearance of infant mortality, but at least a continuing further decrease to an even lower level of perhaps 3 per 1,000, something which would have been unimaginable in 1990.

Figure 1 shows infant mortality rates observed in England and Wales since 1840, and illustrates the scale and tempo of the changes in infant mortality. There was no progress in the nineteenth century, and the years 1880 and 1890 even showed an increase in mortality. It was only during the first years of the twentieth century that infant mortality started to decrease. It reached levels below 100 infant deaths per 1,000 live births by the end of World War I, and below 50 per 1,000 births by the beginning of World War II. In this 40-year period infant mortality was reduced largely to a third of its level at the turn of the twentieth century. This improvement was the result of general

Figure 1
Infant mortality rates: England and Wales (1840–1997) (deaths before one year for 1,000 living births)

progress in medicine, and also improvements in hygiene, especially concerning feeding practices. Since World War II, that is during a period roughly as long as the preceding one, the infant mortality rate in England and Wales was reduced to a seventh of what it had been. In particular, during the years immediately following the war, the diffusion of antibiotics helped reduce the infant mortality rate to less than 30 per 1,000 at the beginning of the 1950s. Since the middle of the 1980s, infant mortality has been under 10 per 1,000, and one might think that progress would have slowed down since then. Nothing of the kind has occurred, however. On the contrary, since the beginning of the 1990s even more important progress has taken place. Due to the increase in antibiotics the infant mortality crisis has practically disappeared. Until the beginning of the 1940s mortality risks were still acute at this age. England and Wales were among many countries who saw such a development. Comparable trends have been observed in all industrialized countries, although some started earlier and many others a little later.

2. *Persistent Differences Between Countries*

A few years after the end of World War II, there were important differences in infant mortality between industrialized countries (Table 1). In Europe, infant mortality levels can be organized approximately along two geographical axes: mortality increases from north to south, and mortality increases from west to east. A map of infant mortality can be drawn based on a 'center' from which mortality of newborn children goes up as one moves towards the 'periphery.' At the beginning of the 1950s, the situation was relatively satisfactory in only a small group of countries that included Scandinavia, the UK, The Netherlands, and Switzerland, which had rates roughly situated between 20 and 30 per 1,000. It was less acceptable in a second group, composed of Germany, France, Belgium, Spain, and Italy, which had rates between 40 and 70 per 1,000; and it was comparatively disastrous in other countries, namely in Central and Eastern Europe, where rates varied from 80 to 140 per 1,000.

During the subsequent years, all countries benefited from the diffusion of antibiotics and the resulting decrease of infant mortality, but improvements varied. Between 1950 and 1960 they remained under 30 percent for countries already more advanced in the struggle against infectious mortality, and they were also modest in the most isolated of Southern European countries (Portugal, the Balkans), in which infectious diseases are still deadly today. On the other hand, during the same period infant mortality rates were roughly halved in a whole group of Western European (Germany, France, Belgium, etc.) and Central European countries (Bulgaria, Hungary, Poland, Czechoslovakia, etc.). The average infant mortality rate for Europe as a whole decreased from 71 to 42 per 1,000, so there was an improvement of 41 percent. This does not include Eastern Europe, for which data for 1950 are unknown.

Between 1960 and 1970, the improvements were less impressive (31 percent for Europe as a whole), and the average infant mortality rate in 1970 was 29 per 1,000. No country had obtained a rate of less than 10 per 1,000, and the countries still showing rates of more than 50 per 1,000 were the same as before. These were still countries such as Portugal and, in particular, Albania and some Yugoslav republics.

The following twenty years showed stagnation in Eastern Europe and increasing improvement in Western Europe, with a demarcation line which reproduced the division between the two main geopolitical groups at the time. This development was especially clear during the 1970s: the average infant mortality rate was halved in the West, while it was only reduced by a third in the East.

In 1990, infant mortality in Europe was a picture of contrasts. In the West, no country except Portugal had an infant mortality rate over 10 per 1,000. In the East, all countries except Slovenia had rates above this threshold, and some even had 20 per 1,000 (Albania, Macedonia, Romania, Yugoslavia). The most recent data show the permanence of this division; except that a few countries of Central and Eastern Europe (Slovenia and the Czech Republic in particular) now record rates which are equivalent to those observed in the West.

Since 1950, the spectacular decrease of mortality in Europe has not been able to mask the stability of the respective positions of the various countries. Northern European countries, Switzerland, and The Netherlands have always held places in the highest rank, while the lowest ranks have always been occupied by Albania, Bosnia-Herzegovina, Macedonia, Romania, and Yugoslavia. Another clear phenomenon is the relative gap between the most advanced countries and the most backward ones. This increased until about 1980. At the end of the 1990s, it decreased but remained comparable with the differences of 50 years previously. The infant mortality rates of the three most advanced countries in 1999 were a fifth of those of the three most backward countries, just as in 1950.

In non-European industrialized countries, progress was similar to that in Western Europe. The case of Japan deserves special notice. In Japan, a country of 126 million inhabitants, the infant mortality rate (4 per 1,000) has been the same as in Sweden or in Switzerland, countries of only a few million inhabitants.

On the whole, the last years of the twentieth century were important years of improvement. Infant mortality has dropped to 5 per 1,000 in a growing number of countries, and this pace of improvement remains unbroken. There is surely no possibility of eliminating

every risk of death in this age group, as newborn babies are especially fragile, but a rate of roughly 3 per 1,000 might be reached in the early twenty-first century.

3. Components of Infant Mortality

Infant mortality is a complex and heterogeneous phenomenon. It depends on the circumstances of pregnancy and delivery, as well as on genetic factors. In addition it reflects the newborn child's fragility towards attacks from its external environment, especially infectious disease.

We can separate two large groups of causes, namely 'endogenous mortality,' which results from congenital anomalies, circumstances of pregnancy, or accidents during delivery, and 'exogenous mortality,' which results from external causes. As detailed statistical data about the causes of death are often missing, it was thought to be possible to distinguish these two components by an examination of deaths during the first year of life. An example is provided by J. Bourgeois-Pichat, who designed a graphic method for a biometric analysis of infant mortality at the beginning of the 1950s (Bourgeois-Pichat 1952). His method was based on the following hypothesis: every death which occurs in the last eleven months is exogenous. In any case it may be observed that the share of infant mortality assigned to months one to 11 is practically invariable both in time and in space; it does not depend on the level of infant mortality. Later observations showed that this hypothesis was not always correct. In fact, an approach based strictly on the length of life leads to a more operational result. We may distinguish between:

neonatal mortality, meaning mortality occurring during the first 27 days after birth, which is divided into *early* neonatal mortality for the first week, and *late* neonatal mortality for the three following weeks; and

postneonatal mortality, i.e. mortality occurring between the 28th day and the first birthday.

Moreover, in order to take into account the crucial characteristics of mortality at the time of birth and the difficulty in distinguishing between a child who died just before delivery and a child who died during delivery, the category *perinatal mortality* includes stillbirths and neonatal deaths (or even sometimes only the early neonatal deaths). Stillbirths are outcomes of conceptions presumed viable based on the length of the pregnancy or on the weight or height of the child.

Along with the various components of infant mortality just indicated, there are corresponding rates calculated either only from live births (neonatal and postneonatal mortality rates) or from the total number of births including stillbirths (the perinatal mortality rate).

Table 2 contains the components of infant mortality in most industrialized countries around 1995. (The countries are listed according to an increasing rate of infant mortality.) Early neonatal mortality, i.e., mortality during the first week, is higher than the other components except in Belgium, Moldova, and Romania. In fact, the mortality risks of the first year are mostly concentrated in the first early days of life. More accurate risk calculation, done on a day-per-day basis, shows that the first day in particular has a very high risk. Nearly 30 percent of the average total first-year deaths occur on this single day in countries where the infant mortality is under 10 per 1,000.

Differences between countries are more apparent with postneonatal mortality (a difference by a factor of 10 between Sweden and Romania) than with late neonatal mortality (a factor of 7 between Japan and Latvia). Late neonatal mortality is, in turn, more diverse than early neonatal mortality (from 1 to 5 between Japan or Sweden and Macedonia). However, these differences are smaller among the richest industrialized countries. For instance, between the 15 countries of the European Union, the ratio between neonatal mortality rates is as 1 to 2 between Finland and Greece, and a little more than 1 to 3 between Sweden and Belgium for postneonatal mortality.

The respective shares of neonatal and postneonatal mortality of total infant mortality have changed appreciably during the last few decades. Decrease of infectious mortality, again a result of increased use of antibiotics, brought about a rapid decrease of postneonatal mortality, thereby increasing the share of deaths occurring during the first four weeks of life. Progress in neonatal medicine has led to important success in detection and treatment of diseases of the newborn. That is why it has been possible to save more of these infants or at least keep them alive longer. More and more deaths due to endogenous causes occur after the first four weeks i.e., during the postneonatal period. But at the start of the twenty-first century the share of neonatal deaths is starting to increase again: it is at about 70 percent in the UK, Sweden, and The Netherlands, and it is over 60 percent in France. A mark of new progress can be seen in this increase: children whose lives were only extended by a few weeks or months are now being saved, or at least they increasingly reach the decisive mark of their first birthday.

4. Causes of Infant Deaths

It is difficult to compare causes of infant deaths in industrialized countries even though most of them have detailed statistical data at their disposal. Despite standardization efforts on the part of the World Health Organization, there are still national peculiarities in diagnosis, codification, and tabulation. However, some characteristics do emerge. The overwhelming majority of modern infant deaths are caused by conditions that originated in the perinatal period and by congenital anomalies. These two cause groups account for more than 70 percent of deaths and also have a striking age pattern. Congenital

anomalies and conditions originating in the perinatal period show up in the extreme frailty of the newborn children who die just after birth. Infectious diseases, notably those of the digestion system or the lungs, are only marginal, often under 5 percent. The rate of accidents is also very low, rarely over 3 percent of the total number of deaths, which is evidence of the protection and care afforded newborn children. Finally, sudden infant death syndrome is often responsible for anywhere between 10 and 20 percent of infant deaths, making it the primary cause of postneonatal mortality.

These remarks mainly pertain to countries that have mortality rates of less than 10 per 1,000. In other countries, especially in Central and Eastern Europe, where infant mortality rates are still over 20 per 1,000, infectious diseases have a more prominent place. A more accurate analysis of congenital abnormalities and of conditions originating in the perinatal period can be done with the help of the data for France in Table 3. From 1950 to 1994 congenital anomalies decreased by a little more than half, and conditions originating in the perinatal period decreased by nearly 90 percent. Within this group, mortality linked to complications during labor and delivery or to an obstetric trauma was not even cut in half, while other causes, particularly those linked to prematurity, decreased by 98 percent. Because of this differential development, the hierarchy of the various causes of deaths was modified appreciably, as follows:

(a) The difference between the frequency of deaths resulting from congenital anomalies and deaths due to conditions originating in the perinatal period is decreasing. If this continues, congenital anomalies could become the leading cause of infant mortality.

(b) Of the conditions originating in the perinatal period, the share of deaths linked to circumstances during delivery was raised to about two thirds (compared with only 15 percent in 1950).

These facts suggest that new improvements in the struggle against infant mortality are essentially derived from better detection of congenital anomalies, either permitting treatment 'in utero' or resulting in an abortion, and through new improvements in delivery conditions.

5. *Child Mortality*

Child mortality, that is death between the first and the fifth birthday, is measured by a rate equal to the ratio of the deaths of this age and the average population in the same age range. (This is different from the infant mortality rate, which is obtained by dividing the number of deaths by births.) In most industrialized countries this rate is under 0.5 deaths per 1,000 children of this age; the lowest rate in 1995 was 0.17 per 1,000 in Sweden. Only a few Central and Eastern European countries have a rate above 0.5 per 1,000, particularly Estonia, Moldova, Romania, and Russia, where it is over 1 per 1,000. Child mortality is much lower than infant mortality, as the rate of death between one and five years on average is one twentieth of rates during the first year of life.

Child mortality has dropped everywhere since the end of World War II, but the rate of improvement varies according to the country in the same way as in the case of infant mortality. In Northern Europe the child mortality rates, which had been below 1.5 per 1,000, were reduced between five- and eight-fold; whereas in the Southern European country Portugal child mortality is about one-twenty-fifth of what it was at the beginning of the 1950s.

These improvements reflect a decrease in the total causes of death at this age. For instance, in France all diseases causing childhood deaths were reduced by 90 percent between 1950 and the mid-1990s, and accidents decreased by nearly 70 percent. When one takes this differentiated development into account, the weight of accidents is increasing. In 1950 one in every six childhood deaths was due to an accident; at the end of the twentieth century it was more than one in three.

6. *Factors in Infant Mortality*

There are many factors that influence infant mortality, and they are apparent at every level. The following, simplified categories can be distinguished:

(a) political and socioeconomic factors of a country, which reflect its development, and its financial and organizational ability to supervise sanitation, to promote actions preventing infant mortality, and to create general access to health care, education, employment, and housing;

(b) factors connected with the child's mother, in particular those with a direct effect on embryo development and on children's health: life conditions, general state of health, and potentially harmful

behavior (consumption of tobacco or alcohol, and so on); and

(c) factors connected with the individual child, notably gender, length of gestation, and weight at birth.

In these complex categories, comprised of closely linked elements, it is difficult to isolate decisive factors. Obviously infant mortality depends on the interaction of many elements, such as the wealth of a country, the quality of its health-care system, the woman's marital status, the mother's conditions of life, her state of health, her genetic history, her level of education, her knowledge of child care, the health of the newborn, and so on.

Since we do not have a model for grading these various factors, we look to risk aggravating factors. Generally, infant mortality in industrialized countries is aggravated when the mother is poorly educated, single, inactive, or belongs to a disadvantaged ethnic minority. Therefore infant mortality follows a social gradient, and a newborn's probability of survival may vary according to the social environment in which it was born (Botting and Cooper 1993, Cnattingius and Haglund 1992, Macfarlane 1996).

Infant mortality is higher for boys than for girls. As both sexes are submitted to the same hazards at this age, higher male mortality is essentially biologically determined (Tabutin 1996). Infant mortality also varies considerably according to the weight of the newborn. The mortality of low-weight children (under 2,500 g) and of very low-weight children (under 1,500 g) is considerably higher than the mortality of heavier children. In Sweden, for instance, six per 1,000 newborn children died before their first birthday in 1990, but of the very low-birth-weight babies, 210 per 1,000 died during the first week of life. The relationship between birth weight and death risk deserves more attention, as the proportion of very low-weight children is now increasing in industrialized countries. This is due to two factors. First, the development of fertility treatment has resulted in an increase in the number of multiple births. Second, improvements in prenatal medicine enable children to be born who previously would have died during gestation or delivery.

Offsetting these risk aggravating factors, we may point out some risk attenuating factors. In particular, the number of pregnancies with a high risk factor is becoming less important because of changes in reproductive behavior. Women are postponing having their first children, and there are now very few families with a large number of children. This results in a lower number of pregnancies among very young and relatively older women. In addition, there have been improvements of detection of various malformations or pathologies in utero, and there is the possibility of either carrying out a therapeutic abortion or of treating such problems. Generally speaking, there have been improvements in techniques that allow for the birth and survival of the frailest children, and these tend to reduce the number of infant deaths, especially during the first week of life.

In the final analysis, it seems as if even lower infant mortality is possible in industrialized countries, especially if social inequalities can be reduced. In the more advanced countries expected progress is very restricted, but there is still the possibility of important improvement in Central and Eastern Europe.

Infant and Child Mortality in the Less Developed World

This year, more than 10 million children below five years of age have died, or will die around the world, over 90 percent of them in developing countries. This death toll represents about one child death every three seconds. The vast majority of these children are dying

from diseases preventable or treatable with simple and low-cost medical techniques. Tremendous progress has, however, been accomplished since the 1950s. The proportion of children deceased below age five declined from about 200 per thousand births around 1950 to 120 per thousand in 1980–5 and 80 in 1990–5. Improvement in health care and sanitation has resulted in the survival of 15 million children who would have died under the conditions of the 1950s.

1. *Mortality Measures*

Numbers of child deaths are rough estimates rather than exact measures because accurate data on child health and mortality in developing countries are not easy to come by. The most obvious measure is infant mortality, but only one-quarter of the world's population lives in countries where death recording is complete, and these are countries with the lowest mortality. However, major data collection efforts have been undertaken since the 1980s and techniques for estimating child mortality have improved so remarkably that it is now possible to make reliable comparisons among all the world's regions and to better understand disease processes in developing countries.

Two measures are traditionally used by demographers to characterize child mortality: the infant mortality rate and the under-five mortality rate. The infant mortality rate is the ratio of deaths below age one during a given calendar year to the number of live births during that same calendar year. The under-five mortality rate is the proportion of children who die before reaching their fifth birthday in a one-year cohort of live births. Both rates are usually provided per thousand births.

2. *Geographic Disparities*

The mortality of young children has declined everywhere around the world. The favorable trend observed at the regional level conceals, however, a wide diversity of situations (Fig. 1). The 50 least developed countries still experience an under-five mortality rate above 150 per thousand and differences between regions and among countries in each continent are increasing continuously.

Latin America has been the first developing region to benefit from medical progress. The decline started in the early decades of the twentieth century and has been continuous since then. Latin America is also the most homogeneous region of all. The overall probability of dying below five is around 50 per thousand. The two poorest countries, namely Haiti and Bolivia, still experience rates of 100 per thousand, but in many countries children survival chances are now close to those observed in Europe or North America (see *Infant and Child Mortality in Industrialized Countries*). This is particularly true in the Caribbean where under-five mortality rates around 10 per thousand are not uncommon.

Asia exhibits the largest internal diversity. The average probability of dying below five is about 75 per thousand but it ranges from 45 per thousand in Eastern Asia to 100 in South-Central Asia, a ratio of more than two to one. Variations are even wider among countries within the same subregion on the continent. To give but a few examples, the infant mortality rate reaches 130 per thousand in Iraq and 100 per thousand in Yemen, more than 10 times the level recorded in Cyprus and Israel, where it is now below 10. Similarly, in Southeast Asia, it is about 115 per thousand in Lao and Cambodia, compared to 10 per thousand in Brunei and only 6 in Singapore. But the overall level of mortality in Asia is largely driven by the two most populated countries of the planet, namely China and India, which experience rates of infant mortality of 45 and 80 per thousand, respectively, and an under-five mortality of 50 and 100 per thousand.

Africa remains by far the region with the highest level of infant and child mortality. 10 percent of all children die during their first year and nearly 15 percent before reaching their fifth birthday. Wide disparities are observed between Northern and Southern Africa on the one hand, where children below age five experience a probability of dying around 80 per thousand, and other regions on the other hand, where the probability reaches over 150 per thousand. Several African countries exhibit extremely high levels of under-five mortality: in Guinea, Guinea-Bissau, Malawi, Mali, Niger, Rwanda, Sierra Leone, and The Gambia, more than 20 percent of all children die before their fifth birthday. However, intraregional variations are smaller than in Asia because few countries have reached a level of infant and child mortality below 50 per thousand.

Intraregional disparities are the result of diverging trends much more than variations in the initial levels of mortality. Indeed, historical research suggests that the infant mortality rate was well above 200 per thousand in preindustrial Europe as well as in developing countries prior to the twentieth century (see *Mortality: The Great Historical Decline*). By 1950, Latin America already presented an average level of mortality significantly below the pretransitional level, by contrast with Asia and Africa. During the following decades, while mortality continued to decline in the former region, the other two main continents of the developing world initiated a significant improvement in the level of infant and child mortality (Fig. 2). In Asia, however, the decline was much faster than in Africa during the period 1955–75. While both regions exhibited similar levels of infant mortality around 1950 (about 180 per thousand), the proportion of children dying during their first year fell by 60 percent

Figure 1
Under-five mortality rate in 1990–5

Figure 2
Infant mortality rate by region: 1950–5 to 1990–5

in Asia, from 160 per thousand to 100 per thousand in 15 years. During the same period, the proportional decline reached 30 percent in Latin America and only 25 percent in Africa.

3. *Causes of Infant and Child Deaths*

As socioeconomic development proceeds, countries move through the epidemiological transition. The

concept was invented by Omran (1971) to describe the shift in disease composition, from infectious and parasitic diseases to congenital and degenerative diseases (see *Mortality, Epidemiological, and Health Transitions*). This trend parallels a change in the age structure of mortality, with an increase in the average age at death. More than 60 percent of all deaths are experienced by children below five in high mortality populations compared to 3 percent in industrialized nations.

3.1 The Predominance of Infectious and Parasitic Diseases

Most of these deaths are attributable to a small number of pathologies. Five diseases, or disease categories, are responsible for over 70 percent of all deaths under age five. The highest toll is due to acute respiratory infections, including pneumonia, the most common cause of illness and death among the children of the Third World. These diseases cause more than three million deaths a year among children below age five. Diarrheal diseases are a close second, with almost one in four of all child deaths. Measles continue to kill more than one million children annually and tetanus, another preventable disease, about half a million, about as much as malaria, to which more than 600,000 deaths are attributed. Most of these diseases also represent a high proportion of morbidity in industrialized countries. They are, however, much less lethal there because of the natural and induced resistance of the immune system of children born in these countries. Malnutrition is a major factor in the weakening of natural resistance, while immunizations are fundamental to the building of artificial resistance.

3.2 The Role of Malnutrition

The major role of nutrition in child mortality processes is now well documented (see *Health and Mortality, Body Stature as a Measure of*). The effect of malnutrition on mortality was overlooked for a long time because malnutrition hardly ever kills directly. Less than 200,000 deaths of children below age five are attributed to either marasmus or kwashiorkor, the most acute forms of malnutrition. However, recent research has demonstrated that malnutrition is an initial or aggravating factor in about 55 percent of all child deaths. Malnutrition is usually the result of a combination of inadequate dietary intake and infection. It affects over one-third of all the children under age five in the developing world.

There exist different kinds of malnutrition. Malnutrition can not only result from a deficiency of protein and energy but also from a lack of vital minerals and vitamins in children's diets. The 1990 World Summit for Children, which was organized under the auspices of the UNICED, singled out deficiencies of three micronutrients (iron, iodine, and vitamin A) as being particularly common and of special concern for children in developing countries. Zinc has been recently added to the list. The general effect of malnutrition is to lower the defenses in children's immune systems, resulting in a greater incidence, severity, and duration of common childhood diseases. Vitamin A deficiency makes children especially vulnerable to infections and worsens the course of many infectious diseases. Death rates in children lacking vitamin A are 20–30 percent higher than in other children. Vitamin A deficiency has been shown more particularly to reduce children's resistance to diarrhea and measles. Not only does malnutrition increase the probability of infectious and parasitic diseases, but diseases also speed nutrient loss and suppress appetite, provoking a vicious circle ultimately leading to death. For instance, in parts of Africa where malaria is common, studies show that about one-third of the cases of child malnutrition are caused by malaria.

In an attempt to reduce the incidence of malnutrition in the earlier months of life, international organizations such as the World Health Organization (WHO) and UNICEF have been actively promoting breastfeeding. Though breastfeeding durations have declined significantly since the 1980s due to the combined effects of commercial pressure and the increased participation of women in the labor force, such efforts have proved useful in encouraging breastfeeding in the poorest countries. Breastmilk contains all the nutrients, antibodies, hormones, and antioxidants an infant needs to thrive during the first six months of life. Breastfed children not only show better immune responses to immunizations, but they also exhibit natural resistance against a number of infectious diseases, gastrointestinal and respiratory in particular. By comparison, commercial infant formulas are an expensive and inferior substitute for breastfeeding. They are frequently overdiluted in order to save money and mixed with unsafe water before being fed to the child in unsterilized bottles capped with an unclean teat. Research indicates that in countries where infant mortality rates are high or moderately high, a bottle-fed baby in a poor community is 14 times more likely to die from diarrheal diseases and four times more likely to die from pneumonia than a baby who is exclusively breastfed.

3.3 Old Curses and New Threats

Old curses have recently intensified. Epidemics of plague and upsurges in cholera have demonstrated a surprising vitality of these diseases in parts of Africa, Asia, and Latin America. Malaria has also showed frustrating resistance to the many approaches tried to combat the disease. The parasite is no longer vul-

Figure 3
Relationship between the probability of dying below five and national income per capita

nerable to some of the most powerful antimalarial compounds available. For a time, the widespread use of pesticides reduced the incidence of the anopheles mosquito transmitting the parasite, but it, too, has developed resistance. In addition to such historically deadly diseases, new threats to the health of children have emerged, the most dramatic of which is undoubtedly AIDS.

AIDS is becoming a major killer of young children in parts of the developing world (see *Mortality and the HIV/AIDS Epidemic*). The AIDS epidemic is now a main public health issue in Africa and in parts of Asia, threatening millions of children with premature death. Its real impact is very difficult to measure because of a lack of statistical data and problems of diagnosis in the countries most affected by the epidemic. The burden of the disease has been steadily increasing for children since the early 1980s. According to recent estimates from the Joint United Nations Program on HIV/AIDS (UNAIDS) and the WHO, about 500,000 children below age 15 are now dying each year from the disease, and nearly 600,000 are newly infected. The majority of them acquire the infection directly from their mothers. Mother-to-child transmission of HIV, also known as vertical transmission, occurs during three segments of life: during pregnancy, during labor and delivery, and through breastfeeding. Recent research tends to indicate that a child stands the greatest risk of vertical transmission (about 20 percent) during the time of late pregnancy and childbirth. There is an additional 15 percent risk that an infant will become infected through breastmilk. Consequently, more than one in three of the babies born to mothers infected with HIV will themselves be infected. Most will die before the age of five. The cumulative number of children infected with HIV/AIDS reached more than six million by the end of the twentieth century, and the mortality of young children has been increasing up to 50 percent in countries most affected by the epidemic, mainly located in Eastern and Southern Africa such as Namibia or South Africa. In Zimbabwe, AIDS has already become the biggest single killer of the nation's under-fives.

In addition to its direct impact, AIDS also indirectly affects the health of children in developing countries. AIDS is an expensive disease. In communities with limited resources, the epidemic diverts a tremendous proportion of the available budget away from basic health care towards intensive care. In countries with mature epidemics, such as Uganda, Zambia, and Zimbabwe, some doctors report that three-quarters of the beds in hospital pediatric wards are occupied by children ill from AIDS. Another indirect effect of the epidemic is the dramatic increase in orphanhood. Nearly 10 million children have been orphaned in the 1990s because of the disease, more than 95 percent of them in sub-Saharan Africa. Because of the very slow changes in sexual behavior, the prohibitive cost of existing treatments, and the difficulty of developing an effective vaccine, the deadly impact of the epidemic is

expected to increase during the next decade in the most affected countries.

4. *Economic Determinants*

Poverty is viewed as the underlying factor of high child mortality in developing countries. Obviously, economic deprivation at the family level affects the health of children. A low purchasing power is related to poorer nutritional diets, the lack of ready access to a safe water supply and proper sanitation, as well as unhygienic conditions in and around homes. Such conditions are typically associated with a high prevalence of childhood diarrhea and they have significant implications for the spread of many infectious and parasitic diseases.

However, there is an unclear relationship between national income and the level of infant and child mortality. The wealthier countries are clearly those in which children are the least likely to die. As indicated by Fig. 3, countries with a GNP per capita above $5,000 have a level of infant mortality below 25 per 1,000. Yet, the relationship does not appear to be systematic to the extent that those countries faring the worse in terms of health and mortality are not always the poorest. There is a wide variety of situations among poor countries with similar levels of national income per capita. To provide but a couple of examples, while GNP per capita in the Lao PDR is significantly higher than in Vietnam ($370 vs. $240), infant mortality is half as high in the latter, reaching 50 per 1,000 compared to more than 100 per 1,000 in Lao. The contrast is even more striking in sub-Saharan Africa where the ratio of infant mortality reaches three to one in countries with the same level of GNP per capita ($500–550), such as Zimbabwe and Guinea, where the infant mortality rate reaches 50 and 140 per 1,000, respectively. Poverty *per se* is thus insufficient to explain geographic differentials in infant and child mortality across the world and other factors must be accounted for.

5. *Political Commitment*

Experience and research demonstrate that without a commitment at the government level, the health of children improves very slowly. Poor countries experiencing a low level of mortality relative to their level of socioeconomic development are those where a primary health care strategy has been implemented early and steadily at the national level, following recommendations first developed at the 1978 World Health Organization conference in Alma-Ata. The strategy associates direct medical intervention, such as immunizations and oral rehydration therapy, to nutrition programs, and to activities indirectly affecting health, such as hygiene, education, and family planning campaigns. China, Cuba, Vietnam, and Costa Rica are well-known examples of poor countries where the primary health care strategy has been successfully implemented. Even countries that have not been able to implement the strategy as a whole but only in part have benefited from a decline in child mortality.

In many regions of the world, the international community has played an important role in promoting primary health care services. WHO, UNICEF, and many other public or private organizations have worked with governments towards the goal of immunizing the world's children against six preventable diseases. Due to very active campaigns carried out during the 1980s, rates of child immunization against measles, tetanus, poliomyelitis, tuberculosis, pertussis (whooping cough), and diphtheria have risen from about 10 percent in the mid-1970s to 30 percent 10 years later and 80 percent around 1990. This achievement has meant the prevention of an estimated three million child deaths a year. However, the proportion of children vaccinated has leveled out since the early 1990s. In some of the poorest countries of Africa, immunization rates have even declined by about 10 percent.

In conclusion, dramatic progresses have been accomplished since the 1970s, so that children in many Asian and Latin American countries do not experience a higher risk of dying than those born in industrialized regions. There remain sources of serious concern for the future of child health in the most deprived areas of the Third World, however, and inequalities continue to increase among subgroups of national populations and among countries. The challenge is now to circumvent economic and political difficulties in order to implement the large-scale health interventions known to effectively reduce infant and child mortality.

Infant Development: Physical and Social Cognition

At the beginning of the twentieth century the received wisdom among psychologists was that human infants have virtually none of the cognitive skills they will later have as adults. Sigmund Freud had infants dreaming away their days in primary process (autistic) thinking, and William James described their phenomenal world as 'a blooming, buzzing confusion.' But since that time dramatic progress has been made in our understanding of infants' minds, and we now know that many of the basic structures of human cognition develop very early in infancy.

The modern era was ushered in primarily by the work of Jean Piaget. In a series of exquisitely detailed observations on his own three infants' ontogenies—first made in the 1930s but only made available to the international community in the 1950s—Piaget documented that from birth infants are actively and continuously exploring their environments, and that their cognition is already organized. On the basis of these observations, Piaget proposed a sequence of six cognitive stages, from birth to 18 months of age, that structured infants' interactions with the world. These stages were wholly general and governed the way infants could physically interact with the environment. He posited six levels of sensorimotor schemes (Piaget 1952), and for the kinds of knowledge infants could construct from these interactions, he posited six corresponding levels of knowledge of the physical world of space, time, causality, and objects (Piaget 1954).

Piaget's most general claim was that human infants are cognitive beings, it is just that their cognition is confined to the here-and-now of sensorimotor interactions with the world. Thus, for example, for very young infants objects only exist when they are interacting with them, and space is only experienced as self and other movement. The engine of Piaget's theory—the mechanism that takes infants beyond the sensorimotor level and on to more adult-like ways of conceptualizing the world—was action in the concrete sense of manipulation of objects. In Piaget's theory, neonates begin with their five senses totally uncoordinated and with objects as ephemeral perceptions only. But as they act on objects and perceive the effects of particular actions through the various different senses simultaneously, the senses become coordinated and so objects become objectified. Only by the end of the infancy period—after a vast number of sensorimotor interactions with the world—can infants cognitively and symbolically represent external entities in the absence of their own immediate perceptual contact with them.

1. *Beyond Piaget*

Although it gave infants credit for much more complex cognitive processes than its predecessors, Piaget's theory turned out to be still too conservative. The main problem was that Piaget depended almost exclusively on evidence provided by infants' spontaneously produced overt actions, and human infants are indeed very slow to develop motorically. But in the 1970s new methods were developed that enabled researchers to probe and test infants' cognitive competencies without relying on the production of complex motor sequences. These methods were much more experimentally rigorous than Piaget's, and exploited those few actions that infants are very skilled at and engage in frequently; for example, looking, sucking, kicking, and reaching.

The first of Piaget's proposals to fall was the proposal that infants possess five distinct and uncoordinated sensory modalities. In a seminal study, Spelke (1976) had young infants view two different films on adjacent monitors and at the same time listen to an audio recording that matched one of the two visual events (e.g., there was a noise every time an object banged the ground on one of the films). Infants as young as four months of age looked longer at the film that matched the audiorecording, suggesting at least some form of intermodal integration. At around the same time, Meltzoff and Moore (1977) discovered that newborn infants (less than 48 hours old) reliably imitated adult behaviors directed to them; such things as tongue protrusions and mouth openings. Given that infants perceive the adult face visually but perceive their own facial movements only proprioceptively, skills of intermodal integration were once again implied.

These two pioneering studies demonstrated that Piaget was wrong about early intermodal integration, but they did much more than that. First, if infants coordinate information from the different sensory modalities practically from birth, it is possible that this cross-modal information gives them a more objectified understanding of objects at an earlier age as well. These studies thus initiated a plethora of new research into infants' early understanding of the world of space and objects. Second, these studies and others that followed them demonstrated that infants possess considerable knowledge about the world before they can actively manipulate objects or anything else in their environments. Thus, Piaget's focus on action as the mechanism of development was called into serious question. Third, Meltzoff and Moore's study of

neonatal imitation in particular opened up exciting new questions about infants' early emerging skills for dealing with the social world—an arena of development about which Piaget had very little to say. Finally, and perhaps most importantly, Spelke's study demonstrated that infants' looking preferences could be used to ask very specific and very important questions about their cognitive skills. This new, child-friendly technique (along with the related technique of visual habituation–dishabituation) enabled researchers to answer questions about infant minds that Piaget never thought it possible to ask.

Buoyed by these spectacular new findings and powerful new methodologies, researchers in the 1980s and 1990s opened up a number of new and exciting windows on infants' cognitive development. These may be grouped, roughly, into findings about: (a) perception and learning, (b) understanding of the physical world, and (c) understanding of the social world.

2. *Early Perception and Learning*

Infants' perception of the world is surprisingly adult-like from a surprisingly early age. This general fact has been established mostly with habituation and paired-comparison techniques. In the typical habituation paradigm, infants are repeatedly exposed to a stimulus until their visual attention to the stimulus decreases to a pre-established level, essentially until they become bored with the stimulus. During a test phase, the infant is then shown a novel stimulus and the familiar stimulus simultaneously (i.e., paired comparison method) or one after the other (habituation method) and visual attention is again measured. If infants look longer to the novel stimulus, but continue to look away from the familiar stimulus, it is inferred that they can discriminate between the two stimuli. In such habituation studies, young infants discriminate among various properties of stimuli such as color, size, and shape (see Johnson 1998), perceive voices and sounds (e.g., Kuhl et al. 1992, Pegg et al. 1992), and even particular odors (Marlier et al. 1998). Other research has shown that much of this performance is based on cross-modal information. For instance, newborns manifest a visual preference for a novel image that corresponds to the shape or texture of an object that was previously orally explored (i.e., Meltzoff and Borton 1979, Gibson and Walker 1984). In addition, they reliably turn their head and eyes in the direction of a sound source, meaning that spatial location from this early age is specified by both auditory and visual information (Muir and Clifton 1985). By four months of age infants reach for an object that they see in the light, but will also reach when they only hear the object making a sound in the dark (Clifton et al. 1993).

Infants also are able to learn new things quite rapidly from soon after birth. Using instrumental learning paradigms, infants are reinforced for producing a particular type of behavioral response such as kicking their legs or sucking at a particular rhythm or speed. Infants readily learn such associations and are generally eager to modulate their actions to produce interesting outcomes. In one of the first studies to use such a paradigm, 4–12-month olds sucked on a dummy nipple to turn on a visual light display. With only three minutes of experience with such response–stimulus conjugation, infants significantly increased their rates of sucking compared to infants whose sucking produced no contingent outcome (e.g., Siqueland and DeLucia 1969, Kalnins and Bruner 1973, Lewis et al. 1985). In addition, newborn infants learn to modulate their actions to see an image of their mother as opposed to a stranger (Walton et al. 1992), to hear their mother's familiar voice or a story that was repeatedly read to them while in utero (DeCasper and Fifer 1980), and even to hear speech sounds from their native language (Eimas et al. 1971). Indeed, eight-month-old infants are so skilled at learning that they are able to pick up statistical patterns in their perceptual input with two minutes or less of exposure to a disembodied voice, played while the infant is playing on the floor and seemingly paying little attention (e.g., Saffran et al. 1996). Infants can extract these same kinds of patterns from other kinds of perceptual inputs as well; for example, sequences of arbitrary tones or even lights (Saffran et al. 1999).

3. *Understanding the Physical World*

Going a step beyond the perceptual abilities of infants, researchers have also designed paradigms to assess infants' physical knowledge at an age before they can even reach for or manipulate objects. Using one or another variation of the habituation technique, infants typically are familiarized with some event as they watch it several times; for instance, seeing one object pass behind a screen. Then during a testing phase, the infant sees the same event, but this time the screen is removed and the infant sees one of several possibilities. For example, they might see the original object in an improbable position, two objects, perhaps a different object in the position, or no object at all. As young as three months, infants look reliably longer at improbable compared to probable outcomes. From these kinds of studies, researchers have found that infants as young as two or three months possess much physical knowledge of the world and readily engage in physical reasoning about objects, relying upon principles such as object solidity, object continuity, the notion that two objects cannot be in the same location at one time, and the notion that objects exist continuously in space (see Spelke 1994, Spelke et al. 1992).

Similar techniques have also been used to assess infants' object concept more directly. In one classic study, commonly referred to as the Draw Bridge Study

(Baillargeon et al. 1985), infants were familiarized to a screen rotating alternately from upright to flat on a table. Following this familiarization phase, infants saw a solid object that was placed behind the screen, making it impossible for the screen to rotate flat onto the table. During a test phase, they saw either a possible event—the screen stopped moving at the position where the solid object would have obstructed its motion—or an impossible event—the screen rotated flat to the table, seemingly passing through the solid object. Infants as young as three months of age—before they are reaching for, grasping, or manipulating objects—looked reliably longer at the impossible event. These findings suggest that infants have a rudimentary concept of objects that enables them to reason about and predict their basic physical transformations. In a related series of studies, Wynn (1992) has shown that infants are surprised when they see one object disappear behind a screen and then, when the screen is removed, two objects are there (or they see two objects behind a screen but later only one is there). These studies evidence some basic understandings of quantities of objects as well.

Habituation paradigms have more recently been extended to assess the ability of young infants to relate objects to one another, to categorize them, and to recall information about them. In a study of infants' understanding of basic causal relations, six-month olds were habituated to either a noncausal event in which two objects moved independently or to a causal event in which one object collided into the other. Following habituation, infants then observed a reversal of the event. Infants who were habituated to the causal event looked longer when the causal event was reversed. In contrast, those infants who had watched the noncausal event did not seem to notice the role reversal (Leslie 1984). Dishabituation to role reversal only in the causal sequence suggests that infants detected the relations among these objects in the original events. Of course, the question of whether infants are endowed with an understanding of causal relations from birth or whether such understanding develops in a more progressive manner remains open (e.g., Oakes and Cohen 1990). In any case, such findings point to the precocious inclination of infants to perceive the relations and potential meaning among objects and events in the world.

In studies of categorization, infants are pre-exposed to one or more members of a particular category. They are habituated to these members and then shown a novel stimulus that does not belong to the category. As with traditional habituation paradigms, it is assumed that infants classify the stimulus as different from the familiarized category if they look longer to the new test stimulus as compared with a within category exemplar. Impressively, at least by the middle of the first year, infants come to represent a variety of categories such as spatial relations, geometric patterns, faces, and animals (e.g., Eimas and Quinn 1994, Quinn and Eimas 1987, Roberts 1988, Sherman 1985). Other common paradigms used to investigate infants' ability to categorize information have relied upon sequential touching or object manipulation. The sequential touching paradigm exploits infants' inclination to touch and explore objects, and is considered analogous to an adult-like object sorting behaviour. By 9–12 months infants simultaneously touch the objects from one category before touching objects from the other category and differentially categorize objects from global and basic-level categories (Mandler and McDonough 1993, Sugarman 1981).

In terms of early memory, using conjugate reinforcement paradigms in which they are reinforced to kick their legs in order to learn about the features of objects hanging from a mobile, young infants readily learn and recall experiences and retain this information over several days and sometimes weeks (i.e., Rovee-Collier 1995).

4. *Understanding the Social World*

Modern research has found that young infants also exercise impressive cognitive skills in understanding their social world. Soon after Meltzoff and Moore (1977) found that young infants would match some adult behaviors, Trevarthen (1979) and others discovered that they also interact with adults reciprocally in patterned ways. The first research of this type simply noted that young infants and their mothers interact with one another in a kind of turn-taking sequence, sometimes called a protoconversation (see Bullowa 1979 for a review). This discovery was followed by more rigorously controlled investigations.

Most important is the so-called still-face paradigm. In the traditional paradigm, infants engage for several minutes in a normal face-to-face interaction with an adult social partner. Then dyadic interplay is halted when the adult suddenly adopts and holds a neutral still face for about one to two minutes. Infants as young as two months respond to such perturbation with increased negative affect and gaze aversion (Tronick et al. 1978). This reaction to the still face is interpreted as the expression of social expectations by the infant and the sense of a disruption of positive coregulation (Muir and Hains 1993). Other evidence derives from the interpersonal contingency paradigm designed by Murray and Trevarthen (1985), in which infants interact with their mothers over a television monitor. In this study, infants sometimes watched their mothers interacting with them live, and at other times watched a replay of their mothers' behavior. At two months of age, infants reacted more positively to their mother interacting with them 'live' compared to watching a replay video.

The development of social expectations and the social behavioral repertoire of human infants develops rapidly over the course of the first year. It is also

important to note that subsequent work has established a number of compelling phenomena concerning neonatal imitation; for example, the fact that six-week-old infants will seek to reproduce even extremely novel behaviors (Meltzoff and Moore 1994). Nevertheless, there are still some investigators who are not convinced that what infants are doing in these studies is truly imitation, rather than something much less cognitively sophisticated such as preparing for object exploration (e.g., Anisfeld 1991, Jones 1996).

At around 9 to 12 months of age infants begin to engage in a new type of social interaction. Specifically, they begin to engage in interactions that are triadic in the sense that they involve the referential triangle of child, adult, and some outside entity to which they share attention. Thus, infants at this age begin to flexibly and reliably look where adults are looking (gaze following; Scaife and Bruner 1975), use adults as social reference points (social referencing; Sorce et al. 1985), and act on objects in the way adults are acting on them (imitative learning; Meltzoff 1988)—in short, to 'tune in' to the attention and behavior of adults toward outside entities. At this same age, infants also begin to use communicative gestures to direct adult attention and behavior to outside entities in which they are interested—in short, to get the adult to 'tune in' to them (Bates 1979). This revolution in the way infants relate to their worlds begins when infants understand other persons as intentional agents like the self who have a perspective on the world that can be followed into, directed, and shared (Tomasello 1995, Carpenter et al. 1998)—and it presages the emergence of symbolic language, the ultimate tool of joint attention (Tomasello 1999).

5. *Conclusion and Prospects*

The overall picture is thus of an infant much more cognitively competent than James or Piaget ever imagined. From the first few months of life, in many cases before they even reach for or manipulate objects, human infants perceive a world of stable objects, and they soon can categorize, quantify, and perceive causal relations among these objects in some fundamental ways. They also are especially attuned to other persons and interact with, and even imitate, them in special ways.

It is not the case, however, that all researchers agree totally on this picture. Of most immediate concern, some researchers have questioned the interpretation of studies based on preferential looking or habituation. The question is not about the findings themselves, but rather about whether they might be more parsimoniously interpreted as evidence of perceptual strategies and expectations, not high-level cognition (Bogartz et al. 1997, Haith 1998). Thus, while looking time measures indicate that four-month-olds show sensitivity to the solidity of physical objects (i.e., Spelke et al. 1992), if children are asked to physically interact with the exact same experimental arrangement they do not evidence the same sensitivity to solidity until two to three years of age (Hood et al. 2000). A major challenge for future research in infant cognition is thus to determine whether such findings simply reflect different extraneous task demands placed on relatively fragile cognitive beings or whether, instead, they reflect different processes of human cognition. Perhaps relevant to this question is recent research into the cognitive processes of nonhuman primates, who show many—but not all—of the same cognitive skills as human infants (Tomasello and Call 1997).

In all, recent research in infant cognition has been among the most exciting in all of the behavioral and cognitive sciences, unearthing on a regular basis infant competencies that few would have expected just a few decades ago. Research in the coming decades will be aimed both at making more such discoveries and also at determining what these discoveries mean in the larger context of human evolution and ontogeny.

Infant Education

Infant education in the family context, without any intervention program, is largely understood as a nondirective and caring activity for a baby to secure survival, to meet physiological as well as psychological needs, and to provide both emotional warmth and

cognitive stimulation well-tuned to the growing competencies of the infant. More than 'education' concepts like 'socialization' or 'enculturation' highlight the major targets of early child care and instruction under nonintervention conditions. The concept 'infant education' is used mostly to describe programs that have been developed by public institutions (state, community, church) and aim at children's competence enhancement at a very early age by intervention. Programs try to compensate early deprivations which encompass wider environmental and economical hardship in living conditions, as well as parental incompetence and disengagement to raise a healthy and competent child. Infant education addresses children directly by focusing on the infants as developing individuals and it is also directed towards parents and communities for establishing educational facilities which foster the infant, contribute appropriately to the maintenance of physical health, and provide stimulation and emotional attention for developing children's social and cognitive skills.

1. Definition of Concept

1.1 Addressees

Programs aim both at risk and nonrisk children. Risk children are children who grow up in poverty, with unmarried or divorced mothers, in a violent environment or with health problems. Nonrisk children do not show these characteristics, but they still may lack cognitive and social competence, good emotion regulation, and a feeling of well-being. The dual approach to reach both risk and nonrisk children emphasizes a group or even mass orientation rather than a focus on individual help. 'Education' in infancy is often associated with a too formal approach to teaching, but most programs do not only aim at reaching the children but include parents and address the quality of interaction between caretakers and infants. Thus, infant education can be defined as an institutionalized preventive intervention for families with infants.

1.2 Contents of Programs

Participants in these programs are parents who intend to maximize their child's potential at an early age, with the help of a mediating person (e.g. community support), or by giving the child into an institution such as special day care center. Infant education focuses on basic aspects of early development such as mutuality in mother–child interaction, emotion regulation, rhythm of attention, support for exploring, and aid that a child can learn to soothe him- or herself when being distressed or in need for comfort. Aside from stimulation and affectivity provided by the caretakers, infant education encompasses also the enhancement of developmental sensitivity in parents for age-appropriate forms of stimulation and attention. Some projects strongly concentrate their efforts on parents and teach them to implement the program during communication with children in order to compensate infants' possible deviations from a normative course of development.

2. Intellectual Context of Infant Education Programs

An old dream of mankind is to enlighten the entire next generation by appropriate education, to invent the 'superbaby,' that is, a new generation of human beings superior to the present generation. After longer periods of intellectual stagnation such as, for example, after World War II in the USA, a time characterized by prosperity and the Cold War in the 1950s, the so called 'Sputnik shock' mobilized public activities in the USA and Western Europe to identify unexploited intellectual capacities in the population. At the same time, new ideas and fantasies flourished about more equality and more liberty in a better society.

2.1 Programs Focusing on Finding More Intellectual Capacity and on Creating Increased Equality

Early intervention programs in the 1960s and 1970s concentrated mostly on cognitive stimulation. The main target group were African-American children from families living in poverty. The basic assumption underlying these programs was the belief that early intervention could help find intellectual reserve capacities, equalize chances at school entry, and support children in acquiring basic skills. Moreover, the intention was also to prevent educational, physical, social–emotional, and cognitive problems during later development. The curriculum movement during the 1960s believed that, in the sense of Amos Comenius, all things could be taught to all. However, evaluations of programs brought sobering results: After some immediate gain in IQ points during the program inside the institutions, children rapidly lost most of their gains outside the institutions (Schafer 1970).

Starting from these results, new projects were designed which focused more on a family, rather than in a child-oriented approach (e.g. Levenstein 1970). Mothers were included in the programs as teachers of their own children and this time results confirmed the expectations. Inclusion of mothers or even the entire family showed an increase in program effectivity compared with interventions where only infants were included.

2.2 Programs Focusing on Early Optimization of Learning Capacities

Stimulation at a very early age was believed to guarantee the highest degree of fostering the child's

available capacity. Infant education was driven by the philosophy that the more stimulation a baby receives, the better off he or she will be in later life. Early teaching was applied by parents who felt responsible for the children's chances to successfully enter college and university and later make it to the top. In expensive infant schools, toddlers were taught letters and numbers, they had to listen to the music of Beethoven, Mozart, or Bach, and they were confronted with paintings of Van Gogh, Matisse, or Toulouse-Lautrec. However, the intense teaching and emphasis on intellectual excellence was during a time when children need parental attention, warmth, and love to a high degree, and many experts in early development warned parents not to exaggerate their pressure for high achievement on the kids to become bright intellectuals and neglect their needs for social and emotional attention.

3. *History of Infant Education*

To enculturate a child as early as possible has been a salient issue already during the times of early humanism in Europe. After the long period of scholasticism new ideas began to emerge about the potential of infants and new education programs were formulated aiming at a general liberalization of human thinking. Contrary to Augustin (AD 354–430) who saw the infant as a two-edged subject, a rude, culture-free, and wild being on the one hand, and a hope in the future, a possible multiplier of Christian faith on the other. Beyond that, Anselm of Canterbury (1033–1109) was one of the first few scholars who formulated concrete guidelines for early education. Children should be supported from infancy on, given enough time for play, and instructed without physical punishment. Erasmus Rotterdamus (1466–1536) went a step further when he emphasized in his work 'on early scientific education of children' the eminent role of the mother for infant education. His friend and colleague Juan Vives (1492–1540) instructed mothers to talk very carefully to their children, particularly during the first years. Both Erasmus and Vives underlined the high responsibility of mothers for the quality of development in early childhood and stressed the importance of the dialogue between mother and infant.

3.1 *Theoretical Background: Evolution and Behaviorism*

Over time, tremendous changes occurred in the conceptualization of infant education. Beliefs about possible influences on infants' development run between the two extremes of 'nature' and 'nurture'; beliefs about what should be transmitted in education and enculturation can be found between 'conservation of tradition' on one end and 'creation of the new human being' on the other. After Darwin and his publication *Descent of Man* (1871), human development was seen by many as mirroring the evolution process of the human species. According to Ernst Haeckel, infant development was considered to 'replicate' human evolution. Intervention during the early years appeared to be rather ineffective or useless, the growth of skills and abilities was believed to be a kind of natural unfolding process (Hall 1883). However, the rise of animal psychology and learning theory at the turn of the century changed the view dramatically. Now, the infant was believed to be totally malleable by environmental manipulation (Watson 1928).

3.2 *Extension of Program Aims*

Behavioral roots and the belief that learning processes can be manipulated by changes in environmental conditions led to the early intervention programs in the 1960s which concentrated on children from poor and underprivileged families. When during the 1970s activities and competencies of infants were further investigated, early stimulation was believed to be a necessary prerequisite to optimize development. With the intention to maximize their children's potential at a very early age, middle-class parents began to teach their children academic topics by applying techniques of programs developed to boost underprivileged children. In the 1980, infant education changed its basic character from a compensatory to a competitive philosophy. The war on poverty in the 1960s turned to become a combat for enhancing the chances of middle-class children. 'Everyone wants to raise the smartest kid in America rather than the best adjusted and happiest kid' (Brazelton, cited in Langway et al. 1983, p. 44).

4. *Current Theory and Research*

Home environments had not been systematically observed for a long period of time. Since the 1930s, interest in the observation of children's natural environment had decreased dramatically, and there was no conceptualization about the transmission of deprivation from the larger environmental conditions to the children's proximal environments. In reaction to the nonlasting effects of cognitive improvements, new programs were started using mothers as teachers. Thus, children could keep a continuing relationship with the mother as the programs were addressing the mother–child dyad directly. Results showed that cognitive and emotional components seemed to reinforce each other.

4.1 Increasing Evidence of Infants' Early Social Competencies

Experimental studies have amply shown infants' early social competence to imitate their mothers' facial movements or even to restart a 'frozen' interaction with their mothers by producing new facial expressions to stimulate their communication partners (Tronick 1989). This research brought forward the idea that babies are capable to acquire skills—mostly intellectual ones—even at a very early age but that they also need a stable and warm relationship with a primary caregiver.

During the 1970s, studies comparing children with specific language skills with control groups showed the importance of the mother–child relationship for the acquisition of language (Baumrind 1971). The main difference consisted in the mode of verbal stimulation and interaction styles. Mothers of early competent children let their children continue their activities and did not intervene or disrupt, they changed their instructions according to the growing cognitive competence of their children, and gave more and more elaborate advices if required. Children began to ask for help in a more and more sophisticated manner. Those who were classified low in their competence had mothers who intervened, interrupted activities, and demanded to follow instructions. These children had less chances to explore and to understand. The best summary for these differences in learning conditions was given by Hess and Shipman (1965): 'The meaning of deprivation is the deprivation of meaning' (p. 885).

4.2 Emotional Implications of Early Day Care

From the 1980s on, the general use of day care increased considerably. Programs were now developed not to compensate children's growing up in poor environments but rather to meet the needs of working middle-class mothers to push their children to high cognitive abilities. Long debates began whether day care could be harmful to children's emotional development, particularly when Bowlby's (1973) concept of a 'secure base' as formulated in his attachment theory was considered. Detrimental effects for children under three years were expected when separated too long from their mothers. However, research on day care exhibited balanced results, taking day care as a given and collecting descriptive evidence about children's experiences in different kinds of day care programs. Quality day care was created as a demand for communities to consider the wealth of children as the highest criterium (Belsky et al. 1982). Belsky and Steinberg (1978) reviewed the main studies dealing with day care and pointed to the following results: day care has neither beneficial nor deleterious effects, children growing up in high-risk environments do have benefits, and early day care is not disruptive of the child's emotional bond with the mother.

5. Evaluation of Programs, Cognitive Effects in Longitudinal Studies

The first evaluation studies which tried to measure long-term effects of early intervention programs did not produce results that could easily encourage evaluators to implement more similar intervention programs. There had been quite a number of intervention programs for disadvantaged African-American children from lower social classes during the 1960s and early 1970s (Hess and Shipman 1965, Karnes et al. 1970, Schaefer 1970, Lambie et al. 1974). Most of these programs led to some gains in children's IQ, but gains did not persist for long after school entry. Later, a debate started about the usefulness of home-based versus center-based programs. In the end, consensus was reached that there are some long-term effects, when children's proximal environments, that is, their mothers or even the families, were included in the program.

5.1 General Factors Contributing to Long-term Effects

In a review evaluation describing long-term effects of early intervention programs on later academic achievement, Rutter (1987) mentions four aspects for continuous effects into middle childhood: '(1) IQ gains do not persist long after school entry unless the intervention also continues; (2) there are some modest lasting increments in scholastic achievements (in some studies only); (3) intervention is followed by some positive changes in the attitudes of children and parents, and of teachers toward the children; and (4) most especially, intervention results in a lower proportion of children requiring special educational treatment' (p. 1270). Quite similarly, the 'Consortium,' a group of independent researchers who studied long-range effects of early intervention (Lazar and Darlington 1982), found four overall effects of early infant education programs: (a) positive effect on meeting later school requirements, (b) significant gain in IQ points which lasted over time, (c) increase in self-esteem associated with higher performance in school, and (d) effect on positive maternal attitude toward the child's school performance. Rutter (1987) interpreted these results as the possibility of both a direct and an indirect impact on children's development such as improvement of cognitive performances and a positive influence on self-esteem on the one hand, and on attitudes toward learning in general on the other. Increased parental aspirations may trigger a positive cycle of achievement.

5.2 Specific Factors Contributing to Long-term Effects

More recent evaluations in the 1990s underlined the importance of family support in programs for infant education. For example, a program which first promoted family support and then offered preschool education in an institution could promote better preparation for school readiness and higher achievement in school. In the Carolina Abecedarian Project (CAP) and its replication, the CARE project, where the beginning of intervention was very early, at 6 to 12 weeks of age, and lasted longer with intensive care, up to five years of age, a whole scale of different activities and supports was offered to the participating families: full-day developmental day care, occasional home visits, parent–group meetings, on-site medical care and a toy-lending library. During school age, intervention lasted three years, and consisted of a home–school resource teacher who provided an average of 15 home visits per year to assist parents in supplementing school instruction (after Weissberg and Greenberg 1998, p. 904). These programs try to change parents' behaviors and attitudes toward both the child and the school (Schweinhart et al. 1993, Sameroff 1991). Such programs can also prevent delinquent behavior and maladjustment as newer studies have shown evaluating programs with frequent home visits which seem to enhance parents' competence and improve family functioning when this is also combined with a supporting community as a complementary component (Yoshikawa 1994).

6. Probable Future Directions of Theory and Research

After the experience of continuous disappointments of high hopes in changing children's environmental disadvantages by infant education programs during the 1960s and 1970s, and after a dramatic change in public interest from compensation to competition in early childhood, now the thinking about children and their healthy development in a changing society should find a new balance. In the late 1990s, the impact of new knowledge about infants' very early competencies on the one hand, and on dispositional as well as environmental effects on the individual course of development on the other has opened a more holistic view on children and their development. Physical, emotional, and cognitive growth are seen as being strongly intertwined. As evaluation studies have shown, intervention on only cognitive aspects did not lead to expected compensatory or optimization effects. It is hoped that early education will recover as a discipline which not only addresses disengaged parents of disadvantaged children on the one hand, and highly motivated and already highly privileged parents on the other, but as an area of research producing advice for all young parents. As dual earner careers in young couples having children need early instructions about the needs of infants and their developmental changes, the early cognitive stimulation is only a single component and not the entire gamut of necessary conditions which a child needs to grow up healthily. After a period of focusing on cognitive stimulation in children, perhaps now the time has come to emphasize other aspects such as relationship quality, emotion regulation, and early rhythm in mutuality between child and mother as prerequisites for the successful development of skills and abilities and the growth of life competence.

K. Kreppner

Infanticide and Induced Abortion

Abortion and infanticide are among the methods human societies and the individuals within them use to affect net fertility. Deliberate actions to prevent conception despite sexual intercourse are referred to as contraception, while actions intended to prevent a pregnancy from yielding a live birth are referred to as induced (as opposed to spontaneous) abortion, and actions intended to prevent a newborn from growing to a viable adult are referred to as infanticide.

1. Methods and Prevalence of Infanticide and Abortion

Infanticide has been observed among most mammal species and is recorded in nearly all human cultures. Infanticide is usually indirect, in that children are abandoned rather than being actively put to death (but see Boswell 1988, who argues that abandoned children were often raised by a third party, if only to be sold as slaves). In addition, some children die from other forms of extreme neglect verging on infanticide (e.g., by being left at a foundling hospital, by being accidentally smothered while sleeping in the bed with adults, or by being inadequately fed by a wet nurse).

In many premodern societies, infanticide appears to have been common and demographically important. Survivors of attempted infanticide figure prominently in Western literature (Moses, Oedipus). Reports for European cities in the eighteenth century suggest that a quarter of all children were abandoned to foundling hospitals, where the probability of surviving to adulthood appears to have been well below a third. Some forms of abortion were known in premodern societies (e.g., herbal remedies, massage, or insertion of foreign objects into the uterus), but they had substantially less than perfect effectiveness, often involved considerable risk to the woman, and do not appear to have been widely used (though the prevalence of abortifacients in the premodern period is the subject of some scholarly debate; see Van de Walle 1994). In Western Europe and the US, abortion appears to have become more effective and demographically important in the mid-nineteenth century.

In the modern period, most abortions are performed surgically, using vacuum aspiration (in which, often under local anesthesia, the uterus is emptied through suction induced by a syringe or a pump) or dilation and surgical curettage (in which, usually under general anesthesia, the cervix is dilated and the lining of the uterus is scraped). Legal surgical abortion performed during the first three months of pregnancy is much safer to the pregnant woman than a live birth (death rates of about 1:100,000 vs. 10:100,000); rates of complication and death are much higher for illegal abortions performed outside of regular medical facilities.

More recently, a medical approach to inducing abortion within three weeks after a missed period (7 weeks after the last period) has become widely available. This method, called RU-486/miferpristone/Mifeprex, has been widely used in Europe since 1988 and was approved for use in the US in 2000.

In addition, medical approaches on the boundary between contraception and abortion have become better publicized and more widely available. Specifically, special purpose 'morning after pills' or even a high dose of some oral contraceptive within three days after intercourse cuts the probability of pregnancy by about 75 percent, apparently by inhibiting ovulation or preventing a fertilized egg from implanting in the uterus (a process that usually takes six to nine days after intercourse).

Because of its ambiguous legal and moral status, information on abortions is difficult to collect. Not even all countries in which abortion is legal collect information on abortions as part of their vital statistics system. Furthermore, even when such reports are collected they often appear to be too low (in the US perhaps by 10 percent). Survey-based prevalence estimates appear to be even lower (in the US perhaps by 40 percent) and the degree of under-reporting is not uniform in population subgroups. These problems with survey data are likely to badly bias survey-based estimates of pregnancy rates and contraceptive failure rates. Thus, our knowledge of the prevalence of abortion is poor.

The available evidence suggests that the prevalence of surgical abortion varies widely (see Henshaw et al. 1999). Worldwide there were estimated to be about 46 million abortions per year in the mid-1990s (slightly less than half of them illegal). This figure implies about 35 abortions per 1000 women age 15 to 44 (the 'abortion rate'), about 26 abortions per 100 known pregnancies (the 'abortion ratio'; though note that the

abortion ratio is sometimes defined as abortions per live birth), and on average about one abortion over each woman's lifetime (the 'total abortion rate'). In Russia and several other countries in Eastern Europe, the total abortion rate is above 2; in most of Western Europe and the English-speaking countries the rate is below, often well below, one-half. In the United States, the rate is 0.69. Asia, Africa, and South America are between these two extremes, but with considerable intra-regional variation.

In the US, for which detailed information is available (Koonin et al. 2000), the abortion ratio peaked in the mid-1980s and has since fallen by about 15 percent. (The patterns for the total number of abortions and the abortion rate are similar.) About 43 percent of all women are projected to have an abortion during their lifetime. Finally, 58 percent of women having abortions report that they had used a contraceptive method during the month they became pregnant, though usually the less effective methods (over half were using the condom) and the available evidence suggests that the methods was not always used consistently or correctly.

Pregnancies are most likely to be terminated by abortion for relatively young and old women (about a third of all pregnancies for women under 25 or over 40), for blacks (compared to whites; a third vs. a sixth), and for unmarried women (40 percent vs. 7 percent). About half of all abortions are the woman's second or higher-order abortion. These and other characteristics of those having abortions suggest that abortions are more common among those who lack financial and social resources and perhaps have too little control over their lives. Finally, while women sometimes choose to abort because of rape, incest, fetal abnormalities, and threats to their physical health, the overwhelming share of abortions are due to conventional motivations for family planning—not wanting another child now (or ever) because of financial considerations, relationship problems (not married, not wanting a child with this partner, lack of support from current partner), and life course issues (still in school, age).

2. *Attitudes Towards Infanticide and Abortion*

Evolutionary biology suggests that infanticide should be rare. Natural selection acts to maximize reproductive success. Infanticide appears to lower the number of offspring. Thus, we would expect a taboo on infanticide. Infanticide is, however, known in many mammal species and in most human societies.

More general models suggest, however, that infanticide can increase the net number of surviving offspring and thus is likely to be the result of natural selection. Specifically, given the very long period from birth until independence for humans and given the hunter-gatherer ecology in which the human species is understood to have evolved, attempting to raise two closely spaced children was likely to lead to the death of both of them. Anthropological evidence from modern hunter-gatherer populations suggests that prolonged breast-feeding led to interbirth intervals of three to four years. If a birth occurred despite breast-feeding, infanticide would increase the net number of surviving children. Similar analyses apply to the birth of twins and unhealthy infants (Scrimshaw 1984).

Moreover, modern Western discussion of infanticide, abortion, and even contraception has been strongly affected by Judaeo-Christian perspectives on the value of life and the need to treat human beings as ends, not means (see Posner 1992). Depending on when—for the purposes of defining murder—'life' is considered to begin, infanticide or abortion may be 'murder' or at least morally problematic (though perhaps balanceable against other considerations; e.g., the health of the mother, rape, and genetic defects). Most modern legal systems consider 'life' to begin at birth, so under this definition infanticide is murder, but abortion is not. It is, however, important to note that in modern Western societies, even the taboo on infanticide is not absolute; many individuals would allow a profoundly deformed or severely mentally retarded newborn to die. In contrast, the Catholic Church treats a fetus as a full-person (until 1869 from 'quickening,' thereafter at conception) and thus views abortion as murder.

Even for those who do not consider 'life' to begin until birth, abortion is morally ambiguous since the fetus represents a potential life. Polling data for the US suggests considerable ambivalence about abortion and its appropriate legal status and strong opposition in some subpopulations. On the other side, proponents of abortion advocate it as a form of fertility control, as a way of saving lives of women who would have illegal abortions, and in terms of the right of a woman to make informed and voluntary decisions about childbearing.

The combination of the moral ambiguity of abortion and strong institutional opposition from the Catholic Church and conservative Protestant groups has led to legal regulation of abortion in many countries. Abortion was almost universally illegal in the early twentieth century. This first changed in the early years of the Soviet Union, where from 1920 to 1936 abortion was legal, widely available, and encouraged as the primary method of fertility control. In the period after World War II, abortion was first legalized in the Scandinavian countries, much of Eastern Europe, and Japan; and later in most of Western Europe. In the US, several states legalized abortion beginning in the mid-1960s, and in 1973 abortion became legal nationally with the controversial Roe vs. Wade decision of the US Supreme Court finding a constitutional right to abortion before viability (at that time, 28 weeks; with improving medical technology, several weeks earlier).

At the beginning of the twenty-first century, abortion is legal in almost all of Europe (though restricted in Germany) and most of Asia (sometimes, as in the case of Bangladesh, in the form of 'menstrual regulation'; see Dixon-Mueller 1988), but illegal in most of Africa and South America. In many of the places where abortion is illegal, the abortion rate is nevertheless substantial (e.g., much of Africa and Central and South America). Furthermore, the strictness with which such laws are interpreted and the frequency of prosecution vary widely.

Even in places where abortion is legal, in particular the US, and Southern and Eastern Europe, the specific conditions under which abortion is allowed (e.g., permissible reasons, gestational age, facilities and practitioners, parental notification or consent for minors, counseling and waiting periods) are often restricted by law. In addition, the details of those regulations and whether government health programs fund abortions are politically salient (e.g., they appear in public referenda, are issues in campaigns for public office, cause problems for the funding of foreign aid) and fluid. Similarly, abortion has been prominent at UN conferences and policy debates about family planning.

3. *Behavioral Models and Empirical Analyses*

Standard models for the use of contraception suggest that the prevalence of abortion should be affected by the perceived costs and benefits of children (and their determinants), the broadly defined cost of abortion (i.e., monetary costs, time costs, and psychic costs), and the broadly defined cost of other methods of fertility control.

Beyond these insights from the general theory of fertility control, theoretical approaches to abortion focus on the temporal position of abortion between conception and birth. This approach suggests two paths to abortion. First, especially in places where contraceptives are difficult to obtain, some women do not contracept, planning that if they become pregnant, they will abort. Second, some women do contracept but plan (sometimes only implicitly) to abort if they experience a contraceptive failure. The limited survey evidence suggests that both paths are important. In the US, slightly more than half of women having abortions report that they were contracepting at the time of conception; the rest were not using any method.

Abortions following contraceptive failure appear to result from two different phenomena. First, the standard modern life-course—early initiation and high prevalence of sexual activity and a desired family size of about two—implies that many women must contracept for over 200 months. Thus, even given consistent use of contraceptive methods with low failure rates (e.g., the oral contraceptive), a sizeable fraction of all women will experience an unintended pregnancy during their lifetime; many of them will choose abortion. Second, among those nominally contracepting (i.e., using any method at some time in the previous month), some subpopulations have high pregnancy rates. Such rates appear to be due to a combination of selection of a method with a high use failure rate (for example, the condom, chosen partially because it protects against sexually transmitted diseases) and inconsistent and ineffective usage of the method (e.g., not taking every pill every day). These two phenomena lead both to abortions and to high rates of voluntary sterilization.

Social psychological considerations also appear to be important. Some women choose not to contracept because of ambivalence about their sexuality (e.g., they deny that they are sexually active, or that they plan sex). Other women choose not to contracept (or not to contracept effectively) because they underestimate the probability of conception (e.g., they underestimate their own fecundity or they overestimate the effectiveness of their method as used) or highly discount the future. For these women, abortion is a second chance that allows them to remedy the effects of their earlier denial or incorrect perceptions.

Finally, some women choose abortion rather than contraception because they learn something because of the pregnancy. Particularly in parts of Asia, it appears that abortion is used as a tool for sex selection and yields an imbalanced sex ratio. Similarly, some women become pregnant in order to learn the true intentions of a partner, and abort if the revealed intentions are unfavorable. Some empirical studies find an increase in nonmarital births with lower costs of abortion, which is consistent with this motive for abortion. These ideas have been extended to models of equilibrium in the labor market, where they imply that the availability of abortion lowers women's bargaining position in the marriage market and reduces the marriage rate. (Men need no longer promise marriage in order to get sex and need no longer marry a woman if she becomes pregnant; Akerloff et al. 1996.)

Statistical analyses of the determinants of abortion and the effects of abortion regulation have been hampered by the difficulty of measuring abortion rates. Early work considered country-level time-series for contraception, abortion, and fertility. More recent work has applied difference-of-difference methods to time-series of cross-sections data to explore the effect of specific public policies and abortion access on abortion and fertility (e.g., Joyce and Kaestner 1996, Klerman 1999, Levine et al. 1999).

Rational-choice analyses using dynamic programming methods suggest that raising the cost of abortion should be expected to increase both contraceptive use (and other methods for fertility control such as decreasing coital frequency and delaying marriage) and realized fertility. While abortions are often common even when abortion is illegal, legalization of abortion in Europe and the US sharply increased

abortion rates and decreased fertility. In addition, public funding of abortions in the US through Medicaid appears to raise abortion rates and lower fertility rates for blacks. Given poor measurement of contraceptive prevalence, it has been difficult to estimate the effect of changes in the cost of abortion on the prevalence of contraception. In principle, the effect could be detected as the difference between the change in the number of abortions and the number of births. The clearest case appears to be Romania's banning of abortion after a period when it was legal. The number of births increased much less than the previous number of abortions (even after accounting for illegal abortions) and there were reports sharp decreases in coital frequency. Similar effects appear to have been present when abortion became legal in other countries of Eastern Europe, especially when experience with contraceptives was of short duration (Frejka 1983).

Similarly, decreasing the cost of contraception should be expected to increase contraceptive prevalence. This should prevent unintended pregnancies, some of which would have been terminated by abortion; thus lowering both the abortion rate and the fertility rate (see Rahman et al. in press for evidence from Bangladesh). Such substitution has been used to explain the simultaneous increase in contraceptive prevalence, decrease in abortion, and decrease in fertility in Russia in the early 1990s, in Hungary in the late 1960s and early 1970s, in Japan in the 1960s; and in Kazakhstan in the 1990s with the introduction of a USAID contraceptive distribution program. Similarly, the (broadly defined) low costs for contraception, easily available without stigma, appear to explain high rates of sexual activity, high rates of contraception, but low rates of abortion and low fertility in Western Europe.

Infectious Diseases: Psychosocial Aspects

Infectious diseases are illness caused by invasive pathogens, such as viruses, bacteria, fungi and parasitic infestations. When the germ theory of disease was established by Pasteur and Koch in the nineteenth century, a mechanistic view of infectious disease became dominant, with illness depending on exposure to the agent and the virulence of the infection. However, the ascent of immunology in the mid-twentieth century shifted the balance towards a recognition that the strength of bodily defenses plays a significant role in infectious disease.

Psychosocial factors are relevant to the experience of infectious disease in two principal ways.

(a) Psychosocial factors may influence the acquisition of infection or the reactivation of latent infection. Much recent research on upper respiratory illnesses such as the common cold and on herpes virus infections (genital and oral herpes) has been directed at this possibility.

(b) Psychosocial factors may affect the course of infectious illness once it is developed, influencing the duration and severity of symptoms.

Readers interested in more detailed overviews of psychosocial aspects of infectious disease are referred to recent reviews (Cohen and Williamson 1991, Zorrilla et al. 1996, Steptoe and Cohen 1999).

1. Mediating Processes

There are four general processes through which psychosocial factors such as acute and chronic life stress, social support, and coping may influence the acquisitional course of infectious disease.

1.1 Exposure to Pathogens

Since infectious diseases are caused by pathogens, any changes in exposure that are stimulated by psychosocial factors may influence the chances of becoming ill. For example, some people respond to distressing events in their lives by seeking social support and mobilizing social networks. This might have the unwanted effect of exposing the individual to more respiratory infections. Alternatively, people may respond by social withdrawal, reducing contact with airborne pathogens. Differences in exposure to infections resulting from crowding and other factors probably account for much of the socioeconomic gradient in conditions such as infectious mononucleosis (glandular fever). Exposure to pathogens is a key issue in the prevention of outbreaks of serious waterborne, airborne and sexually transmitted infections in the developing world, but little psychosocial research has yet touched on this topic (Aboud 1998).

1.2 Changes in Behavior

Health behaviors and lifestyle have an influence on infectious disease. Smoking, alcohol consumption, and physical exercise all influence vulnerability to infection and the duration of symptoms. Malnutrition is probably the principal cause of diminished immunity and susceptibility to infection across the world. Although severe protein energy malnutrition is rare in developed countries, undernutrition is common among the elderly and impairs immune resistance. If the pattern of health behaviors is altered in relation to psychosocial factors such as life stress, then the acquisition and course of infectious disease may be modified. Behaviors can have direct effects on infectious disease, such as when sexual behavior stimulates the reactivation of latent herpes virus, or the acquisition of human papilloma virus and risk of cervical cancer. Behaviors related to health service utilization are associated with socioeconomic status in the developing world, and play an important role in determining risk of diseases such as malaria (Castilla and Sawyer 1993).

1.3 Symptom Reporting

People vary substantially in the extent to which they attend to physical sensations and recognize them as symptoms of illness. Research on illness behavior has shown that the same infection may elicit quite different levels of complaint, work absence, and health service utilization, depending on levels of psychosocial stress. Negative affect also influences symptom reporting and illness behavior, with more symptoms being reported in distressed individuals independently of objective illness (Feldman et al. 1999).

Figure 1
Schematic outline of the link between infection, immune defenses, psychosocial factors, and illness

1.4 Suppression of Bodily Defenses

The final possibility is that psychosocial factors influence susceptibility and the course of infectious disease by modifying physiological defenses. Depending on the infectious agent, skin abrasions, immune processes, or mucosal barriers may be involved. One of the principal interests in psychoneuroimmunology research has been the possibility that psychosocial factors reduce immune defense, allowing infections to become established that would otherwise be resisted. These hypothetical associations are illustrated schematically in Fig. 1 (Steptoe 1998). The upper panel illustrates the pattern of healthy normal response to minor infections, where the individual mounts an adequate defense that excludes the infection and prevents illness. In the lower panel, exposure to the infectious agent takes place against a backdrop of impaired immune function due to psychosocial stimulation that is not sufficient to prevent illness from developing.

These mediating processes are not mutually exclusive, and one of the difficulties in research on infectious disease lies in teasing out the various pathways through which the acquisition or duration of infection are affected.

2. Methodological Aspects

The processes mediating between psychosocial factors in infectious disease outlined in Sect. 1 have important implications for how research on this topic is carried out.

2.1 Verification of Infection

Interpretation of associations is enhanced greatly by objective verification of infection. If infection is assessed merely by the subject or a family member, then it is not possible to rule out symptom reporting biases, and spurious associations between psychosocial factors and unfounded symptoms may be identified. Objective verification allows the timing of infection in relation to psychosocial stimuli to be established, so that causal sequences can be described. The most precise verification is possible in experimental studies of infection, where volunteers are infected deliberately with metered doses of virus or bacteria. The acquisition of infection then is assessed by culturing samples obtained some days later. Unfortunately, biochemical verification of infection is difficult and invasive in naturalistic studies, requiring repeated sampling of blood or nasal washes (for upper respiratory infection) from the individual under investigation. As an alternative, clinical examination by health professionals or trained observers is valuable for objectively assessing the occurrence of infection.

2.2 Standardized Measures of Symptoms

Since symptom reporting can be influenced by psychosocial factors independently of objective infection, it is important to reduce variability by employing standardized measures. These measures detail the number, type, and duration of symptoms. Work on upper respiratory infection, for example, typically assesses 10–14 standard symptoms of colds. Such indices are particularly useful in assessing the duration and severity of symptomatic episodes.

2.3 Measures of Health Behavior and Biological Factors

One of the most important implications of the discussion of mediators in Sect. 1 is that adequate measures are taken of social activity, smoking, alcohol consumption, sleep patterns, diet, and other health behaviors. Analysis of these variables will establish whether changes in health behaviors account for variations in vulnerability to infections. Measurement of hormonal and immunological factors is of course extremely interesting in developing an understanding of mediating biological processes.

2.4 Longitudinal Designs

Many studies of infectious disease have utilized cross-sectional or retrospective designs, with assessments of the frequency of infection in the past, along with measures of stress and other factors. Such studies have been used to find out whether the number of infections over the past month or year was greater among individuals who experience more life stress or have poorer social supports than others. Cross-sectional and retrospective studies are limited in the inferences that can be drawn, since selective recall biases may operate. For example, it is possible that individuals with depressed mood will recall more episodes of infection, and also report more negative life experiences or poorer social supports than others. As with many topics in health psychology, the most convincing data derive from longitudinal studies in which psychosocial factors are assessed prior to illness, so that prospective links can be established. Studies involving repeated measures of psychosocial, behavioral, and biological factors are particularly strong, since they allow the time course of vulnerability to be established.

3. Experimental Studies

Many studies have investigated factors such as stress in relation to infection in animal models. Animal studies do not suffer from many of the methodological problems inherent in human research, but are limited

in terms of the subtlety of psychosocial investigation. This literature has been reviewed recently (McCann et al. 1998, Rabin 1999).

Experimental studies of infection in humans are of course rare, and are only justified for mild forms of disease. But an important program of work on colds and other upper respiratory tract infections has been conducted by Sheldon Cohen and colleagues in the UK and USA that throws considerable light on the role of psychosocial factors. In these studies, volunteers free of infection are inoculated with standard doses of a virus. If an appropriate dose is administered, not everyone will become ill. Differences in the subsequent rates of infection and illness must, therefore, be due to differences in vulnerability. Social activities are limited by quarantine, and health behaviors such as smoking are controlled, so psychosocial impairment of bodily defenses can be evaluated.

Cohen et al. (1991) demonstrated with this paradigm that susceptibility to common cold viruses was associated directly with a psychological stress index created through an amalgam of measures of major life events over the past 12 months, perceived stress and negative affect. The dose–response association was independent of age, allergic status, and other risk factors. Later work has established that chronic stressors such as long-term work problems and relationship difficulties are particularly relevant. By contrast, social networks have a protective effect, with lower susceptibility to experimental infection among volunteers with more extensive and diverse social networks. Cohen et al. (1997) found that the rates of infection and illness were more than four times greater in volunteers with limited social networks, compared with high social networks, after adjustment of control variables.

These studies have established clearly that psychosocial factors can influence vulnerability to infectious disease. They have been less successful in identifying psychobiological mediators, since susceptibility is not associated with catecholamines, cortisol, or various markers of immune function. However, more recent work from Cohen's group has shown that associations between psychological stress and the severity of symptoms were related to the levels of the inflammatory cytokine interleukin-6 (IL-6) production in the nasal passages following influenza administration. More severe symptoms were experienced by participants who reported higher perceived stress, and were accompanied by raised IL-6. This suggests that inflammatory mediators may be involved in symptom production in stressed individuals.

4. *Colds and Upper Respiratory Illness*

Upper respiratory illnesses are caused by many different types of microorganism. The common cold is a viral infection, and more than 200 different viruses have been implicated. Acute sore throats are commonly caused by streptococcal bacterial infection, while influenza is a viral disease. Naturalistic studies of psychosocial factors in upper respiratory illness involve assessing spontaneous illnesses in people living their everyday lives. They have shown similar effects to those identified in experimental studies, albeit with less control over confounding factors (Cohen and Williamson 1991, Steptoe and Cohen 1999). For example, a number of studies have followed volunteer populations over several months with periodic measures of life stress, coping, health behavior, and illness. It has been demonstrated in both adults and children that susceptibility to colds is greater in people who experience high rather than low life stress. Interactions between life-events stress and social support have also been observed, with lower incidence of colds among individuals reporting high support. In addition, episodes of upper respiratory infection have been shown to be preceded for one or two weeks by high levels of perceived stress or a high frequency of minor life events (hassles). Since the acquisition of an infection is followed by several days of incubation, studies of this kind suggest the pathways outlined in Fig. 1 (right panel) may be operating. However, it is not yet proved feasible to obtain detailed neuroendocrine or immunological data in naturalistic studies. The mediating mechanisms therefore remain unclear, and it is possible that some of the associations observed are due to changes in exposure to pathogens rather than psychobiological influences on bodily resistance.

5. *Psychosocial Influences on Symptoms*

The interaction between the brain and the immune system is two-way, with behavioral function being affected by immune responses as well as psychosocial factors influencing the immune system. It has been recognized over recent years that the behavioral concomitants of infectious disease such as lethargy, loss of appetite, increased sleep, and loss of interest in the outside world are stimulated in part by immune products such as interleukin-1 (McCann et al. 1998). These cytokines are released as part of the biological response to infection, and help to coordinate the pattern of behavior that conserves and protects the organism, and may thereby be adaptive in promoting survival.

In humans, psychosocial factors not only affect susceptibility, but also the duration and severity of symptoms. This has been studied in relation to upper respiratory illness. In experimental inoculation studies it has been found that symptom reporting is associated positively with perceived stress and with certain personality profiles. Patterns of psychological coping are also relevant. One study assessed the duration of

symptoms of naturally occurring colds in a sample of children (Turner Cobb and Steptoe 1998). Prior to the study, patterns of coping had been assessed with standardized measures. It was found that children who typically dealt with stress using problem-focussed coping strategies tended to suffer from colds for a relatively short time. In contrast, children who stated that they used avoidant coping strategies such as distraction and social withdrawal experienced colds of longer duration. These effects remained significant after statistical adjustment for gender, age, family composition, social class, parental smoking, and parental alcohol consumption. It is possible that those who used distraction and avoidant coping strategies failed to respond directly to their illnesses, and did not take the necessary steps in terms of self-care and activity restriction that might prevent lengthy episodes of symptomatic disease.

6. *Recurrence of Herpes Virus Infections*

Herpes simplex viruses cause a range of diseases, the most common of which are oral herpes (cold sores) and genital herpes. Different types of herpes virus cause the two diseases. Both forms of herpes infection are common and typically benign, though they may cause considerable distress. In more than half of cases, the virus is not eliminated following first infection, but becomes permanently established in sensory ganglia. In some individuals the virus is reactivated periodically, and this leads to a recurrence of infection. Reactivation is partly under immunological control, and may take place when immune surveillance is impaired by psychosocial factors.

Studies of both types of herpes infection have been carried out which suggest that, in some cases, recurrence of infection is preceded by periods of negative mood or stress. Colds also seem to be important in the triggering of recurrent oral herpes. A meta-analysis of 16 studies indicated that depressed mood was associated with recurrence of herpes simplex virus infection, while stress was not (Zorrilla et al. 1996). However, the models of stress that have been employed in this area have been relatively simple. They have evaluated the experience of stressors alone, and not the interaction between stressors and psychosocial coping resources.

Another type of herpes virus is Epstein–Barr virus (EBV), responsible for infectious mononucleosis (which may present as a sore throat). A few studies have shown that stress and negative moods are associated with this type of infection. Interestingly, there is also psychoneuroimmunological work that throws light on the role of EBV. It has been shown that antibody titers for EBV are raised by life stress, for example, during the period prior to important academic examinations, or in people experiencing marital conflict (Kiecolt-Glaser et al. 1988). A raised antibody titer suggests that EBV has been reactivated, and allowed to replicate due to failure of immune control. If unchecked, the reactivation may lead to fresh episodes of illness.

7. *Other Infections*

One important type of infection with extensive psychosocial ramifications is human immunodeficiency virus (HIV); this will not be discussed here, since it is examined elsewhere in the Encyclopedia. Other types of infectious illness such as urticaria, streptococcal throat infection, and tuberculosis have also been studied, but data are too limited to draw general conclusions. A large range of more severe infections such as poliomyelitis, rabies, and salmonella have been investigated in animals, with evidence for increased vulnerability with exposure to psychological stressors (Peterson et al. 1991). However, there are important variations with species, age, concomitant disease and prior exposure, and these make it difficult to draw simple inferences for humans.

8. *Conclusions and Future Directions*

It is likely that research on psychosocial influences on infectious disease will become increasingly important over the next decade. One reason is that it is now recognized that infection and inflammatory processes play an important role in 'noninfectious' diseases such as coronary atherosclerosis, peptic ulcer, and gastric cancer (Lorber 1996). Limited psychosocial research on these conditions from the perspective of infection has been carried out. Indeed, most research on psychosocial aspects of infection has been carried out on a limited group of infections, and much remains to be learnt about resistance to fungi, parasites, and other microorganisms. The recognition of the importance of psychosocial factors in vulnerability and adaptation to infectious disease may lead to new and more effective methods of helping people cope with these illnesses.

Inferences in Discourse, Psychology of

If listeners or readers understand discourse, they understand much more than what is stated explicitly in the sentences. On the basis of their knowledge of the language and their knowledge of the state of affairs in the world, they are able to understand what has been left implicit in the text but is intended to be communicated. In text (a),

> (a) There were municipal elections yesterday. Because the majority of the lower town voted for the local party, there was a shift toward the left in the city council. But the right-wing party was not completely disappointed. It had expected to lose much more.

readers can infer that the local party is a left-wing party; that there is a causal relation between many people voting for a particular party and that party getting a stronger representation; that there are height differences in the town and that the town is probably located on a river bank; that the city council used to be more right-oriented; that there is a contrast between the shift toward the left and not being completely disappointed, and consequently that the shift is a reason for being disappointed and that there are other reasons (worse expectations) why the right-wing party was not so disappointed; and that 'it' refers to the right-wing party and not, for example, to the city council. All these pieces of information are not stated explicitly in the text, but readers do understand them. They are called inferences.

An inference is defined as information that is not expressed explicitly by the text but that can be derived from the text on the basis of the comprehender's knowledge and that is encoded into the representation the comprehender constructs of the text. In this article, the notion of inference is restricted to the derivation of implicit information that occurs in spontaneous language processing. These inferences are distinguished from logical deductions in reasoning and problem solving (Johnson-Laird 1983, see also *Reasoning with Mental Models*), such as the logical deduction 'Some artists are chemists' from the premises 'Some beekeepers are artists. All beekeepers are chemists.' Logic is concerned with the assessment of the validity of arguments in reasoning. Although listeners and readers certainly make logical deductions, and some inferences can be considered as logical inferences, everyday language behavior is not characterized by the evaluation of the validity of the arguments in reasoning.

Two kinds of inference in everyday language behavior can be distinguished. The first kind is an inference that is the derivation of new information. This is what in ordinary language is called an inference. For example, from the sentence 'John selected his stranston shoes because there was much mud,' the reader can infer that apparently stranston is a material or brand that has advantages if there is much mud. Given that the reader is not familiar with stranston, the reader cannot know that the conjunction 'because' is correctly used. However, by assuming that the sentence makes sense, the reader can derive the inference as new information. The second kind of inference is an activation of available knowledge. Examples from text (a) are that 'it' refers to the right-wing party, and that, given the contrastive relation indicated by 'but,' a shift toward an opponent party is in general a reason for disappointment. This kind of inference in general is not called an inference in everyday language, but most of the psycholinguistic research focuses on this kind of inference.

1. *Issues in Inference Research*

There are two issues that make inferences an important topic of research in language understanding. In under-

standing a discourse, the number and variety of inferences that may be derived from the discourse seem to be almost unlimited. This may lead to a computational explosion. Yet, the human processing system has limited capacity, and comprehension is accomplished too quickly for many time-consuming inferences to be made. Therefore, the first issue is how to account for the control of inferences: Which inferences are made and which ones are not made? This issue will be discussed in Sect. 3. The second issue concerns the inference as a process. What constitutes the process of making an inference; how does the inferred information get activated and deactivated; how does the information in the text interact with the reader's knowledge? Some aspects of the process of inferring will be discussed in Sect. 4. This article focuses on inferences in reading because most of the psycholinguistic research on inference addresses reading.

2. Methods in Inference Research

The questions whether an inference is made and when it is made can be investigated by measuring specific aspects of reading behavior. The measurements are made during the reading of the words or sentences that trigger the inference (*on-line methods*) or after reading those words or sentences (*off-line methods*).

2.1 Off-line Methods

The assumption underlying off-line methods is that the inferences are encoded into the mental text representation, as is information that was expressed explicitly by the text, and therefore that they can be investigated in tasks such as reproduction, recognition, and verification. In a *reproduction* task, the reader is required to reproduce the text after having read it. Information that was not stated explicitly in the text but that is reproduced by the reader is supposed to be inferred by the reader. In a *recognition* task the reader has to judge whether particular words or sentences occurred in the text. The rationale of the recognition task is similar to that of the reproduction task. Information that is incorrectly judged as having appeared in the text is assumed to be inferred. Many people who had studied the sentences, 'John was trying to fix the birdhouse. He was pounding the nail when his father came out to watch him and to help him do the work,' incorrectly recognized the sentence 'John was using the hammer to fix the birdhouse when his father came out to watch him and to help him do the work.' This indicates that an *instrumental inference* ('hammer') was made (Bransford and Johnson 1973). Reproduction and recognition tasks can indicate whether the inferences are made but in general cannot distinguish whether the inferences are made during reading (at encoding) or during the measurement (at retrieval). In a *verification* task, readers judge whether the content of a sentence is true or false with respect to the content of the text. Not only the accuracy, but also the reaction time for the verification or the recognition can be important. If inferred information is recognized or verified as quickly as explicit information, this is an indication that the inference is made during reading, and not at the moment of the off-line task. Off-line methods are used frequently in combination with on-line methods to answer the question of when inferences are made.

2.2 On-line Methods

On-line methods are employed during reading and aim to detect the ongoing inference process immediately. The assumption is that inference processes require time. Therefore, they are detected by a long reading time at the moment the inference is made, relative to a control condition in which no inference is made. Reading times are measured in a self-paced reading task in which the reader by pressing a button exposes successive units of text (words or clauses) in a window on a computer screen. The interval between button presses is defined as the reading time for the unit of text. For example, for understanding the second sentence in 'Mary got the picnic supplies out of the car. The beer was warm,' the inference is required that there was beer among the picnic supplies. Therefore, the reading time for the second sentence in this sequence should be longer than in the sequence 'Mary got the beer out of the car. The beer was warm' (Haviland and Clark 1974). Reading times are also measured in eye-tracking recordings that reveal what the reader looks at and how long. This makes it possible to measure fairly exactly when the inferences are made. Just and Carpenter (1978) found that the gaze duration on 'killer' in 'The killer left no clues for the police to trace' is longer if this sentence is preceded by the sentence 'The millionaire died on a dark and stormy night' than if the sentence beginning 'The killer … ' comes after the sentence 'The millionaire was murdered on a dark and stormy night.' Reading the word 'killer' requires the information that the person was murdered; this information has to be inferred after 'die' and is explicit in 'murdered.'

Other methods are administered immediately after the reading of the word or sentence that triggers the inference and can be considered on-line methods. In these tasks, a word is presented as a probe during reading, at or shortly after the moment that the inference is supposedly made. The probe is related to the information that is presumably inferred. An example is the probe word 'break' after the sentence 'No longer able to control his anger, he threw the

delicate porcelain vase against the wall.' The task may be to decide whether or not the string of letters of the probe forms a word (*lexical decision*), to decide whether or not the probe word had been presented in the previous sentence(s) (*probe recognition*), or to pronounce the probe word (*naming*). The assumption is that if the inference is encoded into the text representation, the lexical decision time for the probe and its naming time are shorter and the time needed to indicate that 'break' did not occur in the text is longer than in a control condition (see Sect. 4.1) in which the inference is not made. The status of the different lexical techniques is not quite undisputed. In some investigations, it is claimed that these lexical tasks are sensitive to transient activations (i.e., inferences that are activated only for a short time) rather than to inferences. In particular, naming is sometimes considered a task that does not reflect the nature of the text representation and, accordingly, does not reflect inferences that are encoded in the text representation. In other studies it is suggested that lexical decision and probe recognition, in contrast to naming, register the fit of the probe with the preceding context rather than the encoding of inferences.

3. *Some Established Findings in Inference Research*

The issue that has stimulated much psycholinguistic research on inferences since the early 1970s is the following question: Which inferences are made and which ones are not made? This issue was investigated by looking for classifications of inferences, on the assumption that some kinds of inference are made during reading and some other kinds are not.

Most common is the distinction between *necessary* and *elaborative inferences*. Inferences are called necessary if without them the text representation is not coherent. Inferences that are not necessary for coherence are called elaborative, optional, or embellishing. Two aspects of coherence can be distinguished. *Referential coherence* is achieved by the fact that a sentence in a text deals with entities that are expressed earlier in the text. Linguistic devices to indicate referential coherence are referential (or anaphoric) expressions, such as pronouns and definite noun phrases that refer to an antecedent in the text (see *Anaphora Resolution*). *Relational coherence* is achieved by the fact that the content of a sentence has a conceptual relation with other sentences, such as a causal, contrastive, or concessive relation. Relational coherence can be expressed by conjunctions. If, in text (a), the inference about the co-referentiality between 'it' and 'party' or the inference about causality between 'voting' and 'shift' is not made, there is no coherence between the sentences. The pronoun 'it' is considered as an instruction to find a particular referent; the conjunction 'because' is considered as an instruction to find a causal relation in the context. If such instructions are not executed, the representation is not coherent. In this way, inferences triggered by referential expressions and conjunctions contribute to the coherence of the representation.

The notion of *necessary inference* is sometimes defined in a different way and contrasted with *pragmatic inference*. An inference is necessary if it follows logically from the propositions in a text. From 'John is taller than Pete and Pete is taller than Bill', it follows that John is taller than Bill. The causal inference between the propositions with 'voting' and 'shift' in (a) is not only necessary for the coherence, but also necessarily follows from the text. It can be deduced from the conjunction 'because' and is called a conventional implicature.

Inferences that do not follow logically from the text are called pragmatic inferences.

Another distinction that is made frequently is that between *backward* and *forward inferences*. Backward inferences relate the current part of the text to an earlier part. Forward inferences anticipate information that might be expressed in the subsequent text. Backward inferences contribute in general to the coherence of the text and are in that sense necessary inferences, while forward inferences are not. Backward inferences are much more restricted than forward inferences: the reader can anticipate a great number of things.

Inferences can also be classified with respect to their content. This yields a list of inferences that can be extended *ad libitum*. It includes inferences about instruments, causes, consequences, goals, time, place, and protagonists.

Established findings in inference research (Singer 1994, Van den Broek 1994, Garrod and Sanford 1994) are that necessary inferences—i.e., inferences that achieve coherence between sentences—are made during reading. These inferences are in general backward inferences. Elaborative, embellishing inferences are not made during reading; they are not required for comprehension. They are in general forward inferences. There are many possible forward inferences that can be made, and, since they do not achieve coherence, there is no motivation for making them. Inferences that can necessarily be derived from the text are far from always made; in general, it depends on whether they contribute to the coherence or not.

4. *Trends in Inference Research: Toward a More Differentiated View on Inferences*

The research discussed in the previous section can be characterized by two views on inferences. First, inferences were considered as dichotomous entities: they are made or not made. Second, inferences were described with respect to their function in the text:

whether they are made or not depends on whether they contribute to the coherence of the text. Since the late 1980s and early 1990s, there has been a gradual change in inference research. The recent trends will be discussed in two subsections. First, the dichotomous view on inferences is being replaced by a process view on inferences: What happens if an inference is made? Second, attention has shifted from the function of inferences in the text to the availability of information and knowledge as determinants of inferences, and in this way to the role of the reader.

4.1 The Process Character of an Inference

The shift in attention toward a process view on inferences was stimulated by research on forward inferences. Presumably, the reason was that backward inferences were well established and that the idea that forward inferences are not made was not quite convincing. Several studies (McKoon and Ratcliff 1986) demonstrated that forward inferences about very predictable events can be made, but are only partially or minimally encoded. After presentation of several sentences, among them, 'The director and the cameraman were ready to start shooting when suddenly the actress fell from the 14th floor,' the word 'dead' was presented as a probe for recognition. If an inference about dying were encoded in memory, it would interfere with the correct answer 'no.' When the target word was preceded by another word from the same sentence, an interfering effect did indeed occur, but when the target word was preceded by a neutral word (e.g., 'ready'), no interference occurred. This result was interpreted as evidence for a minimal encoding of the inference, such as 'something bad happened,' because a prime word from the same sentence was necessary to strengthen the match between the probe word and the memory representation.

Other research demonstrated that inferences are built up and decay over time. First, forward inferences are not generated until some time after the presentation of the words the inference is based on. Experiments in which the time between the context that primes the inference and the presentation of a target word to detect the inference is varied indicate that a delay of about 1 s is necessary for the inference to be built up (Calvo et al. 1999). This observation may explain why no evidence for forward inferences was obtained in most of the earlier studies. If, in a reading experiment, subsequent information that does not support the inference is presented very quickly, the inference is not built up. However, if readers can read at their own pace or if subsequent information supports the inference, forward inferences can be built up. Second, an inference can be made for a brief period of time. It need not remain active. Keefe and McDaniel (1993) found that the naming latency time for the word 'break' was shorter after 'One day, no longer able to control his anger, he threw a delicate porcelain vase against the wall' than after the control sentence, 'One day, unable to control his impulses, he went out and purchased a delicate porcelain vase,' when the probe word was presented with a short delay after the target sentence, but there was no facilitation when there was an intervening sentence between target sentence and probe. They argued that forward inferences are drawn but are quickly deactivated. But the likelihood that forward inferences are encoded seems to increase if the information to be inferred is foregrounded and salient, and if the inference concerns a causal relation (Klin et al. 1999).

4.2 Availability of Information and Reader's Knowledge as Determinants of Inferences

Whether inferences are made or not depends not only on the function of the inference in the *text*, but also on whether the *reader* has information and knowledge available. This has been acknowledged in the currently most pervasive theories of inferences: the *minimalist theory* and the *constructionist theories*. In the minimalist theory, language processing and inferencing are described largely in terms of bottom-up processing of the information in the text. In the constructionist theories, the reader's search for meaning and the reader's knowledge play an important role, so that understanding entails a considerable amount of top-down processing.

In their minimalist theory on inferences, McKoon and Ratcliff (1992) argue that only two kinds of inference are drawn spontaneously during reading: inferences that serve to achieve *local coherence* and inferences that are based on *easily available information*. Local coherence refers to coherence between propositions that are not farther apart in the text than one or two sentences. Information is easily available if it is expressed in the current two or three sentences or if it is well-known general knowledge, such as instances of categories (collie—dog). In this way, the availability of information in the text is defined in terms of the linear structure of the text. But, as constructionist theories point out, information that is globally relevant, such as information about the goal of the protagonist, is not only available at the moment of reading the sentence that expresses that information, but remains available throughout longer stretches of the discourse. It is higher-order information in the hierarchical text structure. This information is shown to be available in the absence of local incoherence (Myers and O'Brien 1998).

In constructionist theories, the knowledge of the reader plays a much more important role than in minimalist theory. According to constructionist theories, readers construct a *mental model* or a *situational model*. Such a model contains not only the information in the propositions of the text but also

information that is constructed by the reader, including elaborative inferences and global inferences (Johnson-Laird 1983, Garnham and Oakhill 1996, Zwaan and Radvansky 1998). Many participants (Bransford and Johnson 1973) who heard a sentence such as 'Three turtles rested on a floating log and a fish swam beneath them' recognized, incorrectly, the sentence, 'Three turtles rested on a floating log and a fish swam beneath it,' but participants who had heard the sentence, 'Three turtles rested beside a floating log and a fish swam beneath them,' did not often recognize incorrectly the corresponding sentence with 'it.' Apparently, comprehension requires the activation of knowledge about spatial relations.

The central idea in the constructionist theory of Graesser et al. (1994) is that reading is considered as a search for meaning. The readers' goal and knowledge guide the reading process. Readers try to construct a meaning representation that is coherent both at the local and at the global level. They try to explain the actions, events, and states mentioned in the text; i.e., readers try to answer 'why' questions with respect to the text. According to this theory, inferences concerning causal antecedents and superordinate goals are made because they explain actions in the text, whereas inferences about causal consequence and subordinate goals and states are not made because they do not contribute to the explanation. Currently, there is some debate on these claims of constructionist theory. What is undisputed is that the reader's knowledge is an important factor in controlling inferences. Even local inferences are not made if they do not address information that is part of the reader's knowledge (Noordman and Vonk 1992).

5. *Outlook*

Considering the state of the art in inference research, we can expect some developments. First, attention will be paid increasingly to the role of knowledge in inferences. This concerns knowledge from long-term memory, but also knowledge from previous parts of the text. Second, inference research will move in the direction of reading models. In fact, the incorporation of knowledge in inference research will emphasize inferences not so much as an isolated research topic, but as a component of the reading process. In reading research, some bottom-up models, such as construction-integration (Kintsch 1998) and resonance (Myers and O'Brien 1998), and top-down models (based on constructionism) have been developed recently. Progress in inference research will be made if inference processes can be integrated in such reading models.

Inferences, Psychology of

From a legal perspective, inferences are easily defined by contrasting them with direct assertions. Assertions have physical representations, e.g., they exist on paper, whereas inferences do not; and asserting a falsehood can lead to a criminal conviction, whereas implying a falsehood is typically not a crime. One of the important findings of inference research has been to show that this black and white distinction between inferences and assertions does not hold for the cognitive processes involved in inferencing. This insight led to a reconceptualization of the goal of comprehension and attempts to define the computational processes involved in inferencing. The main approach has been to determine which classes of inferences are typically made in comprehension. This research has been characterized by controversy and has uncovered a number of methodological problems in assessing the occurrence of inferences. Nonetheless, it has convincingly demonstrated that inferencing is not a single cognitive skill that individuals may be more or less good at because it is very dependent on knowledge, a finding confirmed with brain imaging.

1. Is Explicit Always Easier?

Although intuition might suggest that explicit information should always be easier to process than implicit information, one of the great insights of inference research has been to show that this notion of processing ease rests on a faulty assumption about the primary goal of language comprehension. It was initially thought that the goal was to construct a representation of the meaning of the text. In this view, explicit information is easy because it is direct, whereas implicit information requires an effortful process of determining what information is missing and then supplying it. Early studies of inferencing reinforced this view that inferring implicit information is more difficult than processing explicit information. For example, Haviland and Clark (1974) found it took longer to read a target sentence when the preceding sentence only implicitly mentioned the referent of the target sentence rather than explicitly mentioned it, as in:

Implict: *Herb took the picnic supplies out of the car.*
Explicit: *Herb took the beer out of the car.*
Target: *The beer was warm.*

However, many early studies also showed that, as far as the memory representation was concerned, implicit information was functionally no different than explicit. For example, Bransford et al. (1972) found that people could not even recognize whether statements had been implicit or explicit when they could be integrated to form a story. Perhaps more remarkable was the finding that implicit information could be more accessible in memory and thus easier to verify than explicit information. Potts (1972) found that when the statements referred to a linear ordering, e.g., A is bigger than B, B is bigger than C, explicit statements were more difficult to verify than implicit statements; this is because the explicit referred to adjacent terms whereas the implicit referred to referents more distantly spaced in the ordering. These memory studies were soon supported by reading time studies that also found that explicit was not always easier than implicit. For example, Sanford and Garrod (1981) found that it took no longer to read *The clothes were made of pink wool* when it was preceded by the implicit *Mary dressed the baby* than by the explicit *Mary put the clothes on the baby*.

In order to accommodate findings such as these, the field underwent a change in its meta-assumption about the goal of comprehension. The goal for the comprehender was no longer representing the text but rather representing what the speaker intended the text to be about. This was referred to as the mental model view of discourse (Johnson-Laird 1983). In this view, the difference between what is given and what must be filled in with an inference is defined relative to the comprehender's knowledge structures, not the text. But since knowledge structures cannot be observed, the distinction is not so black and white. The advantage, however, is that this perspective allows explicit information not always to be easier. It also accommodates the fact that making information explicit is not even necessary for effective communication; for example, when two people know each other well, just a few words can function to activate the appropriate knowledge. It also accommodates the fact that being explicit can actually be objectionable; try making all the thoughts behind even a simple sentence explicit. The result is typically the kind of incomprehensible verbiage found in legal documents; incomprehensible because the words serve to detour one from the intended knowledge structures.

The mental model view better accommodated the data—both data showing that explicit is not always easier, and data showing that the meaning of a text and the ease with which it can be processed vary with the comprehender's knowledge and the context in which it occurs. However, it left the notion of what an inference is ambiguous. Because the comprehender's knowledge cannot be observed, inferences have continued to be defined as information not explicit in the text. Ease of processing, however, is now defined not by whether or not information is in the text, but rather by how closely it corresponds to the comprehender's knowledge. Depending on the par-

ticular comprehender, the computational processes of inferencing can range from simply activating existing knowledge to generating new knowledge with extensive computational effort.

2. *Computational Processes in Inferencing*

Computational models are specified by their inputs, the processes that operate on these inputs, and their outputs. There is wide agreement on the inputs to inferencing, namely textual elements and the comprehender's existing knowledge. There is less agreement on the processes and outputs. One issue concerns whether simply activating a concept that was not explicit in the text is a legitimate case of drawing an inference. For example, does activating *spoon* when comprehending *stirred the soup* constitute an inference? At issue is whether inferencing must involve constructing new knowledge. If merely activating information counts as inferencing, then one needs to distinguish between at least three levels of activation; these vary in how long the information stays activated and how easily it can be referred to by subsequent text. At the simplest level, there is information that is merely activated in long-term working memory, then there is information selected as focal in working memory, and finally information that actually gets incorporated into the long-term representation of the text (Kintsch 1998). Related questions concern how other structures in the text serve to enhance and suppress activation (Gernsbacher 1990) and whether the activation of the inferential information occurs as a function of automatic resonance or whether an effortful search of memory is required (Myers and O'Brien 1998). Finally, there is the issue of size of the output. It can range from an activated concept, such as *spoon* in the above example, to a proposition, e.g., *that one event caused another*, to a set of propositions constituting a higher-order knowledge structure, e.g., *one's schema for romantic relationships*. The problem for the field has been using a single term, *inferences*, to refer to such a broad range of knowledge structures and computational processes. As the field makes progress in specifying the computations, it is likely to begin classifying inferences according to the type of computations required (Kintsch 1998).

3. *Types of Inferences*

The past two decades of inference research have been dominated by a quest to determine which types of inferences (as defined by type of information, not type of computation) are typically drawn during comprehension. This question is central to several enterprises. One is the design of artificial intelligence language understanding systems; designers need to know which types of inferences are typically drawn so that they can get their programs to function as typical language users. Another is the study of individual differences in language and cognition. Deficits in inferencing can only be assessed by knowing which inferences nonimpaired individuals typically draw. Finally, those developing computational models of inferencing need to know which types of inferences have behavioral consequences.

Early research identified *bridging inferences*—inferences that bridge the gap between two textual elements—as typically drawn (Haviland and Clark 1974). They are also called *backward inferences* and *coherence inferences* because when a gap in coherence is detected, the comprehender works backward to build a bridge to the preceding text; to illustrate with the example from Haviland and Clark given earlier, connecting *beer* to *picnic supplies* involves making the bridging inference that the picnic supplies must have included beer. What constitutes a gap and what constitutes coherence presupposes a theory of knowledge and a theory of how the language maps on to that knowledge; although the field is far from such a theory, some of the dimensions of coherence have been specified. Research shows that backward inferences are made to maintain referential, causal, and temporal coherence (Graesser, Millis and Zwaan 1997).

Another class of inferences is *forward inferences*, also called *elaborative* or *predictive* inferences. Whereas backward inferences are made to establish coherence and are assumed to occur at coherence breaks in the text, forward inferences merely elaborate the developing representation and can occur at any point. Compelling reasons have been proposed for making forward inferences, and it is often said that more skilled readers make more forward inferences. However, there are also costs associated with making such inferences. For example, if *spoon* is inferred from *stirred the soup*, reading a subsequent sentence about *the spoon* might be facilitated by having spoon already in an active state. However, if the text proceeds to identify some other term as the instrument of the stirring, e.g., *stick*, having inferred spoon could be costly. Hence it is an interesting empirical question as to whether such forward inferences are drawn. The types of forward inferences thought most likely to occur and thus the ones that have been studied the most are instrument inferences (e.g., inferring *spoon* from *stir the soup*), inferences about the likely consequences of events (e.g., inferring *cut* from *stepped on jagged glass*), and instantiations of general terms (e.g., inferring *cow* from *milk the animal*).

In a review of this research, McKoon and Ratcliff (1992) concluded that few forward inferences seem to be drawn. They characterized the comprehender as operating according to the *minimalist hypothesis*. It states that the only inferences typically drawn are those required for local coherence and those involving activations of readily available pre-existing associa-

tions. This started quite a controversy. To many researchers, minimalism represented a return to the earlier text-centered view of comprehension. They argued for the more knowledge-based, *constructivist* view (Graesser et al. 1994), and produced several studies arguing against minimalism by showing that even when texts are locally coherent, inferences related to global coherence are still typically drawn (e.g., Myers et al. 1994). Yet to be determined, however, is the role of computational effort in making global coherence inferences. To the extent that these inferences are only made using minimal processing, such as resonance with activated knowledge structures (Myers and O'Brien 1998), the notion of the comprehender as a minimalist processor may still be valid.

4. *Methodological Issues*

The main paradigms used to assess inferencing can be divided into two classes: *activation measures* and *memory measures*. Activation measures detect inferences by determining whether the inference concept is in an activated state relative to some control condition where the inference would not be expected to be drawn. They include reading times for a sentence where the inference might be drawn, and also reaction times to make a lexical decision or name a word related to the inference. Memory measures require subjects to access their mental representations of the text and determine if the inference is part of that representation. They include cued recall, sentence verification, question answering, and recognition tests.

Much has been learned about the methodological problems associated with these measures (Keenan et al. 1990). The main problem with memory measures is that they do not allow one to determine whether the inference was made during comprehension or if it was made as a result of the test. Because memory tasks require a person to go back to their representation of the text to determine if information is present, they provide the person with another opportunity to draw the inference. This is a real problem if one seeks to know whether inferences are being drawn on-line as the text is being understood.

Activation measures have two problems. First, not everyone counts activating a concept as making an inference. Second, inference concepts may be activated spuriously by virtue of their association with other words in the text, a phenomenon referred to as word-based priming. For example, if the concept *dead* is activated by the sentence *the fashion model fell from the roof during the photo shoot*, it may either indicate that a forward inference was drawn about the model being dead from her fall or it may be that *dead* is activated because it is related to *shoot*. Thus, activation measures of inference require assessing activation relative to a sentence that controls for word-based priming.

The need to control for word-based priming points to the general problem of what the proper control condition is for assessing inferences. The commonly used procedure of comparing reading times on explicit to implicit versions may be contaminated by surface form memory facilitating performance on the explicit. Thus, implicit may be slower than explicit, not because a time-consuming inference needs to be made, but because it does not match the target sentence on surface form.

The point in time when an inference is assessed may also affect whether or not it appears to have been drawn. Activation assessed immediately following the target text segment may suggest an inference was drawn, whereas a test occurring at the end of the passage may not detect the same inference because the activation dissipates if the inference is not incorporated into the long-term representation of the text.

Because the different types of tasks used to assess inferencing can yield different results, it is important that research aimed at determining the types of inferences made during comprehension use more than one measure of inferencing, with multiple control conditions, and assessments at various points in time. Converging operations such as these can help dispel the distorted picture of inferencing that can emerge when classes of inferences are confounded with the methods used to assess them.

5. *Individual Differences in Inferencing*

The literature on individual differences in cognition typically refers to inferencing as a unitary skill. It is thought to be a skill that young children or poor readers need to develop (Yuill and Oakhill 1991), and it is thought to be a single skill that can be selectively impaired with certain types of brain damage, e.g., to the right hemisphere (Beeman and Chiarello 1998). While it is recognized that there exists a range of skill in inferencing, this range is typically attributed to other factors, such as working memory capacity. Thus, as one's working memory capacity increases, so does one's inferencing skill, because with greater working memory capacity the inference process can connect more widely separated segments of text. This view of inferencing as a single process does not fit with the range of computational processes in inferencing described above. Nor does it recognize the fundamental reliance of inferences on specific knowledge structures. People cannot be categorized as generally good or poor at inferencing because the occurrence of inferences depends on having appropriate knowledge (Noordman and Vonk 1992). Furthermore, brain damage may not impair a general skill of inferencing so much as impair select knowledge structures, resulting in an inference deficit only in a certain knowledge domain. For example, autistic patients can

make inferences about the physical causes of events but not social causes (Happe 1994).

Brain imaging studies of discourse processing are currently in their infancy. These studies contrast connected discourses to single sentences and have shown increased activation in the temporal lobes and the posterior cingulate cortex for discourses. Most interesting, however, is the finding that the brain areas involved in discourse processing vary as a function of the knowledge domain tapped by the inference processes (Fletcher et al. 1995). Such brain imaging results support the richly complex view of inferencing that has emerged from behavioral studies.

Infertility: Demographic Aspects

Infertility was, until recently, the neglected problem of reproduction, overshadowed by concerns about unwanted or unplanned pregnancies and by attention to rapid population growth. Yet for women, men, and couples who are not able to have the children they want, the problem looms large. In 1994, the United Nations International Conference on Population and Development adopted a Program of Action that included the following definition: 'Reproductive health is a state of complete physical, mental and social wellbeing, and not merely the absence of disease or infirmity, in all matters relating to the reproductive system and its processes. Reproductive health therefore implies that people are able to have a satisfying and safe sex life and that they have the capability to reproduce and the freedom to decide if, when, and how often to do so' (United Nations 1994). For the first time, policy emphasis was given to the capability to reproduce. This article first defines infertility and discusses its measurement, and then offers an overview of the extent of infertility and its consequences and treatment. Noncontracepting and contracepting populations are dealt with separately.

1. Definitions and Measurement

For many years, couples who had 12 months of unprotected intercourse without conception were considered infertile. Yet, it is well known that significant proportions even of young, fecund couples do not conceive in that period of time and do so later without any treatment. The World Health Organization (1975, 1993) recommends that a two-year period without conception be used to define infertility. These definitions are appropriate for identifying couples who may want to seek medical treatment.

Social scientists have adopted a definition based on the inability of a noncontracepting sexually active woman to bear a liveborn child (Pressat and Wilson 1985). The clinical definition is based on inability to conceive. The demographic definition is broader, including both inability to conceive and inability to carry a pregnancy to term. Primary infertility is defined

as the inability to have one child, while secondary infertility occurs when a woman who has borne at least one child is unable to have another. As in most fertility analyses, the woman is emphasized for two reasons: it is far easier to identify the mother of a child than the father, and reproductive capacity diminishes with age far more rapidly for women than for men. It should be noted that it is only rarely possible to distinguish between infertility of the *woman* and infertility of the *couple*.

The level of infertility in a population is usually measured by the proportion of reproductive age women who are infertile and the age-specific proportions infertile (e.g., the proportion infertile at age 20, 25, etc.). Some analyses have been based on asking women in a survey whether or not they have experienced trouble having a wanted birth, and whether they have tried for at least two or three years to bear a child. This method has the advantage of collecting direct information from women about the problems they have encountered.

Another approach uses records of a woman's age at marriage and at each successive birth and can only base infertility estimates on the demographic definition, since no information on difficulties in conceiving is available. The proportion of women who do not have a birth within two years of marriage or of the previous birth is much higher than the proportion who do not have another birth (Trussell and Wilson 1985, Larsen and Menken 1989). Lengthy birth intervals are common in populations in which babies are breastfed, especially without supplementation, for many months. Larsen and Menken (1989) recommend counting a woman as infertile only after five years without a birth. They refer to a woman who has a child and does not have another birth within five years as *subsequently infertile*, beginning the month after the last birth. The proportion of women subsequently infertile at age 15, 20, 25, etc. offers a good estimate of the age pattern of infertility in the population. Note that although we refer to *women*, we actually have in mind *couples* classified by the woman's age.

These methods are most appropriate for populations in which there is little use of contraception or other means of fertility control. Demographic data give us no opportunity to demonstrate whether or not those who control fertility through contraception or abstinence are infertile. If a contraceptive user goes five years without a birth, it may be because she is an effective user; alternatively, she may be infertile. Estimates of infertility that assume all contraceptive users are fertile will be too low. Some analysts, therefore, have based their estimates only on those who are *not* using contraception. But couples who control their fertility may be doing so because they have all the children they want. They may be the most fertile group in the population.

If infertility is measured only from those who are *not* contracepting, the estimate will be too high, since non-users are likely to include those who have not yet achieved the number of children they want, perhaps due to their infertility. Simulation studies offer the possibility of assessing how sensitive the infertility estimates are to the proportion of contraceptive users in the population. Larsen (1994) found that estimates were robust to contraceptive use by about five percent of women.

2. *Noncontracepting Populations*

Primary infertility affects only a very small proportion of women. Bongaarts and Potter (1983) suggest that fewer than 3 percent are biologically incapable throughout their lives of ever having a child. Among the Hutterites, a noncontracepting, high-fertility American community, infertility rises only modestly until age 35 and more rapidly thereafter. Table 1 shows the percent subsequently infertile among Hutterite women in the middle of the twentieth century. Infertility was quite low for young women, e.g., just 3 percent for 20–24-year-olds. Larsen (2000) estimated infertility for 28 countries that conducted World Fertility Surveys or Demographic and Health Surveys between 1978 and 1997 in Africa, the region with the highest known infertility in the world. Even the low-infertility countries, exemplified by Rwanda and Togo in Table 1, have more infertility than the Hutterites. The African increase in infertility with age is in part due to biological aging, but most must be attributed to disease.

The most striking aspect of infertility in Africa is its wide variation, which can occur within as well as between countries. High rates of secondary infertility occur in a band of countries across sub-Saharan Africa. In six countries that Larsen studied, over 30 percent of women aged 30–34 are infertile. She estimates that women in these countries average 1.7 fewer children than they would in the absence of reproductive problems. High infertility in this region was first noted by Retel-Laurentin nearly 40 years ago in parts of the Central African Republic. These high rates are attributed to very early initiation of sexual intercourse, and sexually transmitted diseases (STDs). The primary infertility-causing diseases appear to be gonorrhea and chlamydia, which can, if untreated or treated improperly, lead to occlusion of the Fallopian tubes, thereby preventing ova from descending from the ovary to the uterus.

Evidence is accumulating that infertility today may be related to HIV infection. HIV-infected women, even if they are asymptomatic, have lower fertility rates than non-infected women. This finding raises great concern about the accuracy of estimates of HIV infection, since one basis for such estimates is HIV testing of pregnant women who come to clinics for prenatal care. If HIV-positive women are less likely to come, the estimates of proportions infected are too low.

Table 1
Levels of infertility in selected populations

One explanation proposed for this high infertility is that Arab slave traders spread STDs to indigenous populations of the areas in which they worked. Another explanation has to do with migrant labor, which was concentrated in urban areas and, in many places, involved primarily men. Long family separations, it is suggested, led to a rapid rise in prostitution and STDs, which were then carried back to wives in rural villages. This theory has also been applied to the spread of HIV/AIDS. In addition, the multiple sex partners entailed by the practice of polygamy in much of Africa promotes the spread of any STD that is brought into the marriage.

Rightly or wrongly, infertility in Africa, as in most places, is usually attributed to the woman, and consequences are greater for women than men. Infertile women may garner less respect in their communities, face higher rates of divorce and polygamy (as husbands take additional wives in the hope of having more children), and higher risks in old age of having few or no children to help support them.

Much of infertility in contemporary developing countries is preventable through postponement of sexual initiation until full female maturity, preventive measures such as condom use and few sex partners, care during pregnancy, and prompt treatment for STDs before pelvic inflammatory disease (PID) and scarring occur. Yet even without the burden of HIV/AIDS, health systems are rarely able to provide treatment, and the HIV/AIDS pandemic has reversed all the gains in life expectancy that were achieved in many African countries in the latter part of the twentieth century.

3. *Contracepting Populations*

As mentioned above, infertility is difficult to measure in countries in which fertility control is used extensively. In 1995, 27 percent of all women and 41 percent of married women of reproductive age in the USA had chosen sterilization, either of the woman or the man, to terminate childbearing. Fertility surveys showed impaired fecundity (defined as three years without bearing a wanted child and trouble reported in childbearing) affected 6 percent of women aged 15–24, 11 percent of 25–34-year-olds, and 13 percent of 35–44-year-olds. Especially in the oldest age group, the proportion is lower than the actual proportion infertile because of extensive contraceptive use and sterilization, which mask infertility (Chandra and Stephen 1998). A French survey conducted in 1988 showed that only just over 6 percent of women who wanted another child did not manage to become pregnant after at least several years of trying to do so (Leridon 1992).

Yet there are persistent fears that infertility in industrialized countries is higher than previously believed and even is on the rise. In part, such fears were catalyzed by a French study from 1982 of conception rates among women coming for artificial insemination.

The study showed a sharp drop-off after age 30, and that was widely interpreted as indicating a similar drop-off for all women. An accompanying editorial suggested that women who were delaying childbearing to establish a career would have to alter their plans and have their babies early if they were to have them at all (Menken et al. 1986). The US data for the 1970s and 1980s did not show any change, but the most recent fertility survey (Chandra and Stephen 1998), which is from 1995, indicates a higher proportion of women who report impaired fecundity. However, over that time there was a much greater increase in fertility among older women. In 1982, there were 21.2 births per 1,000 women aged 35–39; the figure increased by over 60 percent in 1995, to 34.3 births per 1,000 women. For women aged 30–34, the birth-rate increased almost 30 percent. Clearly, a higher proportion of women were trying to have a child in 1995 compared to 1982. Therefore a much higher proportion was not using contraception, which can mask infertility problems. Yet, the rise in the proportion reporting impaired fecundity was not much higher—13 percent for the oldest age group in Table 1 and 11 percent for women aged 25–34.

Several potential causes of a real increase in infertility include increases in abortions and STDs, and a decline in semen quality. A number of studies have found no confirmation of the notion that women who have induced abortions in modern clinics or hospitals suffer increased infertility. In about 20–40 percent of STD cases, women who have gonorrhea or chlamydia develop PID and about 20 percent of women with PID become infertile. The proportion of women who reported they had PID declined from 14 percent in 1982 to 8 percent in 1995, but some fear that this decline is not real but is due to more 'silent' infections that women do not recognize. For over 25 years, there have been suggestions that the quality of human sperm has been declining, perhaps as the result of environmental changes. An analysis of over 60 studies published between 1938 and 1990 (Carlsen et al. 1992) concludes that the decline is genuine and speculates that it may have reduced male fertility. As yet, there is no confirmation of this result, but concern remains, both about the effects of STDs and of environmental effects on semen.

But the fears appear to be greater than warranted by these concerns. Several explanations why infertility may be overestimated in the media and by the public have been suggested (Aral and Cates 1983, Menken et al. 1986, Bongaarts 1982). First, as suggested earlier, infertility was previously overshadowed by problems of controlling *unwanted* fertility. More women and couples who want no more children are using more effective contraception and sterilization, thus reducing the numbers of unwanted births. A secondary effect of this change may be that fertility appears to be under individual control. There is an expectation that conception should occur quickly once individuals decide they want to have a child. Leridon (1992) refers to this phenomenon as 'impatience to conceive.' A second reason may be that the medical profession now sees a higher proportion of its clientele made up of those who *are* having infertility problems. But the explanation for this change more likely lies in the fact that those who have had the number of children they want, have chosen methods of fertility control that remove the necessity for visits to specialists in childbearing, leaving the doctors' offices and clinics to those in need of infertility treatment. A third reason is the delay in childbearing that means that more women are hoping to have a child at older ages when, indeed, their fecundity may have declined, without any increase in infertility among women their age. Finally, the silence concerning infertility has been broken and the ways to handle infertility have changed, drawing more attention to infertility issues than before. Adoption of children who clearly are not the biological child of one of their adoptive parents has increased, making visible the choices their parents have made. High-tech treatment of infertility is routinely discussed and used by parents in the hope of producing a wanted child, and the media publicizes the successful results. The increased attention in no way means that the incidence of infertility has changed.

4. *Summary*

Infertility from senescence increases gradually with age. Variation is quite local and is influenced by disease patterns, especially of STDs. In contracepting populations, the perception of infertility varies with the proportion of people who want only a few children and stop after having them. Those who are infertile are, therefore, more likely to be among those attempting to have their first or additional children, thus increasing the perception of the prevalence of infertility. Clearly those who postpone childbearing until their late 30s are at an increased risk of infertility. In much of the world the most pressing need is for prevention and treatment of STDs that can prevent people from becoming parents of the number of children they desire.

Influence: Social

When an individual's attitude, opinion, cognition, or behavior is forcefully developed or changed through physical sanctions or punishment, the process at play is called 'power.' However, when the creation or change is 'voluntary' or 'unconscious' the process is called 'influence.' The term 'social influence' in the broadest sense refers to all influences that individuals receive from all types of formal institutions, other individuals, and informal groups.

Formal institutions include schools, mass media, and business corporations. This article focuses on the influence of mass media as an example of the influence of formal institutions, before going on to consider personal influence and informal group influence.

1. *Mass Media Influence*

While the influences of home and school are dominant during childhood, the influences of the mass media become increasingly more pervasive after individuals reach adolescence. When radio surged in popularity among the masses during the 1930s it was feared that mass communications, especially radio, had a powerful and instant effect on a population's attitude and behavior. This fear was reinforced by the success of the Nazis' propaganda machine in Germany and the large-scale panic in the USA in 1938 caused by a single radio program called 'The Invasion from Mars' (Cantril et al. [1940] 1966). This radio play, broadcast without any prior warning by Orson Wells's Mercury Theater on CBS, was so realistic and caused such widespread panic that some people actually thought Martians had landed on Earth and sadly committed suicide. As a result, the apparent immediate influence of mass media came to be compared to a fast-acting hypodermic injection or an atomic bomb.

Empirical research on the influence of mass media, however, gradually revealed that it could not be that overwhelmingly influential. It was found that although mass media might reinforce people's existing attitudes and opinions, or even create new ones, they could hardly convince people to change already strongly held beliefs (Klapper 1960). It was also found that even though mass media information might reach each individual directly, its influence did not. Influence, if any, was thought to reach individuals through so called 'opinion leaders' (Katz and Lazarsfeld 1955). This view of the mass media's weak influence, however, was later challenged by several new 'powerful media' theories.

One of these theories deals with the 'agenda-setting effect' of mass media (McCombs and Shaw 1972). Even if the mass media's persuasive power is limited, especially in the short run, they exert a strong influence on people's perception of the salience of each issue. There are 'good news' and 'bad news' stories for everybody and for every organization. If the mass media persistently play up the 'bad news' events surrounding some political candidate or party it will affect the readers' or viewers' attitudes, and thereby the result of an election. In such a case, the mass media are not actually persuading their readers or viewers to change their minds; they are merely taking advantage of conventional social norms and reinforcing existing attitudes. Nevertheless, mass media can influence individual behavior (such as voting) by setting the priority of people's attention in regards to the issues that are being debated.

Another important role of mass media is that they tell their readers or viewers what other people are thinking. In other words, mass media inform their audience what the prevailing 'public opinion' is regarding each issue. In doing so, mass media tend to amplify the opinions they support. In an extreme case the mass media might treat a minority opinion as if it were that of the majority or some new ineluctable trend. As a result, the holders of the minority opinion, supported by the mass media, become louder and more strident while those of the majority opinion lose

their voice and fall increasingly more silent. Thus, through the 'spiral of silence' mechanism orchestrated by mass media, the majority opinion comes to be replaced by that of the minority (Noelle-Neumann 1984).

2. *Personal Influence*

The 'opinion leader' mentioned above refers not only to professional opinion makers such as journalists, critics, and university professors but to all men and women who influence others around them on a daily basis, in some specific area, such as local politics, fashion, sports, travel, medical care, or even cooking. These opinion leaders are often asked for advice by people who look up to them. To meet such expectations, they expose themselves to the mass media more extensively than their followers. Opinion leaders compare and evaluate opinions and information that is first presented by the mass media. As a result, the influence of mass media first takes place among opinion leaders who in turn regurgitate their latest batch of news to their followers in the form of guidance or advice. Even if a person's opinion is shaped by the mass media, that opinion may be quickly replaced by that of an opinion leader because such people's opinions are trusted more by their followers than are those of the mass media. This process is called the 'two step flow' of social influence (Lazarsfeld et al. [1944] 1968).

Another explanation for this 'personal influence' is provided by the 'cognitive consistency theory.' According to this theory, people are affected by those whom they like because the cognition that one likes someone and the cognition that one's opinion is different from theirs is psychologically inconsistent and therefore uncomfortable. In such a case, it is predicted that people would change their opinion of, or attitudes toward, the person in question (Festinger 1957, Heider 1958, Newcomb 1953).

3. *Group Influence*

It is known that people tend to conform to the group that they belong to, participate in, or even just happen temporarily to be part of. In other words, the group tends to influence its members. There are several reasons for this conformity. One of them is that other people's behavior in the same group often functions as a stimulus or reminder. For example, if one sees other group members starting to eat, one feels hungry. Another reason is 'fear of isolation.' Not only humans but also many animals know almost instinctively that it is safer to be with the group than to be isolated. The atavistic 'fear of isolation' may be primitive and instinctive but makes sense. It is highly probable that to be isolated costs much more in terms of survival than it would to behave as a group member because, generally speaking, the group has far more information, experience, knowledge, and wisdom than each individual member. There really is safety in numbers.

It is for this reason that each individual usually has several 'reference groups.' 'Reference groups' are similar to 'opinion leaders.' Individuals are loyal to the norms, opinions, and inclinations of their reference groups. These reference groups may be their families, companies, local communities, or governments. Sumner's (1906) notion of an 'ingroup' or 'we-group' is a typical example of the 'reference group.' While individuals are loyal to the 'ingroup' or 'we-group' they tend to be indifferent or sometimes hostile to the 'outgroup,' 'they-group,' or 'othersgroup.'

Some Japanese sociologists and social psychologists think that what functions as social pressure or constraint on each individual is caused by an abstract social construct called *seken* rather than the influence of specific groups. According to them, individuals are conscious of three different kinds of 'societies.' The first is *miuchi* or *uchi*, which originally meant immediate family but can be applied to close relatives and other immediate-familylike small groups. The second is *tanin* or *soto*, meaning 'others,' 'outsiders,' or 'strangers.' This is not the same as Sumner's 'outgroup' because *tanin* is not by any means recognized as a group or a collection of groups. People may be indifferent to *tanin* but are not hostile to it (unlike Sumner's 'outgroup'). Finally, *seken* literally means 'world' or 'society.' Specifically, this is the area between the 'immediate family' and the 'others.' This area consists of people whom you know and who know you (other than immediate family members). Friends, neighbors, acquaintances, and relatives are examples.

An important concept used to explain social pressure and constraint is that of shame. Before whom do people usually feel ashamed? People do not feel ashamed before strangers. People do feel ashamed before their immediate family members, but they know that family members will eventually understand and forgive them. It is of *seken* that people are most afraid. *Seken* will remember failure, scandal, or misconduct for a long time and will not forgive as easily as immediate family members might. *Seken* may seem to refer to 'reference groups' but these are different because *seken* is not a group or a collection of groups and people are not always loyal to *seken*.

The same is true of 'keeping face.' Where do people 'lose face'? It is in *seken*. Therefore, individuals are always concerned with *sekentei*. There is no equivalent single word in English, but *sekentei* refers to how your friends, neighbors, acquaintances, and relatives think of you. Thus, according to Japanese sociologists and social psychologists, *sekentei* is a powerful source of social pressure and a ubiquitous constraint on individual attitudes and behavior (Inoue 1977). This theory may be more applicable to collectivistic soci-

eties (where human relations are more important) than to individualistic societies. But even in individualistic societies people do have a sense of 'shame' and 'face,' so this Japanese theory should be helpful in explaining, at least in part, the causes and effects of social influences in individualistic societies too.

Informal and Underground Economics

There is a widespread feeling that a substantial and increasing share of value-creating activities take place outside the official economy. This holds, in particular, for developing and transition economies, but also for high-income economies. Such activities are not recorded by the system of national income accounting, which has become the accepted standard in all countries of the world.

The existence and increase of an underground economy gives rise to four major sets of concerns. The economic and social conditions of individuals, households, and countries are evaluated in a biased way if one relies on the official statistics. Thus, the official number of unemployed persons may hide that an (unknown) share of them actually work and receive wage income. As a consequence, the macroeconomic policies are likely to be too expansionary and social policy too excessive. A second concern is the loss of tax revenue, as underground activities escape taxation. A third concern interprets the underground economy as an indicator of an unhealthy relationship between citizens and government. The taxpayers are dissatisfied with the public services they get for their contributions and seek to redress the balance by escaping to the underground economy. It is feared that such a reaction makes a government unable to finance the public goods necessary for an economy and society. A fourth concern goes even further, and fears that an underground economy undermines the cement of society because it favors everyone acting in his or her own interests, while solidarity is renounced. In contrast to these concerns, the existence of an underground economy has also been seen in a positive light. Opponents of extensive state activity welcome the limits imposed on taxation and regulation, and applaud the dynamism and flexibility in the underground sector.

1. Denominations and Definitions

The phenomenon is known, and has been discussed in literature, under many different names: informal, unofficial, irregular, parallel second underground, subterranean, hidden, invisible, unrecorded, and shadow economy or moonlighting. In several languages, the term most often used is 'black economy' ('le travail au noir' in French, 'Schwarzarbeit' in German, and 'svarta sektor' in Swedish).

No single definition exists, but it depends on the purpose. The most precise and predominantly used definition seeks to relate the underground economy to officially measured national income: it comprises all presently not recorded productive (i.e., value-adding) activities which should be in the gross national product (GNP). This definition allows us to compare and to add the underground economy to GNP.

This definition excludes two major activities:

(a) Production that by convention is not part of GNP, in particular private household activities. The evaluation of its size has engendered a research area of its own. Depending on the approach and measurement technique in developed economies, the household sector comprises between 30 percent and 50 percent of GNP.

(b) Tax evasion is not value-adding but redistributional and is therefore not included as such in the above definition (e.g., when taxes on interest payments are evaded). However, in general, no taxes are paid on underground activities (such as moonlighting for house building) which are value-adding. Thus, underground activities and tax evasion are related, but certainly not identical. Tax evasion has also become a research area of its own. For the United States,

between 1973 and 1992 for example, it has been estimated that 17 percent of total taxes owned have been evaded.

The underground economy should not be identified with illegality. Some activities are perfectly legal but are not subject to taxes (e.g., because of their small size), and therefore escape measurement in official statistics. Other activities are legal as such, but taxes are evaded. Finally, on illegal activities (such as drug production and distribution), no taxes are paid.

Broader definitions of the informal and underground economy, depending on their purpose, include private household production and redistributional activities. In the following, the more narrow definition considering unrecorded productive activities will be focused on.

2. *Measurement Approaches*

The major effort of economists has been to measure the size of the underground economy relative to official GNP; its size compared to other countries, and its development over time. The other social sciences, especially sociology, have put more emphasis on the structure: who participates where? The respective studies often provide highly detailed analyses of particular regions, industries, and types of underground activities. A considerable part (it varies strongly from country to country) of informal activity is undertaken as a second job and part-time. This allows underground workers to be eligible for social security benefits and makes detection more difficult. Not surprisingly, casual work is dominant (if not the only kind of work) for illegal immigrants. In developed economies, casual work is most prevalent in the following sections: in agriculture (especially seasonal labor), in construction, and in the services sector, particularly in repairs (automobiles and other) and cleaning, in hotels and restaurants, as well as in wholesale and retail trade. Accordingly, among the occupations with most illegal work are cleaning persons, waiters, people working at home, construction and mechanical workers.

In the 1980s and 1990s, the quest to measure the size of the underground economy led to interesting methodological innovations, i.e., the challenge to 'measure the invisible' resulted in new measurement methods. Three general sets of measurement approaches can be distinguished.

2.1 *Direct Approaches*

An obvious way to analyze the underground economy is to undertake surveys among (supposed) suppliers and demanders of casual services. This method allows us to gather a detailed picture of the structure of this sector. However, because a substantial part of these activities is illegal, the interviewees may not be prepared to disclose their involvement. Somewhat surprisingly, research suggests that disclosure is not a serious problem. Typically, men are more involved in the underground economy than women, the young more than the old, people without work more than employed people, and the most prominent sectors are construction and all kinds of services. In contrast, where substantial capital assets (which are visible) are needed, less underground activity is observed.

A second direct approach is based on auditing of tax returns undertaken by tax collection and social security administrations. A sample of tax-payers is scrutinized in depth and under threats of sanctions for failing to collaborate. This approach provides detailed information on the biggest evaders, in particular the self-employed, who have better opportunities for concealment. Capital income also lends itself easier to evasion than labor income. Tax audits have proved unable to reveal all tax evasion, and are limited to taxable activities. As a large part of tax evasion is redistributional, that part is not relevant to the narrow definition of the underground economy.

The two direct methods (surveys and tax auditing) have the disadvantage of permitting point estimates only. Moreover, it is unlikely that they capture all 'shadow' activities, so they can be seen as providing lower bound estimates. They are unable (at least at present) to provide estimates of the development and growth of the shadow economy over an extended period of time. They have, however, one considerable advantage—they can provide detailed information about shadow economy activities and the structure and composition of those who work in the shadow economy.

2.2 *Indirect or Discrepancy Approaches*

The underground economy is reflected in discrepancies showing up in various markets. Persons working in the unofficial sector are able to *spend* more than their officially recorded income. The discrepancy between the two may be observed at the level of individual households, as well as in the aggregate national accounts. This approach is questionable, as this expenditure–income discrepancy may either be due to measurement errors (which is indeed often the case) or to reasons unrelated to the underground economy (e.g., the use of credits, or reductions in wealth).

Another discrepancy may be observable in the *labor market*. A decline in official participation rates, or a low participation rate compared to other countries, may be an indication of unofficial work. But again, the discrepancy may be related to other factors. Moreover, this approach is unable to isolate those persons who are at the same time active in the official and the unofficial economy (which seems often to be the case, according to other approaches).

A third discrepancy may be visible in the *monetary market*. The dominant approach starts with the

assumption that underground transactions are paid in cash in order to make detection more unlikely. The size of the underground economy is reflected in the amount of cash used in a country beyond that used for official transactions. This approach is elegant and easily applicable because the amount of currency is well documented. The assumption that unofficial activities are transacted in cash is, however, questionable. Empirical research suggests that between 20 percent and 30 percent of the unofficial activities are not paid in cash, i.e., either by payment in kind or via a bank. This fact is especially bothersome for the currency demand approach when the share of cash payments changes over time and differs between countries. A significant portion of some currencies is held outside the country issuing it; thus the US dollar is widely used in South America and Asia. Again, the discrepancy is influenced by many factors unrelated to the underground economy, such as the use of credit cards. Finally, it is problematic to infer the size of the unofficial sector from currency transactions, because the velocity of cash circulation may differ between the official and the unofficial sector. Some of the difficulties just mentioned have been successfully addressed by more recent research. Thus, the use of credit cards and the amount of currencies outside a country have been taken into account. Most importantly, instead of comparing the actual use of cash to the one deemed necessary for the official economy, a cash demand function is empirically measured, i.e., econometrically estimated. This allows us to check for influences (such as changes in the interest rate or the increasing use of cash substitutes) unrelated to the underground economy. Moreover, the extra use of cash has been directly attributed to causal factors, in particular to an increase in the tax and social security burden. Figures for the size and development of the shadow economy can be calculated by comparing the difference between the development of currency when the direct and indirect tax burden and government regulations are held at their lowest value, and the development of currency with the current (higher) burden of taxation and government regulations. The currency demand approach is one of the most commonly used approaches.

The most recent discrepancy approach looks at *physical inputs*, in particular the use of electricity. How much electricity would normally be used to produce the official national income is calculated. The excess use can be attributed to the underground economy. This approach again has the great advantage of relying on easily available data, which is a distinct advantage for developing and transition economies. However, not all underground activities use much, if any, electricity, and the relationship between production and electricity used may change over time, or differ between countries, due to substitution and technical progress.

A general problem of all discrepancy approaches is that one has to assume a base year without underground economy. Only then is it possible to attribute the existence and rise of a discrepancy to the underground economy.

2.3 The Model Approach

This method focuses on the causes and effects of the underground economy. By constructing a model, it seeks to identify the unobserved sector in between.

Three sets of factors are taken to be the main motivators of whether to engage in the unofficial economy:

(a) The burden of taxation and social security contributions as well as government regulations provide incentives to exit the official economy. The latter hinder or even prohibit activities in the official economy (e.g., because of lacking work permits, especially for foreigners), which provides an incentive to undertake them unofficially. This holds, of course, also for illegal activities such as the production and distribution of drugs. An important reason for exiting the official sector is the restrictions imposed on working time. Low work hours, long holidays, early retirement and, above all, unemployment, are important reasons for moonlighting.

(b) The expected punishment of working in the underground economy provides a disincentive for doing so. It consists of the probability of being caught and the size of punishment. For persons outside the established society (for example, illegal immigrants), or for self-employed persons, expected punishment is lower than for other persons, and therefore a higher rate of participation in the underground sector is likely.

(c) The moral costs are another disincentive to be active in the underground economy. A good citizen has moral qualms about undertaking a forbidden activity. These moral costs are closely related to 'tax morale' which motivates citizens to pay their dues to the state.

The effects of the underground economy are reflected in the traces visible in the labor, money, and product markets discussed above. A specific econometric technique called 'unobservable variables approach' allows us to estimate the size of the underground economy. This technique seeks to identify the size of the underground sector, which cannot be observed itself, but whose causes (e.g., tax and social security burden, unemployment etc.) and whose effects (e.g., fall in the participation ratio) can be measured. This approach is the most comprehensive and builds on a well-structured behavioral model, but it requires a large amount of data. As these are often not available (in particular not for developing and transition economies), this approach is not generally applicable. The estimation technique moreover tends to be statistically fragile (i.e., small changes in specification and values of variables strongly affect the estimates).

3. Empirical Estimates

The following tables serve to indicate approximate magnitudes of the size and development of the underground economy, defined as productive, value-adding activities, which should be part of GNP. Table 1 presents a rough comparison of the size of the underground economies relative to GNP for a selection of Western European countries, Japan, and the United States for the mid-1990s, using the currency demand approach.

The South European countries (Greece and Italy) have an underground economy almost one-third as large as the officially measured GNP: followed by Spain, Portugal, and Belgium, having a shadow economy between 20 and 24 percent of (official) GNP. According to these estimates, the Scandinavian countries also have a sizeable unofficial economy (between 18 and 20 percent of GNP), which is attributed mainly to the high fiscal burden. The 'central' European countries (Ireland, The Netherlands, France, Germany, and Great Britain) have a smaller underground economy (between 13 and 16 percent of GNP), probably due to a lower fiscal burden and moderate regulatory restrictions. Smaller underground economies are estimated to exist in countries with relatively low public sectors (Japan, the United States, and Switzerland), and comparatively high tax morale (United States and Switzerland).

Table 2 provides a rough comparison of the size of the underground economy relative to official GNP for a selection of developing and transition economies for the beginning of the 1990s, using the physical input (electricity) demand approach. Some of these countries (Nigeria, Egypt, and Thailand) are estimated to have an underground sector nearly three-quarters

Table 1
Size of the underground economy relative to GNP in various European countries, mid-1990s. Estimation based on the currency demand approach

Greece Italy	27–30 percent
Spain Portugal Belgium	20–24 percent
Sweden Norway Denmark	18–23 percent
Ireland France Netherlands Germany Great Britain	13–16 percent
Japan United States Austria Switzerland	8–10 percent

Source: Compiled from Schneider and Enste (2000)

Table 2
Size of the underground economy relative to GNP in various developing and transition countries, at the beginning of the 1990s. Estimates based on the physical input (electricity) demand approach

Developing Countries	
Africa	
Nigeria Egypt	68–76 percent
Tunisia Morocco	39–45 percent
Central and South America	
Guatemala Mexico Peru Panama	40–60 percent
Chile Costa Rica Venezuela Brazil Paraguay Columbia	25–35 percent
Asia	
Thailand	70 percent
Philippines Sri Lanka Malaysia South Korea	38–50 percent
Hong Kong Singapore	13 percent
Transition Economies	
Central Europe	
Hungary Bulgaria	24–28 percent
Poland Romania	16–20 percent
Slovakia Czech Republic	7–11 percent
Former Soviet Union Countries	
Georgia Azerbaijan Ukraine Belarus	28–43 percent
Russia Lithuania Latvia Estonia	20–27 percent

Source: Compiled from Schneider and Enste (2000)

Table 3
Growth of the underground economy relative to GNP for selected West European countries and the United States, 1960–95. Estimates based on the currency demand approach (rounded figures)

	1960	1995	Percentage point increase
Sweden	2 percent	16 percent	14.5 percent
Denmark	4.5 percent	17.5 percent	13.0 percent
Norway	1.5 percent	18.0 percent	16.5 percent
Germany	2 percent	13.2 percent	11.2 percent
United States	3.5 percent	9.5 percent	6 percent
Austria	0.5 percent	7 percent	6.5 percent
Switzerland	1 percent	6.7 percent	5.7 percent

Source: Compiled from Schneider and Enste (2000)

the size of officially recorded GNP. In many countries, the size is one-quarter to one-third of GNP. In Asian countries, with a comparatively low public sector, high tax morale, or high expected punishment (Hong Kong, Singapore), the underground economy is estimated to be similar to that in many 'Northern' European countries.

Transition economies are estimated to often have substantial unofficial activities, many around one-quarter of GNP. An exception is ex-Czechoslovakia where, according to these estimates, the underground sector is clearly around 10 percent of GNP.

Table 3 reports estimates of the growth of the underground economy (relative to GNP) for selected Western countries and the United States, using the currency demand approach.

The Scandinavian countries (Sweden, Norway, and Denmark) and the German-speaking countries (Germany and Austria) exhibit a sizeable increase of the underground economy within the 35 years covered (1960–95), and tend to understate the respective effects on unemployment. Also the countries with a low share in the beginning (Switzerland and the United States) show a significant increase, with the US share more than doubled. Sizeable increases have been estimated, with few exceptions, for all types of countries and all kinds of approaches: the increasing importance of the underground relative to the official economy is a robust phenomenon. It has been attributed to many different causes, but the most important and most often cited ones are the rise in the burden of taxes and social security contributions, the increase in public regulations, especially on labor markets, as well as a long-term fall in civic virtue in the population.

4. *The Effects of the Underground Economy on the Official Economy*

In order to study the effects of the underground on the official economy, the underground economies have been integrated into macroeconomic models; this yields an extended macromodel of the business cycle, as well as tax and monetary policy linkages with the shadow economy. As a result, it becomes clear that these effects should be taken into account for tax and regulatory policies. The presence of a shadow economy tends to overstate the inflationary effects of a fiscal or monetary stimulus, and tends to understate the respective effects on unemployment. When the growth of the shadow economy and the 'official' economy are positively related (which is likely to be the case when entry costs into the shadow economy are low due to a low probability of enforcement), an expansionary fiscal policy has a positive stimulus for both the formal and informal economies. It has also been found that the US productivity slowdown over the period 1970–89 was vastly overstated, as the under-reporting of income, due to the more rapid growth of the US shadow economy during this period, was disregarded.

The underground economy is beneficiary insofar as it responds to the economic environment's demand for urban services and small-scale manufacturing. The casual sector provides the economy with dynamic and entrepreneurial spirit and can strengthen competition, increase efficiency, and put effective limits on government activities. The casual sector contributes to the creation of markets, increases financial resources, and transforms the legal, social, and economic institutions necessary for accumulation. Moreover, a substantial part (up to 70 percent) of the earnings gained in the shadow economy is quickly spent in the official sector and thus boosts the official economy. These expenditures tend to raise consumer expenditures as well as (mostly indirect) tax revenues.

5. *Policy Consequences*

The growth of the underground economy over the few last decades and its effect on the official economy, both in general perception and scholarly research, has prevailingly been evaluated as a negative development,

which should be counteracted. In particular, politicians and public officials have pointed out that the state's capacity to provide the desired public services is undermined because tax revenue is lost. But not all commentators share this view. Some see it as a welcome and effective limit on the tendency of governments to continually raise the fiscal burden, and to impose more and more bureaucratic restrictions on the economy and society. More generally, the rise of the underground economy is interpreted to indicate that the relationship between the state and the citizens is fragile and needs improvement. It has also been argued that many developing and transition economies would break down or function at a much lower level of production and welfare if the underground economy did not exist.

The fight against the underground economy is a recurrent theme in many countries. The dominant method is to increase deterrence. The probability of being caught is raised by more regular and intensive controls, often by the police. Punishment is raised by imposing higher fines and, in severe cases, prison sentences. Both consumers and suppliers of goods and services produced in the underground sector are targeted.

The success of such deterrence policies is rather doubtful. In the case of the underground sector related to drugs, prostitution, and alcohol prohibition, the effect has turned out to be at best weak, if not counterproductive. Many persons active in the underground economy move more deeply into illegality in order to make detection more difficult. As a result, the underground activities become more criminalized, and more difficult to observe and to influence. Well-organized and ruthless, organized crime (often called the Mafia) becomes more dominant.

A deterrence policy need not always be a failure, but the successes tend to be short run. Provided the demand for underground goods and services remains intact, the profit opportunities in the underground economy become so large that supply reappears and the underground economy recuperates. A less oppressive policy is to lure people into the official economy by legalizing parts of the underground economy, and by facilitating the move into the official economy (e.g., by granting an amnesty). Such measures have proved to be only moderately successful.

A positive approach to raise the motivation to stay in the official economy by improving the efficiency of public services, reducing the tax and social security burden imposed on labor, and/or by raising civic virtue, has been used only rarely. Many policy makers doubt whether such measures work at all. In any case, they are effective only in the longer run. One possibility is to adjust public supply more closely to what the citizens desire, and to lower cost for a given quantity and quality of public supply. This can be attempted by streamlining public sector activities (e.g., by New Public Management). A more fundamental way is to improve the political process by opening the political arena to contending interests, and by strengthening the democratic participation rights of the citizens.

Informal Reasoning, Psychology of

Informal reasoning occurs when a given task, its components, and/or its outcomes vary in degree of certainty or acceptance. This is in contrast to reasoning found in tasks based upon logic and mathematics, which involve certainty and soundness. This article begins with discussion of terminology related to

informal reasoning, followed by a selective review of informal reasoning research, and concluding with consideration of theoretical issues.

1. Terminology

In psychology, reasoning typically refers to the process by which a person makes an appropriate inference that is based upon some particular given information. Inferences may be generated and evaluated, the latter based upon the inference's appropriateness. The inference may be a conclusion or it may fill in an information gap. The reasoning also may consist of a complex series of steps in which particular information is organized and/or used with inferences, thereby enabling the reasoner to reach a goal. Reasoning in designing an experiment or buying a car would be examples of a larger reasoning context.

The term informal reasoning suggests that there are two types of reasoning, formal and informal. This terminology is unfortunate because the distinction is primarily one of task and not of reasoning. Formal tasks are generally those of deductive reasoning as found in logic that has its origins in Aristotle's development of logic. Such tasks, for example, employ the categorical syllogism, structures of conditional logic, or mathematical problems, as proving a theorem. Furthermore, until relatively late in the twentieth century, psychological research on reasoning was dominated by the use of formal tasks. Such research had as a central question whether a person could evaluate a syllogism or some other structure accurately with respect to its validity. If not, the question became why the error was made. Also, a related issue was the question of whether humans are rational, with rationality defined in terms of correct performance on a given formal task.

Examples of tasks involving informal reasoning are making a decision, determining routes and distances to a destination, arguing with a son or daughter, or writing a political speech. Evaluation of performance on such tasks occurs via use of two criteria, the acceptability of the reasoning and the reasoner's effectiveness in reaching the goal.

Informal reasoning tasks differ from formal tasks in at least three ways: first, formal tasks may be transformed symbolically and evaluated, as 'All A are B,' etc., which makes these tasks content-free. Indeed, it is primarily when meaningful content is used that individuals stray from logical performance. In informal reasoning tasks, understanding the content is always critical. Second, evaluation in the formal task requires determining whether the reasoning is consistent with the rules of validity for the particular logical structure under study. In the informal case, evaluation is performed in relation to the acceptability of the contents of the reasoning and effectiveness in reaching the goal. Third, statements found in formal structures are regarded as true or not true; in the informal situation, statements may be regarded as true, not true, or at some particular level of certainty or acceptance between these extremes.

The language structure most common to informal reasoning is the argument. In particular, it is the form of an argument referred to by Aristotle as the enthymeme. This structure is a claim supported by a reason (or premise supporting a conclusion). Indeed, most informal reasoning research has been conducted in the context of argumentation.

2. Informal Reasoning Research

2.1 Argumentation Skill

A number of studies have demonstrated that young children are able to state claims and justify them. Children, however, need to have knowledge of and perhaps interest in, the subject matter of the argument. Young children, for example, will argue about the possession of a toy. If child A has a toy and child B takes it, child A may not only claim ownership of it but also may provide reasons why child B should return it.

The reasons offered by children have been classified. For example, children of ages approximately three to five were observed in a playroom situation (Eisenberg and Garvey 1981) in which one child would make an assertion such as 'Give me the toy' and the child with the toy would say 'No,' sometimes adding a reason. The first child then indicated why he or she should have the toy, and the conflict would sooner or later reach a conclusion. The strategies used, in ascending order with respect to adaptiveness and resolving the conflict, were insistence, mitigation or aggravation, conditional directive (if you will do X, I will do Y), and compromise. Although compromise was the best resolution strategy, a number of studies have shown compromise is found infrequently in conflict situations.

Similarly, the persuasion skills of preschool children have been studied. Children were asked to convince 'mother' or a friend to buy or share a toy. Occasionally there was a negative response to the child and the question was how did the children respond to these negative replies. Bargaining and guarantees were the most frequently used strategies, with boys tending to invoke norms and appeal to a sense of fairness more than girls, and girls making more requests (Weiss and Sachs 1991).

Children at least as young as age five are also able to make and justify moral decisions. Children were asked if they would pull hairs from a tiger, something that would hurt the tiger, if the contents of the hair were going to make some people well. Younger children tended to say no while older children were likely to

answer yes. Both age groups provided supporting reasons. Similarly, children promised to help each other finish tasks in order to be able to attend a baseball game. When the game was called off because of rain, younger children felt the promise should be kept while older children did not. In both of these studies younger and older children differed in what reasons and norms they invoked in making their decisions; older children and adults understand more of the contractual nature of agreements whereas younger children use less complicated norms such as that you do not want to hurt animals. In addition, the argument has been made that young children argue in much the same way as adults, but their world knowledge and social knowledge are less developed than older people (see Stein and Miller 1991).

As children become older, they improve in their knowledge of, and use of, argument skills. Indeed, older children are more skillful in generating counterarguments and refutations. The issue, however, is complicated by the role of subject matter knowledge and intellectual ability. In one study (Means and Voss 1996), the improvement in argument skill performance with age was demonstrated for the one-third of the students scoring highest on intellectual tests. Students in the middle third improved some, but those in the lowest third did not improve over grades 5–11. Furthermore, not only did knowledge of the subject matter (drugs) increase with intellectual ability, but intellectual ability was related to how well the students were able to use their own knowledge.

While children as young as three years of age demonstrate the ability to state arguments, generating written arguments does not occur until a later age. This probably occurs because writing includes mastery of a number of interrelated skills. Following a classroom debate on the topic of pollution, children of ages seven or eight were able to write a positioned argument about the pollution while children over age 14 were able to write a more developed argument involving, for example, counterarguments and refutations. Student involvement in the topic also enhanced performance. Also, another task demonstrated that student knowledge of the structural components was related to their essay performance, thereby suggesting a general learning of argumentation skills (Golder and Coirier 1994).

2.2 *Argumentation in Adults*

The generation and especially evaluation of arguments by adults has received surprisingly little research. In one study (Kuhn 1991), people in their teens, twenties, forties, and sixties were asked three questions: why students failed in school, why so many prisoners return to prison, and what produces unemployment. The investigator analyzed the protocols in relation to statements of possible causes (theories) and the related justification (or evidence) thereof.

Kuhn classified the stated theories as single cause, multiple parallel cause, or multiple alternative causes. While no differences were obtained for gender or age, more educated people tended to state more complex arguments. Kuhn also distinguished between evidence and pseudoevidence. Evidence consisted of demonstrated covariation, causal relations, or was indirect. Pseudoevidence, essentially being illustration, occurred when individuals provided a scenario such as 'My classmate failed in eighth grade. He would go home, his parents were working until late, and he had to take care of his brothers.' Some people provided no evidence, taking their theory as evidence. While on less than half of the opportunities individuals provided genuine evidence, education level again yielded higher performance. Pseudoevidence was quite prevalent, with many participants feeling it was sufficient as a justification. The idea that a story provides evidence even though it does not provide a test of the theory is used in many everyday situations, including political speeches and advertising. Kuhn also found that people who worked in one of the domains of the three questions showed more knowledge of the topic, but reasoned in much the same way as people of their corresponding educational level. Philosophers were able to discuss evidence appropriately, a finding from which Kuhn concluded that knowledge of topic and argumentative skills are two different things, in that you may learn one without learning the other. College education, however, teaches or should teach what constitutes knowledge within a domain and the nature of evidence and arguments within that domain.

When individuals are asked to generate arguments for and against a given position, a bias occurs in which the person states more arguments supporting his or her own position than the other position. This my-side bias has been found in children as young as five years and with adults. The role of sociocultural context in argument generation has been shown by Zammuner (1997) who, conducting the study in Italy, found results consistent with the idea that more arguments had to be generated by those people in favor of abortion rather than those opposed to it because the illegality of abortion in Italy required that a stronger case had to be made for it.

2.3 *Reasoning as a Dialectical Process*

While the discussion of informal reasoning thus far has focused on the individual, informal reasoning is also found in dyadic and larger social settings. Vygotsky (1978) maintained that reasoning is acquired via a dialectical process in which a person, when interacting with others, corroborates, contradicts, or puts in question what he or she already knows.

Reasoning then develops via this interaction. This view suggests beliefs may be modified via such interactions.

In one study dyads discussed a controversial issue, with dyad members congruent or incongruent in their respective positions. The experience tended to move people away from extreme positions to more central positions. Their dialogs also showed incorporation of information and reasoning from the partner.

As with the children, informal reasoning has been observed in adult conflict situations. Hofer and Pikowsky (1993) studied the reasoning in the dialogs of mother and daughter arguments. Daughters, in their effort toward independence, tried to weaken or reject the mother's arguments while stating their own preferences. Mothers, in their effort of control, supported and explained their own arguments and asked questions with the daughters responding to them. Arguments were seldom resolved.

Informal reasoning has also been studied in major negotiation contexts. In an analysis of the transcripts of three high level political meetings, including the Hitler–Chamberlain Munich dialogs, Axelrod (1977) found that the data did not support a debate model. Instead, progress in the conference negotiations was made by the insertion of new ideas that frequently were derived from an examination of the two positions.

How contradictory information is processed has been studied in an educational context. Sometimes individuals ignore contradictions, assimilating them into their existing knowledge base. Other times they do 'knowledge building,' that is, they examine the contradictory statements, consider the implications of them, and modify their knowledge to take them into account. The contradictory statements could be rejected, but if they are, it is for reasons considered during the process (Chan et al. 1997).

Being able to reason well has long been regarded as an important educational goal. The goal is most frequently found in statements related to critical thinking. A number of investigators cited have noted that acquiring argumentative skills and subject matter are not the same thing. Yet the two are related. If one is going to argue about a historical issue, knowledge of that issue is critical. At the same time, argumentative skills are also needed, and these are probably acquired via subject matter learning, especially but not exclusively in history. Students are likely to need more experience in using the knowledge they have acquired in argumentative and other contexts in order to acquire argumentation skills.

3. *Theoretical Issues*

In her criticism of the deduction–induction distinction, Govier (1987) noted that the definition of induction is indefinite; it could even mean everything that is not deduction. Moreover, a strict definition omits some important forms of reasoning such as causal, by analogy, counterfactual, casuistry, case-based reasoning, pro and contra evaluation in decision making, conflict and negotiation, and reasoning in persuasion. The scope of informal reasoning also is indefinite; all of the forms of reasoning mentioned and others could be regarded as types of informal reasoning. Indeed, defining it in a more limited way would be extremely difficult.

With respect to theory, there is no theory of informal reasoning *per se*. Instead, there are theories pertaining to the types of informal reasoning such as those of analogical reasoning, argumentation, problem solving of ill-structured problems, causal reasoning, conflict resolution, and various approaches to decision making. These theories are relatively specific and have not been integrated. The present article focuses on argumentation both because of its cross-discipline pervasiveness and because it is basic to informal reasoning. The focus however, suggests the need to consider three related issues.

The scope of informal reasoning goes beyond the examples of this chapter. In academia, it is readily observed in history and the social sciences, but it also may be found in science. Dunbar (1995), for example, studied the thinking of scientists in microbiology and cell biology laboratories. The thinking involved evidence evaluation, analogies, and problem finding, generally not formal logic structures, but obtaining information, using it, and making judgments about data interpretation and subsequent research.

As previously noted, deductive reasoning has had a privileged position in the study of reasoning. But the arguments found in informal reasoning are of the claim-support type, which it has been argued consists of a syllogism with a missing premise, thereby making it deductive. But Govier (1987) makes the point that any claim-supporting argument can be made logically sound by adding one or more premises. This makes logical soundness of an enthymeme trivial and points to the importance of the enthymeme as a means of justification and/or persuasion.

Informal reasoning is also closely related to rhetoric. In the last half of the twentieth century two works, by Toulmin (1958) and Perelman and Olbrechts-Tyteca ([1958] 1968), have been instrumental in renewing interest in rhetoric. Each emphasizes a jurisprudence model to reasoning rather than a model based upon logic. Toulmin's model describes components of a single argument, with the other work emphasizing argument schemes and the role of the audience. While these works have been criticized, it seems reasonable to assume that future work in informal reasoning will involve the rhetorical function of informal reasoning.

J. F. Voss

Informal Sector

The notion of the informal sector emerged from international research on Third World urban development in the early 1970s as a name for activities and enterprises escaping formal economic regulation. It and other terms for nonregulated economic activities have since been applied to research in the West, yet the bulk of informal sector research continues to be undertaken in the Third World. The focus has shifted from detailed descriptions of informal sector activities in different settings, to questions about their absorbtive capacity and potential for growth, to dynamics of informalization in general, including its gendered nature. This shift entails conceptual clarifications of the nature of informal sector activities and their implications for understandings of economic growth dynamics in general.

1. Meanings of 'Informal'

The term 'informal' is more of a residual notion than a concept, defined in relationship to something else, that is, to what it is not. The term 'sector' implies linkages to the rest of the economy. In social science scholarship since the early 1970s, including policy research and development economics, and in applied work, the term 'informal' has been used variously for a segment of a labor market, a set of activities, a nonregulatory status, a form of insertion in labor markets, a type or size of firm, and a general characterization of an economy. The phenomena to which the 'informal sector' refers are not new. Before this notion became current, social scientists were well aware that persons who do not perform labor for wages are not necessarily without work, although they are often counted as such in official statistics.

The 'informal sector' gave a name to economic activities that occupied large portions of urban populations in Third World countries. The scholarship that has arisen around it has characterized the linkage to the wider economy in two main ways. Perhaps the most common characterization of this relationship stems from Hart's work in Accra, Ghana, in the early 1970s. Hart coined the term 'informal economy' for a wide range of income generating activities with varying degrees of legality. He termed them informal so as to contrast them with formal, contractual wage labor (1973). The second characterization is influenced by the work of de Soto (1989) in Peru that explained informal sector activities as a response to ineffective state intervention, a result of the failure of both the state and the market to provide employment, housing, and services.

2. Informality: Sector or Process

Since the early 1970s, the informal sector has been a subject of extensive debate and research in which the principal focus has been on Western policy interventions aimed at increasing economic growth in developing countries. Some scholars also began to explore what was variously labeled irregular, black, underground, shadow, or hidden economies in the US and Europe, and some illuminated the operation of the second or parallel economies in socialist planned econ-

omies. While criminal activity *per se* usually is not considered part of the informal sector, petty scams and workplace pilfering are (Henry 1978). And the informal sector provides organizational practices and networks that facilitate drug trafficking and smuggling.

The chief questions raised in this scholarship concern the content, structure, and dynamics of the informal sector, that is, what to include and exclude, how precisely to differentiate it from the formal sector, and what growth potential it may have. Some scholars have suggested alternative terms and frameworks, such as casual work, petty commodity production, or householding and provisioning (Bromley and Gerry 1979, Mingione 1991). Still, the informal sector notion continues to be widely used for lack of any better descriptive term. Despite their conceptual misgivings, most scholars agree that discussions about economic life must take account of informal economic developments in their relationship to the wider economy. For example, MacGaffey (1991) found informal activities to be so central to efforts at making a living in Zaire during the last half of the 1980s that she characterized them as the Real Economy.

The idea of 'popular' or 'informal economies' is another way of highlighting the pervasiveness of nonregulated economic practices, recognizing their overall importance. Thinking processually about 'informalization' avoids the arbitrariness of sectoral dichotomies. It also helps to bridge the conceptual gap between production and reproduction, directing attention to household strategies and the ways in which household composition, stage of development cycle, and the gender and age of members introduce cultural assumptions into the division of labor. Yet although women and children are a highly visible segment of many informal markets, development advocates have only recently begun to pay attention to the relationships of age and gender to informal sector developments. For further discussion, see *Apprenticeship: Anthropological Aspects*; *Center–Periphery Relationships*; *Economic Anthropology*; *Urban Anthropology*.

2.1 The 'Informal Sector' and Third World Development

Research into informal sector developments in the Third World has clustered around two particular Western policy interventions aimed at promoting economic growth. The first cluster of work was influenced by Hart's research among migrants in Ghana that identified an 'informal economy' of self-employment, legitimate and illegal as opposed to regularized wage labor (1973). International development agencies were at this time concerned about the failure of industrialization efforts to improve economic growth in much of the Third World. Hart's observations were absorbed quickly into development policy directed at satisfying basic needs by harnessing informal income opportunities. In the International Labour Office's Kenya mission, for example, such activities were explained as 'a way of doing things' (ILO 1972), characterized by ease of entry, reliance on indigenous resources and family ownership, smallness of scale, labor intensive with adapted technology, skills obtained outside the formal school system, and unregulated and competitive markets. Here, as elsewhere in the developing world, governments were encouraged to take a positive role, ceasing to demolish unauthorized housing, changing trade and licensing procedures, and providing technical and outreach support to informal sector activities.

The second cluster of work on the informal sector appeared in the wake of the International Monetary Fund's (IMF) structural adjustment programs, particularly from the last half of the 1980s on. Many of the policy measures (e.g., employment retrenchment both in public and private work, introduction of value added taxes, removal of subsidies on food, fertilizers, and housing, and introduction of user fees in schools and hospitals) advocated by the IMF and the World Bank to transform state-controlled economies into market economies had adverse effects on already vulnerable groups. In fact, the volume and differentiation of informal sector activities increased across much of the Third World during the 1980s. Strapped for revenue and burdened by accelerating international debt, many governments began encouraging interventions by local and external nongovernmental organizations (NGOs). The centerpiece of this renewed policy attention is 'micro-enterprises' and their enhancement through credit arrangements and the provision of basic training in technical skills. Many observers who were disenchanted with the lackluster performance of Third World governments over the previous decades viewed informal sector activity as examples of free market initiatives. Perhaps more than any other scholar King (1996) has documented, with rare longitudinal insights, the local effects of these shifting policy interventions on the activities and achievements of informal sector artisans in Kenya.

2.2 The 'Informal Sector' and the West

Informal economic activities take place in advanced industrial countries as well as in the Third World (Ferman et al. 1987, Portes et al. 1989). Small-scale enterprises that bypass official regulation and off-the-book labor practices provide products and services that are traded and consumed throughout most of the West today. These activities are in parts of the US associated with immigrant communities, whereas in parts of Europe, for example Italy, they are based on artisanal enterprises and putting out systems. In the second or parallel economies of the former socialist countries in Eastern Europe, producers and consumers supplied, swapped, and bartered goods and services to

alleviate market shortages, avoiding the bureaucratic bottlenecks of centrally planned economies. Studies such as these are demonstrating that informal sector activities in the West are not exclusively associated with a bygone era of economic history, but keep reappearing in different places, operating in a variety of politico-economic contexts.

3. Policy Concerns

Definitions of the informal sector have important implications for the identification of target groups and types of intervention. If the informal sector provides an economic safety net, it does so differently, depending on type and level of activity, the resources brought to bear on its operation, and the local cultural context that shapes the participation of actors (Rakowski 1994). Whether a growth potential in fact exists requires understanding of the nature both of the activities in question and of the social relations that structure them. Some researchers avoid such discussions entirely by using descriptive terms like 'micro-enterprises.' But micro-enterprises encompass a range of activities that draw on widely diverse access, require different types of resources and inputs, and above all, they put the young and the old and women and men to work on unlike terms. Unless the economic and social nature of such activities is accounted for in more specific terms, development assistance risks being restrictive, thus jeopardizing the very goals of expanding employment and income generation that it seeks to promote. Anticipating that persons with few means may forfeit loans, some credit schemes, for example, target better-off participants, in this way accentuating already existing socioeconomic differentiation rather than reducing it.

4. The Market Meets the 'Informal Sector'

Since the 'informal sector' term was coined in the early 1970s, the economic context in which research on this topic first emerged has changed. Shifts in the global economy are altering production processes in an international division of labor that is affecting both the industrial West and the developing world, but differently so. Recent scholarship is reckoning with the linkages between local conditions and global forces that are shaping informal sector developments both in the West and the Third World (Dilley 1992). The introduction of 'free market' policies in the former centrally planned economies both in Eastern Europe and postcolonial Africa, for example, is giving rise to new research questions concerning the experiences of ongoing economic transformations. In much of Eastern Europe and Africa, an informal sector culture had been taken so much for granted that its operational principles have become pervasive. Relevant questions in such settings concern the effects of free market operations on members of the many households whose livelihoods were made from informal sector activity.

While the term the 'informal sector' may remain part of our descriptive vocabulary, new scholarship is likely to continue to disentangle the complexities of informal activities that need to be understood in their own right if we are to develop policy programs to support them. The enthusiastic reception in some circles of de Soto's praising of the resourcefulness of the urban poor must be tempered by a recognition of the heterogeneity and change of informal sector activities as well as of the exploitative conditions under which much of this sector's work is carried out, particularly by women and children. Lessening this state of affairs on a global scale requires more than self-help by small-scale entrepreneurs and intermittent external support by NGOs. It invites government action on many fronts to reshape the institutional structures that continue to reproduce livelihoods in the interstices of the economy.

Information and Knowledge: Organizational

Information is data that have meaning. Meaning arises as data are interpreted by sense-making frameworks (Bruner et al. 1956). This sense making depends on what is already known as well as what data are available.

Organizational information derives its meaning from the sense-making frameworks that characterize specific organizations. Many organizational members need information in order to fulfill their responsibilities, so other members gather data and convert it into information. Organizations can acquire data by scanning environmental data sources, by ingesting new members, or through internal activities, such as accounting and research. Most organizations include personnel who specialize in various forms of data acquisition or information processing, and large organizations have departments that focus on such specialties. Organizations convert data into information by discussing the implications of data, by adding to databases, or by feeding data into decision processes. They process information by filtering it, integrating it, disseminating it internally, and interpreting its implications. Nearly all organizations incorporate rules and procedures that cause personnel to initiate actions or to halt actions when they receive information that satisfies certain conditions (March and Simon 1958, Starbuck 1983).

Organizations emit data to mislead or undermine their competitors, and many organizations seek to gain competitive advantages by gathering data that their competitors lack. For example, data gathering and analysis enabled a large cosmetics company to avoid making a costly pricing blunder. This company buys data that are recorded by the checkout scanners in chain stores, and it gets daily reports from sales personnel who record data from retail outlets and transmit them to headquarters nightly. When a major competing firm introduced a new product, this cosmetics firm planned a defensive price reduction on its high-priced product X to keep the new competitor from taking too much business away from X. However, data analyses revealed that the new product was not actually competing with product X but with a much lower-priced product.

On the other hand, data gathering or information processing may be carried out so poorly that they undercut organizational performance. For instance, a rapidly growing health-care insurance firm processed receipts from clients much faster than claims from doctors and hospitals. As one result, this firm greatly overestimated its revenues, underestimated its costs, and made unrealistic predictions about its profits ···until the manager in charge of information processing reported that bill payments had fallen in arrears by nearly a year.

Some research shows that communications in organizations reflect the statuses and aspirations of organizations' members. People in hierarchies talk upward and listen upward (Porter and Roberts 1976). They send more messages upward than downward, they pay more attention to messages from their supervisors than to messages from their subordinates, and they try harder to establish rapport with supervisors than with subordinates. People also bias their upward messages to enhance good news and to suppress bad news.

Other research indicates that formal communications in organizations are generally problematic. Organizations bias their formal reports to win the support of employees, customers, investors, and the general public; and the members of organizations use formal reports to promote their careers or other interests. As a result, formal reports are permeated with misrepresentations and biases, and the organizations that take formal reports seriously are prone to run into trouble (Altheide and Johnson 1980, Hopwood 1972). Such issues make informal communication important. For instance, Grinyer and Norburn (1975) found that more profitable firms pay less attention to the information transmitted via formal reports and rely more strongly on informal communication channels, and that more profitable firms base their analyses on information drawn from diverse sources.

Knowledge is an accumulation of information. Whereas information comprises a flow that changes rapidly, knowledge is a stock that changes only incrementally. Some knowledge is explicit; other knowledge is tacit (Baumard 1999, Polanyi 1966). Organizations can attempt to share and organize explicit knowledge, whereas tacit knowledge remains private and disordered. Nonaka (1994) argued that individuals often acquire knowledge tacitly and this tacit knowledge does not become organizational knowledge until it becomes explicit. Many business firms are attempting to foster the conversion of tacit knowledge to explicit knowledge. One tactic for doing this has been to organize employees into on-line communities that identify and discuss shared issues on intranets.

Activities such as teaching, consulting, and practicing law draw on extensive knowledge without processing large amounts of current information. Other activities, such as bookkeeping and data entry, process much information without using much knowledge. However, distinctions between data, informa-

tion, and knowledge are often difficult to draw, as the conversion of data into information depends on knowledge, which derives from data and information (Dretske 1999, Machlup 1980). Since the meaning of knowledge arises in part from its structure, knowledge reflects the intentions of the people who compile or organize it, and different people often extract different knowledge from a shared flow of information.

Not only is it difficult to distinguish information and knowledge from each other, the labels that people apply to transformations of information and knowledge are often unclear. People who perform very similar tasks may describe their activities as applying old knowledge to new problems, as creating new knowledge, or as preserving knowledge that already exists. For example, it can be difficult to distinguish between creating knowledge and applying it; new knowledge research may have direct applicability, efforts to apply knowledge may yield fundamentally new insights. Indeed, to create valid knowledge about systems as complex as a human body or an economy, people have to apply their current knowledge. Similarly, applying and preserving knowledge complement each other. Merely storing knowledge does not preserve it for long periods, as people must relate it to their current problems and activities. They have to translate it into contemporary language and frame it within current issues.

1. Recognizing the Importance of Information and Knowledge

Strangely, both managers and scholars paid little attention to the centrality of information in organizations' activities until the last half of the twentieth century. Not until the 1950s did articles and books begin to portray managers and work groups as decision makers. It was the 1970s, however, before there were many studies of organizations as decision-making and information-processing systems.

One factor driving recognition of the centrality of information was the rising economic importance of service industries and knowledge-based work. In industrialized countries, the fractions of workers who process information have risen gradually throughout the twentieth century. The fastest growing occupations have been clerical, professional, and technical workers, including managers and administrators. In the latter part of the century, the fastest growing industries included telecommunications, software, and computing services. The United States provides the most extreme case. By 1990, the information sector accounted for three-quarters of the US gross domestic product, and over half of US workers were doing some type of information work.

A second, and possibly more important, factor that has focused attention on information has been development of computer and telecommunication technology. Computers have not only facilitated the processing of information, they have provided metaphors for information processing by both individual people and social systems. Thus, equipped with an appropriate sense-making framework, managers and scholars began to notice the importance of information processing.

In 1958, March and Simon proposed the then novel idea that organizations can be viewed as information-processing systems. March and Simon pointed out that information sources and channels affect organizations' perceptions, intraorganizational conflict, and goal coherence. They emphasized the human limitations that prevent people and organizations from acquiring and processing unlimited amounts of information. They also characterized people and organizations as using programs to process information, a direct analogy to computers. Later, Cyert and March (1963) described some programs used by business firms to make decisions about prices and quantities.

Galbraith (1973) proposed an approach to organization design that focuses on the communication needed to coordinate tasks. He pointed out that programs can substitute for communication. When tasks can be adequately described with programs and personnel follow these programs, personnel can coordinate their actions without much communication. Programs are effective, however, only when organizations face familiar situations. If organizations continually encounter new situations, their old programs will not be effective and personnel will have to coordinate by communicating with each other. Galbraith pointed out that organizations can make communication less necessary by separating tasks into self-contained clusters and by lowering their performance goals, thus leaving some resources underutilized. Organizations can also substitute direct horizontal communication across departmental boundaries for vertical communication up and down hierarchies; this moves decision making down hierarchies to the people who have the needed information rather than bringing information up hierarchies to higher-level decision makers.

Studies of organizational knowledge did not appear in numbers until the 1990s. One theme has been the increasing importance and distinctive characteristics of professional-service organizations, such as health-care agencies, law firms, and public-accounting firms. Knowledge-intensive firms make esoteric expertise the focus of their competitive strategies (Starbuck 1992). As well as becoming more important economically, professional-service organizations have grown much larger and expanded globally (Brock et al. 1999). A second theme has been the importance of information-processing resources and knowledge resources to the profitability of all sorts of organizations. Current thinking about strategic management emphasizes the

usefulness of valuable resources that are rare and difficult to imitate (Barney 1991), and many organizations seek to accumulate valuable and proprietary knowledge that they can exploit strategically. For instance, chemical and pharmaceutical companies employ skilled scientists and spend heavily on research aimed at developing patentable, proprietary products. Some manufacturing firms assert that cadres of experienced and highly trained managers comprise their key assets. Many firms have appointed 'learning officers' who are charged with identifying useful knowledge and disseminating it to personnel who can use it.

It seems likely that information and knowledge will grow more and more important in industrialized societies. This rising emphasis involves several components.

(a) The industrialized societies are shifting away from manufacturing and toward services. For instance, in Europe, telecommunications activities have been growing about 10 percent annually and software and computing services have been growing nearly 20 percent annually.

(b) Knowledge workers and information workers are replacing manual workers. For example, machine-tool operators are giving way to technicians who monitor computer-controlled machines.

(c) Workers of all kinds are gaining more education and more information-processing skills.

(d) Business is investing heavily in equipment for information work. In the US in 1986, information-related equipment accounted for 40 percent of capital investment.

(e) Knowledge-intense and information-intense organizations are emerging and employing millions of people.

(f) Corporations are depending on communications and information processing to maintain their coherence as they globalize. Transoceanic communications have been growing about 35 percent annually, with the faster growth being in the Pacific region.

(g) Firms are forming alliances and coalitions that rely on shared databases and electronic communications instead of face-to-face meetings (Hedberg et al. 1997). Financial analysts have forecast that business-to-business (i.e., B2B) commerce via the Internet will be the fastest growing business activity during the early years of the twenty-first century.

Despite the fact that computers and electronic communications devices have existed in some form for decades and they have become prevalent in Europe and North America, only a small fraction of the world population now has use of computers, e-mail, or the Internet. At the same time, technological development has actually been accelerating. Thus, the effects of these technologies on people, organizations, and societies are only beginning. Some of the current trends appear to be as follows: Organizations are gaining access to more data more quickly. This creates opportunities for surveillance from afar, so 'competitive intelligence' is becoming easier and more productive. In addition, supervisors can more easily monitor the activities of distant subordinates, and organizations can more easily monitor the activities of their partners in alliances. Organizations have more freedom to spread geographically, and they can collaborate effectively without actually merging. Finally, as communications replace physical travel and direct supervision, some employees are engaging in telework and workgroups are replacing hierarchies.

Information Processing and Psychopathology

How do we interpret and impart meaning to information from our surroundings? Does the manner in which we process and interpret information affect our psychological functioning? Peoples' perceptions of the world do not reflect a fixed reality. Rather, perceptions involve a dynamic interplay between the external stimuli that people observe and their highly subjective (and often unconscious) attentional and interpretative processes that allow them to impute meaning to experience. The scientific construct that we now refer to as 'information processing' dates back to Wilhelm Wundt (the father of experimental psychology), who initiated the systematic study of the ways in which people perceive external stimuli.

Although information processing has a long tradition in experimental psychology, applications of information processing models to the field of psychopathology are relatively recent. This is particularly surprising given that several forms of psychopathology clearly involve aberrations in the accurate processing of information. Nevertheless, advances in recent years suggest that the manner in which people process and interpret information does significantly influence their emotional functioning and well-being. Moreover, an information-processing approach to psychopathology promises to refine our understanding of a number of psychological disorders.

1. *Background*

Although the specific emphases have changed, for much of the twentieth century most forms of psychopathology were conceptualized either as disorders of biological origin or as problematic behaviors that resulted from faulty learning. For example, the disorder we know today as schizophrenia was originally called *dementia praecox*, or early dementia, by Kraepelin (1883), who believed that the brains of individuals who developed schizophrenia had begun to deteriorate prematurely. Similarly, scientists ascribed the etiology of depression and anxiety to various neurotransmitters and other biological factors. For instance, depression was hypothesized to result from too little serotonin and norepinephrine (e.g., Schildkraut 1965), and some forms of anxiety were postulated to be linked to a biological 'readiness' to develop fear to specific stimuli (e.g., Garcia and Koelling 1966).

These biological views of psychopathology were refined and strengthened in the 1950s and 1960s with the advent of psychotropic medications as a major treatment modality for schizophrenia, depression, and anxiety. At the same time, psychologists were beginning to develop behavioral conceptualizations of specific forms of psychopathology. Depression, for example, was hypothesized to be caused by the individual exhibiting a reduced repertoire of behaviors. Lewinsohn (1974) contended that the individual's reduced behavioral repertoire led to a decreased rate of positive reinforcement from the environment, which resulted in further reductions in behavior. Similarly, anxiety disorders were conceptualized from a behavioral perspective as a constellation of avoidance behaviors. Phobic individuals avoid the feared object, and people diagnosed with generalized anxiety disorder do not engage in adaptive behaviors through which they would learn that their avoidance of feared or conflictful situations is unwarranted. Moreover, the relief that came from avoiding a feared situation served to reinforce the avoidance behaviors.

These behavioral conceptualizations of psychopathology, and particularly of depression and anxiety, led to the development of effective behaviorally-focused treatments. As was the case with pharmacotherapies, the success of behavior therapy strengthened behavioral conceptualizations of psychopathology. In the 1970s, however, there was a 'cognitive revolution' in psychology.

2. *The Cognitive Revolution in Psychology*

In 1974, W. N. Dember described what he referred to as a 'cognitive revolution' in psychology in general, and in clinical psychology in particular (Dember 1974). Clinical psychologists became concerned with cognitive processes. There was growing dissatisfaction with the simple behaviorist stimulus–response (S-R) learning model of psychopathology, and increasing attention was being given to information-processing models of cognition. The cognitive revolution led psychologists to revisit intrapsychic functioning as a possible cause of psychopathology, opening doors that would reconsider the role of thought in human behavior.

Cognitive scientists became increasingly interested in two areas of human functioning: emotion and automatic processing. Psychologists offered cognitive theories of emotional functioning that emphasized the interaction of cognition and emotion in understanding human behavior (e.g., Bower 1981, Oatley and Johnson-Laird 1987). Psychologists also began to use methodologies developed by cognitive scientists to examine information processing that occurred outside of conscious awareness or control. This line of research focused on such areas as selective attention, implicit memory, and schema functioning (e.g., Kihlstrom 1987). The research activity in these new cognitive approaches paved the way for the study of cognitive functioning in psychopathology, and particularly in those psychological disorders that are characterized by difficulties in emotion regulation.

3. *Information Processing Perspectives on Psychopathology*

Psychological disorders began to be conceptualized and studied from an information-processing perspective. For example, some researchers suggested that schizophrenia is characterized by a breakdown or dysfunction in the filter mechanism that is responsible for screening out stimuli that are not related to the individual's current thought (e.g., Venables 1964). In the absence of that filtering, the schizophrenic is flooded with stimuli. Cohen et al. (1992) refined this filtering hypothesis by suggesting that schizophrenic individuals have a decreased ability to use contextual information to select appropriate behavior. Thus, from an information-processing perspective, persons diagnosed with schizophrenia are hypothesized to be unable to process and filter stimuli effectively, or to use contextual information to guide their thoughts and behaviors.

The growing interest in information-processing approaches to the study of psychopathology had an even greater impact on theory and research in the clinical disorders of depression and anxiety. Cognitive theorists implicated specific patterns of information processing as playing a causal role in the development of depression and anxiety. For example, Beck (1976) ascribes central importance to *negative schemas* in rendering an individual vulnerable to experiencing depression or anxiety. More specifically, Beck postulates that negative schemas, or expectancies, play a causal role in depression and anxiety by influencing negatively the selection, encoding, categorization, evaluation, and recall of stimuli in the environment. That is, people who are prone to developing depression or anxiety are characterized by negative schemas that influence their perceptions of, and interactions with, their environments and, consequently, lead to these disorders.

Beck hypothesized that these negative schemas develop from early adverse experiences in childhood. For people who are vulnerable to depression, these experiences concern loss and failure; for anxiety-prone individuals, they involve themes of danger and threat. Once they are activated, the schemas act as 'filters' through which stimuli and events in the environment are perceived, evaluated, attended to, and remembered. Thus, individuals interpret the information from the environment so that it is consistent with the schemas, selectively attending to particular stimuli or distorting the information to achieve congruence; positive stimuli may be selectively filtered out, and negative or neutral information may be perceived as being more negative than is actually the case.

These negative information-processing biases are postulated to lead to depression or anxiety, depending on the content of the schemas. Thus, from an information-processing perspective, schemas are postulated to play a critical etiological role in predisposing individuals to experience clinically significant episodes of depression or anxiety, particularly in the face of specific events that activate schema-driven information-processing biases. A similar conceptualization of the relation between cognition and emotion has been formulated by Bower (1981). Bower articulated a semantic associative network model in which concepts, emotions, and experiences are represented by distinct nodes that are interconnected within a large network. Within this network, activation of a particular node spreads automatically to adjacent nodes. Thus, the activation of emotion nodes spreads to adjacent cognitive nodes to produce mood-congruent memory. Bower posits that it is this activation of concepts and experiences which is related to the specific emotion that makes it easier to recall events that are congruent with the affective state.

Considered broadly, these cognitive models hypothesize that individuals who are experiencing emotional disorders should be characterized by negative biases in attention and memory. At the time these formulations were proposed, however, there were few reliable methods available for assessing biases in information processing. Recently, however, in large part because of the increasing interest in cognitive science, considerable progress has been made in the assessment of information-processing styles.

4. *How Are Information-processing Biases Studied?*

These information-processing formulations of the causes of various forms of psychopathology stimulated an extraordinary number of empirical studies. Early efforts to examine schematic functioning and information processing in psychopathology relied on self-report questionnaires to assess negative cognitive functioning. Although these were important studies,

the self-report methodology has two significant limitations. First, the information-processing formulations that are being tested with these measures are, in large part, theories of cognitive *processes* as well as cognitive *content*. That is, Beck and Bower formulated hypotheses concerning not only the content of biases in the information processing of depressed and anxious individuals, which concerns themes of failure and loss, and danger and threat, respectively, but more important, *how* stimuli and information involving these themes and this content are attended to, interpreted, and remembered, and how these cognitive processes are related to the course of the disorder.

Unfortunately, although questionnaire methodologies are adequate to examine cognitive content, they are not well suited to an assessment of cognitive processes. Second, because self-report questionnaire measures typically require participants to make conscious, deliberate, and thoughtful responses, they are simply unable to assess the existence and functioning of schemas or associative networks, which are hypothesized to be activated automatically and to operate largely outside of individuals' awareness.

To address these limitations, investigators developed and adapted methodologies derived from research in experimental cognitive psychology to examine the functional role of cognitive biases in a number of forms of psychopathology. In contrast to self-report questionnaire measures, these methodologies permit the assessment of automatic cognitive processes and schematic functioning. For example, several tasks have been developed to examine attentional biases in depression and anxiety. In the *Emotion Stroop Task*, participants are presented with emotionally valenced stimuli printed in different colors. Typically, the stimuli are selected to be relevant to the disorder under investigation: depressed-content words in the study of depression, anxious-content words in the study of anxiety, etc. As in the original Stroop task, participants are instructed to ignore the content, or meaning, of the stimuli and name the color in which each word is presented as quickly as they can. Information-processing formulations posit that the cognitive schemas of depressed or anxious individuals should lead them to exhibit biased attention to loss/failure or threat/danger stimuli, respectively. If these formulations are valid, the participants should be relatively unable to disattend from the content of the emotionally relevant words and consequently, should exhibit longer latencies (i.e., greater interference) to naming the ink colors of these stimuli.

The *Dichotic Listening Task* is conceptually similar to the Emotion Stroop Task. In this task, different information is presented simultaneously through headphones to each ear. Participants are instructed to attend to and repeat (shadow) neutral 'target' stimuli that are presented to one ear, and to ignore distractor stimuli that are presented simultaneously to the other ear. Thus, participants attempt to direct their attention to the ear in which the target stimuli are presented, and ignore stimuli that are presented in the 'unattended' ear. Again, the negative schemas of depressed or anxious persons are hypothesized to make it more difficult for them to ignore stimuli presented to the unattended ear when the stimuli are negatively valenced, than when the stimuli are neutral or positively valenced. This diversion of attention to negative stimuli presented in the unattended ear means that fewer attentional processing resources are available for tracking the 'target' information presented in the attended ear. Consequently, depressed and anxious participants are hypothesized to exhibit a greater number of shadowing errors of the neutral target stimuli on those trials in which the distractor stimuli are negatively valenced.

The *Dot-Probe Task* was developed to examine selective attention to emotional stimuli. In this task pairs of words are presented briefly (generally 500 to 750 msecs) and simultaneously on a computer screen. Both words then disappear from the screen and a small dot appears in the spatial location of one of the words. Participants are required to press one of two buttons to indicate, as quickly as they can, whether the dot replaces the word on the left or on the right. If, as information-processing formulations of psychopathology hypothesize, depressed or anxious individuals are biased to attend to emotionally relevant stimuli, they should be faster to detect the dot probe when it appears in the spatial location of a relevant emotion word (to which they were attending when it disappeared from the screen), than when the dot appears in the location of the neutral word.

Information-processing tasks have also been developed to examine memory biases in psychopathology. Perhaps the most frequently used paradigm involves an assessment of participants' memory for emotional stimuli presented during an experimental session. Participants are instructed first to encode emotionally valenced adjectives, often by rating how well each word describes them. Participants are then required to complete a follow-up task. In some studies, participants are asked to recall as many stimuli as possible. In other investigations, participants are asked to make perceptual judgments as quickly as possible of words that were or were not presented in the encoding task (e.g., lexical decision task), or to complete word-stems of old and new words with the first word that comes to mind (e.g., word completion task).

All of these information-processing tasks permit an assessment of cognitive processes that, until recently, could not be examined empirically. Findings from investigations utilizing these tasks in the study of various emotional disorders have led to refinements and extensions of cognitive theories of psychopathology, and have provided the impetus for studies attempting to integrate the examination of cognitive and biological factors in psychopathology.

5. Results of Studies of Information Processing and Psychopathology

The results of investigations using these new methodologies have clearly expanded our knowledge of information processing and psychopathology. For example, supporting a schema-based theory of anxiety, there is little question now that individuals diagnosed with an anxiety disorder automatically deploy their attention to stimuli involving themes of danger and threat. Thus, anxious persons have been found to show attentional interference effects for danger/threat words on the Emotion Stroop Task and the Dichotic Listening Task, and have also been found to exhibit selective attention to threat words on the Dot-Probe task (see Gotlib and MacLeod 1997, for a review of this literature). There are also some data to suggest that depressed individuals are characterized by a similar attentional bias to loss/failure stimuli on these tasks. Interestingly, however, there is stronger evidence to support the operation of a memory bias for negative material in depressed persons, a specific bias that does not appear to characterize anxious individuals.

A number of theorists have interpreted these differences in the information processing of depressed and anxious persons as evidence of fundamental differences in the nature of these two disorders. Whereas the attentional bias that characterizes anxious individuals is postulated to reflect the chronically elevated vigilance and heightened anticipation and arousal of this disorder, the memory bias observed in depressed persons is evidence of the rumination and regret often associated with this disorder. Indeed, this 'forward-looking' versus 'backward-looking' difference in the information-processing styles between anxious and depressed individuals has led psychologists to formulate distinct evolutionary theories of these two disorders. These differences in cognitive functioning have also led cognitive scientists to revise existing etiologic theories of depression and anxiety and to make new predictions regarding information processing and psychopathology (e.g., Gotlib and Krasnoperova 1998, Williams et al. 1996).

6. Conclusions and Future Directions

The 1990s witnessed a remarkable surge of interest in information-processing approaches to our understanding of psychopathology. Investigations examining negative cognitive biases in the attention and memory functioning of individuals diagnosed with depression and anxiety have yielded findings that contributed significantly to our understanding of these debilitating disorders. New and innovative methodologies continue to be developed to assess the relation between information-processing characteristics and psychopathology. One important recent direction taken by scientists in this field involves the study of the information-processing styles of individuals who are not currently experiencing psychopathology, but who are at risk for the development of emotional disorders (cf. MacLeod and Hagan 1992). In this context, investigators are beginning to assess biases in attention and memory in individuals who have had previous episodes of depression, and in offspring of depressed or anxious parents. The results of these investigations will undoubtedly help us to gain a better understanding of the factors that increase individuals' vulnerability, or susceptibility, to experience significant emotional disturbance.

Findings from studies examining information processing and psychopathology are also beginning to provide the impetus for investigators to assess the interaction of cognitive and biological functioning in emotional disorders. For example, using functional magnetic resonance imaging (fMRI), scientists are examining patterns of brain activation in response to various types of positive and negative stimuli in patients suffering from depression and anxiety. And other researchers are studying physiological arousal of depressed and anxious patients as they process positive and negative information. The results of such integrative investigations will lead to broader theoretical conceptualizations of different forms of psychopathology.

Finally, although it is still early in the process, it is likely that findings from studies of the information processing of individuals diagnosed with different forms of psychopathology will lead to innovations in the treatment of these disorders. Already, cognitive therapies have a strong foundation of empirical support. As results of information-processing studies continue to influence theories of psychopathology, approaches to psychotherapy based on these findings promise to develop in tandem.

Information Processing Architectures: Fundamental Issues

The term 'information processing architecture' refers broadly to the arrangement of mental subsystems that are hypothesized to be active in the performance of one or more psychological tasks. For instance, the simplest, most prototypical and opposed types of architectures are serial (one-at-a-time) vs. parallel (simultaneous) arrangement of two or more separate subsystems or processes. More complex arrangements are mentioned below (see *Additive Factor Models*). Further, there are a number of other aspects of perceptual and cognitive processing that are often included under the 'architecture' label including the questions of the basis on which cognitive processes will cease, various kinds of independence and dependence, and processing capacity. These will be described and discussed.

An early researcher especially pertinent to this review was Donders, a nineteenth-century Dutch physiologist. Donders believed that he could uncover the durations taken by various thought processes through his method of subtraction. The method of subtraction was based on the idea that complicated mental activities were compounded in a simple sequential fashion from less complex parts. Let mean response time be written as $\overline{\mathrm{RT}}$ and response time in general as simply RT. Then, for instance, the scientist might engage the subject in a task requiring both perception and decision and compare $\overline{\mathrm{RT}}$ from that condition with $\overline{\mathrm{RT}}$ from a task requiring only perception. The difference in $\overline{\mathrm{RT}}$s was interpreted as the mean duration of the decision operation.

The issues selected for review here seem elemental in the following sense. The construction of almost any system intended to carry out the processing (e.g., detection, search, comparison, recognition, recall, analysis of various kinds, and so on) of a finite number of tasks or items would have to make decisions on each of the studied issues. In addition, they are somewhat unique in having been subjected to quite general theoretical, quantitative, and methodological analysis; perhaps more than any other such concepts in the field. The issues will be introduced in the context of a popular experimental paradigm and then discussed in more detail.

1. An Experimental Paradigm and the Issues

The concepts to be defined below have figured prominently in studies on short-term memory and visual display search and we shall employ that type of paradigm for illustration. Considerable impetus was given to the information processing approach by several pioneering studies in the 1960s focusing on short-term memory and visual processing, using RT as the dependent variable (Atkinson et al. 1969, Egeth 1966, Sternberg 1966). We focus on Sternberg's short-term memory search paradigm (1966) for illustration. Short-term memory is specified operationally by the tasks requiring the retention of a small number of items for anywhere from a few seconds to several minutes. In this paradigm, a varying number (less than or equal to the number that can be maintained in short-term memory without error) of items, for instance, randomly arranged letters, is presented to the experimental participant. This is called the memory set. Then, a few seconds later, that participant is presented a so-called probe item and the task is to indicate very quickly, but at a very high level of accuracy, whether or not the probe was contained within the memory set. As introduced above, RT is the primary dependent variable of interest here, although a substantial history of work with accuracy also exists.

The first, and in some ways the most critical question, referred to the temporal structure of comparison of the probe item with the memory items. A hallmark of many early information processing models was seriality of operation, that is, each subsystem or component could operate only when preceding mechanisms were completed and only one could operate at any given time. Thus, *seriality* has the

connotation that no overlap of processing times occurs, in addition to the sequentiality of starting times. This latter type of constraint is referred to as *discrete flow*. The alternative possibility arose early on that all the items might be searched simultaneously, that is, *in parallel*. This issue of processing architecture can refer to the manner of treatment with regard to items within a single stage of processing, for instance memory search, as in the present case, or to the arrangement of larger components of the system, such as stimulus encoding vs. memory storage.

Of course, arrangements other than serial vs. parallel are possible, for instance, a system being serial part of the time and parallel part of the time. When all operations under focus begin at the same time but can finish at different times, the system (or mode of processing) is of course, simply parallel. However, when operations can feed into other components, but with overlapping processing times, the system is said to have continuous flow, rather than discrete flow. A great deal has been learned about discrete-flow architectures of considerable complexity over the past two decades (see *Additive Factor Models*). We will confine ourselves to serial and parallel systems and other processing characteristics that these can involve.

The primary RT durations under study in the memory search task are those associated with comparison of the probe to the memory items. Nonetheless, other time intervals, such as those associated with early sensory processing and late motor components must also be taken into consideration. It is a usual, but by no means uncontested assumption, that these so-called residual times are serially arranged with the process under study and are also stochastically independent of the latter (Dzhafarov 1992, Luce 1986, Townsend and Ashby 1983).

Besides the architecture issue, *independence vs. dependence* among the processing times of the items is also an important question. Another critical concept is that of *capacity*, which refers to how processing times are affected by the number of things to be worked on (Townsend and Ashby 1983). This is most easily illustrated with a version of parallel processing where the system slows down when the number of items that is being processed increases (that is, *limited capacity*). However, limitations in capacity that are indirect, even with serial processing, can be conceived. For instance, a serial processor might speed up as it goes through the items, due to warm-up effects, or slow down due to inertial factors or fatiguing of the processor. Even though capacity and independence are logically separate notions, they can interact. For instance, an important type of parallel system, one that can mimic serial processing, assumes that as the processing of each item is completed, its processing capacity is reallocated to remaining items (Townsend and Ashby 1983). This obviously affects the overall RT, but also creates a positive dependence among the item processing times.

Yet another important notion is that of *stopping rule*. Depending on the task, it may or may not be necessary for the participant to process all of the items in order to make a correct response. In the memory search paradigm, if the probe item is present and located in the current stimulus set, the processing can cease at that instant, without finishing the remaining items. This possibility is known as *self-termination*. However, since short-term memory search consumes only a few hundred milliseconds it is possible that the system nevertheless completes all items. This event is called *exhaustive* processing. On probe-absent trials, it is necessary to process all of the memory items in order to be sure of correctly making a 'no' response, that is, exhaustive processing must occur. In some experimental designs, all the items are probes. These need not be physically identical. For instance, the task might be to say 'yes' if any of the items is a vowel and a target-present trial could contain all vowels. This latter case permits the possibility of *first-terminating* or *minimum time* processing. Of course, it is an empirical question as to whether any kind of self-termination can actually take place in high-speed perceptual or cognitive operations, and must be addressed experimentally in each case.

Although the serial and parallel class of models both contain an infinite class of possibilities, the serial notion has traditionally been attached to a particular serial model that assumes identical processing time random variables on each item, independent of the number of items in memory (i.e., the load) and of the order of processing the items. It is also often assumed that the individual processing times are themselves mutually stochastically independent. We call this the *standard serial model*. Let the density of processing time for each item be designated $f(t)$ and that for the independent residual processing time be $g(r)$, where T and R are the respective random variables for t and r. Then the density on a probe-absent trial, $p(\mathrm{RT} = t)$, or $p(t)$ for short, is just the mathematical convolution of the n processing densities and the residual time density: $p(t \mid \mathrm{EX}) = f_1 * f_2 * \ldots * f_n$ where each f_i, $i = 1, \ldots, n$, is a replica of. The expected or average theoretical RT is $\mathrm{E(RT)} = n \cdot \mathrm{E(T)} + \mathrm{E(R)}$. Notice that processing is exhaustive, as designated by EX in the left-hand side, in this case. In the case of self-terminating (ST) processing on a probe-present trial, the number of items finished before the probe is found is itself a random variable. Under usual conditions, the probability that the probe will be found in the ith processing position is just $1/n$, so the average density for this case, is just $\mathrm{E}\ [p(\mathrm{T} \mid \mathrm{ST})] = (1/n)\, \Sigma_{j=1}^{n} f_1 * f_2 * \ldots * f_{i-1} * f_i$ times. Similarly, the expected RT, with $\overline{\mathrm{RT}}$ as the sample statistic, is just $\mathrm{E(RT \mid ST)} = (1/n) \cdot \Sigma_{i=1}^{n}$ $\mathrm{E(T)} + \mathrm{E(R)} = [(n+1)/2] \cdot \mathrm{E(T)} + \mathrm{E(R)}$, which yields the time honored result that this line has half the slope of that for the exhaustive serial RT.

The concept of parallel processing, like serial processing, is usually confined in the experimental litera-

ture to a very special kind of parallel processing. Processing is often said to be parallel if average RT is invariant across increases in load. When exhaustive processing has to occur, as in the probe-absent trials of memory search, this stipulation actually implies a very unusual kind of parallel processing, unlike the situation with the standard serial model. For instance, consider a set of parallel models with independent processing times, with the additional provision of unlimited capacity, in the sense that the probability distribution on completion time for each item does not change as n is increased. This class of models serves as a prototype of parallel processing in an analogous way to the standard serial model class just presented. Let us call this class the standard parallel model.

Let $g(t)$ be the fixed density function on processing time for each of the n items. Then $E[RT \mid EX) = E\{MAX[T_1, T_2, \ldots T_{n-1}, T_n]\} + E(R)$, where R is as above and T_i is the processing time of the item in position i. We drop reference to R which plays no role in the function shape, letting PT stand for processing time, that is, $PT = RT - R$. Then $E[PT \mid EX] = \int_{t'=0}^{\infty} [1 - G(t')]^n \, dt'$, where $G(t)$ is the cumulative distribution function associated with g. It is straightforward to show from this formula that mean RT is indeed an increasing, concave function of n (Townsend and Ashby 1983, p. 92). Note that $g(t)$ is invariant across values of n. Hence, many investigators use a very restrictive and typically unrealistic criterion for parallelity when they demand flat rather than increasing functions $\overline{RT}$ of n, even under exhaustive processing conditions.

It can also be observed that if mean exhaustive $\overline{RT}$s are flat functions of n, then mean self-terminating (again, a single position exists in the memory list that contains the probe) times would actually be decreasing, within the same model—a strong prediction which apparently has never been checked in studies using this logic. Thus, in the rare cases where flat exhaustive $\overline{RT}$ functions are actually found with exhaustive processing, the implications are quite strong. Models that can make such predictions are considered in Townsend and Ashby (1983, Chap. 4).

In contrast, in the case of ordinary self-terminating processing when a single position contains the probe, standard parallel models do predict a flat $\overline{RT}$ function. This can be readily intuited, since only the channel which processes the probe matters in self-terminating processing, and it is independent of all the rest (and is of unlimited capacity into the bargain). Finally in this model, mean first-terminating times should decrease with n.

2. *Mimicking Dilemmas*

As mentioned earlier, one of the driving forces behind mathematical meta-modeling in this area was the discovery that mathematical representations of diametrically opposed psychological principles could nevertheless sometimes mimic one another, even to the point of mathematical equivalence of their defining probability laws (Murdock 1971, Townsend and Ashby 1983). Hence, we will take some time here to outline the state of the art with regard to such questions within the present set of issues.

Consider a model for the processing times of n items under fixed experimental conditions. With regard to the parallel–serial issue, suppose no assumptions are made other than the probability mixture of generalized convolutions in the case of seriality and joint distributions on processing times in the case of parallelity. Then the parallel and serial classes of models are equivalent, in the sense that mappings can be provided that homeomorphically carry one joint density into the other (Townsend and Ashby 1983).

Nevertheless, over time, accumulating theoretical results have demonstrated that if the scientist is willing to make further restrictive, but sometimes still very general (and reasonable) assumptions about the models, and/or more complex experimental designs are utilized, the parallel–serial issue can be decided. For instance, certain rather fundamental differences between serial and parallel processing can be explored in experimental methods designed to exploit those differences (Townsend and Ashby 1983).

3. *Factorial Methodologies for Architectures*

One of the most promising and general approaches to identifying mental architecture is that based on the notion of *selective influence* of experimental factors, a notion first employed in tests of strict seriality by Sternberg in his well-known *additive factors method* (1969) (see also *Additive Factors Models*). All factorial methodologies, like the original Sternberg strategy depend on the *selective influence assumption*, namely that distinct experimental factors affect distinct processing components (i.e., subsystems), the assumption of selective influence. It can be assumed that $RT(X + \Delta X, Y)$ refers to the case where the X factor has prolonged RT but Y is at base level, and so on. Basically, the fundamental statistic for the original method and for most extensions, was the *mean interaction contrast*, MIC. The MCI is defined as

$$MCI = \overline{RT}\,(X + \Delta X, Y + \Delta Y) - \overline{RT}\,(X + \Delta X, Y) - [(\overline{RT}\,(X, Y + \Delta Y) - \overline{RT}\,(X, Y)].$$

Schweickert (1978) in his *latent mental network theory* contributed the first major extension of the additive factors method involving more complex architectures under the assumption of selective influence. Townsend and Ashby (1983) found that the

mean interaction contrast distinguished parallel and serial stochastic models when selective influence, was assumed and Schweickert and Townsend (1989) produced general theorems for Schweickert's latent networks, within a stochastic setting, and assuming exhaustive processing. (See *Additive Factor Models*; *Network Models of Tasks*.)

Although the early theorems in all this work were accomplished in the context of exhaustive processing, analogous results can be found in the case of self-terminating and first-terminating processing times (e.g., Townsend and Nozawa 1995). Because Sternberg's original ideas inherent in his additive factors method have been extended in so many new directions, it has been suggested that the general approach be referred to as *systems factorial technology* (Townsend and Thomas 1994). For instance, one novel strategy has been to enlist entire RT distributions in providing more powerful tests of parallel vs. serial processing or other related architectures (Dzhafarov and Schweickert 1995, Roberts and Sternberg 1993, Townsend 1990, Townsend and Ashby 1983; see also Balakrishnan 1994). For instance, in analogy to the mean interaction contrast, the scientist can form a contrast function composed of the double difference (corresponding to the double difference in mean RTs in the usual case) of cumulative distribution functions. This new statistical function turns out to be very helpful in assaying mental architecture (Townsend and Nozawa 1995). Another example of the use of entire distributions will be reviewed below.

The assumption of selective influence is critical to the legitimacy of systems factorial technology. Much has been learned in recent years about its foundational underpinnings, what may go awry if it is violated, and about certain experimental indications of its failure (Dzhafarov 1997, Townsend and Thomas 1994).

4. *Discriminability Results on Other Issues*

The question may be raised as to whether the other processing issues defined earlier also suffer great problems in identification within the search paradigm. With regard to the stopping rule, mathematical investigations have shown, somewhat ironically, that the same types of memory search data that were incapable of deciding the parallel–serial question could in many instances prove that processing was self-terminating rather than exhaustive, although it is more difficult to prove that processing is exhaustive (Townsend and Colonius 1997).

Nevertheless, recent theoretical and empirical discoveries utilizing the entire RT distributions rather than means provide much strengthened tests of architecture (parallel vs. serial) and in addition allow one to firmly distinguish stopping rules at the same time. In fact, assuming selective influence at the distributional level, Townsend and Nozawa (1995; see also Townsend 1990) proposed an experimental design they called the *double factorial paradigm* in which investigators can test architecture and stopping rule as well as capacity within the same block of experimental trials.

The most difficult issue of the ones under discussion is that of stochastic dependence, even though it plays a vital role in processing systems. Interestingly, at this point in time, dependence is more readily and more directly assessed within experimental designs based on accuracy rather than RT (Ashby and Townsend 1986).

5. *Challenges for the Future*

The bringing together of mathematics and experimental methodology has lead to a useful stratagem that we call meta-modeling. It facilitates the development of experimental methodologies that are capable of testing broad classes of models, rather than highly specific models, against one another. This approach is especially helpful when attempting to settle well-defined issues, for example diametrically opposed concepts such as parallel vs. serial processing. It may be more difficult to use this strategy with highly complex and detailed models of phenomena (e.g., Van Zandt and Ratcliff 1995).

Meta-modeling has arguably led to striking advances in the ability to decide experimentally a number of elementary, but major, issues in the purview of human information processing over the last several decades of the twentieth century. Some of these were outlined above. However, many challenges remain. For instance, long-standing challenges relate to the somewhat pesky residual time component introduced earlier. It is difficult to know in many cases how successful our various strategies can be until its nature is firmly tied down. As noted earlier the residual time is usually assumed to be in series with, and stochastically independent of, the other processing components (Luce 1986, Smith 1995, Townsend and Ashby 1983). However, this assumption may be and has been challenged. Thus, it has been contrasted with the extreme opposite assumption of perfect correlation, but still within a series arrangement of the residual component with the other stages of processing (Dzhafarov 1992).

The most time-honored approach has been to attempt to separate the residual time component from those under study employing Fourier analysis, assuming stochastic independence of these components. This has proven to be a tricky and arduous strategy. Luce (1986), and Sheu and Ratcliff (1995) provide useful reviews and commentaries on this approach. Another kind of powerful, if often difficult, approach regarding the residual time component has been to

prove that experimental predictions hold true regardless of its presence (Dzhafarov and Schweickert 1995, Roberts and Sternberg 1993; Townsend and Ashby 1983).

The residual time problem also abuts a more general possibility, namely that processes in the same forward sequence may not satisfy discrete flow, but rather obey continuous flow properties. For instance, almost all systems based on differential and integral equations would fall into the continuous flow class. Some intriguing progress, both theoretical as well as empirical, has been made on certain subclasses of such systems (McClelland 1979, Miller 1993, Schweickert and Mounts 1998), but much more remains to be done.

Information Society

It is commonplace to regard 'information' as a defining feature of the contemporary world. Commentators routinely refer to us living in 'information societies,' to our operating in a 'global information economy.' These sorts of observations respond to the indisputable growth of information in recent years, something manifest in new media and media products and in the growth of educational provision, and more generally evidenced in the widespread permeation of information and communications technologies. Though it has become popular to describe societies such as the United States, Germany, and Japan as information societies, as a concept the term is open to criticism.This centers on the claim that the information society represents a novel social system, one which is characterized by differences from what has gone before. Against this, there are other thinkers who insist that activities have become more informationally

saturated, but this has not in any major way changed their basic patterns.

1. Definitions

It is possible to identify six ways of defining an information society, each analytically separate. Five of these may be considered as belonging to a single category, one which seeks to establish quantitative measures of the information society.

1.1 Technological

Technological conceptions center on an array of innovations which have appeared chiefly since the late 1960s. The suggestion is that their impact is so profound as to lead to a reconstitution of the social world. All commentators in this category echo themes previously articulated by Marshall McLuhan (1964), and technological indicators are the most widespread in discussions of the information society (e.g., Feather 1994).

For example, Alvin Toffler (1980) suggests that the world has been impacted by three 'waves' of technological innovation, each as unstoppable as the mightiest tidal force. The first was the agricultural revolution and the second the industrial revolution.The third is the information revolution that is now engulfing us and which presages a new way of living.

More recently, futurism has been stimulated by computing's capacity to transform telecommunications, to merge the two technologies. It is this spread of computer communications technologies, to create what is now often thought of as an 'information superhighway,' that currently inspires most speculation about a new society in the making (Negroponte 1995).

1.2 Economics

This approach charts the proportional growth in economic worth of informational activities (Machlup 1962, Porat 1978). If one is able to plot an increase in the proportion of gross national product accounted for by information businesses then logically there comes a point at which one may declare the achievement of an 'information economy.' Once the greater part of economic activity is taken up by informational activity rather than say agriculture or manufacture, then it follows that we may speak of an information society.

1.3 Occupational

This is the approach that is most favored by sociologists. Here the occupational structure is examined over time and patterns of change observed. The suggestion is that we have achieved an information society when the preponderance of occupations is found in information work: thus the information society is said to have arrived when clerks, teachers, lawyers, and comedians outnumber colliers, steelworkers, dockers, and builders.

In Daniel Bell's (1973) writing, the decline of manufacturing employment and the rise of service sector employment is interpreted as the loss of manual jobs and its replacement with white-collar—and hence informational—work. More recent studies suggest that work is becoming more 'knowledge intensive' (Lash and Urry 1994), activities such as design, media and management requiring more intelligence and education than hitherto (Reich 1992, Leadbeater 1999).

1.4 Spatial

Here the major emphasis is on information networks which connect locations and in consequence can have profound effects on the organization of time and space. A key idea is that electronic highways result in a new emphasis on the flows of information, something which leads to radical revisions of time–space relations. In a 'network society' constraints of the clock and of distance are relieved, corporations and even individuals being capable of managing their affairs effectively on a global scale, with remarkable consequences. This approach has been most authoritatively developed by Manuel Castells in his trilogy, *The Information Age* (1996–8), though Castells (2000) himself refuses to use the concept 'information society.'

1.5 Cultural

The cultural conception of an information society is the most easily acknowledged, yet the least amenable to measurement. Its starting point is that there has been an unprecedented explosion of symbols and signs over recent years. There is simply a great deal more information about than ever before, a point easily appreciated when one reflects on the extraordinary growth of symbols in today's society (media, clothing, even body shape all contribute to this environment). Today we have round-the-clock television, continuous music supply, advertisements at every corner, fashions and styles displayed everywhere—so much information that it can seem perverse not to conclude that this is indeed an 'information age' (Poster 1990).

2. Problems of Definition

Criticisms of attempts to define the information society return us to thinkers who, while acknowledging

the growth of information, refuse to endorse the idea that we have in consequence entered into a new type of world, an information society.

Objections revolve around discontent with quantitative measures when they are used to designate qualitative change. The central criticism is that quantitative indexes of the spread of information and information technologies cannot be interpreted as evidence of deep-seated social change. On the contrary, they can be regarded as the consolidation of established patterns of interest and control.

Definitions of the information society offer a quantitative measure (numbers of white-collar workers, percentage of GNP devoted to information etc), and assume that, at some unspecified point, we enter an information society when this begins to predominate. But there are no clear grounds for designating as a new type of society one in which all we witness is greater quantities of information in circulation and storage.

Furthermore, it is at least intellectually possible to imagine a radically different sort of society coming into being, one that may even merit the title information society, though this transformation may be manifested in only small quantitative increases of information. That is, it may be feasible to describe as a new sort of society one in which it is possible to locate information of a qualitatively different order and function, though quantitatively information changes may appear small. This does not require that we discover that a majority of the workforce is engaged in information occupations or that the economy generates a specified sum from informational activity. For example, it is possible to imagine an information society where only a small minority of information experts hold decisive power (science fiction writers, such as H. G. Wells in *The Time Machine* and Kurt Vonnegut in *Player Piano*, do this where they portray the domination of an intellectual élite).

3. *Theoretical Knowledge*

Indeed, there is a sixth conception of the information society which posits something like this. It suggests that an information society is one in which theoretical knowledge takes precedence over the practical. Humans throughout history responded to conditions as they found them, while today things are organized, harnessed, and controlled by starting from known theoretical principles such as laws of motion, chemical reactions, and the stress capacities of metals. Daniel Bell (1973) first suggested this 'primacy of theoretical knowledge' (though the emphasis of his book was on the numerical growth of white-collar employment). It has been extended by Nico Stehr (1994) who defines a 'knowledge society' as one in which theoretical knowledge is constitutive of virtually everything that we do, from designing new technologies to making sense of our own lives. Such a conception echoes the work of Anthony Giddens (1990) who argues that heightened reflexivity is essential to the conduct of contemporary affairs. Accordingly, there is a heavy reliance on theoretical knowledge, conceived here as that which is abstract and generalizable. For example, sewerage treatment plants, air traffic control, and even dating agencies closely and routinely monitor their (and other) activities, results of which are continuously fed into established but malleable 'expert systems' that are designed around principles aimed at producing optimum results (such as potable water, safety margins for aircraft, success rates of relationships).

There are problems here in clarifying what constitutes theoretical knowledge (Kumar 1978, pp. 219–30), but it is noticeable that this conception evokes a qualitative rather than quantitative change in information/knowledge to designate a new form of society. This emphasis sets it apart from the five other conceptions of the information society reviewed above. These identify an information society as a new type of society by presuming that a qualitative change can be defined by calculating how much information is in circulation, how many people work in information jobs, how much more media output there is, and so on. What we have here is the assumption that quantitative increases transform into qualitative changes in the social system.

4. *Continuity and Change*

Most of the criticisms of information society conceptions come from those who reject the contention that there has been a systemic social change. They refuse quantitative measures of information's growth which exclude analysis of the content of that information while yet alleging that more information will transform society. As a rule, these critics argue that increases in information serve specific interests and thereby function to perpetuate the status quo. It may be helpful if we compare these opposed theories of continuity and change.

There are several theories emphasizing change and information's centrality to this process. Not surprisingly, these endorse a conception of the information society. Of those available Daniel Bell's theory of postindustrial society remains the most robust.

4.1 *Postindustrial Society*

Bell's theory argues that we may trace the transition from a preindustrial, through an industrial, to a postindustrial society by charting shifts in employment. In preindustrial times most people found work in agriculture; in the industrial epoch, employment was chiefly in factories engaged in manufacture; and in the postindustrial society most work is in services. Since most service work is nontangible person-to-

person activity, then the material with which people operate in postindustrialism is information. This contrasts with work in agricultural societies where people struggle against nature, and it is different to industrial society where work was chiefly with machinery. Accordingly, postindustrialism is synonymous with an information society.
Criticisms include:

> Postindustrial theory is historically dubious. For instance, the great expansion of the service sector, evident in all advanced societies during the late twentieth century, has been fueled by dramatic declines of employment in agriculture rather than in manufacture. Such empirical patterns cast doubts on Bell's claim that societies have shifted employment from agriculture, through industry, to a service society (Kumar 1978, pp. 200–4).

> The theory is neoevolutionist, implying a directionality to history that is questionable. Critics regard this vision of change as unwarranted in view of events such as world wars, genocide, and the re-emergence of ethnically based nationalisms in recent decades, not to mention the threats posed to the environment by phenomena such as global warming, nuclear energy, and acid rain.

> Bell argues that the motor of change is increased productivity, which allows first a transfer of workers from the land to industry and later a shift from industry to services without loss of wealth. Continually increased productivity in agriculture and industry is required to fund the uninterrupted expansion of services. To critics of Bell this is a deterministic explanation of change.

> Bell misunderstands the expansion of the service sector, seeing it as a consumer of resources supplied by industry and agriculture. Bell 's theory posits that agriculture and industry are regarded as the wealth-creating sectors of society and that gains achieved there allow society to spend that wealth on services that use it up. However, this perception ignores the intimate ties of the service, agricultural, and manufacturing sectors in an integrated economy, in particular being blind to the central function of producer services (e.g., banking, finance) in the day-to-day operation of an advanced economy. The real economy is not divisible into neat halves, but is rather integrally connected into an organic whole. As such, Bell's entire theory is cast into doubt (Gershuny and Miles 1983).

> The features Bell highlights as heralding the coming of postindustrialism are all long-term aspects of industrial development (e.g., rationalisation, growth of services, expansion of white-collar work), so how can he claim that these announce a new postindustrial age? (Kumar 1995).

4.2 Informationalized Capitalism

Turning from this account, we encounter the work of Herbert Schiller, whose argument is that the information explosion is part and parcel of the advance of capitalism in and beyond the late twentieth century.

There are three key refrains in the writing of Schiller. The first draws attention to the pertinence of market criteria in informational developments. In this view it is essential to recognize that information and communications innovations are decisively influenced by the market pressures of buying, selling, and trading in order to make profit. To Schiller the centrality of market principles is a powerful impulse towards the commodification of information, which means that it is, increasingly, made available only on condition that it is saleable.

The second insists that class inequalities are a major factor in the distribution, access to, and capacity to generate information. Bluntly, class shapes who gets what information and what kind of information they may get. Thereby, depending on one's location in the stratification hierarchy, one may be a beneficiary or a loser in the 'information revolution.' The decisive factor in access to information is the ability to pay, something which ensures that within advanced societies like the UK and America there is an information rich that can purchase virtuoso services, while there is an information poor (Schiller 1996) that must be satisfied with what Schiller calls 'garbage information' (mass entertainment, advertisement-supported television, junk mail, etc.), while the same process is manifest globally with information rich societies such as the United States and information poor who are reliant on Hollywood leftovers to fill their impoverished television schedules and on Western news agencies to report what is happening around the world (and even in neighboring countries).

The third key contention of Herbert Schiller is that the society which is undergoing such momentous changes in the information areas is one of corporate capitalism. That is, contemporary capitalism is one dominated by corporate institutions which are concentrated organizations that command a national, and generally international, reach. For this reason, in Schiller's view, corporate capitalism's priorities are especially telling in the informational realm. At the top of its list of priorities is the principle that information will be developed for private rather than for public ends.

Clearly these are established features of capitalism. Market criteria and class inequalities have been important elements of capitalism since its early days, and even corporate capitalism has a history extending over a century, though many of its most distinctive forms have appeared in the late twentieth century. But to Herbert Schiller this is precisely the point: the capitalist system's long-established features are the key architectural elements of the so-called 'information society.' From this perspective those who consider that informational trends signify a break with the past are not credible since, asks Schiller, how can one expect the very forces that have generated information to be superseded by what they have created?

The 'information society' therefore reflects capitalist imperatives and, simultaneously, these informational developments sustain and support capitalism. In this

way Schiller accounts for the importance of information in ways which at once identify how the history of capitalist development has affected the informational domain and, at the same time, how information has become an essential foundation of that historical development (cf. Sussman 1997).

Several criticisms may be leveled at Schiller's analysis of the information domain. These include:

> The possibility that social change may be examined on at least two different axes: on the one hand, along an axis of feudalism to capitalism, while on the other, along an industrial to a postindustrial/information society axis. One might consider the argument that Schiller and Bell talk across one another because they are looking at different aspects of social change. Schiller's account paints an unrelentingly negative picture of the spread of information under the aegis of corporate capitalism, one which suggests a nostalgic vision of information before the intrusion of capitalism. But just how valid is this depiction in view of our knowledge of illiteracy rates even in the nineteenth century, lack of education, and the demonstrable inadequacy of reading material for working people?
>
> Schiller's focus on information inequalities may be a useful remainder of class differences, but his binary division into the information rich and poor is sociologically crude.

5. *Conclusion*

Though the concept of the information society has achieved considerable popularity in and outside academia, it appears to have limited value for social scientists. The most acclaimed analyst of information today, Manuel Castells (2000) has even recommended that 'we should abandon the notion' (p. 10). As we have seen, the defining criteria are vague and imprecise. The concept has some heuristic value (Lyon 1988), in so far as it encourages interest in and debate about developments that are of inarguable significance. However, the most serious objection to the concept is that the claim that it represents a profound social transformation cannot be supported on the basis of the quantitative indices that are usually advanced. Clearly, there are more information and communications technologies, information is of greater economic weight, and there are more information occupations. But the idea that these signal a shift towards a new society is mistaken. As Krishan Kumar (1995) insists, the information explosion

> has not produced a radical shift in the way industrial societies are organized, or in the direction in which they have been moving. The imperatives of profit, power and control seem as predominant now as they have ever been … The difference lies in the greater range and intensity of their applications … not in any change in the principles themselves (p. 154).

This being so, it is ironic that the most persuasive conception of an information society, that which centers on the role of theoretical knowledge, is the least examined by information society adherents.

Information Society, Geography of

The 'information society' is a historically specific term, referring to contemporary societies in which the production and exchange of information, dramatically accelerated by the growth of information technologies (IT), has become a defining feature of social activity. Information exchange has always been central to the functioning of society, but only since the 1950s has it become broadly separable from face-to-face communication and identified as a distinct sector of economic production. The 'geography of the information society' explores how IT, telecommunications structures, and the geography of human activity are co-evolving in such societies, paying attention to the two-way relationship between technological developments and sociospatial processes, and to the associated growth of geographic information and geographic information technologies.

The geography of the information society is related to the somewhat older subdiscipline of communications geography, but itself is a recent and rapidly evolving area of study. The first major publications on this topic date from the late 1980s (Hepworth 1990, Robins 1992, Kellerman 1993). Earlier work focused mostly on economic aspects of the geography of the information society, but increased attention is being paid to cultural and political aspects. This article focuses on geographical processes driving the development of IT, the geographical organization of the production and use of these technologies, and their impacts on space, place, and the geographic scale of influential societal processes.

1. *Geography and the Information Revolution*

The digital computer drives the explosion of IT that are qualitatively increasing humankind's ability to communicate remotely. Telegraphs first enabled spatial flows of information to be separated from face-to-face communication, and thus from geographical restrictions on human movement. The telephone and the telefax extended this capacity but virtually all telecommunications are now integrated into digital computer networks.

Information technologies are the latest in a very long history of communications technologies which have been developed to satisfy three processes fundamental to a spatially extensive society: (a) The need for the production and exchange of commodities to occur increasingly rapidly over greater and greater distances, 'the annihilation of space with time' (Harvey 1985 p. 35); (b) the need to exert control over larger and larger social systems of increasing geographic scope; and (c) the human desire for liberation from the limitations of daily life in particular places, by learning about and experiencing other places. The information revolution can be seen as transcending the shipbuilding yards, ships, and ports of the nineteenth century, and the automobile factories, highways, and garages of the twentieth century, with the Silicon Valleys, satellite systems, fiber optic cables, and teleports of the twenty-first century.

The widespread availability of geographic information and geographic IT is increasingly important as this revolution proceeds. Computing and transmission networks can now readily handle the complexity of spatial data and the digital maps that can be produced with them. Geographic information systems (GIS) are increasingly available for manipulating and displaying such data. A wide range of other geographic IT producing or analyzing geographically referenced information, such as satellite reconnaissance systems and geographical positioning systems (GPS), are increasing the capacity of certain social actors to access geographic information immediately almost anywhere around the globe.

2. *The Spatial Organization of the Information Economy*

As the production, storage, and exchange of information have become key sectors of economic activity, a new economic geography has been emerging. In part this reflects the location of producers of IT, and partly it is a result of the impact of IT on the locational patterns of other economic activities. Particular attention has been paid to the mushrooming of new clusters of innovative IT firms, in such places as Silicon Valley, Cambridge, UK, and Tokyo-Yokohama, Japan. These are paradigmatic examples of technology districts, which have grown as a result of dynamic external economies created by the elevated pressure to both collaborate and compete with nearby rivals. This is contrasted with a different locational logic for the mass production activities associated with producing IT, assembling chips and computers, and reproducing software. Branch plants performing these activities can be found where lower wage workers are available, both within the advanced capitalist countries and in newly industrializing countries and export processing zones in the third world.

An emerging spatial division of labor, between dynamic industrial districts where innovative activities and intellectual labor cluster, and branch plant regions dominated by assembly activities employing unskilled labor, is itself a result of the impact of IT on the geography of production. The clusters represent 'new industrial spaces' that benefit from the ability of small firms using computer-assisted manufacturing technologies to operate as efficiently as large factories, from the advantages of agglomerating close to other such small and dynamic firms, and from 'just in time' methods of minimizing inventories by using IT to ensure that supplies are delivered as they are needed, as in Toyota City, Japan. Information technologies

also enable the operation of subsidiaries to be controlled from distant headquarters. Different components of the production process can then be located worldwide, wherever labor costs, environmental regulations, and agglomeration economies are best suited to that activity, creating commodity chains of global scope.

Such a spatial division of labor is restructuring geographical differences in the location of economic activities, thereby contributing to uneven development, even as it links distant places more closely together with the help of IT. Knowledge-based industries cluster in the new industrial spaces described above, but also in the national and global cities that attract corporate headquarters seeking access to information and expertise. These cities also host clusters of producer service industries providing the information and expertise sought. There is an extraordinary clustering of such activities in a handful of cities worldwide, reflecting the symbiotic nature of knowledge-based activities (Castells 1989).

Attention has only recently turned to the location of the infrastructure through which information flows. Notwithstanding popular perceptions that distance no longer matters in the information society, it has been pointed out that accessibility to the means of transmitting information varies greatly geographically (Graham and Marvin 1996). A number of cities are actively seeking to develop smart office districts and teleports, in the belief that the absence of these is hindering their attractiveness for knowledge-based industries. The availability of computers varies significantly at intra-urban and international geographical scales: Internet addresses cluster in the largest cities, and in the business districts of those cities; teleports are found in relatively few cities; and fiber optic lines entwine the developed world, barely reaching, for example, the African continent. Spatial and social inequality of access to the means of telecommunication has significant implications for the impact of the information society on space and place. This is because investments in telecommunications infrastructure are durable investments that shape the location of activities relying on them, in turn creating demand for new infrastructure investments in the same areas.

Geographic IT are beginning to have a distinct impact on the location of economic activities. Transportation behavior is altering as a result of intelligent highway monitoring systems, on-board navigation systems, and the use of GPS to monitor commercial transportation operators and cargoes. Military surveillance is more effective, and bombing campaigns more spatially selective, as a result of the development and use of such technologies. This affects locations chosen for strategic economic activities (such as weapons manufacture) and is changing the spatial impact of bombing campaigns on the economic infrastructure of a country.

3. *Impacts on Space*

The information society is widely depicted as instrumental in the decline of geographical distance as a significant impediment to societal processes, as well as the growth of globalization. In this view, the capacity of information networks to transfer information or money as easily across the globe as across the street has two interrelated effects. First, there is no reason for human activities to agglomerate together in geographic space; cities and industrial districts are no longer necessary, because distance does not inhibit communication (Mitchell 1995). Second, is the integration of distant events through information networks: the global integration of finance markets, the transnationalization of firms' geo-economic strategies, and the decline of the nation state—harbingers of a global village where social processes operate at the global scale, and thus of the end of geography (Martin 1994). Such claims are far from novel. At the end of the nineteenth century similar claims were made for the telegraph, and they reappear with each new leap forward in communications (Marvin 1988). Yet cities continue to grow and uneven development persists.

In fact, the spread of information networks has contradictory impacts on space, simultaneously reducing and increasing the distance between social actors. Distant territories and markets are connected together in new ways, but not in ways that eliminate inequalities in accessibility. The emerging spatial metric is better captured by the metaphor of spatial wormholes than that of the global village. While certain social actors have access to the channels of cyberspace, through which they are instantaneously connected with related actors in distant places, their immediate neighbors may not be connected at all. This means that the geographical propinquity of social actors does not imply that they are similarly situated with respect to other social actors and places. '[S]pace is not "shrinking," but rather must be perpetually recast' (Kirsch 1995, p.544). Information networks are restructuring the social distance between actors, and thus their situation with respect to one another, in ways that loosen, but do not eliminate, the relation between social distance and physical distance. The ways in which this is happening depend on how and whether different types of social actors, in different places, gain access to particular IT and information.

Information technologies have reduced spatial barriers between different aspects of working life. Elimination of distance barriers has made it easier to relocate routine production and information processing activities to distant lower wage locations, with US corporations placing such back-office activities as telemarketing in San Antonio, Texas, insurance claims in Ireland, or processing the information on consumer warranty cards in the Caribbean (Goss 1995, Warf 2000). This diffusion of routine information-processing activities is counterbalanced, however, by the

agglomeration of nonroutine knowledge-based activities in large national or global cities which become centers of control. The reduction of distance barriers is, thus, also associated with increased inequality.

Processes of suburbanization and exurbanization have also been accelerated by reducing these barriers. Back-office activities are relocated from downtown to suburban areas, and away from inner city work forces, to tap a white female labor force willing to work in such jobs. The growth of telework and telecommuting, as information technology makes it possible to separate work from workplaces, is contributing to the spatial dispersion of urban activities into the countryside. This is widely predicted to reduce differences between urban and rural life, and also personal travel and its social and environmental costs.

In discussing back-office relocation and the effect of telecommuting on urban form, a great deal of attention is given to the degree to which telecommunication can replace face-to-face communication. The need for nonroutine face-to-face interaction has long been recognized as an important determinant of the agglomeration of offices as places for nonroutine information exchange. Analysis of technology districts has similarly emphasized the importance of face-to-face contact in developing the shared knowledge, rivalries, and governance systems that sustain local economic dynamism (Storper 1997). Notwithstanding the continuing evolution of telecommunications technologies, it is argued that they are likely to remain an inadequate substitute for face-to-face communication for much critical decision-making. The kinds of activities that are likely to be remotely located with the help of IT are those that can be completed successfully using relatively routinized communications, and can be coordinated, and monitored, at a distance.

New IT also continually alter the need for, and skills associated with, particular tasks, altering the locations where those tasks are best performed. Telecommunication made it easier to decentralize routine information processing into back offices, only for that process to be reversed as new information systems eliminate the need for manual data entry and expert systems replace telephone operators. Less skilled jobs are replaced with fewer but more skilled software and computer operators and these activities relocate to centers of control (Warf 2000). Similarly, the decentralization of IT associated with the growth of desktop computing and the Internet has led to the recentralization of information storage in clusters of mainframe computers known as 'server farms.' The particular tasks that can be decentralized alter, but a spatial division of labor endures between well-paid knowledge-based activities, based on face-to-face communication, and routine activities in more peripheral and lower-wage locations.

Questions about the degree to which IT will undermine the spatial cohesion of urban areas are paralleled by questions about the desirability of the counter-urbanization which is occurring. Lower density lifestyles may in fact place a greater burden on the physical environment than higher density lifestyles, because high density settlements can economize in transportation and energy consumption. While journey-to-work trips are reduced by telecommuting, other kinds of trips will increase as workers have more freedom during the working day, and it is not clear that the net effect will be reduced travel (Graham and Marvin 1996).

Information technologies are affecting the cultural geography of society, facilitating both personal mobility and the spread of information about remote places as a result of the growth of 'personable extensibility'; that is, the ability of individuals or groups to extend their lifeworlds to embrace distant places (Adams 1995). Telecommunications accelerate the diffusion of cultural norms and trends between cultures, and the homogenization and globalization of cultural norms, particularly the worldwide popularity of US movies, TV programs, popular music, consumption habits, and ideas. Yet the same processes have differentiating effects: US culture is becoming more multicultural as it absorbs cultural influences from elsewhere; French culture is revived in defense against Anglophone influence; and local cultures are learning to use IT to enhance their visibility and coherence.

4. *Impacts on Place and Identity*

Reflecting claims about the impact of the information society on space, it is commonly argued that place as an organizing theme for social life is withering away. Two aspects of place are stressed: the economic coherence and vitality of places; and the relationship between personal identity and place. Arguments about the former reflect those about space. 'The dominant tendency is toward a horizon of networked, ahistorical space of flows, aiming its logic over scattered segmented places…' (Castells 1996, p. 428). In this view the hypermobility of investment capital, facilitated by IT networks and by related processes of economic political, and cultural globalization, undermine the coherence of places and the ability of their inhabitants to control the future of those places. Arguments about the latter discuss how IT undermine the ways in which everyday life is tied into, and shaped by, the places where this occurs; that is, the relationship between identifying with a place and individual identity.

The city of London, a global financial center whose economic livelihood depends on instantaneous calculations of risks and returns drawing on worldwide information flows, has been studied intensively to examine whether place matters in the information society. In this case, place matters greatly. The city 'is a system… dependent on electronic communications but… the increasingly intricate patterns of connection that are able to be produced… trigger off demands for more rather than less face-to-face interaction'

(Leyshon and Thrift 1997, p. 292). The very complexity and quantity of information arriving through the spaces of flows must be interpreted. Thus, a defining feature of economic life in the city is personal contact, familiar cultural rituals of communication, and reliance on personal experience and visual clues to assess the expertise and reliability of informants. As a consequence, key decisions are still taken within the compact space of the city, reinforcing both a sense of and an identification with this place, and enhancing its growth and power nationally and globally. A similar symbiosis between information technology and place exists in other global financial centers.

The possibility that place can be reinforced in an information society has been noted for other clusters of economic activities. Places able to benefit from dynamic external economies are capable of developing and maintaining competitive advantages which draw in and retain investments even in an increasingly interdependent information society. It is even argued that any place can use this strategy to anchor its economic future, although others argue that inherited uneven development means that the search for competitive advantage can reinforce spatial inequality (Leitner and Sheppard 1998).

The commercial deployment of geographic IT may also enhance the importance of place. By classifying consumers into a large number of 'lifestyles' and using GIS and census data to attach one of these categories to each census tract, firms have developed cost-effective ways of geographically targeted marketing—techniques also adopted to target voters in elections. One consequence of such strategies is to shape the choices, consumer purchases, voting, and identity of people in each place, and the meaning of the places in which these practices occur (Goss 1995, Curry 1998).

On the other hand, by reducing the degree to which social practices are associated with particular places, the information society reduces attachment to place and the cohesion of place. Cyberspace is pointed to as exemplifying this. Use of the World Wide Web has made it easier to join electronic communities of geographically scattered individuals sharing particular interests, substituting interaction and identification with such communities for interacting and identifying with geographical neighbors. In addition, the increasing ability of IT to create immersive environments, or 'mirror worlds,' may make experiences with real places less attractive than those with virtual ones. New senses of space and time are being created; the Internet creates a capacity to be in two places at once, and distance is measured by communications time instead of geographical separation. Yet the kinds of identity that result, as identity construction is detached from place, may require less interpersonal responsibility and may never be fully separable from those formed through living in real places (Robins 1995).

Notwithstanding the 'spaceless' nature of cyberspace, the cognitive principles used to make sense of it and the metaphors used to describe it draw heavily on those developed as a result of human experience with material space. Immersive environments are organized by conventional spatial principles; their immersive character stems from their ability to seem indistinguishable from real places; and cyberworlds tend to emulate the spatiality of material worlds. The differentiated geography of communications infrastructures and of access to cyberspace means that there are close relationships between cyberspace and material space (Kitchen 1998, Janelle and Hodge 2000).

The Internet has become a medium which local place-based groups have been able to utilize to promote and gain global attention for their particular agendas, such as the Zapatista movement in Chiapas (Castells 1997). At the same time, the information society is promoting supranational economic and political processes, ranging from global finance markets, to multinational information systems for monitoring migrants and refugees, and the homogenization of practices governing the exchange of geographic information and intellectual property rights (Curry 1998). The information society is contributing to processes of 'glocalization,' whereby both local scale and global scale processes are growing simultaneously in importance (Swyngedouw 1997), but is erasing neither distance nor place.

Information Technology

Information technology (IT) covers any form of technology, that is, any equipment or technique used by a company, institution, or any other organization which handles information. The term information technology was coined probably in the late 1970s to refer to this nexus of computer-based technologies for handling information. It incorporates computing, telecommunication technologies, and includes consumer electronics and broadcasting as it is getting more and more digitized. Spearheaded by the computer, the decades since the mid-1960s have been characterized by extreme development. Since the late 1970s, cheap microelectronics have permitted the diffusion of these technologies into almost all aspects of daily life and have furthermore almost inextricably cross-fertilized and intermingled their multiple application branches, which include industry, commerce, administration, education, medicine, scientific and professional work, entertainment, and domestic work.

Nations with advanced IT-industries have realized that developing competence in information technologies including new media is essential, expensive, and difficult; large-scale information technology systems are gaining economic feasibility and various national research and education programs for stimulating these developments have been founded. The fundamental capabilities that usually are perceived as being essential are: VLSI (Very Large-Scale Integration) chip design, production facilities, and a common infrastructure like the Internet for the storage and transmission of digital multimedia information (including video, audio, and other continuous media data in addition to conventional data and text).

Figure 1
Structural change in the workforce employed in the sectors (I) agriculture, (II) manufacturing, (III) services and (IV) information in the German economy for about the last 100 years (see Grauer and Merten 1997)

1. *Information Technology and Impact on Society*

Computers are transforming the way people communicate, do business, like to entertain, and educate

themselves. This technological evolution has not only had a profound impact on the business community, but also on private and professional lives. The computer evolution, however, has given rise also to serious social issues including the vulnerability of personal information and job security. This evolution has an impact on the whole society. In Fig. 1 the effect of structural change in the employment according to four sectors of the German economy is shown. This pattern of structural change can be observed as similarly in all national economies only with a time shift. The evolution of IT-systems is the basis for the rise of employment in the information sector and the decline in manufacturing by increasing quality and quantity of production. The employment in manufacturing follows the pattern of agriculture in the mid-twetieth century.

The reason that probably all parts of the society are touched by IT can be seen in the fact that the price of computing has dropped by half every 2–3 years (see Fig. 2) in opposite to the increasing costs of producers' durable equipment.

There have been increasing levels of business investment in IT equipment. These investments account for over 10 percent of new investments in capital equipment in developed countries. On the other side the revenues for the information and communication systems industry have increased tremendously since their beginning in the early 1950s. Since the 1990s their importance dominates that of the automobile industry.

Figure 2
The decline of the cost of computing relative to other capital purchases (see Brynjolfsson 1993)

2. *Historical Background*

The abacus is most likely one of the first mechanical counting devices. It has been traced back 5,000 years. Another important step towards computers as we know them today was the counting-wheel. The French mathematician and philosopher Blaise Pascal (1623–62) finally invented and built the *Pascaline* in 1642 to help his father, a tax collector. This counting-wheel design was used by all mechanical calculators until the mid-1960s.

Everyone, from bankers to navigators, used mathematical tables during the industrial revolution. However, these hand-calculated tables were usually full of errors. Charles Babbage (1793–1871) envisioned a steam-powered 'differential engine' and then an 'analytical engine' that would perform calculations accurately. Although Babbage never perfected his devices, they are forerunners for many concepts used in the modern general-purpose computer. A further important step in the development of IT was the introduction of punched-card tabulating machines by Herman Hollerith (1860–1929). The machine was devised for the US Bureau of the Census in 1890 and had an incredible impact on the necessitated time for completing that year's census, reducing it from the usual 8 to a mere two and a half years. In 1896, Hollerith founded the Tabulating Machine Company and in 1924 the company's general manager, Thomas Watson, changed its name to International Business Machine Corporation, a company which has dominated the development of computers for several decades.

The beginning of modern computer history can be marked by the invention of the Z3 computer (electric relays controlled by a program) by the German engineer Konrad Zuse in 1941 and the ABC-computer by Dr. John V Atanasoff, a professor at Iowa State University, a year later. Both systems used the essential principles of modern computers and were based on binary systems.

The key component of these first computers was the electronic tube. These vacuum tubes acted as electronic switches, replacing earlier electromechanical relays. These machines took up a lot of space and generated considerable heat, so that special air conditioning was required; their reliability was relatively poor. Around 1960, vacuum tubes were replaced by solid-state transistors, which were smaller in size, more reliable, generated less heat and operated at much higher speeds. Instructions would be executed significantly faster by these new generation of computers, but due to high expenses, only the largest companies could afford them. In 1963, the Digital Equipment Corporation introduced the PDP-8, which is generally considered to be the first successful minicomputer. It was the answer to an increasing demand for small computers for businesses and science.

Figure 3
The development of the numbers of transistors on a chip and the performance (MIPs; million instructioned per second) known as Moore's Law

The next generation of computers, in the 1970s, were characterized by miniaturized integrated circuits. The IBM System 360 line of computers, introduced in 1964, is seen as a leading system of this time. The System 360 line was designed as a family of computers with upward compatibility to meet the different and growing demands in the companies. Up to the end of the 1970s analysts describe the main force behind IT evolution by the so called Grosch's Law, which explains the economies of scale in computer design (Zerdick et al. 1999). Grosch's Law says that computer performance is a function of costs squared—twice the cost gives four times the performance.

The next period of IT, in the 1980s and the beginning of the 1990s, is characterized by very large-scale integration of circuits, the introduction of the personal computer, and multiple processors in one machine. The driving force behind IT in this period of time is described by the so-called Moore's Law, which means that the number of transistors that can fit on a chip doubles every 18 months (see Fig. 3).

Since the mid-1990s the IT development is dominated by a rapid worldwide growth Internet users. This global communication system is the basis for a new type of business—the Network Economy. The key feature of this period is described by the so called Metcalfe's Law: The value of a network goes up as the square of the number of its users (Shapiro and Varian 1999).

3. *Information Technology and Management*

Apart from the principal economic resources of business—capital, material, and labor—information is relevant increasingly as an input factor. Management decisions are intuitive and expedient without information but not necessarily economical. Access to information and the computer's ability to answer questions and solve problems with high speed and accuracy improves decision-making and helps management to realize objectives, which was not possible in the past. The application of information systems is a key resource in gaining a competitive position. There are several advantages:

(a) customer service has been improved and ex-tended;

(b) the level of efficiency has been raised. Sales and office staff save both time and effort recording information necessary for operations and control;

(c) load and capacity potential has increased;

(d) information accuracy has improved, enhancing the firm's image and reducing loss as a result of errors;

(e) the query and interactive capabilities provide the right information at the right time to the right person; and

(f) management receives important information for planning, control, and decision making.

Certain applications of IT are universal and equally appropriate for many business environments. These so-called functional applications can be found in most organizations and include functions like payroll, accounts receivable, accounts payable, general ledger, inventory management and control, human resource development, budgeting, project management, customer relationship management, supply chain management, electronic business and workflow management. Workflow management refers here to computer-based applications associated with general office work and

involve word processing, spreadsheets, computer graphics, database management software, electronic mail, image processing (facsimile and image scanner), voice processing (voice message switching and teleconferencing as a group productivity tool, call center operations), and office information systems.

Information systems that are designed to process routine business activities across multiple functional areas of large enterprises are called Enterprise Resources Planning (ERP) systems. ERP systems provide such organizations with highly solutions that rely on the use of common database systems. Linkages between different functional activities within an enterprise and across is organizational boundaries are achieved by maintaining all relevant data in a single database. Thus data corresponding to a business transaction are entered into the system only once, and the effect of this transaction on different business processes and corresponding reports can be determined immediately.

Some computer applications are unique to a particular type of business, such as production scheduling (manufacturing, typesetting (publishing), actuarial accounting (insurance), and special effects (multimedia systems) in marketing, advertisement, and entertainment (movies, online theatre scripts). Robotics, computer-integrated manufacturing (CIM), and computer-aided design (CAD) are prominent examples for product development and manufacturing.

Information systems designed especially for top-level managers are called decision support systems (DSS). In contrast, transaction processing systems (TPS) are tools in supervisory management and executive information systems (EIS) refer to information systems utilized by middle management for tactical planning. There are no generally accepted definitions to the above-named information systems.

Higher-level information systems serve a different purpose than those designed for managers at operational levels. The latter systems specify actual operations. Systems for top managers process feedback data and data from external sources in order to forecast trends and put figures into context—information used by middle management to decide what must be done to improve the firm's competitive position.

4. Conclusions

The development of high-performance, high-reliability, comprehensive communication networks, both intra-organizationally and interorganizationally, is emphatically not stationary. Concurrently, both hardware and software technologies are evolving in ways that make it possible to maintain large amounts of information on-line and to have access to this information in conjunction with the communication networks from almost any location with the available distributed databases. Furthermore, an improvement in user-friendliness and the increased capability of advanced personal computers and workstations enables users to work with these systems with little formal training. The improvements include the interconnection of computers in local area networks as well as in regional, national and international networks. In addition, operations on personal computers, workstations, or mainframes are becoming increasingly conferment. The tendency towards open systems, which allow common sets of software to be transferred from one computer make to another, is the basis for this development.

Current development includes the problem of information overload of business managers. What managers need is support in evaluating and selecting data which represents important information for a given problem situation and to transform this data into knowledge for improved decision-making. IT is only beginning to deal with these issues.

Information Theory

1. Introduction

Radios, telephones, televisions, and, last but not least, computers are devices that store, process, and transmit information; today they belong to the basic equipment of the average citizen in the industrialized world. It is

Figure 1
A typical channel for information transmission

no exaggeration to claim that the twentieth century witnessed the greatest revolution of communication and information technology since the invention of the printed book. This vigorous development created the need for a well-founded theory and a rigorous terminology that would allow discussion about information with scientific precision. In 1948, the US electrical engineer Claude Shannon provided a synthesis of the fundamental ideas in classical information theory (1948). For the sake of historical precision it should be noted that some of these ideas had already been put forward, although in less rigorous terms, by Hartley (1928). Yet it was Shannon's achievement to set information theory on firm theoretical grounds. He also discovered the basic mathematical laws of systems that communicate information. Separating relevant information (signal) from irrelevant information (noise) was one of the problems Shannon also tackled and solved. Another problem that Shannon essentially solved was the setting of upper bounds on what can be achieved with a given information-carrying medium or channel. For these seminal contributions to information theory, Shannon is considered its founder.

In telephony for instance, there is a source of information, namely a person speaking into a telephone. The message is the sound that is produced, while the transmitter is composed by the microphone and the equipment that changes this sound into an electromagnetic wave, which becomes the signal. The channel is the space between the transmitting and the receiving telephone, i.e., the receiver. Any static or other phenomenon distorting the signal is called noise. An unambiguous specification of the particular message chosen by the information source has to be transmitted so that the original message can be reconstructed at the receiving point. The receiver reconverts the received signal into an audible sound. Information theory deals with the problem of specifying a quantitative relation between a given message and the set of all possible messages from which it is chosen (see Fig. 1).

2. *Quantifying Information*

Imagine a simple game for two players: one player thinks of a number between 1 and 64 and the other has to guess what the number is by asking only questions that can be answered by 'yes' or 'no.' The strategy followed by a player could be, for instance, to begin by asking the question: 'Is the number less than or equal to 32?'. If the answer is, say, yes, then the player could ask whether it is less than or equal to 16. If the answer is, say, no, then the remaining set of candidate numbers is 17, 18, 19, …, 32. One possible optimal question at this moment—clearly not the only optimal question—would be: 'Is the number less than or equal to 24?'. Clearly, the least number of yes-no questions required to determine the number is 6. Roughly speaking, the amount of information contained in the message describing an event out of a set of possible events corresponds to the number of yes-no questions needed to isolate that event from all others in the set, following an optimal strategy. If, in the game above, the number to be guessed were, for instance, 23 then the sequence yes-no-no–yes-no-yes, beginning from right to left, is a code for the number 23 that

Figure 2
Quantifying information

corresponds to the strategy described above and the specification of the message would then be this ordered sequence of 'yes' and 'no' obtained as answers. The unit for measuring information is the bit. One bit of information corresponds to a message describing one event out of two equally likely events. Two bits correspond to a message describing an event out of four equally likely events. One event out of 2^N equally likely events has N bits of information, or, in a somewhat more suggestive form, it has $-\log_2 1/N$ bits of information (see Fig. 2).

If an event with probability $1/N$ has $-\log_2 1/N$ bits of information, it is natural to extend this measure to an event with probability p by establishing that it must have $-\log_2 p$ bits of information. It was shown by Shannon that the negative logarithm of the probability is the only function satisfying all the properties one expects from information (see also Luce 1960). Characterizing the properties of this measure for information and the concepts related with it was one of Shannon's breakthroughs. Given a set of N events with probabilities $p_1, p_2, \ldots, p_N$, the amount of information associated with the ith message is $-\log_2 p_i$ so that the expected value of information per message is given by

$$\mathrm{H} = -\{p_1 \log p_1 + p_2 \log p_2 + \cdots + p_N \log p_N\}$$

This quantity represents the uncertainty contained in the source. Shannon had originally called this expression the average information of the message set. It was John von Neumann who convinced Shannon to introduce the term 'entropy' for average information, seeing the natural connection between average information and entropy in thermodynamics. The term entropy stems from thermodynamics and was introduced by Rudolf Clausius, who formulated the second law of thermodynamics in 1850 (the entropy of an isolated system is always increasing until it reaches its maximum). He composed the term entropy with the two Greek roots 'tropein' (turn) and 'en' (into) in analogy with the term 'energy'. Entropy takes on its smallest value, zero, when there is one message that is certain to occur (i.e., the described event has a probability 1) and all other messages never occur. Intuitively, there is no information in a message that was *a priori* certain. Maximal entropy occurs when all messages are equally likely, which corresponds to the situation of greatest uncertainty about outcomes. The ratio of the uncertainty of a source to the maximal entropy possible on the same set of symbols is the relative entropy of the source, and

$$\text{“}1 - \text{relative entropy”}$$

is the redundancy of the source. The specification of a message as a (finite) sequence of binary symbols (say, for instance, 0 for 'no' and 1 for 'yes') is called a 'code word' for the message. An important feature of the average information, H, is that it determines the saving in transmission time that is possible, by proper encoding, because of the statistics of the message source.

Based on the concept of information Shannon introduced measures for information rate as well as for channel capacity. He stressed the fact that information has all the properties of matter: it can be transported, compressed, and segmented into small pieces. The diagram in Fig. 1 can be viewed as a transportation system. The channel can be seen as transporting matter from a source to a receiving site. In this situation, there are two important quantities: the rate at which information is produced at the source and the capacity of the channel. Obviously if the rate of production is greater than the capacity of the channel, it will be impossible to transport the full output of the source. Suppose, however, that there is a device—the encoder—at the source that, just like a mill, cuts information down into smaller pieces, then 100 percent efficiency can be achieved. Shannon proved that, if the information rate at the source is less than the channel capacity, then encoders and decoders can be constructed such that the source output is recreated at the destination with as small an error probability as desired. Conversely, if the information rate at the source is greater than the capacity, then the error probability cannot be made arbitrarily small.

Information and related concepts have led to a unified and theoretically sound treatment of uncertainty and reduction of uncertainty in statistics and decision theory. In the set of all distributions on a finite sample space the distribution that maximizes entropy is the uniform distribution, for which all single elements are equally probable. Laplace's *uncertainty principle* (1812) advised to assume that a distribution in uniform, whenever no further knowledge is at hand. For far more than one century probabilists and statisticians searched for an adequate extension of the uncertainty principle to the case when partial information on a distribution is available. Information theory provided the ideal extension via the concept of entropy: it was called the *maximum entropy principle*, or MaxEnt. It states that whenever some of the marginals of the distribution are known, one should assume that the distribution is the one—and only one—that maximizes entropy in the set of all distributions with those marginals. By doing this one guarantees that no additional information is added to the distribution. A family of important algorithms has been developed for the construction of the MaxEnt distribution (Bishop et al. 1975). The MaxEnt principle and algorithms for constructing the MaxEnt distributions form the fundamental ingredients for the designation of *a priori* distributions when events are not equiprobable.

An excellent, modern survey of information theory and its applications was provided by Cover and Thomas (1991).

3. Conclusions

Information theory has had a major impact on behavioral science and on cognitive neuroscience. Psychologists have discovered important relationships between the amount of information in a stimulus and reaction time to the stimulus. An important finding concerns the adaptation of participants to the statistics of information conveyed by presented stimuli and their ability to recognize redundancy of information in stimuli. This leads to shorter reaction times. Another important finding concerns human short-term memory: Pollack (1953) and Miller (1956) noted that basic information is coded in 'chunks.' The ability to form chunks enables organisms to make better use of their limited capacity short-term memory. Because short-term memory appears to be capable of holding only five to seven chunks, efficient information processing depends on the ability to pack more information into a single chunk. Grouping into doublets (two-bit-chunks) and recoding (e.g., 00 = A , 01 = B, 10 = C, 11 = D) can double the number of bits that can be held in short-term memory at a given time.

Forming triplets or larger groupings further increases the number of memorized bits in a nonlinear way. There are constraints to this procedure. Chunking is only effective with sufficiently long presentation-times. With presentation-times under 0.5 seconds, no successful grouping takes place (Kleinberg and Kaufman 1971). Yet with presentation-times of 1 s and longer there is a clear advantage in using chunks. An excellent, by now classical, survey of applications of information theory in psychology was provided by Attneave (1959).

Information theory has allowed a treatment of redundancy in language. For example, the sentence "Sm mn in ths rm us glsss" can be understood as 'Some men in this room use glasses', although several vowels have been deleted. Shannon studied the redundancy of English language and discovered that English texts can be reconstructed when 50 percent of the letters, chosen at random, are deleted. Other important applications of information theory deal with word perception. If the source vocabulary is small, humans are able to perceive words nearly perfectly, whereas perception becomes increasingly difficult as the source vocabulary becomes larger (Miller and Selfridge 1950).

In cognitive neuroscience, information theory has become an essential tool for understanding brain function. Modeling the brain as an information processing machine has led to important advances in both theory and practice. The production of action potentials (spiking) of neurons can be discretized and interpreted as a binary process. In this way, a temporal sequence of spikes can be represented as a binary vector of 0 and 1. All information coming from sensory inputs is processed by neurons using this simple binary language. Hebb conjectured (1949) that neural information processing cannot be understood just in terms of the behavior of individual neurons. Rather, the brain must be viewed as a system of so-called cell assemblies, wherein information processing occurs as an emergent property resulting from the interaction of these cell assemblies. Hebb's conjecture has received a great deal of experimental confirmation in the last decades of the twentieth century (Gray et al. 1989). The famous binding problem, or problem of identifying an object by recognizing individually and 'binding together' features that characterize the object, appears to be solved by means of synchronization of spiking activity (Singer 1994). Theoretical neuroscientists have developed many different approaches to modeling how information is stored in the brain. The most convincing and persistent model has been the associative memory (e.g., Palm 1980) that stores similar patterns close to each other, where the closeness between patterns is measured in terms of information overlap.

Information, Economics of

1. Introduction

Prior to the 1980s, the 'economics of information' usually meant the economics of search. Search began in the 1960s with the seminal research by George Stigler, which spawned an enormous and growing literature. Both search and noncooperative game theory are considered in this article. As we will see, they are closely related and much can be gained by fostering a closer relation.

Stigler modified competitive price theory by noting that price is a random variable with a given cumulative distribution function. He thereby enlarged price theory to include the search activity necessary to gather information about prices. He defined search as follows: 'A buyer (or seller) who wishes to ascertain the most favorable price must canvas various sellers (or buyers)—a phenomenon I shall term "search".' The author of the famous text *The Theory of Price* knew that search theory would receive widespread attention because of its intimate link with price. That is, the primary reason for the almost immediate influence of Stigler's work was his focus on price uncertainty. Any such major change in price theory eventually would reverberate throughout all of economics. This is what has occurred since the 1960s.

The game theory meaning of the 'economics of information' centers around the formation, continuation, and dissolution of contractual relationships. The incentives of parties to a contract are determined by the different information possessed by each. To exemplify these asymmetric information problems, consider an auction of a valuable object with the following information structure. There are two buyers and one seller. One buyer is willing to pay more for the object, while the other has more information about the object's relative price. If the buyers can collude, 'the Nash program directs us to view this collusion as the outcome of a process of communication where each player has choices about what to say. In this process, the more-informed buyer may try to mislead the less-informed buyer about the value of the object, and the less-informed buyer should rationally take this possibility into account' (Myerson 1999, p. 1075). All problems of incentive-based 'economics of information' can be formulated as Nash noncooperative games.

While Stigler's information model fits snugly into standard price theory, Nash's noncooperative game theory complements price theory, but is not reducible to it. Stigler's fit is snug because he takes the distribution of prices as exogenously determined. This corresponds to the basic assumption of price theory—consumers accept prices as exogenous. Thus, the equilibrium problem is not addressed. Nash enlarged the scope of price theory so interactive behavior can be studied in almost any social institution. This was apparent only after the contributions by Harsanyi, Selten, Kreps et al., thereby explaining the long period between Nash's discovery and its adoption by the economics profession.

In recent years these two research programs have started to merge. Search is embedded in Abraham Wald's sequential analysis in that it determines when the process of information collection should terminate. Gideon Schwarz (1994) notes that Wald used the theory of two-person zero-sum games to unify statistical inference. Statistical inference was viewed as a game played by the statistician against nature. Statistics from this game theory perspective was called decision theory. One of the most important topics in decision theory is optimal stopping. Thus, game theory is as applicable to search as it is to other informational problems in economics.

2. Search Theory

2.1 Introduction

Modern search theory solves the problem of when to terminate the collection of information and take an action. Search is the confluence of two seemingly unrelated intellectual streams: the formal evolution of optimal stopping rules beginning with Cayley (1875) and the verbal, common sense literature found in Knight (1921) and implicit in Adam Smith. The first stage of this confluence occurred when Stigler (1961) blended these two streams with his fixed-sized-sampling rule. The second stage replaced the fixed-sized sampling rule with an optimal stopping rule, thereby combining the insights of Stigler, Bellman, and Wald.

The third stage seeks the source of an endogenous distribution of prices (wages) to replace the exogenous distribution in the Stigler and sequential models. This large and complex research effort was initiated by Rothschild (1973). The fourth stage replaced the one-sided sequential model with a two-sided equilibrium problem, where there is competition and interaction among optimizing agents. This ongoing research is based on the matching and bargaining models devised by Diamond, Jovanovic, Maskin, Mortensen, and Pissarides.

In the early work on search, many economists placed a much higher value on the verbal insights of common sense, when they sought a solution to a search perplex. Mathematical formulations of these insights were undervalued. Today, the situation is somewhat reversed in that formal analysis is ap-

plauded, while common sense is depreciated. Both attitudes diminish economics. The first does not encapsulate insights in a formal model. Hence, testing and extensions are difficult if not impossible. The second closes off economics from the imaginative intuitions of common sense.

2.2 Intuitive, Common Sense Precursors to the Economics of Search

See Lippman and McCall (1993) for further detail.

In 1930, Cannan clearly saw the *moral hazard* problem associated with unemployment insurance. He also noted that the best strategy for a job-seeker was to 'Take what you can get now or hold out another week, when something better may turn up.' With the advantage of hindsight this looks very much like the reservation wage policy.

In 1932, Hicks recognized the unanticipated unemployment effects of the search which is connected to the presence of imperfect information, when he claims that firms' 'knowledge of opportunities is imperfect [whence] it is not surprising that an interval of time elapses between dismissal and re-engagement during which the workman is unemployed.' His statement that 'the unemployment of the man who gives up his job in order to look for a better one' recognizes that voluntary unemployment is joined with search as a productive activity.

An early explicit statement viewing search unemployment as a productive activity was made by Hutt in 1939.

> A worker … may refuse immediately available work … because he feels that to accept it will prevent him from seeking for better openings. … When actively searching for work … he is really investing in himself. … He is doing what he would pay an efficient employment agency to do—the search for a better opening is worth the risk of immediately foregone income (Hutt 1977, p. 83).

In addition to the labor literature anticipating the job search model, other prominent precursors in the economics of search include Knight, Schumpeter, and Alchian who were concerned with the search for natural resources, the search for inventions, and evolutionary economics.

Knight (1921) was keenly aware of the ancient activity of prospecting for natural resources 'where the possibility of securing wealth by the discovery of natural resources is known … resources will be attracted into the field of searching for them in accordance with men's estimates of the chances of success in relation to the outlays to be incurred.'

Schumpeter (1942) continued the advance toward Stigler's introduction of search in his concern for uncertainty and the opportunistic contractual behavior which uncertainty fosters.

> Practically any investment entails, as a necessary complement of entrepreneurial action, certain safeguarding activities such as insuring and hedging. Long range investing under rapidly changing conditions … is like shooting at a target that is not only indistinct but moving—and moving jerkily at that. Hence it becomes necessary to resort to such protecting devices as patents or temporary secrecy of processes or, in some cases, long-period contracts secured in advance.

In Alchian's (1951) evolutionary view, innovations may result from bungled imitation as well as from conscious efforts to improve. He considers innovation, like prospecting for natural resources, as a form of search.

It should also be noted that Simon (1951) suggested a stochastic theory of the employment relation resembling Wald's sequential analysis rule. In this remarkable paper, Simon also studied credible threats and promises, reputation and cooperation in a pre-game theory environment. He thereby suggested a connection between the two meanings of the 'economics of information.'

No one contributed more to the informal literature on the importance of information to economic decisions than Hayek. While not specifying an explicit search rule, Hayek (1978) clearly saw the importance of the concrete knowledge and special decisions made by millions of dispersed individuals. The key which facilitated the transition from *particular* knowledge to a *specific* decision was the price system:

> The recognition that a man's efforts will benefit more people and on the whole satisfy greater needs, when he lets himself be guided by the abstract signals of prices rather than by perceived needs, and that by this method we can best overcome our constitutional ignorance of most of the *particular* facts, and can make the fullest use of the knowledge of *concrete* circumstances widely dispersed among millions of individuals, is the great achievement of Adam Smith.

Thus for Hayek the crucial economic problem is the search for and use of dispersed knowledge whose common source is the price system.

The evolution of job search reveals how useful economic models are generated by *both* formal mathematics and common sense. The origin of the mathematical strand may be quite remote from practical applications, while the original intuitive insight may have little if any formal content. Nevertheless, as both strands evolve a threshold emerges. When this threshold is hit, a moment of insight occurs which unifies the two strands into a new economic model, illuminating a whole set of previously invisible phenomena. The success of the new approach is gauged by empirical data analyzed by novel econometric procedures that are frequently novel.

2.3 The Formal Development of Search Theory

See Lippman and McCall (1993) for further detail.

Stopping rules emerged from a very practical problem: Johannes Kepler's search for a wife in 1613. His procedure was a version of the secretary problem,

which was formally designed by Arthur Cayley in 1875 and rejuvenated more precisely by Leo Moser in 1956. (See Ferguson (1989) for a scholarly treatment of the secretary problem's evolution.)

In 1961, D.V. Lindley solved the following version of the secretary problem. The decision maker selects from n candidates who are presented in random order, with no recall of rejected candidates. The ability of the candidate is revealed at the presentation. This information tells the decision maker nothing about the abilities of the remaining candidates. The payoff function is 1, if the best secretary is chosen, and 0, otherwise. The optimal policy for large n is to interview and reject n/e of the candidates, and then choose the next candidate with the highest rank observed. The probability of choosing the best candidate is $1/e$, where e equals 2.718.

In 1960, MacQueen and Miller posed and solved the house-hunting problem. Independent, identically distributed offers $X_1, X_2, \ldots$ arrive one at a time. The return from stopping after n observations is $R_n = \max(X_1, \ldots, X_n) - nc$. MacQueen and Miller found the stopping rule N which maximized ER_N, where E is the expectation operator.

In 1961, Stigler formulated his fixed sample size model. The buyer obtains n price quotations for the item he wishes to purchase. A cost c is incurred each time a quote is made. The mathematical formulation of Stigler search is: choose the sample size n to minimize $E\min\{X_1, \ldots, X_n\} - nc$.

In 1970, the house-hunting problem was applied to job search in a simple model by McCall. The fixed sample size of Stigler's model is replaced by a stopping time N and the sequential decision model of search is given by: select a stopping time N to maximize $E\max\{X_1, \ldots, X_n\} - Nc$.

The optimal stopping time is: accept the first offer which exceeds the reservation wage ξ. The reservation wage ξ is the solution to the first-order condition

$$c = \int_x^\infty (y-x)\mathrm{d}F(x) \equiv H(x) \tag{1}$$

where $H(x)$, the marginal gain from one more offer, is strictly decreasing and convex. The first-order condition has ξ as its unique solution since $H' < 0$. The economic interpretation of the first-order condition is: equate the marginal cost c of taking an additional offer with the expected increase in the return from taking one more search. It has been shown that ξ is the expected return from search (see Lippman and McCall 1976). The time until an acceptable offer is obtained, a period of frictional unemployment, is a geometric random variable with mean $[1-F(\xi)]^{-1}$.

2.4 Equilibrium Price (Wage) Dispersion

Rothschild (1973) raised the important question of the existence of an equilibrium price dispersion, namely, what gives rise to the nondegenerate price distribution assumed in simple search models. This question provoked an enormous literature on equilibrium search models which sought a positive answer to Rothschild, thereby negating Diamond's (1971) finding that all sellers charge the monopoly price. In Diamond's model, buyers are identical, sellers are identical, and buyers have the same search cost. If the rules are reversed—buyers instead of sellers make take-it-or-leave-it offers and sellers incur search costs—then markets clear at the competitive price. The preferred way out of this dilemma is to introduce heterogeneity into the model. In McMillan and Rothschild (1993), there are several sources of heterogeneity among the 31 papers surveyed. They include differences in sellers' production costs, buyers' search costs, buyers' beliefs about the offer distribution, sellers' time varying prices, buyers' inventory holdings, and advertising which yields differential buyer information. Burdett and Mortensen (1998) obtain a unique equilibrium solution to a game where a continuum of employers establish wage offers and a continuum of workers search sequentially. If workers search when unemployed *and* employed, wage dispersion is achieved.

2.5 Two-sided Search and Bargaining

Since the early 1980s, the early one-sided optimization search models have been generalized to two-sided equilibrium search models. This research combines game theory with search theory by introducing bargaining into the formation of matches. The steady-state equilibrium is the intersection of best reply functions for workers and employers, i.e., a Nash equilibrium, *when utility is nontransferable*. If utility is perfectly transferable, the matched pair bargains until either an agreement or an impasse is reached. The Nash solution is the equilibrium of this cooperative game. See Burdett and Wright (1998).

McMillan and Rothschild (1993) note that the joint study of bargaining and search fortifies each. In the search theory used by Diamond (1971) and in the price dispersion models described above, after a seller is located by the searching buyer, the seller presents a take-it-or-leave-it price offer. But in many circumstances these offers lack credibility, i.e., the seller has an incentive to bargain if his offer is rejected by the buyer. In bargaining theory, it is usually assumed that a single buyer and a single seller are locked in their negotiations. In fact, each often has the option of searching for another trading partner.

2.6 Econometric Methods

The sequential search model gave rise to a sequence of novel econometric methods beginning with the work

of Heckman and Singer; and Kiefer and Neumann. Structural estimation has been developed to estimate sophisticated models that have grown from the simple sequential model.

The impetus for structural estimation was Lucas' insight that reliance on reduced-form estimation in policy analysis gives rise to systematic forecasting errors. This insight is a consequence of the rational expectations hypothesis, which is a version of the Nash equilibrium. Thus, the estimation of search models relies on the pillar of contract and incentive models. Indeed, most structural estimation has been conducted within Markov decision processes. These processes are natural for modeling stochastic sequential decision making. Control variables d_t and state variables s_t, $t = 1, \ldots, T$ characterize the decision process. The individual is represented by three primitives: a utility function $u(s_t, d_t)$ denoting preferences at time t, a Markov transition probability $p(s_{t+1}|s_t, d_t)$ denoting the agent's beliefs about future states given current states and decisions, and the discount factor β. The optimal decision rule δ is obtained via dynamic programming. See Gotz and McCall (1980) for an early application.

An error term ε_t is usually imbedded in the discrete decision process. This insures that the econometric model is nondegenerate. The structure of the error term is determined by the specifics of the problem. The error term is a fundamental element of the overall optimization, a remarkable rise in its stature compared to earlier econometric models. It is now considered an unobserved state variable, the usual state variable s_t being decomposed into (x_t, ε_t), where x_t is a subvector observed by the econometrician and ε is observed only by the agent.

Rust (1994) identifies practical and theoretical reasons for the recent interest in structural estimation. Theoretically, 'structural estimation is the most direct way to assess the empirical validity of a specific Markov decision process model.' On a practical plane, 'structural models can generate more accurate predictions of the impact of policy changes than reduced-form models.' This practical reason lies at the heart of the Lucas critique: reduced-form estimates are unreliable forecasts of policy changes because they ignore the impact of policy on the 'deep parameters' (u, p, β). Wolpin (1995) is an excellent survey of this literature by one of its founders.

2.7 *The Effects of Labor Market Policies in Equilibrium Search Models*

Over the past decade there has been an increasing interest in economic models that study the flow of jobs and workers among diverse states. Most of this research relies on equilibrium models and emphasizes the frictions in both search and recruiting. Using a rich set of data on flows in labor markets, this research studies job creation, job closure, unemployment, and labor mobility. Matching and equilibrium are crucial to the theoretical approach. Decisions made by employers on the demand side of the market are highlighted. A comprehensive review of this prodigious literature is Mortensen and Pissarides (1999).

Ljungqvist and Sargent (1995a, 1995b) have devised sophisticated extensions of the simple sequential search model to study equilibrium unemployment behavior in European countries. In Sweden, they recommend a smoothing of the distorted incentives in the labor market by adopting less generous unemployment benefits. In European welfare states, their equilibrium search model finds that:

> when the generosity of unemployment insurance increases, the upward pressure on the unemployment rate eventually dominates the reduction in labor mobility due to high marginal income taxes. The higher unemployment rate is caused by unemployed workers reducing their search intensity and increasing their reservation rates. Higher unemployment pushes taxes upward which in turn increases the unemployment rate further, and so on.

3. *Contracts, Incentives, and Asymmetric Information*

3.1 *Introduction*

The past two decades of the twentieth century have witnessed dramatic changes in economic theory. Several years ago most graduate texts in economic theory were founded on price theory. Today, in the major economic departments, economic theory revolves around noncooperative game theory. Price theory has been relegated to the back seat. Before the ascendance of game theory, the emphasis in economics was on the usefulness of economic models in explaining empirical phenomena. While this emphasis persists, it has been overshadowed by the quest to apply strategic thinking to resolve economic problems.

The key ingredients of this remarkable transformation are: the Nash equilibrium (NE) concept, Harsanyi's characterization of contracts with asymmetric information as noncooperative games, and Selten's explicit consideration of time and the elimination of equilibria associated with noncredible threats and promises.

Nash's equilibrium is a strategy for each player where each strategy is a best response to the strategies of the other players in the n-person noncooperative game. This concept pervades economics. As a simple example, consider the traveler who drives a car first in the US and then in the UK. He drives on the right-hand side of the road in the US as does everyone else. When he visits the UK, his best response to British drivers is to drive on the left side. These Nash equilibria are akin to rational expectation's equilibria.

The NE is not immaculate. Jack Hirshleifer (private communication), sees

> two major problems with NE: (1) Each player's decision is supposed to be a 'best reply' to the opponent's corresponding choice. But the Nash protocol requires *simultaneity*. Thus, neither side *knows* the opponents' strategy to which it is supposed to be replying optimally. Without that knowledge, how can someone make a 'best reply'? ... (2) ... the 'best reply' has to be to the opponent's *strategy*, and not just to his observed *actions or moves*. In all but the very simplest cases, only a tiny fraction of a player's full strategy will ever be visible. ... So in general the player can never know whether his current strategy is or is not a 'best reply' to what the opponent has in mind. ... NE is fine for 'toy worlds' of our textbooks, but I remain skeptical of its general predictive validity.

van Damme and Weibull (1995) observe that 'John Harsanyi showed that games with incomplete information could be remodeled as games with complete but imperfect information, thereby enabling analysis of this important class of games and providing a theoretical foundation for "the economics of information".' Signaling, moral hazard, and adverse selection are prominent members of this class. A game is said to be one of *complete information* if Nature makes the first move and this move is observed by all players. A game has *perfect information* if each *information set*—the set of nodes in the tree such that one is known to be the actual node—is a singleton. See Rasmusen (1989). Harsanyi adopts a Bayesian approach assuming that each player may be of several types—a type specifies the information a player possesses regarding the game. The resulting refinement of Nash's equilibrium is called a Bayes–Nash equilibrium.

Reinhard Selten was the first to refine the Nash equilibrium for analysis of dynamic strategic interactions. Such refinement is necessary since many equilibria entail noncredible threats and do not make economic sense. Selten's formalization of the requirement that only credible threats should be considered, the concept of *subgame perfect equilibrium*, is used widely in the industrial organization literature. It has generated significant insights there and in other fields of economics.

At first it was not clear how the problems of asymmetric information could be formulated as noncooperative games. Indeed, much significant research in signaling and insurance was performed in the 1970s with little reference to game theory. These models generated important economic implications, but were stymied by problems of equilibrium and credibility. This was changed suddenly when fundamental papers by Kreps and Wilson (1982) and others showed that this research could use the deep insights of Harsanyi and Selten to illuminate credibility and equilibrium. The ensuing unification of industrial organization was analogous to the epiphany that occurred in search theory when optimal stopping, dynamic programming, and matching were applied to search problems.

3.2 Principal-agent Models

This section is a brief discussion of three of the most important asymmetric information models: moral hazard, adverse selection, and signaling. All three belong to the class of principal-agent models. In these models, the principal P designs the contract. The agent A either accepts or rejects the contract depending on the expected utility of the contract vis-à-vis the utility from other alternatives. Finally, the agent performs the task specified by the principal. The two parties are opposed in that the revenue for the agent is a cost for the principal and the effort of the agent is costly to him and beneficial to the agent. In determining the optimal contract between principal and agent, this opposition must be resolved. Macho-Stadler and Perez-Castrillo (1997) see this as 'one of the most important objectives of the economics of information.'

There are two parties to a P–A model. One is informed while the other does not know a crucial piece of information. For example, in the insurance P–A model, the insurance company is the principal and the insuree is the agent. It is usually assumed that the agent knows his health status, whereas the principal is uncertain. The P–A model is a bilateral monopoly. Hence, the nature of the bargaining process must be specified. For simplicity, it is assumed that either P or A receives all of the surplus. For example, P does this by stipulating a 'take-it-or-leave-it' contract, which the agent either accepts or rejects. Salanie (1997) notes that bargaining under asymmetric information is very complicated: 'There is presently no consensus among theorists on what equilibrium concept should be used.' Salanie observes that: 'the P–A game is a Stackelberg game in which the leader (who proposes the contract) is called the principal and the follower (the party who just has to accept or reject the contract) is called the agent.'

The actual bargaining in a concrete setting is unlikely to have this 0–1 structure, where the game terminates if either an agreement or disagreement happens. Instead, the bargaining may continue or, more likely, the disgruntled agent will search until he finds an acceptable contract. Such a model would combine the P–A analysis with search theory.

3.3 Three Principal-agent Models with Asymmetric Information

Moral hazard occurs when the agent's actions are not observed by the principal. More specifically, moral hazard is present when the subject's actions are: (a) influenced by the terms of the contract, and (b) in a way that is not fully specified in the contract. These hidden actions are evident in automobile insurance contracts, where the driving behavior of the insuree is not known by the insurance company. The contract usually has a deductible to mitigate the risk to the insurance company.

Adverse selection occurs when the agent is privy to pertinent information before the contract is finalized. This information is hidden from the principal. Adverse selection is evident in health insurance contracts where certain characteristics (health status) of the agent are imperfectly known by the insurance company. An insurance contract is designed for each group with a particular health characteristic (sickly or healthy) so that each member of the group has an incentive to buy it.

Signaling occurs when one of the parties (the agent) to the contract has pertinent information regarding his type. Before entering the contract, the agent can signal the principal that he has this type, i.e., the behavior of the informed party conveys (signals) the type information to the uninformed party.

A key observation is that each of these asymmetric information models can be represented as a noncooperative game. The crucial equilibrium concept is a refinement of the Nash equilibrium. For example, the signaling game has a perfect Bayesian equilibrium. Excellent discussions are given in Gibbons (1992) and Macho-Stadler and Perez-Castrillo (1997).

One of the most important topics in the economics of information is the optimal design of contracts under symmetric and asymmetric information. In the symmetric case, the principal designs the contract so that the expected marginal payoff equals the marginal cost of effort. If the principal is risk neutral, then the optimal contract is one in which the principal accepts all the risk and the agent is, therefore, fully insured, receiving a payoff that is independent of the outcome. In the asymmetric case, the situation is much more complicated. The optimal contract balances the conflict between two opposing goals: efficiency in the allocation of risk between principal and agent and maintaining the incentives of the agent. For lucid presentations of the analysis, see Macho-Stadler and Perez-Castrillo (1997) and Salanie (1997).

4. Future Developments

It seems clear that the merger between search and game theory will continue. The benefits from this include: strategic thinking will become even more apparent in search models and the econometric testing of game theory models should develop into a cottage industry alongside experimental testing. Search models will continue to be used to evaluate labor policies like cross-country unemployment and other macro issues. Their use in other economic areas should also flourish.

In his evaluation of the applications of Nash equilibrium, Selten claims that we still know little about actual behavior and that empirical research and theories of bounded rationality are needed. Rubinstein (1995) is more emphatic. 'Economic theory should deal with the real world. It is not a branch of abstract mathematics even though it utilizes mathematical tools. Since it is about the real world, people expect the theory to prove useful in achieving practical goals. But economic theory has not delivered the goods.' Many would dispute the final sentence, but most would agree that game-theoretic models require extensive econometric testing. This has already begun, with structural estimation being the favored method, but much remains. This is an exciting time for the economics of information.

Infrastructure Investment

The city building process is a product of infrastructure investment. At the most general level, the term infrastructure describes the underlying foundation of the physical and social facilities of the city (Seeley 1993, p. 20, Konvitz 1985, p. 130), both the physical systems and technologies, and the health, education, and welfare facilities that knit the city into a collective fabric. From this perspective, Herbert Muschamp (Perry 1995, p. 1) observes that, 'infrastructure is shorthand for the structural underpinnings of the public realm.'

While such an encompassing approach to infrastructure has conceptual resonance, most studies carve a more particular focus (OECD 1991, Neutze 1997, Graham 2000), defining infrastructure as the underlying physical foundation of the city: the material systems, networks, and technologies (roads, water and sewer systems, power grids, and telematic networks) that serve key urban relations; the social flows, economic exchanges and political relations of the city. This foundational primacy of physical infrastructure affords it a rather unique status in the literature: namely, the bridges, roads, and water systems of the city are not described simply as important physical artifacts but as investments in the city building process. The returns on such investments are measured in terms of a society's economy, health, and social well-being.

Hence infrastructure scholarship and policy often begin with the normative position that the more an urban population is able or willing to invest in physical infrastructure, the more apt the urban settlement is to prosper economically and benefit socially from the resulting conditions of efficiency, health, and human development. This is perceived to be as true in new or emerging urban centers as it is in the established cities of the developed world, thereby making issues of definition, public or private provision of such systems, finance, and technology equally important to every modern city

1. Infrastructure: Evolution from Private to Public Function

The term 'infrastructure' as it is employed here, is relatively new: a conception of the late twentieth century that is used to describe the systemic applications of technology to the needs of urban society, producing what historian Joel Tarr (1984, p. 4) calls the 'technological sinews' of the city: its transportation networks, power grids, utility systems, and telecommunicative linkages. For much of the nineteenth and twentieth centuries, urban physical facilities were not viewed systemically as 'physical 'networked' services' (OECD 1991, p. 19), but as either privately produced, geographically individuated 'internal improvements' or equally decentralized, governmentally generated 'public works.'

For, example, the seventeenth-century invention of the British toll road, the late eighteenth-century canal systems, and the early railways were initially proprietary responses to the requirements of the Industrial Revolution. Technological advances in water treatment, electricity, gas distribution, and modes of communication were virtually all developed by private inventors and investors. Only later, as the impact of such inventions on the dramatic and uneven shifts in urban populations, levels of disease, congestion, and fire became apparent, did they come to be viewed as a public responsibilities or goods. Even then, cities' 'different…business leaders, politicians and professionals' (Tarr 1984, p. 5) would take years to determine which technology or proprietary service was the right one and more years to decide how to plan, pay for, and ultimately build the service (Konvitz 1985, Anderson 1988). For example, the benefits of water and sewage treatment to health and economic development were

well known by the middle nineteenth century, but it took US cities until 1940 to build such systems. World wide, hundreds of millions of urbanites live in political-economic environments that still do not offer reliable water and healthy sewage systems, transportation systems, or power

As such, the history of successful infrastructure investment is less about the direct impact of technology and more about the interaction between technology and society (Tarr 1984). Put another way, recent scholars posit that infrastructure networks are both social and technical: they are always contested and their impacts on cities are never neutral (Graham 2000). No matter how 'public' the good is perceived to be, the impacts of telecommunicative grids, transportation roads, and energy will always privilege some places and people over others (Swyngedouw 1993).

1.1 Public Infrastructure Investment

However convoluted its investment process and uneven its impacts, infrastructure investment became essentially public practice in the twentieth century, carried out either by governments or heavily regulated private firms. Several reasons are offered for this (Neutze 1997, Perry 1995). First urban infrastructure often serves the essential health and well-being of the citizenry, requiring full citizen access to such services at reasonable cost. Second, this implies the provision of goods at a scale and price (given the elasticity of demand of several of these services) that is beyond the capacity or interest of private providers. Third, urban infrastructure goods often constitute natural monopolies, whereby it is less costly to have a single provider than several service delivery systems. For example, it would be very costly to have competing water and sewer companies putting parallel networks of mains and pipes under every street in a city to give consumers a choice of systems. Fourth, some forms of urban infrastructure produce almost exclusively public goods or externalities (or services which can not be used by one consumer without also being made available to all), such as public roads, sidewalks, and parks. Fifth, equity can require that certain key benefits of urban infrastructure should not be withheld from any citizen. (Neutze 1997, pp. 29–31)

1.2 Special Purpose Governments

Just as the conditions of scale, cost, and equity have led to public provision of physical infrastructure, the sheer size and the accompanying obligations of debt and delivery of infrastructure systems has often led one level of government (especially national governments) to offload many of these services on to lower levels of government. Municipal governments in turn have further devolved the delivery of infrastructure, one by one, to special purpose governments or public authorities (Sbragia 1996, Perry 1995). In the United States, for example, such governments issue the majority of all bonds used to finance infrastructure investment. It is argued that such decentralized structures work well to:

(a) preserve and circumvent local and state debt limits, maintaining the legal requirements of general municipal fiscal balance while allowing special purpose, extra-municipal public agencies to generate debt, raise revenue, and build physical infrastructure networks; and

(b) create more direct relationships between the government and the capital markets, thereby better satisfying market requirements for enhanced credit risk management (through municipal debt guarantees, or bond insurance, or policies of securitization, such as the provision of bank letters to offset credit exposure, etc.) in order to pay for infrastructure.

Critics of such public corporations point to their privatistic practices as evidence of the increasing transformation of government into 'business' (Walsh 1978). Adherents suggest that the privatization of public infrastructure services in general and through special purpose governments and public authorities in particular is part of the century-long move away from the inefficiencies of the state and back to the private sector as the best, most stable source of infrastructure investment (Smith 1999).

2. Infrastructure Investment as Public/Private Practice

In many ways, the dominant normative consideration of public infrastructure investment has come full circle, with a twist. Where conditions of scale and cost, and developmental importance made infrastructure investment essentially a public or governmental function at the beginning of the twentieth century, the very same issues are challenging the capacities of the state and forcing new mixes of public and private service delivery at the beginning of the twenty-first century. The government, at national and local levels, is finding it difficult to fully conceive, finance, build, or efficiently maintain modern systems of urban infrastructure. This is held to be equally true for basic infrastructure systems in the emerging urban centers of the developing world (Smith 1999) and for advanced telematic systems of telecommunication and digital media that are radically transforming the space of urban flows in general (Graham and Marvin 1996).

2.1 Emerging Cites in an Urban World

Nowhere are these arguments more forcefully made than in the literature on infrastructure development in emerging cities. Increasing patterns of economic globalization and migration into cities are central features of global geographic and social development.

Sometime in the last decade of the twentieth century, the world became 'urban,' more than 50 percent of the global population could be found living in towns and cities. The emerging cities of this new urban world face tremendous infrastructural challenges with limited technological and fiscal resources, and yet they represent stable and viable places to ever more people (Clark 1996).

Just as issues of health, transportation, and scale challenged the United States and Europe at the beginning of the twentieth century, similar patterns, at an even greater scale, challenge the emerging urban centers of Latin American, Asia, and Africa in this century. Millions continue to move to the cities without access to basic infrastructure facilities such as safe water, sanitation, and garbage disposal.

2.2 *Financial Practices: A Public-Private Mix*

While national governments remain the single most important source of infrastructure delivery in the emerging urban world, the costs, which can be as high as 10 percent of GNP, suggest that they cannot do it alone. They must attract domestic and international equity capital for private investments in the infrastructure. This requires the move to Western-style financing schemes and patterns of governmental devolution of infrastructure investment, making it a more 'public-private' activity worldwide.

In the past, municipalities (especially in developing countries) were able to combine their own taxes with central government transfers to build public works, but now infrastructure demands make them just as fiscally burdened as their national governments. In addition, they are required by both the national government and international banks to 'forge partnerships with financiers, private operators and constituents' (El Daher 1997, p. 1). The sources of revenue available to governments to pay for such services generally fall into three categories: (a) taxes, (b) user fees, and (c) other forms of leases (and purchase agreements) and revenue schemes. Depending on their success in using these sources of revenue, cities' infrastructure investments require the organization and constitution of government to accommodate new debt structures, create relationships with the capital markets, and regulate public-private infrastructure agreements. In certain key areas, infrastructure investment is becoming even more privatized or transferred to the private sector through deregulation, concessions, contracting out, and private management and control agreements.

2.3 *Access to Private Investment Markets*

Considering all of this, a most important signifier of infrastructure investment in cities is their access to the credit markets, that is providing the institutional transparency, strong government regulatory power, debt guarantees, and revenues needed to secure an attractive private investment climate in which to develop infrastructure. While these are common issues of municipal infrastructure finance everywhere in the urban world, in no places are they any more evident than in developing countries where not only can the fiscal strength of the municipality be open to question, but also the very existence of a stable viable domestic credit market can be equally problematic. Cities in developing countries often have more success generating direct private investment in fully privatized public works than in creating the stability of process required of a local municipal bond market.

In a rapidly urbanizing world and uneven investment climate, nongovernmental intermediaries like the World Bank, the IMF, the Inter-American Development Bank, and the Asian Development Bank have become important sources of infrastructure investment policy. They attempt to provide debt guarantee instruments and policy strictures designed to influence the creation of stable domestic capital entities, with the larger purposes of not only institutionalizing long-term markets but also enhancing governmental legitimacy across regimes.

3. *Infrastructure Investment and Urban Development*

Infrastructure investment is an important way to view the urban. It represents networks of technology and urban life, binding them together in patterns that are clearly important elements of cities and their development. It comprises a substantial share of the sunk physical capital of cities; materially delivering the networks of heat, light, water, telematics, and power that are central to urban life; without them modern cities do not exist (Graham 2000, p. 115). The material grids of such components of the urban landscape and their accessibility go a long way toward explaining what is meant by the 'developed' and 'developing' urban world.

The study of infrastructure investment provides an understanding of the state as a site of debt and public regulation and the market as a site of capital and risk-generated requirement. The restructuring of the market into risk niches and intermediaries and the state into devolving agencies of delivery and transfer in both developed and developing urban centers are central characteristics of infrastructure investment as a public-private practice of the new urban world. More generally the full implementation of infrastructure investment is a key element of the dominant practices of urban political economy: the structuring of government, the creation and regulation of capital markets, the conditions of uneven urban economic

development, and the socio-technical networks of service and underservice that represent the distributions of power in the city and globally (Tarr 1984, Swyngedouw 1993). In sum, the study of infrastructure investment is the study of urban development.

Infrastructure: Social/Behavioral Research (Japan and Korea)

1. Phases of Development After 1945

Modern social science originated outside Asia (Inoguchi 1995). In Japan and Korea, which was under Japanese colonial rule for much of the first half of the twentieth century, modern social science meant, initially, European-born Marxism planted onto Asian soil. Hence, the social sciences meant the opposition science, *Oppositionswisssenschaft*, the science those opposing the regime adopted to reveal the oppressive and exploitative nature of the system. Marxist influence permeated the social sciences deeply. Coupled with the overtly nationalistic overtones characteristic of Asia, Marxism was not necessarily conducive to the early adoption and diffusion of behavioral and social sciences that characterized the American scene of the 1950s and 1960s. In other words, the dominance of Marxism in the social sciences meant higher barriers against the adoption of American-style behavioral and social sciences even in the 1950s and 1960s.

Furthermore, the earlier dominance of state science, *Staatslehre*, the science that purported to be useful to the state's governance, had a lingering influence on the fledgling social sciences in the first half of the twentieth century and beyond. Instead of trying to come up with law-like generalizations, state science was interested in supplying specific, concrete, and context-based knowledge. It encouraged historical and institutional description. State science was interested in applied subjects like law and economics, but not political science, sociology, or social psychology. State science was interested in history and geography, as far as they could be utilized in running the country and the colonies. Therefore, in Japan and Korea in the 1940s and 1950s, the traditions of the opposition science and state science, two most overtly politically conceived traditions, slowly adopted the American-style social sciences of the 1940s and 1950s in a mutually reinforcing direction.

Nevertheless, American-style social sciences started to permeate steadily into the rest of the world after 1945. The remarkable development of the American model of the professional academic market in the first half of the twentieth century prepared the United States to excel itself in the social sciences in the latter half of the century. As carefully portrayed by Zunz (1998), it is characterized by competition, based on a certain set of criteria within the academic community, and the loosely orchestrated concertation of government, industry, and the mass media to nurture and make use of academic resources and products. Furthermore, the influx of many European refugees stimulated the American scene dramatically. The number of Nobel Prize winners from the United States was modest each year between 1901 and 1937, some-

what comparable to the figure of Japan after 1945. Thereafter, it rose dramatically, achieving a dominant share (Inoguchi 1989).

Three major features of American-style behavioral and social sciences are (a) a strong drive to come up with law-like generalizations; (b) a strong commitment to systematic, empirical hypothesis testing; and (c) shared beliefs in anonymous referees producing good judgments and improved manuscripts. These features were not necessarily in good harmony with the prevailing academic cultures of Japan and Korea in the 1940s and 1950s. Their interests lay in more historical and contextual descriptions, not necessarily in law-like generalizations. Their efforts to advance the argument were not necessarily made in a sustained fashion of systematic empirical hypothesis testing. They were extremely averse to the idea of their work being anonymously refereed for publications. Thus in the 1940s and 1950s, American-style behavioral and social sciences were not able to make a striking advance in Japan and Korea. Only in the 1960s and 1970s, were they to ride on the tide of behavioral and social sciences as understood and practiced in the United States. The 1960s and 1970s were also the period of the extraordinary economic growth of Japan and Korea. In tandem with economic development, the academic infrastructure was consolidated, and academic orientations came of age in their national environments.

2. *National Environments and Institutional Structures*

The higher educational legacy of imperial Japan, which ended in 1945, contributed most directly to the shape of the academic infrastructure of the behavioral and social sciences in Japan and Korea after 1945. Its major features were:

(a) an elitist structure of imperial universities with the number of professors and enrolled students being highly limited;

(b) a curriculum serving the needs of the government in terms of supplying the elite cadres in applied areas of study such as medicine, agriculture, engineering, law, and economics; and

(c) two European languages, German and French, equally emphasized with English, for students to learn.

After 1945, the number of colleges and universities grew rapidly in US-occupied Japan, where each of the 47 prefectures built a national university. Furthermore, private universities grew in number more dramatically in the 1960s and 1970s. The elitist nature of Japanese universities was played down considerably throughout those years. Rather, Japan, and to a lesser extent Korea, registered a high admission rate of high-school graduates comparable to that of the United States, achieved through a very inclusive enrolment scheme. The nature of the curriculum has also significantly changed in tandem with the extraordinary growth of student enrolment and staff appointment from the 1960s to the 1990s. In the case of the University of Tokyo, for instance, the relative priority of staff appointments remained the same. It expanded in applied science areas, especially engineering, the life sciences, medicine, pharmacology, and agriculture. As of 2000, 80 percent of the annual budgetary allocation goes to those applied science areas. Only 20 percent of it goes to law, economics, literature, education, and other nonscience areas of study (University of Tokyo 2000). However, in most private universities, those applied science areas of study have not been well prioritized in terms of faculty development and student enrollment, thanks to the general paucity of budgetary resources as a whole.

However, this does not mean that a favorable national environment has been created for the development of the behavioral and social sciences. Within the non-applied science areas of study, roughly the traditionally conceived arts and sciences, autonomous departmental status has not been given to the behavioral and social scientific disciplines. The political science discipline has been an appendix to schools of law (a legacy of state science); the school of economics has a curriculum giving very high importance to applied economics and history; and the school of literature has departments of sociology, social psychology, and anthropology without their autonomous status in terms of staff appointment and budgetary allocation. Rather, they remain parts of the schools of law, economics, and literature and sometimes serve as their mere appendices.

In this regard, Korea, unlike Japan, thanks to its nationalism and much stronger American influences in higher education, has developed its institutional structure far ahead of the Japanese imperial legacy. The emphasis on European languages was replaced by the predominant use of English after 1945. This has facilitated the diffusion of American-style behavioral and social sciences.

Turning to the topic of institutional and financial setups, there are three major ways in which behavioral and social science research is conducted:

(a) within the university system;

(b) by extrauniversity institutes; and

(c) the system of project funding through national organizations and foundations.

Behavioral and social science research is predominantly conducted within the university system. Small-scale research is normally conducted by making best use of a small amount of research budget made available to each professor. At some universities, schemes for facilitating larger and more interdisciplinary research exist. However, the size of budget tends to be small. Therefore, once research needs get large in terms of funding needs, one tends to rely on other schemes (the Japan Society for the Promotion of Sciences 2000).

In addition to the university system, there are some research institutes primarily devoted to the planning, implementation, and dissemination of research on national and sometimes international bases. They are either publicly funded or run by the mix of private and public money. In Japan, for example, the National Museum for Ethnographic Research in Osaka, the largest such institute run by public money, focuses on anthropology. The Institute organizes various projects incorporating professors working in universities. The Institute of Statistics and Mathematics in Tokyo, also run by public money, is a similar organization that focuses on public opinion research on national characters and life styles. In Korea, a similar institute, the Sejong Institute, is publicly and privately funded and works on a variety of subjects in sociology, political science, and urban studies.

Some institutes work on more direct, public policy related research topics like 'public policy priorities in aging societies,' while others work on more purely academic subjects like 'life styles, postmodern, post-Confucian, and post-Marxist.' They vary enormously (NIRA 2000, Yamamoto, 2000).

The system of project funding through national organizations and foundations is important in Japan and Korea. In Japan, the Japan Society for the Promotion of Sciences plays roles similar to those of the National Science Foundation of the USA, giving financial support to various academic projects (the Japan Society for the Promotion of Sciences 2000). The National Institute for Research Advancement in Tokyo is an organization funding more public policy focused projects run by various think tanks in Japan and elsewhere (NIRA 2000, Yamamoto, 2000). The Japan Foundation in Tokyo is a foundation run by public money to assist research financially and to disseminate academic, artistic, linguistic, and other professional projects globally (the Japan Foundation 2000). In Korea, too, similar organizations and foundations exist. Many private foundations exist in both countries in addition to these public organizations and foundations. Some focus on gender studies, academic and professional exchanges, human security, and international financial needs, while others give preference to more public policy related projects.

In terms of infrastructure development for the behavioral and social sciences, the university system is central and most helpful after all. Most project focused funding does not support infrastructure development. In order to develop an academic infrastructure, such as building joint centers for survey research or for experimental laboratories, interuniversity consortiums for databases, electronic networks, and publishing houses, one needs to rely mostly on public money.

A joint university center for survey research does not exist in Japan. What exists is the three to five year coalition based on the project funding of scientific research. With it, you build a research team and hire an opinion polling company for the survey. With the ending of the project, everything except the database and published volumes disappears. My own scientific research project is a recent example of this. It is funded by the Ministry of Education over four years (1999–2002). It deals with 'globalization and the cultural dimensions of democracy in 18 societies of Asia and Europe' and has 1,000 in each sample, done by face-to-face interviewing (Blondel and Inoguchi 2000). A number of universities such as the University of Tokyo and Keio University in Tokyo have departments of social psychology and sociology, and research centers/institutes for research by mass communication. However, none of them undertakes such coalition building and coordination roles institutionally.

It is the same with respect to experimental laboratories. Again, they must be built with project funding for scientific research and can be maintained and expanded if, luckily, they continue for several years. One recent example is Toshio Yamagishi's experimental laboratory built to examine modes of trust experimentally and cross-nationally (Yamagishi 2000). With regard to social scientific databases, the University of Tokyo's Institute of Social Sciences (http://www.iss.u-tokyo.ac.jp/) has set up an inter-university consortium for databases in a similar fashion as the University of Michigan's Inter-university Consortium for Social and Political Research. Focusing on sociological, political, historical, and economic Japanese data, the consortium has been quite a success, albeit on a rather small scale, in organizing available databases and making them academically totally open and accessible to its members.

In terms of election networks, again project funding of scientific research by the Japan Society of Promotion of Sciences and the Ministry of Education is vital. Ikuo Kabashima has done so on seven Japanese election panel surveys through the 1990s, producing six published volumes dealing with various aspects of Japanese electoral behavior (Kabashima 1998–2000). Kabashima's database has largely expanded the data bank of the journal called *Leviathan*: *the Japanese Journal of Political Science*. The data bank has been more narrowly focused on election data and has run on a much smaller scale.

Publishing houses dealing with behavioral and social science books do not necessarily thrive in business. Given the fact that academic publishers cannot anticipate the regular purchase of academic books by major university libraries in the order of 300 to 500, the publishing infrastructure needs to be further consolidated. The publishing infrastructure for English language volumes has not been built in any meaningful way. Kodansha International is the only commercially self-sustainable publisher in the English language. It is not primarily oriented to academic books. The United Nations University Press in Tokyo has been quite a success in the late 1990s in continuously publishing good academic books on such topics as democracy, humanitarian interventions, and

the global environment, albeit on a modest scale. It has been distributed in North America by the Brookings Institution Press and has been included in the Columbia International Affairs Online (CIAO) Internet service on new publications. University presses such as the University of Tokyo Press and Kyoto University Press have English-language publishing departments. However, they only publish sporadically and their published books are mostly based on translations of books originally written in Japanese.

3. *Strengthening the Asian Research Base*

Social science research in Asia in general, and in Japan and Korea in particular, in the second half of the twentieth century, has become well institutionalized in its respective national settings and organizational structures. Japan and Korea, having diluted the two strong legacies of state science and opposition science that were prevalent in the first half of the twentieth century, and brought in a new set of American-style behavioral and social sciences, developed a fairly solid foundation for social science research in the second half of that century. Although its infrastructure remains to be much more vigorously improved in the future, the stage is clearly set for its further consolidation, especially in the light of the two pronounced trends of international cooperation and cross-national comparisons.

In Japan and Korea, as well as in Asia in general, international cooperation started with the United States. The United States has been a senior partner for Asia in general and Japan and Korea in particular for the whole time. Through bilateral research and teaching with the United States, by 2000, both latter countries had enhanced their national foundations of social science research. Toward the end of the twentieth century, it was clearly discerned that the trend in international cooperation had come to encompass the United States as well as Asia. Politics and economics matter here. In much of the latter half of the twentieth century, regional cooperation did not flourish much in part because of economics and politics. However, in the last decade of the twentieth century, Asian countries (here meaning the Asia-Pacific countries: Japan, Korea, China, and the 10 Association of Southeast Asian Nations members) came to interact among themselves.

It is not surprising that the new trend of enhanced intraregional research cooperation is in broad harmony with the increase in intraregional trade and the frequency of intraregional summit meetings. To a considerable extent, it looks as if the then newly found regional (i.e., Asian) identity pushed such a trend. However, this trend was primarily due to the very strong interest in cross-national comparisons. Once national achievements have been completed more or less in terms of per capita national income and high levels of literacy, a sort of looking around and probing the cross-national propositions in social science research has become a norm, replacing the traditional approach by focusing on national patterns and developments. It is still far from claiming the beginning of an Asian social science.

Yet, a number of such seeds have already been sown and the prospect is not so bad. Let me give a couple of examples. Demography and the sociology of social mobility have been one of those areas of research where cross-nationally standardized observations are relatively institutionalized. The Japanese Sociological Association's panel study of Japanese social mobility, which started in the 1960s, has been further enhanced by incorporating comparative measurement and analysis in the 1990s (Seiyama and Hara 1999). The societies chosen for comparison are industrialized democracies of the West and fledgling democracies of the Asia-Pacific region. Another example is a new project comparing values, norms, and life styles of nine Asia-Pacific societies. It plans to utilize the Gallup Millennium Survey done in January 2000 in 82 countries (Tomiie and Mano 2000, Emiko and Satoko 2000). The co-directors, Ahn Chung-Si of Seoul National University and Takashi Inoguchi, have been running this project.

Up to the late 1990s, the leadership for social science research cooperation in Asia-Pacific used to come primarily from the United States. Increasingly, since then, the trend is for intraregional cooperation by local initiatives, whether from Korea, Japan, Singapore, or Australia. Since there has not been an all-inclusive regional social science research council taking conceptual leadership and funding facilitation like the United States Social Science Research Council has long done, one cannot claim too much at this stage. However, one can easily discern budding initiatives and publications on such subjects as national identity, globalization, democratization, human rights, and civil society. Universities such as the University of Tokyo, Yonsei University, Chularonkorn University, the National University of Singapore, and the University of Malaya as well as think tanks like the Institute of Southeast Asian Studies (Singapore), the Japan Center for International Exchange (Tokyo), and the United Nations University (Tokyo) are major agents for more academically oriented undertakings. With the resultant, cumulatively enhanced networks within the Asia-Pacific, one can hope with some cautious optimism that one can start discussing some budding features of social science in the region. These would surely synthesize a diversity and openness of views and angles that would come up with empirically testable comparative propositions on major trends and patterns of democratization, digitalization, and globalization, and their differentiated impacts on local societies.

Infrastructure: Social/Behavioral Research (Latin America)

The social sciences in Latin America present an array of manifestations, differing widely across disciplines and types of institution. There is also a great deal of variation in the nature of graduate and postgraduate training, research experience, and professional employment. At a time when significant developments take place in the international agenda of research methodology and interdisciplinary approaches, the regional intellectual map reveals great dynamism at the same time that it unveils the presence of persistent vulnerability and stagnation.

1. Graduate Training

The Latin American tradition of tertiary studies opens the door to regulated professions after five years of study and, despite the fact that courses with nonprofessional titles have arisen in the various social fields, the association with university education historically has been quite clear. The social, legal, communication, and behavioral sciences are clearly in the majority (29.2 percent of enrolments). If we include in them economics and administration, their proportion rises to 41.3 percent. The group that results from adding together educational disciplines and the humanities represents 18 percent of the total enrolment which, added to the above-mentioned disciplines, gives a figure of 60 percent of higher-education student population devoted to sociocultural and educational disciplines.

The range of courses in the social field is not homogeneous either between countries in the region or within one and the same country. Within a motley and variegated picture of the social science field, the main systems producing the greatest numbers of graduates with first degrees are those of Mexico, Brazil, Argentina, Peru, Colombia, and Venezuela. The social and human sciences take the lion's share of enrolment in all higher-education systems, including those of Latin America, for the simple reason that professional activities requiring language proficiency and general knowledge about society and the contemporary world are much more numerous than those requiring specialized and technical knowledge. Adding all the disciplines related to the social field they total half a million graduates, or 62 percent of the total graduate population from higher education.

Two main groups of social science courses may be distinguished. The first one is oriented to the employment market (basically for people who already work or who seek a secondary-school position and/or general training). The second, much smaller, comprises the traditional more academically oriented disciplines.

1.1 Market-oriented Courses

Expansion of higher education, especially from the 1970s on, swelled the number of students in the social sciences and the humanities, who were recruited largely from those who had been unsuccessful in applying for more prestigious courses. Such students seek an ill-defined professionalization that the university is unable to supply in satisfactory measure, since it requires much more structured supervision than the university is prepared to offer. The majority

of students enroll in courses with high drop-out rates and conferring dubious professional status and are from social backgrounds manifestly less privileged than those seeking to enter more competitive social professions. Thousands of students enter higher education inadequately educated and enroll in private institutions which pay the teachers badly or do not provide the minimum working conditions needed, or in the 'difficult' mass departments of public universities. The climate of lack of motivation prevailing in such departments and schools explains why many teachers who wish to do research seek refuge in postgraduate work.

Curricula for the market-oriented courses—administration, social service, law, teaching, communication, and others—have often been weak at both undergraduate and postgraduate level because, being based on extremely pragmatic educational schemes, they have virtually no academic or disciplinary traditions of their own. They are like hybrids unable to reproduce, despite the efforts they often make to copy the academic rituals of the more established disciplines (congresses, specialist journals, research projects, postgraduate programs, etc.). Professional training in the social sciences is a difficult and controversial issue. New social demands imply changes in the definition of the problems to be considered. One way to proceed might be to include the subjects of applied courses in the central work agenda of the most highly qualified social scientists, thus expanding their range of subjects and their involvement in topics normally considered to lie outside their specialty. This is not an exclusively Latin American problem, though. The available evidence shows that two very different types of teacher co-exist in the most successful market-oriented courses: persons from the world of production, business, or services proper who, as part of consultancy activities, move between the academic sector and those other sectors and who convey to the students the practical and applied meaning of their occupations, and academic social scientists responsible for research and for ensuring the academic and intellectual quality of the courses (Schwartzman 1997).

In general, the field of the social professions is being taken over by administration, economics, and law, and by various administrative courses peculiar to the technical sector, such as industrial engineering, with little remaining for the traditional social science faculties. Taking into account that social science courses are among the most inefficient in terms of numbers of graduates compared with enrolled students, and concentrating here only on enrolment figures to give an idea of the size of the population involved, it may be observed that among the 10 most popular degree-level courses in Mexico, that of chartered accountant took first place in 1996 (34,653 enrolled students), followed by law (20,983 students) and administration (20,523 students). Medicine came fourth with 8,609 students. In absolute terms, administration, law, teaching, and arts courses in Brazil in 1997 each have more than 100,000 registered students, constituting a third of the total number of enrolments for higher courses (administrative courses have the highest enrolment of all, with 160,000 students, followed by law; engineering occupies third place with 130,000, and accountancy and economics come sixth and seventh with 89,000 and 68,000 students, respectively). In Argentina, the courses with the greatest number of registered students in the public universities in 1994 were law, with 82,896 registered students, psychology with 23,446, social communication with 11,741, and economics with 4,524. The private universities accounted for the highest number of students registered for courses in administration and economic sciences: 38,801 students; law, political science, and diplomacy 26,386, and other social sciences 12,624, with a grand total of 77,811 enrolled students (62.4 percent of total enrolments in the private universities, not counting another 12.3 percent for the humanities).

1.2 The Traditional Academic Courses

The social sciences in the stricter or more 'academic' sense, including sociology, anthropology, and political science, are taught in smaller departments or schools and involve small groups. As they are related more closely to research and postgraduate activity, they are referred to under these headings. The more traditional social disciplines, history and geography, expanded from the 1940s onwards in countries like Brazil, in order to meet the needs of secondary teaching, in accordance with a French tradition that proved impossible to revive before it was overtaken by the dramatic deterioration suffered by secondary education in the region. The profession of secondary-school teacher gradually lost its luster, in the overall crisis that overwhelmed that level of study. However, history and geography renewed themselves in several countries and produced valuable modern professionals and research schools.

The most recent quantitative surveys of the social sciences report certain common symptoms in the region which indicate a certain stagnation on the part of the traditional social disciplines: a drop in enrolments, cancellation of research programs and units in the public sector, a greater uncertainty among students of these subjects about their professional future, a growing reduction in suitably attractive economic opportunities for research and teaching, and a wide variety of problems at educational establishments, *inter alia*, form part of the fluctuating fortunes of the social disciplines. Paradoxically, however, most study plans, regardless of the level concerned, place the emphasis on a professional profile with a bias towards research. While there are greater differences within the public and private sectors than between individual

institutions belonging to each of the two sectors, public institutions appear to place greater emphasis on research-oriented training, although this is invariably a very small part of academic activity.

1.3 Teachers' Recruitment

The recruitment of academics in higher-education institutions in the social and administrative sciences increased most between 1970 and 1992, when it acquired its greatest ascendancy. The mass explosion in tertiary-level enrolments was such that these academics were for the most part absorbed into university life. The absorption rate in Mexico was as follows: 56.5 percent were recruited into teaching positions as soon as they finished their first-degree studies or even without getting a degree (35.4 percent), only 2 percent having a doctorate and 4.3 percent a master's degree, and without teaching experience (60.5 percent), without having practiced their profession (30.4 percent) or without any research experience in research (91.8 percent) (Gil et al. 1994). In the early 1990s 60.8 percent of academics still only had a first degree and 13.5 percent a specialization diploma. At the other extreme were the natural and exact sciences, with 54.4 percent doctor's and master's degree holders. The academic training levels of university personnel rose strongly in most countries during the late 1990s, as a result of conscious efforts by national authorities. However, not always the postgraduate studies in which they engaged themselves to improve their qualifications culminated successfully.

Data on developments in the teaching profession in Argentina suggest that its composition there and in certain other countries (like Mexico) suffers from structural problems, such as the very small proportion of full-time contracts compared with the total. Only 4.5 percent were full-time and 19 percent half-time by mid-1990s. The rest (76.5 percent) were part-time, contrasting with the basic and technological sciences where the picture was mainly one of full-time and half-time teaching. In other countries, such as Brazil and Venezuela, efforts have been made to introduce full-time teaching in universities, although in the latter, deteriorated work conditions in public universities in the 1980s and 1990s have resulted in a lower number of full-time positions and an insufficient replenishment rate of posts vacated by retiring staff.

2. Postgraduate Courses

Demands for credentials of formal academic training have risen significantly. People often go in for postgraduate courses in order to improve their skills and/or obtain higher qualifications that will confer formal institutional recognition on their ongoing academic careers. Yet it is clear that the postgraduate phase is not exclusively synonymous with a high level of research but can also mean greater professionalization. Despite the stated expectations and aspirations of master's and doctorate programs as channels contributing to raise the research capabilities, the training of researchers is limited because these programs appear in many cases to remain fundamentally divorced from research activity. Researchers and the institutions where they work often experience great difficulty in linking research and teaching, owing to the existence of rigid institutional thinking. In many institutional contexts in Latin America, research and education are juxtaposed rather than integrated activities.

In Brazil, for some decades, postgraduate courses in social sciences were developed around the master's degree, which assumed great importance and became a sort of mini-doctorate until full doctorates began to be introduced much later (Durham 1991). Government policy was already recommending in 1965 that a research doctorate should be distinguished from a professional doctorate, with the same distinction being applied to master's degrees. Failure to observe that recommendation caused serious difficulties in the different fields. Despite the regulatory intention behind initial government planning, the growth in postgraduate courses in the 1970s went out of control. There were too few qualified lecturers, postgraduate courses were introduced in already saturated regions, programs requiring little investment proliferated and an expansion exceeding the human and financial resources available occurred. More recently, CAPES (Coordination of Advanced Training for Higher-level Personnel) has been performing a useful task of monitoring and evaluating postgraduate courses, thus helping to raise and homogenize quality standards of performance. In 1997 it accredited the following courses in the social field: in the applied social sciences, including law, administration, economics, architecture and town planning, land-use planning, demography, information science, communication, social service, and industrial design, a total of 143 courses between 104 master's degrees and 39 doctorates; in the human sciences 178 master's degrees and 87 doctorates, which include the traditional humanities (philosophy, history, education, theology, and geography) and the social sciences (sociology, anthropology, psychology, political science). A third area (with 69 master's and 41 doctorate courses) comprises linguistics, the arts, and the fine arts. Master's courses in the social field altogether account for 27.7 percent of all master's courses validated by CAPES and for 24.37 percent of all doctorate courses. The greatest number of courses per discipline is found at master's level in education (47 master's degrees and 20 doctorates), the arts (44 master's degrees and 29 doctorates), and psychology (28 master's degrees and 16 doctorates), with high figures also being observed for economics (26 and 11), administration (23 and 8), and sociology (21 and 12).

In Mexico, the other Latin American country with a high proportion of postgraduate courses, it has not been possible to identify the total number of courses for the social sciences, although information has been obtained on enrolments and graduates. Registered postgraduate numbers in the social sciences in 1997 were 37,160 (42.3 percent). If the education and humanities population is added to this, a figure of 53,550 (61 percent) is obtained.

The growth in the number of postgraduate students in the various social disciplines and the humanities is uneven and significant differences exist between courses at the various levels. The specialization level is dominated by courses leading to professional qualifications, for example, administration (1,083 enrolments), law (1,359), taxation and finance (2,231), psychology (558), and sales/marketing (435). The master's degree level also has many students enrolled in professional qualifying courses in administration (16,923), law (2,851), taxation and finance (2,425), and psychology (2,248) but it already shows the presence of some courses directed at training for research, for example, in economics and development (2,104), social sciences (603), and communication sciences (518). At doctorate level, with much lower numbers, law enjoys the greatest number of students (478), followed by the social sciences (342), anthropology and archaeology (246), and economics and development (158). With regard to the most relevant disciplines for promoting a core of social researchers, only a modest expansion is noted at master's level, which can be attributed to the absence of diversified options on the labor market and to the fact that the academic market does not appear large enough to absorb future new researchers. A particularly noticeable drop of 44.5 percent in sociology enrolments has occurred since the mid-1980s. During the same period the number of economics students underwent a major increase of 270.4 percent, in anthropology the figure grew by 62.8 percent, and in history by 66.3 percent. At doctoral level, although increases are found in the five social and human science research disciplines, there are only 952 students at that level, representing 15.5 percent of total doctorate numbers in 1997.

3. *Social Research and its Institutional Loci*

The bulk of current centers has been established since 1970, especially between 1970 and the early 1980s. The proliferation of centers in the last third of the twentieth century seems to be inspired by needs of various kinds. Part of the reason for this can be found in the impetus given to the whole of higher education throughout those years. Many were set up as an aid to teaching, others because of the need to explain local or regional realities or on account of some particular social or cultural problem. The smallest number were probably established in order to promote theoretical, methodological, and instrumental progress and innovation. It is also important to note, however, that a considerable proportion of the existing centers has been set up since the mid-1980s, with an emphasis on education, economics, anthropology, and sociology centers. Other centers were also set up for history and administration during this period. Certain disciplines, such as education and anthropology, although cultivated in a large number of traditional centers, have recently received a boost that increased their number. Institutional and disciplinary variety is the norm.

Different social science trends and models are found in the region: at one extreme, are the early 'modern' programs, such as the Sociology Institute of Buenos Aires University and, soon afterwards, the Torcuato di Tella Institute, in Argentina; FLACSO in its several branches (Buenos Aires, Brasilia, Santiago, San José, Havana, Quito, El Salvador, Guatemala, México D.F., and Santo Domingo), born as a cooperation initiative between UNESCO and the governments of the region and aimed at promoting education, research, and technical cooperation in the social sciences throughout the subcontinent; the University Research Institute of Rio de Janeiro (IUPERJ), the Postgraduate Program in Social Anthropology (PPGAS) of the National Museum, also in Rio; the Brazilian Center of Analysis and Planning (CEBRAP) in Sao Paulo; the Department of Political Science in the Federal University of Minas Gerais, and the Integrated Master's Degree Program in Economics and Sociology (PIMES), which was taken over by the Federal University of Pernambuco in Brazil; El Colegio de México; the National Institute of Anthropology and History (INAH) of México; the Institute of Sociological Research, which was soon renamed as Sociology Institute of the University of Chile and the Center for Economic Research and the Sociology School in the Catholic University of Chile; and the Development Studies Center (CENDES) in Venezuela.

At the other extreme are the programs created through the efforts of groups of lecturers, who utilized the material, administrative, and personnel resources available in the undergraduate departments and survived by 'stealing' undergraduate facilities. Between these two extremes arose programs at the new, more flexible, more modern, and less bureaucratic universities where the shift in activities from the undergraduate to the postgraduate phase enjoys more institutional support, which in turn helps to attract external financing for research and infrastructure. Los Andes and del Valle Universities in Colombia, the University of Campinas (UNICAMP) and Brasilia University (UNB) in Brazil, the Ibero-American University and the Autonomous Metropolitan University in Mexico are in this situation. The courses with the most satisfactory results seem to have enjoyed a greater relative autonomy in their links with university administrative structures.

Many recent centers have been set up with inexperienced staff who are trained to below doctorate level, while the more experienced researchers remain at the more soundly established centers. The proportion of researchers under the age of 35, however, is noticeably small, which indicates an aging tendency on the part of the researcher population and suggests an uncertain future for some of these disciplines. In Brazil, considerable effort has been made to ensure the highest possible level of training for university lecturers involved in postgraduate activity and in research. Argentina, Chile, and Mexico in recent years have established government programs for providing further and refresher training for the teaching staff covering, among other things, the postgraduate training of academic personnel. Colombia boosted its general postgraduate scholarship program during the 1990s with the support of COLCIENCIAS, but of late seems to have lost its dynamic edge.

The level of geographical concentration of research units in the various countries, particularly the largest, have tended to fall since the 1970s, resulting in a slightly more balanced distribution, although a strong concentration persists in metropolitan areas. In Mexico, all states have research centers in some social discipline, which is not the case in other knowledge areas. There, however, as in Brazil, Venezuela, Colombia, Chile, and Argentina, the persistence of the regional question, despite endeavors to ensure a better distribution of resources and the repeated attempts to establish research groups in the province, suggests that perhaps other causes should also be examined, for example, the possibility that academic institutions in these regions possess less autonomy and are overdependent on the political interests and views of dominant local groups. Situations of this kind can impede the introduction of universal criteria for personnel recruitment and the distribution of resources, thus exacerbating the factionalism inherent in academic structures.

Although the social sciences show a substantial increase in postgraduate courses, no equivalent impact is perceivable on the percentage of recognized researchers in those countries where the formal recognition of researcher status has been introduced. In Mexico, while the creation of the National Researchers System (SNI) led to the formal establishment of a social, institutional, and normative framework for recognition and validation of the researcher's activity and position, it is clear that it also brought with it standard specific requirements with which the academic community is virtually compelled to identify. The social science and humanities field is the one with the smallest concentration of researchers included in the SNI, despite the fact that it has the largest numbers of graduate students and a significant proportion of postgraduate students; and 60 percent (1,053 researchers) are at the lower level, which suggests low productivity according to the program's measuring parameters. Although this is the area of the SNI that has been growing most consistently since 1984, the population willing to participate in this program appears to have reached a ceiling fluctuating around 800 yearly applications.

In Venezuela, a similar program to the Mexican one exists, the Researcher Promotion Program (PPI), with features and trends resembling the Mexican ones. It includes 18.9 percent of researchers in the social science area (270 out of a total of 1,422 researchers in 1997) even though the social sciences account for more than 80 percent of students following degree courses. Nearly 50 percent of the social researchers recognized by the program are situated at the lower level, which implies the minimum productivity acceptable under the program.

The type and rate of production are influenced by disciplinary patterns and traditions: the more 'empirical' or 'pragmatic' disciplines generally are slanted towards production with more immediate implications (e.g., articles); books, on the other hand, appear to be typical expressions of the more traditional disciplines. There are, nevertheless, differences in styles and standards of publishing and, in general, of production of results, even within the same discipline, depending on whether the researcher's approach tends to be local or international. As an illustration of the support and encouragement given to publishing standards, it is worth mentioning the existence of significant publishing industries in Mexico and Brazil, which supply the needs of the educational sector and recently have been responding to pressures upon the academic market to produce a greater number of results in the framework of the evaluation systems laid down.

A large number of social science journals is published in several countries. Given the current initiative of producing the Latin American and Iberian Index of scientific periodical journals (LATINDEX), it is expected that a supplementary regional index to the Science Citation Index, with the scientific production in Spanish and Portuguese will become available in the not too distant future. Meanwhile, several countries have undertaken the task of evaluating the formal and eventually the substantive quality of the journals locally produced and thus several national lists of selected good quality social science journals are available in the National Science Council offices. So far, however, those journals have very limited international visibility (Cetto and Alonso 1999). As an illustration of this, it may be said that the Institute of Scientific Information's Journal Citation Reports (1997 Social Science edition) included only one Argentine journal (*Desarrollo Económico*), two Brazilian ones (*Dados-Revista de Ciencias Sociais* and *Revista de Saúde Pública*), one from Colombia (*Revista Latinoamericana de Psicología*), and four Mexican ones (*Revista Mexicana de Psicología*, *Salud Mental*, *Salud Pública de México*, and *Trimestre Económico*).

In addition to this and turning inwards in the

region, it is observed that despite the existence of a large number of specialist journals, an essay style prevails in many fields. This essay style may be largely the result of an intellectual tradition, but it also relates to the limited market for employment in academic institutions, which means that opportunities for social scientists in the region often have been provided by publishing houses catering for general readership, by the daily and weekly press, by the political parties, by consultancy, and the preparation of technical reports for the governmental and private sectors. An important consequence of such situations frequently has been to restrict the range of topics covered and approaches to working and writing. In many places, issues have concentrated on a limited number of topics and options for discussion around a small number of individuals. This may have hindered the development of a social science involving the use of more complex quantitative techniques or the handling of less fashionable international literature. It is not easy to sustain a debate on any topic in an academic symposium when the results of the discussion bear the imprint, to a greater or lesser extent, of the views of a particular political party or agree with what the journalists of the mass media contrive, or wish, to hear or consider that their readers wish to read, or reproduces discussions and views developed and sustained in the world intellectual centers of Paris or Boston. This has been the price to pay for the role of intelligentsia that many social scientists have assumed in Latin America.

4. *Substantive Issues: Themes and Methods*

At the crossroads of institutional articulation and thematic development in the region is found the Latin American Social Sciences Council (CLACSO). Since its creation in 1966, it has formed the most extensive coordination body for social science research centers in Latin America and the Caribbean, currently including 101 member centers. Its Executive Secretariat has always operated in Buenos Aires. CLACSO has developed a work program which strengthens interchange mechanisms in order to bring about a greater integration of Latin American social sciences and which defends the working conditions of social scientists at member centers and other institutions in the region whose academic activities and/or personnel were marked by years of authoritarian repression in a number of countries. Its postgraduate program was drawn up to deal with two major areas: the Southern Cone Research Program, which, with financial support from the Council, provided aid in the countries of the sub region to researchers experiencing work difficulties because of their political views; and in cooperation with the United Nations Development Program and UNESCO, the Young Researchers Training Program, since it had become apparent that the main problems in the region were a lack of funds for research and the difficulties experienced by young graduates of universities in obtaining funds from international agencies.

In recent years, the Council's academic activity has been directed at its own medium- and long-term planning against a background of institutional reorganization, at rethinking the Working Groups Program in order to counteract the effects of thematic/organizational dispersion, and to continue action in subject-matter areas of particular importance for the analysis of democratization and adjustment processes in the region. Its 20 working groups have a membership of some 3,000 researchers in a program of academic interchange, debates, and publications which is very illustrative of the thematic interests in the region. Among them are youth, international economics; education, work, and social exclusion; memory and human development, poverty and social policy; unions, workers, and social movements; Mercosur and integration; and political parties and electoral systems. In view of the increasing development of various Latin American information networks, the Network of Networks (*Red de Redes*) project was established with the support of the IDRC in Ottawa in order to improve access by the final user to existing information resources by linking up 18 regional information networks. Its web site (URL: http://www.clacso.org) contains extensive information on research institutions in the region, regional databases about researchers and research projects, a virtual library, and other services.

On the cognitive, social, and functional levels, what social scientists do when they claim to be carrying out research is, in fact, extremely varied. Views on what constitutes research not only vary according to fields of academic activity but also depending on ideological and personal approaches and they evolve over time. In Latin America the great diversity that exists in disciplines and research styles mostly has developed in different socio-institutional contexts. Where policies, either general or relating to individual establishments, have existed, however, these have tended towards homogeneity usually patterned on the norms of the physical sciences. New and old themes combine in novel contributions to social understanding. The necessary linkage between the rich accumulated conceptual legacy of the region's social thought and that required by the new heuristics concerns as much the social sciences as the social movements in today's world of change in sociopolitical and technoscientific models.

Infrastructure: Social/Behavioral Research (Russia)

The state of social science is an indicator of the way a nation views, comprehends, and reflects itself. The development of Russian social thought has been continuously deformed by the strict political censorship of different regimes that were able to sever its natural links with the evolving civil society institutions and to enforce protracted periods of academic stalemate. Though it is never possible to suffocate human creativity, originality, and ingenuity, it was possible to trim social science into an awkward but handy configuration by molding its infrastructure and by cutting the requisite feedback communication. The cost of this authoritarian control is a distorted decision-making structure, an extensive type of economic modernization in a largely unstructured, neotraditionalist society doomed to resolve most of its conflicts through discredited, inefficient, yet inevitable state intervention. As the former KGB chief Juri Andropov admitted when he became head of the state: 'We do not know the society we live in.'

Incidentally, in the same year (1983), only 99 empirical social surveys were completed in a country with a population of 283 million. With the collapse of the Soviet Union, the infrastructure of social and behavioral science became spatially dissected along the formerly unimportant state and regional borders. This discontinuity affected the life of the academic community, its research cooperation, the mainstream methodology, and the general perception of reality. More significant was the temporal shift of social gears. The 'frozen' nation with a stagnant social structure suddenly melted down and found itself in a state of unpredictable flux. After a decade of social transformation and market transition, Russian social science faces a challenge of hitherto unstudied empirical disciplinary and interdisciplinary fields, as well as an opportunity for detached comprehension of the overlooked retrospective social realities. Hence comes an objective integrative role for the social science institutions and structures, which they seem now more fit to play, but whether or not that role will be accepted by the power, the market, and society still remains to be seen.

1. *The Rise and Fall of Social Science Instrumentalization*

Many observers note structural, institutional, and research similarities in Western and Eastern European phases of development. However striking they may seem in the past decades, similar trends in the social sciences had been caused by quite different reasons. Their roots go deep into the past. Authoritarian attempts to instrumentalize relations with social thought had started in the age of Enlightenment when, trying to improve her international reputation, Catherine the Great took credit for the first publication of the complete works of Voltaire and awarded a fellowship to Diderot. Her subordinates followed suit by masquerading dire reality behind the faked facades of Potyomkine 'villages' and claiming that every Russian peasant household was getting a hen in their weekly ration. Utopian social experiments in 'forming a new man' also started at that time. But for authoritarian power, encapsulated in a steel frame of ossified bureaucracy, censorship and loyalty were the prime tools of public control and the works of Auguste Comte remained banned until 1889 for ideological reasons. Because it was less strictly controlled, fiction thus gained prominence and acquired a formative role as a reflexive tool of the society. Literature, including F. Dostoyevsky's social and L. Tolstoy's moral writing, became a major source of social thought. This explains an exaggerated and lasting public enchantment with the scientifically versed dogmatic pres-

criptions that were vested with magic power to reshape life along doctrinal lines.

This was precisely what Bolshevik leaders wanted from the social sciences and by the mid-1920s, when revolutionary aspirations petered away, they had gradually usurped this tool, banning the positivist paradigm as well as most Marxist thinking and promoting one of the Marxian strands of thought to the position of the 'only true and all encompassing' social teaching. Russian educational, institutional, and research infrastructures had been trimmed correspondingly as the new doctrine passed itself off as the ultimate solution that could countenance no tolerance of other schools of thought either inside or outside the country. Even the term 'social sciences' fell under suspicion and was replaced by 'societal sciences.'

Sociologists Pitirim Sorokin and Nikolai Berdyaev, together with several hundred other social scientists and thinkers of international renown were expelled from the country. In 1917 St. Petersburg University was closed. After that, no access to the empirical and theoretical work of preceding decades was possible, though university professors continued to share their knowledge with the new generation of students and thus were able to maintain traditionally high standards of education. This dramatic break with the international and indigenous research traditions in the social sciences greatly narrowed their evolving infrastructure. It was soon to be replaced by a new one that was held to be 'socialist in essence and national in form,' and that, in due course, was able to integrate and unify social knowledge (and dogmas) articulation, research, and dissemination across 15 nation states and subsequently in most of Eastern Europe.

For five decades, humanities and the social sciences were divided into the good (Soviet) and bad (bourgeois) traditions. Many disciplines (including sociology, psychoanalysis, genetics, and later cybernetics) were ostracized and banned for three decades until the thaw of the mid-1950s. The unveiled humanitarian story of Russian spiritual resistance bears the names of hundreds of reputed scholars who risked their lives and perished in the Gulag because they dared to think and write in ways that were no longer allowed.

The prohibited, neglected, and suppressed works on a broad range of social science disciplines were rediscovered and made public only in the Gorbachev era. The dramatic change of focus came from the very top and (contrary to the reformist choice made by the Chinese Communist leadership) was well intended rather than well calculated. It had been based on a rather naive assumption that the easing of stringent controls would by itself recuperate the USSR and get it into a common European home. Official Soviet social science had no experience to draw on to predict the effects of transformation on such a grand scale. The impact of the staggering institutional deficiency on the transition had not been anticipated. Though the breaks in tradition could not be recuperated by retrospective publication and bold analogies, the impact of these powerful flashbacks on the society was enormous. Blank pages of national history rediscovered by *glasnost* actually took the entrenched communist moral stands together with the ideologically ossified social institutions off ground and paved a way to the final collapse of socialism.

The instrumental rationale and the general limitations of the social sciences through more than half of the twentieth century were shaped by the supra-nation-state building imperatives and by combat lessons of the two world wars. The Russian Revolution and a devastating civil war had bred a belief in the universal efficiency of the command decision-making system. Totalitarian over-centralization became the most potent tool of governance. The flamboyant behavioral research and social engineering of the early revolutionary years, which ranged from mass blood transfusion to Freudian reactology, were discarded when it became apparent that mere state violence could effectively drain rural resources for accelerated industrialization and militarization. Regular political surveys and extensive social monitoring became the prerogative of the secret police, the territorial party committees, and the state statistical institutions. Most of the social and statistical information had been strictly classified, including the notorious erasure of the complete 1937 All-Union census data. After the reinstitutionalization of sociology in the 1960s and of political science in the 1970s, all politically sensitive academic research was also classified.

In the environment of strict party and KGB institutional control, the only viable dimension of the social sciences infrastructure became predominantly internal. The institutional and administrative traditions of academic-scientific culture depended on such matters as maintaining high academic standards of excellence and disciplinary innovation, principled integrity, nonparticipation in politics. At various times this implied a need for mimicry and a lot of dual thinking, but even with all the lip service to the obligatory official doctrinal tenets, the key elements for professional standards in the social sciences largely remained intact. This may be illustrated by the Academy of Sciences' blunt refusal to remove its academic title from the exiled academician A. Sakharov in spite of the Politburo's stringent demand. In a similar way it declined proposals to establish an academic institute of scientific communism though this dubious social discipline (with corresponding university chairs throughout the country) had been a standard element in higher education since 1963. These distinctions explain a considerable degree of diversity and dissent in social science's orientations under the Communist regime even within a constrained research configuration.

The multi-tiered infrastructure of the social (societal) sciences constructed in the Soviet Union had been conceived as the most monumental in insti-

tutional, spatial, and mass ideological coverage. Its configuration in scope and priorities resembled an inverted pyramid resting on a narrow base of academic research. Academic units had no educational obligations and were more important as institutes dominating in applied and fundamental research. They were relatively independent and had strong institutional linkages with their branches in Siberia, the Urals, and the Far East, as well as with the 15 national academies of science. Two other academies (medicine and pedagogy) oriented toward practical needs had several applied research institutes in public health, demography, and secondary education.

The higher education system, including the university social sciences, had greater regional coverage and was oriented to ideological, knowledge base, and secondary analysis areas of social study conducted mostly in universally spread professorial chairs of Marxism–Leninism or scientific communism and atheism. Several universities had faculties, departments, or laboratories that were science-driven and provided some opportunities for problem-solving work to the graduate and postgraduate students. But both academic and university studies aspiring for an academic qualification, apart from the public defense in corresponding disciplinary councils, had to pass through the rigid screening procedure of the All-Union Attestation Committee.

Over that layer was a plethora of specialized organizational applied research scientific entities that provided special professional services. Set up by various ministries or the state planning committee, they covered themes ranging from cinematography and art criticism to urban planning and healthy food production and to social aspects of military service and combat operations. They would also be loosely related to the extra-university government-directed network of territorial social data monitoring institutions with statistical-quantitative orientation. Overlapping and unnecessary duplication was a specific feature of the party-state system.

Relevant social data collected in every territorial unit would also get to the parallel network of the party committees that could overrule governmental plans and, through *obkoms*, reported directly to the Central Party Committee. The party network designed to boost growth, very soon turned into an institutionalized social impediment to change and development. The greater the discrepancy between normative prescriptions and real life situations, the greater was the need for social indoctrination that, in principle, had to cover the entire adult population of the country. This task was vested in vocational 'institutes' of Marxism–Leninism and in the regular political information gatherings held at all enterprises that were controlled by party committees. A more varied repertoire of social subjects was presented by the lecturers of the All-Union 'Knowledge' society that had its branches in every town.

The well-intended *ad hoc* communist social discretion was practiced as a main form of institutionalized 'scientific' social practice till the early 1960s. By that time, over 100 million peasants had moved out of decaying rural areas and, when extensive exploitation of mass enthusiasm in plowing the virgin lands failed to yield the expected results, the need for a reform finally became apparent to some key decision makers. Externally, the interventionist support of national-liberation movements, the Cuban missile crisis, and growing displeasures in Eastern Europe also spelled out the need for something institutionally more reliable than pure rhetoric and virgin historical materialism. Its proponents in the academy were greatly impressed by the scope and range of coverage of foreign studies at the Amsterdam Sociological Congress (August 1956) and an interdisciplinary social study of technical progress had been started on the UNESCO initiative. The Soviet Sociological Association was established in June 1958—a decision driven more by a desire to put on a better international face rather than by internal necessity. The positive element here was not only an exposure to the international social research agenda but legalization of contacts with foreign, at that time particularly Polish, scholars.

Yet it took the social sciences another decade before there was an institutional breakthrough. The Institute for Concrete Social Research (ICSR RAS) was finally set within the Academy of Sciences in 1968. It launched three major research projects on social structure and social planning, on the management of social processes, and on the history of sociology. Within the first year of its work, 20 social surveys had been made for the Central Committee of the SPSU. But with the military incursion in Czechoslovakia political winds again went in the wrong direction. Economic reforms were curbed and social changes came to a stalemate. The flood of foreign (in Russian translation) and local social science publications turned into a tiny trickle. Ideological blinders were imposed on all social publications including the only academic journal, *Sociological Research* set up in 1974. Institutional constraints once again had turned social studies into the stale waters. In 1972 and in 1976 the staff of the ICSR RAS had been ostracized and the new period of state-imposed stagnation lasted at least until 1988. Reading between the lines had been the favourite pastime of the academic community and innovative research would appear only on the periphery of the social sciences' institutional mainstream.

2. *New Perspectives*

The collapse of socialism liberated the party-state nomenclatura from any social responsibility and during the Yeltsin era much of the democratic reform effort was compromised. In contrast to the 'old deal' pressures, the institutional structure of the social

sciences remains largely unattended, and though its financing still remains below subsistence level, it has gained momentum for development and an impetus for institutional change. 1991 was pivotal in this respect. The Russian Academy of Sciences (RAS) reclaimed its status lost in the 1930s. The Institute of Sociology (www.isras.rssi.ru) split up and the Institute for Social and Political Studies (www.ispr.ras.ru) was formed in Moscow, while the Sociological Institute RAS remains in St. Petersburg. All these institutes together with the other academic research units and related professional associations are subordinated to the RAS branch on philosophy, sociology, psychology, and law. The Institute for Scientific Information in Social Sciences, as well as fundamental science libraries, currently enjoys a special status within the academy.

Other branches in the social sciences include history (institutes of oriental studies, archaeology, culturology, general and Russian history, ethnology and anthropology, history of material culture, military history); economics (institutes of economy, national economic forecasting, market problems, economic problems of the transition, socioeconomic problems of employment, and the Central Economic Statistical Institute); world economy and international relations (institutes of peace, of USA and Canada, of Africa, of Europe, of Latin America, of comparative politology and workers movement, and of world economy and international relations). The next three branches include the literature and language branch (institutes of world literature, Russian literature, Russian language, linguistics, language research, history of arts, problems of architecture, and urban construction); oceanology, atmosphere physics, and geography (institutes of geography, global climate and ecology, water resources, lake research, etc.); and the physiology branch (institutes of man, of human brain, physiology, evolutional physiology and biochemistry, higher nervous activity and neurophysiology, of medical and biological studies, etc.) This incomplete list is intended just to outline the continuity of the maintained range of publicly financed academic research activities throughout the painful transition period.

With the democratic changes, foreign donor foundations have moved in and academic grants were offered to various projects in the national social sciences. Focused on pivotal issues, these grants provided an alternative infrastructure that helped to invigorate research and exchange programs, to write the new textbooks, and to disseminate these publications in the provinces. George Soros was the first and the most effective in these promotional and support activities, starting with his 'cultural initiative,' later transformed into the 'open society institute' and with the Research Support Scheme that promotes cross-cultural academic cooperation. His efforts were followed by a number of Western private philanthropic institutions like Carnegie, MacArthur, and the Ford foundations. Two newly established indigenous funds RFFI and RGNF (the Russian Fund for Fundamental Research and the Russian State Scientific Fund) are also active in this market. Thus, a competitive wedge has been established in social science activities.

A considerable proportion of support funding helped to keep afloat all the Russian academic journals including Sociological Studies (*Sotsiologicheskiie issledovanija*) (http://www.isras.rssi.ru/R_SocIs.htm), Sociological Journal (http://win.www.nir.ru/socio/scipubl/socjour.htm), Journal of Sociology and Social Anthropology (http://www.soc.pu.ru:8101/publications/jssa/), and the Social Sciences Journal. This continuity seems important as it helps to maintain high academic standards. More significant, however, is the free market competition among the emerging private publishers. In the 1990s the stock of the available translated literature and publications in the social sciences has grown considerably, giving ample place for the requisite variety of innovation, yet the public libraries frequently can afford neither expensive new books nor subscriptions to the foreign academic periodicals as the traditional state policy of obligatory purchases and hard currency allocations to the libraries has been stopped. An unexpected side effect of the democratic and market changes has been another structural constraint and challenge to the functional foundations of the social sciences: their traditional sphere has been invaded by a range of recently founded self-appointed 'academies' that find their rationale mostly in trading their own academic titles to those who crave this special sort of prestige. At the same time, various surrogate subcultures have grown up on the fringes of the academic sphere, offering the public their para-science services. Strategic rethinking of the present truce with various new forms of mass occultism may be one of the institutional tasks for the social sciences in the twenty-first century.

Turning financial constraints into a window of opportunities, a great number of freelance and private research structures came into the emerging market for the social sciences. They now range from the abovementioned panacea institutions to the recently founded social monitoring units (also including the 'black PR' foundations for efficient policy) in the President's administration, to private analytical firms (institutes), and subcontracted focus groups. Some of the new nonacademic structures have NGO status but their activities—that need thoroughly checked documen tation—may cover important segments of social life, particularly when they systematically monitor new developments and conduct empiric surveys. The Committee of Soldiers' Mothers and the ecological 'Kedr' movement are good examples of such organizations. On the contrary, such well-established organizations as trade unions that had infinitely more advantageous institutional resources have failed to maintain their social niche in this time of transition.

Private independent institutions that consistently operate within the domain of academic science started to emerge in the end of 1980s. The oldest of them, the public opinion polling center Vtsiom (http://www.wciom.ru) has accumulated in the last decade of the twentieth century a database with over 2,000 polls and, together with the other active monitoring institutions like the Fund for Public Opinion FOM (http://www.fom.ru) and Romir, has gained considerable weight in sociopolitical surveying. Due to decades of political void in Russia, the role of the polling institutes and the media at the beginning of the twenty-first century is more formative than informative. In these circumstances, sociologists are worried that public-opinion polling has been turned into a surrogate instrument for political manipulation. It appears that with the help of social technologies relayed through media channels even political nonentities, like the Edinstvo/Medved party, can win seats at elections after less than six months of campaigning—as evidenced by the last elections for the Duma and the presidency (in 1999 and 2000 respectively). In the first decade of the twenty-first century, the rapidly shifting nexus between the vested interests and social science application will become the most rapidly evolving institutional configuration.

Recent developments in higher education have introduced paid education in both private and state institutions. Major changes in the curriculum have reoriented the students to multiple courses in market-related disciplines, yet behavioral and social studies are also gaining prominence. Sociology has replaced Marxism as an obligatory course in university education, with more than 250 new departments established throughout the country. The state standard for sociology currently lists 14 obligatory themes in the history of sociology, 12 in sociology, and 13 themes in the methods of research. Apart from structural educational changes, empirical social studies have become a regular activity in university science, for instance in the Center for Sociological Research MSU (http://www.opinio.msu.ru) or in the work of the Sociological Research Center of the Federal Education Ministry (http://www.informika.ru/windows/goscom/cinorgan/socio/first_pg.html). Many universities are becoming active in their student research and degree exchange programs viewed as a precondition for futher professional training. But, on the whole, the budgetary and structural limitations in the higher education reform leave little place for radical changes in the traditional forms of university research. Such instruments as Internet resources are rapidly forming the most promising base for strengthening student research and university science. The social science infrastructure of today is still not systematically presented on the Internet, but since about 1997 major efforts have been made to form the aggregate professional platforms and networks that would integrate individual and institutional websites.

This may be illustrated by the Psychological Net of Runet (http://www.nsu.ru/psych/internet/index.htm); the Organizational Management Consultants Net (www.odn.ru); History and computer server (http://kleio.dcn-asu.ru/aik/index.html); by the recently established (1999) Russian Sociological Net (RSN) (www.isn.ru) which has a database of about 100 research institutions and projects (www.isn.ru/sociology.shtml); by a directory of Russian sociological sites (www.isn.ru/sociology/public/sociology.htm) that offers an online periodical COSNET.RU (www.isn.ru/index42.shtml); and by the Russian archive of working documents on economics and sociology (www.ieie.nsc.ru:8101/r-archive/index.htm).

With the massive growth of computerized information gathering and processing one can anticipate the increasing diversification of services rendered through the traditional social sciences' infrastructure, by the NGOs, and by the private freelance commercial agencies. Digital forms of cultural representation are offering new vistas that will both preserve and transcend local cultures. It now seems quite apparent that the transnational social change secures the social sciences a place of prominence in this rapidly evolving cross-cultural discourse.

Infrastructure: Social/Behavioral Research (United States)

Progress in science presupposes an infrastructure that sustains research and exchange of new scientific information, that prepares requisite personnel, and that advances cumulative knowledge of the empirical world. This is no less true in the social and behavioral sciences than elsewhere in science and engineering. While science is increasingly international, with its

own sustaining infrastructure, a primary base for advancing science exists within each nation. In the USA, the foundations of the existing infrastructure for the social and behavioral sciences (hereafter, social sciences) were laid in the early decades of the twentieth century and subsequently expanded just after World War II (WWII). At the beginning of the twenty-first century, however, certain limitations of this infrastructure are apparent. Perforce, these factors may constrain progress in social sciences in the USA and may fail to encourage a full participation in or realization of an international science of behavior and society as the new century unfolds.

1. *What is Infrastructure?*

For most of science, 'infrastructure' conjures up images of national laboratories, orbiting telescopes, polar weather stations, or supercolliders; in other words, bricks, mortar, and the research instruments of 'big' science built and maintained at great expense. What this image misses, even for the natural and physical sciences, are the myriad elements of science organizations, such as national academies and scientific associations, funding sources and review systems, libraries and databases, theoretical models and methodologies, journals and other communication media, and advanced training programs that separately and collectively sustain and advance the research enterprise of individuals. In fact, it is easier to say that 'infrastructure is an indispensable adjunct to the efforts of individual scientists' (Prewitt 1995) than it is to specify what comprises the comprehensive and necessary elements of science infrastructure. This may be especially true for the social sciences for which the 'bricks and mortar' components of infrastructure are fewer or less obvious (CBASSE 1998). Thus, any definition is apt to be rather arbitrary if only to the degree that from the myriad enabling elements some selection must be made, lest the list be boundless and the definition, useless.

At a level of abstraction, the terminology, infrastructure of science, emphasizes shared and sustaining resources that not only make scientific research possible for individuals but also add value—often multiplying the value—of individual research activity. 'Shared' refers to what is accessible as a public good for a science, something whose value is not diminished by multiple uses or that produces economies of scale or multiplier effects. For example, a multimillion dollar investment in building an instrument for magnetic imaging of the mind at work is much like a similar dollar investment in a 10-year panel study of a nation's youth as they leave school and enter the workforce. Many investigators can use both 'instruments' for a great variety of analytical studies, each of whose value is not diminished, indeed, perhaps even made greater by virtue of others using the same instrument for different scientific projects. This is especially true when such projects—all conducted at low additional marginal cost because of the same base investment in the 'instrument'—allow for the aggregation of information and therefore newly emergent information not available from the separate studies. For example, multiple time-series of different topical domains might cross-reference brain images over time in cognitive and in emotional activity, or, from the same sampled cohort, might interrelate the economic outcomes of the school to work transition and of the trajectories of social development over the same period. The term 'sustaining' refers to necessary resources without which the advance of science would be slowed or halted, or, would be very expensive to nearly impossible to reconstruct if left to deteriorate. For example, if the US congress were to cut the funding of the National Science Foundation in half for, say, a four-year period because of a change in political or fiscal priorities, research universities might be forced to close some laboratories or institutes, and some might even redirect their missions. A 40-year time-series on the American electorate, broken for a decade, may never retrieve the value it would have had were it not interrupted (much like temporarily 'turning off' a telescope designed to capture rare events, like the birth of a supernova).

2. *Historical Development of Infrastructure*

Most of the foundations of the infrastructure of the social sciences at the end of the twentieth century were laid in the two decades prior to WWII and just after its conclusion (Prewitt 1995, Bulmer 2001). In the earlier period, a remarkable convergence of interests within the leadership of private philanthropy and of the burgeoning social science disciplines and their national associations yielded an extraordinary array of institutions and resources that were to both consolidate and accelerate the growth of social research as a 'science of society.' Elements of this new infrastructure included the University of Chicago and its celebrated Chicago School of community-based social research, the Social Science Research Council in New York City, the National Bureau of Economic Research, and what later was to become the Brookings Institution in Washington, DC. In the later period, with the rapid evolution of the federal administrative state following the great depression and especially after WWII, the National Science Foundation and the National Institutes of Health funded an expansionary phase of basic and mission-related research. Most of this science-building activity occurred within the nation's research universities, themselves a product of the postwar era. Yet the two growth periods for infrastructure resulted from different interests and

goals and emerged from distinctly different historical moments. The course of social sciences in the USA reflects the history of its infrastructure just as much as it does the intellectual biographies of its leaders and evolving corpus of scientific contributions (Deutsch et al. 1971).

2.1 The Foundational Period

At the close of the nineteenth century, the roots of what was to become American social science drew their energy from investigative journalists and reformers in settlement houses and from statisticians seeking to count unemployment and develop statistically reliable representations of labor markets in local areas (Bulmer 2001). It would be incorrect to speak of an infrastructure of social science as such at that time, because the nature of social inquiry was hardly scientific in the sense of being driven by intellectual curiosity and disciplined by interrogating ideas and conclusions with careful measurements of social phenomena and behavior. Statisticians such as Carroll Wright were developing crude labor statistics for the state of Massachusetts after the civil war, mirroring the 'statistical movement' in Victorian Britain and the 'probabilistic revolution' pioneered by Quetelet and others in Europe during the early to mid-nineteenth century (Bulmer et al. 1991) . However, what drove even this descriptive, social statistical enterprise was related to—perhaps even dominated by—what motivated muckraking journalists and also reformers and advocates for the poor like Jane Addams and W. E. B. Du Bois at the beginning of the twentieth century. This was a concern—often embedded within progressive reform ideology—about the apparent fragility of democracy and threats to economic self-sufficiency in an America beset with racial and labor conflicts, massive numbers of immigrants, and unstable economic cycles with impoverishment for many.

This nonscientific concern at the beginning of the twentieth century did lead to systematic social investigation, largely in the hope of pointing the way to reforming society, relieving the misery of the destitute, and preserving democracy. The Settlement House movement, devoted to improving the lot of urban poor, inspired and drew upon a series of mapping projects and urban surveys, e.g., Hull House Maps and Papers; Du Bois' The Philadelphia Negro, the Pittsburgh Survey. These proto-scientific inquiries in the late nineteenth and early twentieth centuries, some commissioned and funded by the Russell Sage Foundation in New York City in the interests of improving social welfare, comprised one cornerstone of the Social Survey Movement. And in turn, they gave impetus decades later to what was to become modern statistical sampling and survey research during and just after WWII (Converse 1987, Bulmer et al. 1991).

Private philanthropy, created by industrial capitalists (or their families) like Andrew Carnegie, the Rockefellers, and Russell Sage in the nineteenth century and administered by charitable foundations bearing their names, provided the initial means and set a scientific course for social science's development in the early decades of the twentieth century (Bulmer and Bulmer 1981, Prewitt 1995). To that extent, these private foundations created the first explicit infrastructure for a scientific social science. Whether this investment was motivated by the self-protective interests of a capitalist social class (i.e., Fisher 1993) or reflected deeper religious and humanitarian concerns in the public interest (i.e., Bulmer 2001, Lagemann 1989) can be debated. In any case, the early infrastructure of social science emerged from a fortuitous convergence of the announced goals of philanthropic foundations and the coalescence, within the USA, of defined social science disciplines—history, political science, psychology, economics, anthropology, and sociology (Ross 1991). An important additional element of that early infrastructure was the creation of graduate schools at a few universities, starting at the Johns Hopkins University in 1876 and then at Clark, the University of Chicago, Columbia, Harvard, and Yale.

As for the foundations, leaders such as psychologist Beardsley Ruml at the Laura Spelman Rockefeller Memorial drew inspiration from the natural and medical sciences as a means of understanding and (it was presumed) controlling the phenomenal (empirical) world and set as a goal the creation of a corresponding science of society. This science of society was not an end in itself; it did not reflect so much a commitment to science *per se* than to use rational analysis and scientific research to reveal the 'root causes' of the massive problems of industrial America and thereby to overcome them. Investment into research and the scientific enterprise, e.g., into the putative causes of urban poverty rather than exclusively into assisting poor families, reflected a broad sea change in the goals of private philanthropy in the early decades of the twentieth century (Prewitt 1995). This change in philanthropy led to the creation of several research institutes in medicine and the natural sciences, e.g., the Rockefeller Institute for Medical Research (1901). But it also coincided with the rapid emergence of several additional foundations and organizations that supported the development of social and behavioral research, e.g., the General Education Board (1903); the Milbank Memorial Fund (1905); the Russell Sage Foundation (1907); and the Carnegie Corporation of New York (1911). Subsequently, these in turn created several core elements of infrastructure: the National Bureau of Economic Research (NBER), established in 1921 under the leadership of economist Wesley Mitchell, was created by the Carnegie Foundation; the Brookings Institution, in 1927 (after consolidation of several other organizations, including the Institute

for Government Research, founded in 1916 with Rockefeller monies); and the Social Science Research Council (SSRC), incorporated in New York City the 1920s with Rockefeller backing.

The early history of the SSRC amply illustrates the evolving close partnership between private philanthropy and university-based research of the social science disciplines after World War I. At the core of this history is a very effective network of leadership within the foundations and the small set of elite university research programs—leadership that circulated between these two worlds and galvanized common cause to promote a positivist science of society. Charles F Merriam, president of the American Political Science Association, spearheaded a cadre of counterpart economists, sociologists, and historians (and joined later by anthropologists and statisticians) with commitments to a scientific approach in their respective fields but also to multidisciplinary research inquiries. They founded the Social Research Council (SRC) in 1923 to use a scientific, interdisciplinary approach in analyzing the problems of society, to develop new methodological tools for this science of society, and to assist university-based academic programs in training a new generation of social scientists for this agenda. Merriam and colleagues considered but ultimately rejected the idea of affiliating with the American Council of Learned Societies (ACLS). (The ACLS was chartered in 1919 to represent the USA within the Union Academique Internationale; it was one of the first councils to span the social sciences and humanities and to represent and develop their scholarship.) Instead, they pursued, unsuccessfully, incorporation within the National Research Council (NRC), the operational arm of the National Academy of Sciences, which at that time incorporated only the fields of psychology and anthropology, the disciplines bearing closest affinity with the natural sciences. The SRC might have failed were it not for Beardsley Ruml, newly appointed director of the Laura Spelman Rockefeller Memorial and recent Ph.D. in psychology from the University of Chicago. By 1922 Ruml had $2 million per year to invest in developing a science of society, but he was uncertain that university-based disciplinary departments, or the associations *per se*, would progress rapidly in that direction. Ruml had endorsed Merriam's unsuccessful bid to be incorporated into the NRC and suggested that the SRC add 'Science' to its name (and thus it became the SSRC). Subsequently, Ruml and the Memorial began a steady flow of financial resources to the SSRC and through it, to university-based faculties to develop their methodological capacity and the volume of science-inspired research into the burgeoning set of social problems of the era. As a Chicago-educated behavioral scientist, Ruml found common cause with Merriam, Chicago faculty member. During this era, the SSRC functioned as the social science counterpart to the NRC and at the same time served as adjunct to the Memorial as a 'pass-through' foundation. Between 1923 and 1929 the Memorial distributed about $40 million for social research and advanced (quantitative) methodological training, much of it distributed through the SSRC (Bulmer and Bulmer 1981, Featherman 1994). Ruml later served briefly as dean of social science at the University of Chicago; and in 1929 the Memorial became the social science division of the Rockefeller Foundation.

As for the social sciences disciplines themselves, their progress as empirically based research fields can hardly be understood without acknowledging the catalytic importance of universities and their gradual transformation as centers for academic research as well as for their original mission of educating undergraduates (Geiger 1993). Here, too, the role of the foundations and private investment in creating this element of infrastructure in the early twentieth century cannot be overlooked, even though their support of universities was quite selective and targeted (Bulmer 2001). For example, the Rockefellers provided foundational financing for the University of Chicago and encouraged its evolution toward a research as well as a teaching university. While the modern research university was not to emerge in the USA until after WWII, universities like Chicago and Columbia were notable incubators of empirical social scientific inquiry much earlier than 1940. At Columbia, for example, a statistical approach in research began in 1890 under the influence of Richmond Mayo-Smith and Franklin Giddings and in the genre of its time was focused on local conditions and problems of urban life. Later, just prior to WWII, the Bureau of Applied Social Research and the leadership of Paul Lazarsfeld elevated Columbia's prominence in empirical social science and embraced national issues and scope as context for refining social theories and quantitative methodologies. Likewise, at the University of Chicago, the seminal empirical studies of W I Thomas on Polish immigrants to Chicago, published just after WWI, were to give rise to a 'Chicago School' of sociological research in 1915–35, under Robert E Park, Ernest Burgess, and William F Ogburn (Bulmer 1984) and to a nascent science of American politics after 1920, with leadership from Charles Merriam and his students Harold Gosnell and Harold Lasswell. However, notwithstanding these and a few other notable examples (e.g., the University of Wisconsin in economics and political economy; the Institute for Research in Social Science at the University of North Carolina, founded in 1924), the presence of social science departments in teachers colleges and teaching universities of the period was quite modest and not given to encouraging research. The notable exceptions usually were tied to investments by foundations and private philanthropy (Bulmer 2001).

The incubation of the social science disciplines within their university base in the three decades prior to WWII yielded several important outcomes. At a

few universities, especially those with graduate schools, research groups provided context and exemplars for a more cumulative development of these young fields as academic disciplines. They increasingly asserted claim to intellectual legitimacy in their own right and not simply as means to the end of social reform. And they evolved as more differentiated (one from the other) disciplines with their own basic concepts and methodological approaches, modeled more or less upon positivist natural science. Prior to the early decades of the twentieth century, and without much infrastructure to sustain it, signal events in the development of the social sciences were episodic and failed to cumulate (Bulmer 2001). For example, the American Social Science Association, created in 1865, was the precursor to the American Economic Association and also the National Conference of Charities and Corrections. Its failure to provide sustenance for a social 'scientism'and its ultimate disappearance doubtless stemmed from the heterogeneous mixing of proto-scientists and social reformers and the related inability to resolve internal tensions between the advancement of social inquiry toward science and the promulgation of a reform agenda (Furner 1975, Haskell 1977). Later, organizations such as the NBER and the Brookings Institution offered a different kind of continuity and cumulation. Their role in effect transformed the origins of proto-social science as a tool in the hands of the reform minded into what, after WWII, would give claim to be objective scientific expertise provided to the world of public administration and public policy (Prewitt 1995). It was the few universities with graduate schools and active research programs, however, that fostered the growth and independence of disciplinary departments of academic social science, intellectual projects worthy in their own right (Shils 1979). This, in turn, was associated with a professionalization of social scientists according to discipline, leading to a disassociation from the reform-minded and social planners.

These university-fostered developments during the foundational period should not be overstated, however. The cadre of social scientists within academe was small and the effects of key leaders of the period—Mitchell in economics, James B Watson in psychology, Merriam in political science, and Ogburn in sociology—were pivotal. And whether within academe or other organizations like the NBER and the Brookings Institution, the practice and refinement of a more scientific social inquiry became a goal in its own right. Toward the end of this pre-WWII period, social science research meant pursuing intellectual curiosity, constructing propositions about the phenomenal social world and behavior, and measuring constructs and collecting data to verify those propositions. 'Social scientists began to construct a naturalistic social science as an end in itself, and under the influence of instrumental positivism, erected positivist scientific method into the chief standard of inquiry' (Ross 1991 pp. 467–8, as cited in Bulmer 2001). Nevertheless, the legacy of the Settlement House Movement, of Hull House itself, was to inspire the development of America's first graduate schools and after WWII, schools of public administration and policy at some of the nation's most eminent research universities with strong positivist social science traditions. One could argue that in the roles American social and behavioral science played and sought to play in the public policy arena during the second half of the twentieth century, academic scientists never fully disassociated themselves from advocacy and the taking of normative stances (Lynn 2001, compare Prewitt 1995).

Throughout the foundational period, however, the government of the USA played a rather insignificant role in creating the early infrastructure of the social sciences. Most government existed at state and local levels; the federal administrative state grew in size and political importance only after the great depression and WWII. While the USA census dates from 1790, the US Bureau of the Census was created as a permanent federal agency in 1902. The first commissioner of the US Bureau of Labor Statistics, the statistician Carroll Wright, was recruited from Massachusetts, where he had created the first such statistical bureau in the USA a decade after the civil war. Other elements of a federal statistical system emerged subsequently (see *Statistical Systems: Censuses of Population*; *Statistical Systems: Labor*; *Statistical Systems: Health*; *Statistical Systems: Education*; *Statistical Systems: Crime*, and *Statistical Systems: Economic*).

Events like wars and economic depressions, and governmental response to them, have channeled the evolution of the social sciences during the foundational period. For example, WWI mobilization of American men and their screening for fitness and assignment gave rise to nonexperimental but nonetheless quantitative psychology, to the psychometric assessment of personality and mental abilities (drawing upon European precursors). This war effort spawned basic research on individual differences but also an 'applied industry' of psychological and educational testing (Carson 2001).

Perhaps the signal contribution of government to the social sciences in the foundational period was President Herbert Hoover's appointment in 1929 of a blue ribbon research committee to assess trends in American society, especially in the aftermath of the stock market crash. Hoover, an engineer by training, believed in using scientific information to make better management decisions and to solve problems. The committee of leading academic social scientists (chaired by NBER economist Wesley Mitchell) was funded by Rockefeller monies, not by the federal government, and the research was staffed at the private SSRC in New York City. Nevertheless, on the eve of what was to be known as the great depression, this committee afforded national visibility and presidential

legitimacy to the nascent science of society that the foundations had sought to create. William Ogburn, Chicago sociologist headed the SSRC research effort, and the committee filed its multivolume report, *Recent Social Trends in the United States* in 1933, after Hoover had left office. The report took the view commonly accepted at the time: if facts and trends about households, towns, and institutions could be discerned clearly and measured precisely, then surely rational decision-makers would use the information in the enlightened public interest. This view contrasted sharply with the orientation of the Social Survey Movement earlier in the century, when data were collected directly in the service of correcting urban problems (Bulmer 2001). However, the report was widely criticized. Within elite academic circles as represented by leadership within the SSRC, deep reservations emerged about the potential distorting effects of association with political agenda setting, especially the compromise of scientific objectivity and of basic intellectual inquiry. In the emerging federal policy world of the New Deal era, the report was dismissed for its lack of politically informed analysis and interpretative prescription: the facts could not and would not speak for themselves. What administrative decision-makers of the emerging federal state sought was knowledge for action in a political arena and tested against the requirements of political decision-making (rather than against the requirements of academic social science professionals seeking legitimacy through objectivity; Lynn 2001).

This dialectic between scientific objectivity and prescription was to become a continuing theme in the post-WWII evolution of social science and its infrastructure. The dialectic represented contrasting points of view of the raison d'être for social science, of its legitimacy. And as the role of federal government in creating additional infrastructure and public funding for social science increased, ultimately displacing much if not all of the role played by the foundations and private philanthropy, the dialectic punctuated the evolution of these fields of science and of public support of them.

2.2 Period of Punctuated Evolution

The great depression and the New Deal and subsequently American participation in WWII contributed to growth in the size and political scope of the federal administrative state. Scientists and engineers, as well as their social and behavioral counterparts, contributed to the war effort in a wide variety of federal agencies. Within the Department of Agriculture, for example, studies of the war's impact on the farm economy and households gave rise to more refined survey research and its technology, especially probability sampling. Because science and technology were so instrumental to the war effort, federal expenditures on research and development (R&D) rose from $100 million in 1940 to $1.5 billion in 1945 (Featherman and Vinovskis 2001). The leadership of Vannevar Bush in the newly created Office of Scientific Research and Development was pivotal in this expansion of federal R&D. Bush also forged links between eminent scientists in the few research universities of the time and the needs of federal agencies and of the war effort overall. Thus, WWII created the funding infrastructure for a lasting partnership between the federal government and the universities and stimulated the fluorescence of the research university.

The effectiveness of this university–government partnership during the war prompted President Truman and Congress to establish the National Science Foundation (NSF) in 1950. The size of a role for federal support of civilian R&D, especially for the support of basic research during peacetime, was debated. And the place of the social sciences—viewed at best as 'applied' and not 'basic' science—within the mission of the NSF was heavily contested. Expenditures for these fields represented a mere 1.2 percent of the NSF budget in 1956 and grew only to 1.6 percent ($890,000) by the end of NSF's first decade (Larsen 1992). Additional support for social and behavioral research emerged in an expanding National Institute for Health (NIH) in the postwar years, although as a federal 'mission' agency, the NIH focused its resources on biomedical and other health-related science. Indeed the pattern of scattering federal support for science across such mission agencies, and the NSF for more basic research, has impeded a consolidated and centralized federal science policy (and corresponding decentralized decisions about science funding) since the close of WWII. Funding for the social sciences came less from federal sources than from the foundations, but on a steadily declining basis after mid-twentieth century. Whereas the Rockefeller and Carnegie Foundations were prime supporters of social science before WWII, the newly created Ford Foundation was prominent in the 1950s. For example, over this period, the Behavioral Sciences Program at the Ford Foundation dispensed nearly $43 million for social research and advanced methodological training in universities (Featherman and Vinovskis 2001).

During the same postwar period, economists (most prominently among social scientists) were recruited into new elements of an expanding Executive Branch. For example, the President's Council of Economic Advisors was established in 1946. But the most rapid expansion of the federal administrative state occurred in the 1960s during the Kennedy and Johnson presidential administrations. The federal government became one of the largest employers of social and behavioral scientists (Featherman and Vinovskis 2001). This was a period of jarring racial turmoil and wide public perception of unsolved and longstanding social problems of crisis proportion, such as poverty

amid plenty. The Great Society initiatives of the Johnson presidency, and large federal social welfare expenditures (over $60 billion in 1970, a 142 percent increase over the decade), drew upon social science research for technical guidance. At the NSF, a Social Science Division was created, expanding somewhat the legitimacy of these fields. Similarly, Congress created a National Institute of Education in 1973, and it promoted a broad agenda of research and of evaluation of school reforms. Correspondingly, support for social research blossomed from $384 million in 1961–2 to $803 million in 1966–8, with half coming from federal mission-oriented agencies (Featherman and Vinovskis 2001). And also in this period, both academic and more policy oriented social scientists joined faculties of programs and schools of public policy at a growing number of research universities. Thus, as with WWII, the so-called War on Poverty and associated aspects of the Great Society added to an expanding infrastructure, its funding, and its personnel base for social and behavioral sciences.

If the 1960s and early 1970s constituted something of a 'golden era' for social science, its infrastructure, and the role of its practitioners in policy circles, the era did not last long and ended for many in disillusionment. Large-scale quasi-experiments such as Project Head Start and the Negative Income Tax experiment, conceived and designed by social scientists in league with public policy officials, failed to demonstrate large or lasting impacts (White and Phillips 2001, Gueron 2001).

Solutions to social problems proved far fewer, more intractable, than promises; and social scientists argued openly among themselves about seemingly arcane (to politicians and the public) reasons for failure (Aaron 1978). Politicians and the public gradually came to the view that public monies invested in social research were irrelevant if not wasteful. Meanwhile, another war, this one in Southeast Asia, deeply divided the American public during the Johnson and Nixon presidencies. Academics in general, and social scientists within universities in particular, tended to oppose this war. From the perspective of the more politically conservative administrations of Presidents Nixon and Reagan, the anti-Vietnam War had so politicized and radicalized the professoriate that research scholars, especially in the social sciences, could no longer be trusted to provide objective research and evaluations (Featherman and Vinovskis 2001). By the mid-1980s federal funding for the social sciences had been cut back draconically.

In the closing two decades of the twentieth century, few signal events affected basic infrastructure of the social sciences. As if as a bellwether for social science in these times, however, two gradual developments are noteworthy. Following the Watergate episode and resignation of President Nixon, Americans grew ever more cynical and distrustful of government in Washington, and government itself, especially during the Nixon and Reagan presidencies. Academic social scientists, perhaps with the exception of economists and lawyers, retreated to universities to undertake more theoretically inspired research. Those with a policy-orientation either joined expanding faculties in schools of public policy or were recruited into a rapidly proliferating set of partisan think tanks (both liberal and conservative) that ringed the Capitol to provide politically inspired analysis and commentary to their respective constituencies. Importantly, the abundant infrastructure of the golden era, especially in the form of repeated cross-sectional surveys (e.g., the Current Population Surveys; the National Election Studies), longitudinal studies (e.g., Panel Study of Income Dynamics; National Longitudinal Surveys of Youth), and quasi-experiments or intervention studies (i.e., Gueron 2001) provided common databases for both academic and policy inspired research and for often fierce partisan debates over issues such as welfare reform (e.g., Danziger 2001) (see *Databases, Core: Anthropology and Human Relations Area Files (HRAF)*; *Databases, Core: Anthropology and Museums*; *Databases, Core: Demography and Registers*; *Databases, Core: Demography and Genealogies*; *Database, Core: Linguistics and CHILDES*; *Databases, Core: Linguistics, Online Grammars, and Dictionaries*; *Databases, Core: Political Science and Political Behavior*; *Databases, Core: Sociology*; *Microdatabases: Economic*). For some social scientists, the century-long search for relevance as honest research brokers telling truth to power (policymakers) ended in confusion or compromise (Lynn 2001), while others withdrew to develop theory and 'basic' research within the academic cloister.

A second development concerned the NSF, to some extent the NIH, and funding for social and behavioral science. Full directorate status for the social, behavioral, and economic sciences was created at the NSF in the early 1990s, after 40 years of contested status as a basic science and of politically vulnerability as either 'social engineering' or 'reformers with socialist politics.' For the first time, this placed the social sciences on an organizational par with physics and engineering, for example. Similarly at the NIH, an Office of Behavioral Research was opened with a direct reporting line to the Director. These achievements owed much to the intellectual and political lobbying of the Consortium of Social Science Associations (COSSA), the political arm of the professional social science associations based in Washington.

Funding for the social sciences once again increased, although not dramatically in constant-dollar terms and always reflecting growth or decline in the budgets of federal mission-agencies. Furthermore, the stability of Congressional appropriations to these social and behavioral units within the NSF, especially, and the NIH, to far lesser extent, could never be assumed. Congressional appropriation and authorization hearings routinely recorded doubts about, if not fun-

damental attacks upon, the worthiness and legitimacy of the social sciences even as others emphasized their indispensability (COSSA 1999).

2.3 'Y2K' and Beyond

In the dawning years of the twenty-first century, American social science and its infrastructure face an international challenge. Once an unchallenged exporter of social science theory and methods to the world, often in the form of graduate students from abroad who received advanced education and doctoral training in the USA, American social science is joined by robust science planning and research proliferation in Europe and other continents. While social science infrastructure in the USA has many international components (see *International Science: Organizations and Associations*; *Microdatabases: Economic*; *Centers for Advanced Study: International/Interdisciplinary*; *Data Archives: International*), it remains arguable whether this infrastructure is as internationalized as within Europe, for example. There the Standing Committee for the Social Sciences within the European Science Foundation, and successive science protocols emanating from the European Union, take explicit account and fund cross-national projects and infrastructure elements, like data archives and advanced computational facilities on a shared, international basis. These approaches mimic procedures in the 'hard' sciences and engineering, which have been internationalized in the USA and throughout Europe for decades.

Social science in the USA remains robust, a legacy of an abundant infrastructure of the twentieth century (i.e., Deutsch et al. 1971, Gerstein et al. 1988). However, as social science production and training grows more multicentered and less heavily dominated by the USA, as opportunities expand for social and behavioral scientists worldwide to engage in collaborative, cross-national projects with biological and physical scientists about environmental and health-related issues, the infrastructure to facilitate this internationalization becomes important to US participation. At the moment, foreign language training for US social scientists is uncommon and suboptimal, even if English is the language of science. The USA lacks an international science conversation, among social and behavioral scientists, that parallels the continental conversation within Europe about infrastructure or about intellectual strategies for context-sensitive comparative research (see *Infrastructure: Social/Behavioral Research (Western Europe)*). In a century that is likely to require the mobilized resources of social scientists worldwide to tackle the new issues of globalization, as well as the abiding problems of human civilization across locales and regions, US social scientists may need to pay greater heed to internationalization and develop new elements of infrastructure.

Infrastructure: Social/Behavioral Research (Western Europe)

1. *Development after 1945*

Modern social science, having originated in Europe, emerged as an institutionalized activity in research and teaching only after—and strongly influenced by—its powerful development in the United States. Its evolution in the twentieth century bears the imprint of the authoritarian and totalitarian regimes in continental Europe. While emigrant scholars contributed greatly to the development of the social sciences in the US, the scientific evolution in continental Europe became largely interrupted—more so in Germany and also in Mediterranean countries, and, to a lesser degree in France and Scandinavia. (The summary given in this chapter follows the 'four phases of development in the social sciences' as delineated by Martinotti 1999, pp. 87–91; for France, Italy, and Germany see also Wagner 1990.)

By the end of the Second World War, the social sciences hardly played any role in the European universities. For example, in sociology there were only three chairs in France and none in Italy. In West Germany, political science chairs and a disciplinary association did not exist until 1950. To go to the US and study at an American university for some time, therefore, became an almost necessary precondition for the further education and training of social scientists in Europe. Experiencing 'modern society' and learning the new skills of its systematic observation, made a particular impression on young scholars from countries like Germany, Italy, Spain, and Greece which had been isolated from modern culture for decades. But it is also true of the Scandinavian countries, where the proximity of the Anglo-Saxon world favoured cultural transfer.

As the postwar economic recovery progressed, it became generally understood that the social sciences were part of the modernization of Europe, seen as the expansion of the capitalist mode of production as well as the democratization of society, both closely linked with the American model. While this caused conflicts and resistance from traditional cultural elites and the Marxist-oriented intelligentsia, there was an increasing diffusion of quantitative methods of data collection, particularly survey and primary data. While it is true to say that the European social science tradition had its own deep experience in quantitative analysis, one must also recognize that empirical research had mainly been based on the secondary analysis of 'process-produced data,' particularly statistical data collected by public authorities. What was missing in the continental tradition, and particularly in those countries that had been under despotic regimes, was the experience of field research and the collection of primary data (Martinotti 1999, p. 89). Resistance to the introduction of these new instruments, particularly survey methods and sampling techniques, became expressed from different points of view of traditional European scholarship as well as from administrative agencies with their customary statistical procedures.

Under these circumstances it was not before about 1960 that one can speak of a major expansion of research and acceleration of its academic institutionalization. European societies went through a period of economic 'upswing' that made large masses move to the metropolitan centres of industrial development. The postwar generation of young people, mobilized with the rapid expansion of educational systems, grew up as part of a mass culture, reinforced by the media, that provided a setting for the diffusion of ideas, lifestyles and new organizational patterns without precedent in the European experience. The social sciences, particularly the younger and newly built-up ones, notably sociology, became highly attractive to the student generation for a number of reasons: the relatively young age of university personnel, compared with more established disciplines; the less precise definition of the academic institutionalization of the

social sciences; and the proximity of their subject matter to the intellectual and existential preoccupation of the newly mobilized social groups.

From this background there emerged, in all European countries, a demand for theories of political relevance and of significance for diagnosing and overcoming societal problem constellations (see Dierkes and Wagner 1992, pp. 612–15). This interest, with its commitment to change, stood in opposition to the program of a supposedly ahistorical and value-free explanation of social phenomena. Intellectual controversies and debates within the disciplines pitted the American social science tradition against a variety of Marxist approaches and other 'critical' schools with their supposedly more 'enlightened' responses to the demand for a more encompassing understanding and a more 'committed' interpretation of social facts.

With this orientation, major streams of the social sciences, with Paris and Frankfurt as major centres, acquired a somewhat militant role, linking up with new social movements and entering into debates about the engagement of intellectuals. The traditional social structures and actors, however, managed to retain their overall influence and to uphold traditional explanations for problems of economic and social change. Social science research in much of the 1960s and 1970s can therefore be characterized, on the one hand, by innovative work in many areas, e.g., political participation, labor organization, class structure, the 'capitalist state' and problems of personal and sexual relations. On the other hand, theoretical innovation was limited and research perspectives remained concentrated on the nation-state—despite a growing awareness of conflicts posed by North–South differences, the role of multinational corporations, or global environmental problems.

It was in the later part of the 1970s and in the 1980s that the turmoil of debates, the imbalances between issues and approaches, the dividing lines between theoretical and empirical research gradually became superseded by an ongoing process of professionalization, of methodological consciousness and of new theoretical directions. In retrospect, we can speak of a phase of consolidation in the social sciences in the period of economic recovery after the oil crisis. At a time when liberal social philosophies became dominant, with political sentiments tending to be anti-welfare, and economic policies being influenced by monetarism, the overriding mood seemed to run against the interest in social conditions and the study of society. While this indeed in some countries, notably the UK under Prime Minister Thatcher, made for severe cuts and structural changes, the science policy pendulum did not swing to similar extremes in continental Europe. Debates over the social sciences gradually shifted from theoretical controversies to discussions of their 'uses' in public affairs and policy-making. But by and large institutional growth continued, then slowing down to reach a steady state on advanced levels. (See Martinotti 1999, p. 90, Wagner 1999, pp. 29, 39.)

Towards the end of the 1980s, the social sciences had become well-established academic disciplines, and their presence in policy-making had been well advanced. The academic expansion had very much been related to, and benefited from, expectations with regard to practical uses of the social sciences in the process of societal modernization which had become an important objective, actively pursued by parts of the political and economic elites. In the process, the role of intellectuals became redefined, turning from persons reflecting in general terms about the fate of humankind in history and society to experts for matters of steering society and the economy, and providing knowledge usable as a tool in reformist policy interventions. After the end of the high expectations about the 'scientification of politics' allegedly leading to the 'end of ideology,' social research had become a routine element of many policy processes and, more recently, of management in private companies as well (see Wagner 1990, pp. 441ff.).

The increasing specialization of the applied social sciences, as well as the general trends of the professionalization of the disciplines and their institutionalization in universities and research centres, brought about an increasing fragmentation and specialization which has sometimes been related to a tendency of 'deconstructivism' with critical attacks on large theoretical systems and linked to postmodernist movements. But these tendencies more often are understood as part of a more general search for theories capable of combining macrotrends with microsocial and individual dynamics, and, in so doing, aiming at overcoming the traditional juxtaposition of qualitative and quantitative methods, looking for integration in unified research designs (see Martinotti 1999, p. 90).

Having developed to this advanced stage, the social sciences in the 1990s had to reorient themselves under two dramatic changes of focus: first, the end of the East–West opposition, and second, the process of globalization and internationalization in world regions, particularly the construction of the European entity.

There is an ever more strongly articulated need to gain a better understanding of and to contribute to problem-solving in the process of European integration. Developing a concept of European society has become a major challenge for the social sciences which have traditionally evolved around the concept of a nation-state and of national societies under the stresses imposed by industrialization. Only slowly, but with increasing intensity around the turn of the new century, has it become recognized that the tools and working conditions of social research need to be made adequate for the study of new problem constellations and supra-national processes, and that social science policy-making and research programs have to be

oriented towards cross-national comparison and international cooperation, particularly on the European level. (See Dierkes and Biervert 1992, Kaase et al. 1997, Erikson 1999.)

2. *National Environments and Institutional Structures*

At the beginning of the twenty-first century it is fair to say that in the Western European countries, as a whole, the social sciences have become a standard element in higher education, in public debate and media coverage, in policy-making, administration and corporate management. While, generally speaking, the knowledge of social reality and the diffusion of social facts have become vastly expanded in the previous five decades, the infrastructural basis for generating this knowledge has developed differently in the individual countries. The disciplinary boundaries of the social sciences, research approaches, problem orientations, and structural differentiations in the build-up of research facilities have become shaped by the respective national environments with their historical preoccupations, their academic-scientific 'cultures,' their political and administrative traditions. Expectations regarding the usefulness of social science knowledge for policy-making and the periodically strong demand for social science expertise have contributed to the institutional consolidation and at times—in varying degrees from country to country—to a push for new research structures reflecting characteristic orientations, problem constellations, and modes of public discourse. (See Wagner et al. 1991, Neidhardt and Smelser 1992.)

For example, the social sciences in Sweden may, to a considerable degree, be characterized by pointing, on the one hand, to a traditional demand for exact and reliable methods, going back to early studies of migration and social movements, and by referring, on the other hand, to the interaction with social policies in the Swedish welfare state model and thus to particular forms of contributing to problem-solving as well as, in the process, refining the theoretical outlook on society.

Contemporary social science orientations may often be explained in terms of specific historical evolutions. In the Netherlands, for example, there had been an early involvement of social science research in the practical problems associated with the territorial aspects of social planning, and the social sciences had become shaped in a continuous development by the specifically Dutch version of political conflict resolution, the *pacificatie*, and the corresponding development of institutional networks for interest mediation. While the forms of policy advisory work and research contracting in the Netherlands can thus be characterized in terms of pragmatism, tolerance, and depoliticization, it is quite a different picture that one would paint for Austria. Here, in the prewar period, the constellations of political conflict did not allow for the continuity of similar pragmatic approaches, and the modes of conflict resolution established after the war led to the involvement of social science approaches in the specifically Austrian type of corporatism, making for quite a different variant of a more general continental European phenomenon: the integration of social science research in institutional structures of political representation and in channels of communication between politics, public opinion, policy-making and scientific expertise (see Wagner 1990, pp. 460–3).

These examples, while meant to underline the importance of the diverse national settings, may also serve to illustrate a more general thesis explaining social science orientations with reference to historical paths of social and political development. In these terms, the social sciences emerged in Western European countries in a markedly different way from the way they evolved in England and the US, where the continuity of individualism and civil society made for a more pragmatic style of studying social and political problems empirically and with reformist perspectives. The social sciences on the European Continent, in turn, have been characterized by addressing more basically the foundations of a social and political order which—given the traditional social conflicts, ideological cleavages and propensities for radical change in Europe—have time and again been called into question. They have also shown a greater tendency to ascertain their basic categories and critically discuss their knowledge base.

Institutionally, in all Western European countries, the major part of social science research takes place within the university system. This refers first—and for most countries, foremost—to a multitude of small production units attached to professorial chairs in university departments and loosely organized faculties. Depending on the relative number of students and the weight of the professorial teaching load, university research consists mainly of small projects done with students and often linked to their theses.

At many universities we find, under similar names, institutes for social science research as organizational entities meant to provide better opportunities for cross-disciplinary orientation, for cooperating in empirical research and for contracting and administering larger projects with outside funding. But it is only at very few places that such additional forms of institutionalization, in combination with a considerable number of professorial and other staff positions in the respective departments, have led to larger and more consolidated university research centres. In Germany such larger agglomerations of the social sciences exist at the universities of Mannheim, Cologne, Bielefeld, and Munich. (See Neidhardt 1999.)

By and large, however, it is outside the universities that more extensive research structures have become institutionalized. Extra-university institutes form a

second element in the 'academic research system' in as much as they are to some degree publicly funded and not dependent in their agenda-setting on short-term opportunities offered by the markets of policy analysis and corporate consulting, but rather able to integrate individual projects into larger programs. While indeed at times working on research tasks aimed at contributing to problem-solving, such establishments usually understand themselves as knowledge-oriented and 'science-driven,' and are—at different levels—connected to the universities. (See Wagner 1990, p. 441ff.)

These institutes vary from country to country in number, size, and concept, depending on the respective national environment. In some cases there is only one such extra-university institute as a central establishment, like the Greek National Centre for Social Science Research (EKKE) in Athens. The German case demonstrates a functional differentiation in two directions which, for structural reasons, did not easily develop within the universities and thus called for extra-university institutionalization: on the one hand, the *Wissenschaftszentrum Berlin für Sozialforschung* (*WZB*—Social Science Research Centre, Berlin) and some institutes of the *Max-Planck-Gesellschaft* (*MPG*) and of the *Leibniz-Gemeinschaft* (*WGL*) which undertake larger, long-term, internationally comparative or problem-oriented projects in transdisciplinary research groups; on the other hand *GESIS*, a group of social science infrastructure establishments in Mannheim, Cologne and Bonn, which provide professional services in support of social science research by documenting research projects and their results, by advising researchers on project design, by offering courses in advanced methodologies, and by archiving and giving access to empirical data for the purpose of secondary analysis.

Compared with the grand total of resources and activities in the universities, the 'extra-university' sector of the academic research system is still rather small in Germany and even smaller in Italy with only a few institutions of the *Consiglio Nazionale delle Ricerche* (*CNR*—National Research Council). In France, however, this sector is considerably larger, due to the historic separation of the universities from the centres of academic research. The dominant institution is the *Centre National de la Recherche Scientifique* (*CNRS*) which runs a large number of research institutes separately from or in cooperation with universities or *grandes écoles*; for sociology and ethnology, the *CNRS* with its division on the *Sciences de l'Homme et de la Societé* is far more important as a research institution than the universities. Furthermore, there are the *Maison des Sciences de l'Homme* (*MSH*), the *Ecole des Hautes Etudes en Sciences Sociales* (*EHESS*), the *Fondation Nationale des Sciences Politiques*, the social science sections of the Paris Museums, and the *Collège de France*. (See Machin in Lisle et al. 1984.)

The basic institutional set-up of the academic research system is—in varying forms of composition—being supported and complemented by a third institutional element: the system of project funding through national organizations and foundations. To take the German example again, the *Deutsche Forschungsgemeinschaft* (*DFG*), a publicly funded association of institutions of higher education and research, provides good opportunities for good projects—in whatever kind of research design—to be financed, supplementing the existing institutional resources and using peer review procedures to evaluate project applications. Moreover, the *DFG* and, with greater emphasis, other funding organizations (like the *Volkswagen Stiftung*) make attempts to establish researcher networks and cooperative arrangements within larger, more integrated research programs.

In addition to these institutes and programs that are constituted on scientific grounds with a primary interest in knowledge generation, we find in all the Western European countries other types of social science institutions that are— again in different forms and in varying degrees of development—oriented towards practical needs of government agencies and private organizations. These are, first, publicly financed research institutions directly operated by the state and subject to directives from the respective ministry interested in having a particular need covered by research and analysis. As a second type there are privately organized institutes which may have some basic institutional budget, but receive the main part of their resources from contracts for work on projects commissioned by government agencies as well as corporations, unions, the media etc. The 'state-administrative' part of this sector, often with longer traditions, comprises statistical and agronomic analyses, research on land use and regional development, on demography, public health, on education and vocational training etc., usually with a strong empirical-quantitative orientation. Such 'contractual' research became more developed in the 1960s and 1970s, relating to the policy issues of the day, and sometimes developing a marked expertise through repeated studies over time in a given area.

In some nations and at certain periods in their development, this sector may gain considerable—even dominating—weight in the overall spectrum of social science research. (See Wagner 1990, pp. 443–7.) In the context of this chapter however, there is no room for elaborating, e.g., on the importance of the government-directed non-academic research sector in France, on the effects of administrative traditions and statistical-quantitative orientations, or on the channels for linking social science research to the system of 'planification' through, for example, the *Comité d'Organisation des Recherches Appliquées sur le Développement Economique et Social* (*CORDES*).

These different forms of applied research are indeed part of the institutional environment and the operating

modes of social science research in the respective national contexts. However, while they provide career paths for social scientists and demonstrate the public use of social science knowledge, their infrastructural functions remain rather restricted in comparison with the academic research system with its opportunities for research experiences in larger contexts, for methodological training, for internationally comparative ventures, and for exchanges between approaches and orientations.

3. *Strengthening the European Research Base*

Social science research in Western Europe, in summary, has become institutionalized in a variety of national settings and organizational structures, depending on each country's specific historical background and cultural contexts. International exchange and cooperation, first with the United States, then increasingly across Europe, have served to develop the social sciences to higher degrees of professionalization, with a growing interest in cross-national comparison, but have by far not yet come near to what might be called a 'European' social science. At the beginning of the twenty-first century the ongoing process of European integration had still not become adequately developed as a subject of research aiming at understanding the preconditions, the conduct and the consequences of this process. In addition, the European Union itself, its institutions and major policy areas require the increasing attention of the economic and social sciences, and it has become a matter of 'social science policy' concern to evaluate and redirect the structural conditions of social science research in the (Western) European countries and the perspectives of its development 'towards Europe.'

At the outset of such assessments, it has widely become recognized that the fragmentation of the Western European systems—in terms of social, political and economic problems as well as science and research structures—should not only be understood as obstacle and retardation on the path to a truly European outlook. Turning disadvantage to benefit, one can see European social sciences, with their subject matter differing to some extent from country to country, as providing a densely developed empirical basis for generalizations across time and space. With its richness of constitutional, institutional and cultural variations across (and also within) nation states, Europe has come to be interpreted as a 'natural laboratory' for the social sciences, leading to strong recommendations concerning systematic empirical comparative research. (See Kaase et al. 1997, pp. 3–4.)

While the social science infrastructures in the different European countries have so far been mainly directed towards the study of national developments and problem-solving dimensions, the past decades, with still limited success, have put forward the notion of an increasing need for international cooperation and the corresponding infrastructures that make for exchanges, collaborative work and joint projects. Network linkage has been advanced through the establishment of European journals in different disciplines, through a 'Network Scheme' by the *European Science Foundation* (*ESF*) and through European networks of research units. The most successful of these has been the European *Consortium of Political Research* (*ECPR*) with more than two hundred corporate members across Europe in the early years of the twenty-first century. The *ECPR* organizes annual joint sessions of workshops which take place in different countries and bring together about five hundred European political scientists. A similar organization, the *European Consortium for Sociological Research* (*ECSR*), exists for the neighboring discipline.

Meeting grounds for groups of researchers from different countries and opportunities for collaboration on joint projects over a period of time are being offered by institutes of advanced study, particularly the *Netherlands Institute for Advanced Study in the Humanities and Social Sciences* (*NIAS*) in Wassenaar and the *Swedish Collegium for Advanced Study in the Social Sciences* (*SCASSS*) in Uppsala as well as—with a more general orientation reaching beyond the social sciences—the *Wissenschaftskolleg zu Berlin* or the *Collegium Budapest*. The latter, together with other centers of excellence in Central and Eastern European countries, is meant to advance research capacities within its region by, not least, providing links with researchers from Western countries.

In the framework programmes of the European Union the social sciences have not, until the 1990s, played an explicit role other than having been eligible for the funding of networks of younger researchers as part of general 'Human Capital and Mobility' or 'Training and Mobility of Researchers' programs. The Fourth Framework Programme (1994–1998) did for the first time contain a separate program relating to the social sciences, 'Targeted Socio-Economic Research (TSER).' In addition to one part aimed at the evaluation of science and technology policy options in Europe, it included a part on research on education and training and one on research into social integration and social exclusion in Europe. The latter addressed processes of social exclusion and integration, causes of social exclusion, particularly unemployment, the impact of social integration policies, and research infrastructures. (For the EU research programs see *www.cordis.lu*.)

The EU Fifth Framework Programme (1999–2003) contains, as a major instrument, 'Key Action: Improving the Socio-Economic Knowledge Base,' directed at research tasks on the management of societal change, on individual and collective strategies in a changing society, on employment and unemployment and on social cohesion in Europe, on new perspectives

for learning, on governance, citizenship and the dynamics of European integration, and on the challenge of EU enlargement. In addition, the interest in social science research has become expressed in the proviso that all the other, mostly technology-related, EU programs must include social science research work in a proportion of at least five percent of their respective budgets.

For the researchers, participation in the European research programs has, depending on the background of their experiences in the respective national systems of research funding, meant a reorientation towards new requirements and procedures, sometimes deviating considerably from established modes of competitive research application and evaluation. Following critical discussions and corresponding adjustments of program definition, of evaluation criteria and financing mechanisms, criticism, partly even opposition, centered on the bureaucratic procedures, on the professional status and the scientific excellence brought to bear on program design and project assessment, and on the policy orientation of EU research. (For a general discussion of EU research structures and policies see Max-Planck-Gesellschaft 1994.) It remains to be seen whether the social science research task in the sixth and in subsequent EU framework programs will reflect a convergence between competing principles and complementarity between the research programs of the EU, on the one hand, and the ESF with the different national research councils and scientific organizations, on the other.

One item of discussion that may lead to a clarification of perspectives and differentiation of roles, is the desirable balance between basic and applied research in response to the 'European' dimensions of EU research tasks and their relatedness to EU policy areas. (As one position in the discussion, calling for more basic research, see Erikson 1999, p. 32.) One example is the expression of the overall objective of the program, 'Improving the Socio-Economic Knowledge Base,' namely:

> to improve our understanding of the structural changes taking place in the European society in order to identify ways of managing change and to involve European citizens more actively in shaping their own futures. This will involve the analysis of the main trends giving rise to these changes, the analysis of the relationships between technology, employment and society, the re-appraisal of participation mechanisms for collective action at all levels of governance and the elaboration of new development strategies fostering growth, employment and economic and social cohesion. (European Commission Publications; see www.cordis.lu)

Under this general headline, there has been a pronounced emphasis on the infrastructure for the intended European research as expressed in the preamble to the *TSER* program:

> Research … will require high priority for conceptual and methodological work on constructing and integrating data and indicator systems as a common effort of the European social science research community with the aim of becoming comparable Europe-wide and establishing a common research infrastructure (databases on the parties involved and research results; directories and manual glossaries and thesauruses, etc). This is thus not simply a matter of harmonising statistics but rather, it is creating a scientific system of social reporting which can contribute to the basic understanding of social and economic development. An appropriate proportion of the resources allocated to this field will therefore be earmarked for the definition of a strategy for carrying out this work and developing such infrastructure and to the associated pilot projects. (European Commission Publications; see www.cordis.lu)

The interest in 'data integration' and 'research infrastructure' has become reiterated in later policy statements and, with slow progress, been pursued by additional measures, parallel to the thematic calls of the research programs, and with a view to (and seemingly in competition with) *EUROSTAT*, the European Statistical Office. The same direction is followed by the inclusion of the social sciences in EU actions to support 'large-scale facilities' and by promoting 'access to infrastructures,' recently widening the notion of infrastructures from establishments for data processing and archiving to functions of opening up particular research experiences by coordinated international exchanges.

This interest meets with a core concern of the *ESF*, particularly its Standing Committee for the Social Sciences, which has been active, albeit with limited resources, not only in promoting thematic projects in international cooperation, but also in the discussion and recommendation of social science policies and infrastructural development. In this context it has prepared the proposal for a 'European Social Survey' which in a number of respect overlaps with, or runs parallel to, projects partly financed by the European Commission, to develop a 'European System of Social Reporting and Welfare Measurement,' with about twenty national teams, including some eastern European countries.

With the efforts to create a 'European System of Social Indicators,' emphasizing the scientific context and research dimensions of social reporting going beyond 'mere statistics,' an early interest of the European Community of the 1970s is being taken up again, very much in line with the corresponding activities of the *OECD*, following the strong signal given by the so-called Brooks report on 'Science, Growth, and Society' of 1971 with its explicit inclusion of social science research in science policy concepts.

In a report of 1997 for the *European Science and Technology Assembly (ESTAM)*, an advisory body to the EU, a panel of leading social scientists completed a survey of the strengths, gaps and weaknesses of the economic and social sciences in Europe. In this they recommended measures for the support and advancement of interdisciplinarity for problem-driven re-

search, particularly flexible organizational modes to link scholars from different, even distant, disciplines for a limited period of time; the comparability of data, especially longitudinal microdata, and the systematic linkages necessary for multilevel analyses; the research training of young scientists through graduate colleges, summer schools, etc.; incentives for independent work at earlier stages in academic careers; networks between funding organizations for granting money to comparative projects; national concentrations of methodological resources (similar to *ZUMA, the Zentrum für Umfragen, Methoden und Analysen*, in Mannheim) and links between them across Europe. (See Kaase et al. 1997, pp. 4–10.)

The lack of empirical data collected and analysed on the European level, and the need for methodological advancement and for developing a common European research and training agenda, have also been pronounced by Federico Mayor, the former director-general of UNESCO, following a series of conferences concentrated on European perspectives on the social sciences (see Mayor 1998). Opening the horizon of European integration to include the processes of postcommunist social transition, the notion of a social science 'laboratory' built on the diversity of national traditions may also be fruitful in a wider sense: the challenge would thus not only be to comparatively understand social, political, and economic structures in national contexts; it should also call for the study of intersocietal penetration and of arrangements that work towards international cooperation and integration between countries. With this outlook, a pluralist and transnational social science in Europe might also look for closer relations with social sciences in Asia, Africa, and Latin America, in addition to its profound ties with North America.

Injuries and Accidents: Psychosocial Aspects

Everybody is at risk for incurring an *injury*, although some individuals or populations may have greater risk than others. Injuries are consistently among the contributors to disabilities and death, lost years of productivity and potential life at all ages, resulting in incalculable costs and pain to victims and families around the world (Barss et al. 1998). As the impact of infectious disease on death rates was lessened over time due to vaccines, antibiotics, and improved hygiene, unintentional injuries rose as the leading causes of death and disability, especially for the first four decades of human life. Among the leading causes of injury are the categories of motor vehicle passenger

and pedestrian, drowning, poisoning, falls, firearms, and suffocation (Baker et al. 1992). Numerous commissions and expert panels in the international community since the 1970s have issued reports indicting injuries as the most important public health problem (Her Majesty's Stationery Office 1992, Committee on Trauma Research et al. 1985, National Committee 1989, U.S. Public Health Service 1991, 2000, World Health Organization 1999).

1. Scientific Study of Injuries

Social scientists from disciplines of psychology, public health, and sociology, among others, emphasize the term 'unintentional injuries' because the historical and layperson use of the term 'accidental injury' implies the effect of uncontrollable chance, fate, or other capricious events that cannot be avoided. Professionals now believe that the circumstances resulting in injuries can be subjected to scientific study, and therefore injury outcomes are thought to be explicable and preventable (Roberts and Brooks 1987, Robertson 1998). Additionally, unintentional injuries should be distinguished from intentional harm such as child abuse, homicide, or suicide.

William Haddon, Jr., a physician, was the major contributor to the scientific study into the nature and control of injuries across the lifespan. Haddon's model organized the public health approach to examining the interactive aspects of injuries: the host, the environment, and the agent (Haddon and Baker 1981). For example, Haddon proposed comprehensive strategies for changing the deleterious transfer of injury-causing energy from agent to host. Such strategies include, for example, not creating hazardous producing energy in the first place to reduce injury potential, keeping separate energy sources from the host (i.e., the human victim) in either time or space, or developing the host's resistances to damage. Haddon's influence continues to be felt in this field (National Committee 1989, Robertson 1998). Because human behavior is also involved directly in injuries, science disciplines examining behavior contribute greatly to the understanding and controlling of injuries and death.

2. Methodologies to Study Injuries

Professionals studying injuries utilize several empirical methodologies to gain an understanding of the precursors to an injurious event, of the nature or circumstances of the event itself, and of the aftermath or consequences of an injury.

2.1 Epidemiology

The epidemiological method relies on population-wide statistics about the prevalence and incidence of injuries. These analyses are often specific to certain characteristics such as type and cause (e.g., burns, drowning, firearm wounds, or motor vehicle occupant), demographic variables (e.g., age, sex, socioeconomic class of the injured victim), and injury circumstances (e.g., where the injury occurred: street, house, school; how it occurred: fall, car collision, fire). These epidemiological analyses can convey some aspects of injury development in order to suggest where attention is needed to prevent or control injuries (Baker et al. 1992, Robertson 1998). Epidemiology studies have established that motor vehicles contribute to the most injuries of any cause, indicating that speed, road conditions, passenger seatbelt use, driver's alcohol consumption, for example, are related to these injuries and deaths. Different types of injuries vary in predominance at various ages. For children, a developmental relationship of behavior, ability, and environment has been noted: toddlers are injured in falls and ingestion of poisons; school children are hit by cars as pedestrians; adolescents are injured in car collisions as drivers or passengers, in sports activities, and by firearms. The elderly are injured in falls.

2.2 Behavior Analysis

Psychologists often utilize techniques of behavior analysis to study the antecedent—behavior—consequences sequential chain of events to determine how injuries are produced. For instance, some analyses implicate lack of parental supervision in certain children's injuries and impulsive darting into streets after lost balls. By understanding the behavioral circumstances, prevention focused on behavior change can be undertaken such as providing prompts to engage in a safety behavior or issuing rewards for taking safety actions (Roberts et al. 1987). Other psychologists conduct cognitive development research to determine how children and adults perceive hazards and understand warning labels in order to improve their safety actions or develop educational programs for injury prevention.

2.3 Personality Trait Research

Research into personality traits or relatively stable patterns of behavior leading to injuries has not consistently identified an 'accident prone' type, although some people appear more likely to be injured than others. Some sex and age characteristics of the injured victim often are identified (e.g., younger children, adolescents, males) as being at higher risk for certain types of injuries. Temperament type and activity level have been linked to greater injury risks. Contrary to this line of thinking, according to some scientists, identification of individual differences may

not lead to effective injury control (Robertson 1998). More universal precautions for all people will have greater impact in preventing injuries than selecting individuals with identified markers for an intervention effort.

3. Injury Control

Injury control (prevention of injury) seeks to avoid the occurrence of a potential injury by changing the conditions and the behavior leading to injury, or by reducing the degree of damage when an event occurs. Prevention interventions can target (a) the person who is at risk for injury (child or adult), (b) the authority who makes decisions affecting that person (e.g., a parent, teacher, employer), or (c) the environment to limit possibility of injuries (e.g., through legislation and regulation). Two important approaches to these targets of prevention are structural and behavioral interventions.

3.1 Environmental Modifications to Achieve Safety

Structural interventions are those that modify the environment in order to change potential hazards so that people do not encounter them. For example, fence barriers keep people out of swimming pools, abandoned mines, and quarries. Expandable door gates help keep young children from falling down stairs, while landscaped berms and elevated crosswalks separate pedestrians from street traffic. Covers and guards on moving parts in industrial machinery protect workers. Childproof caps on medicine bottles keep children from potential poisons. Another structural approach is to reduce the degree of injury from an unmodifiable hazard when a person is inadvertently exposed to it, such as automatic seat belts or airbags in cars when in a collision and sprinkler systems in buildings when a fire starts. Environmental change is also conceptualized as passive prevention in that injuries are prevented or reduced in degree without the individual having to take safety actions themselves. Legislation or regulation on consumer products is frequently required to achieve environmental change, such as limiting the size of small objects that could cause choking and suffocation in toys marketed for young children.

In some countries, agencies are given some responsibility to review the safety features of consumer products being marketed to the public. In the USA, the Consumer Product Safety Commission implements a number of regulatory acts with demonstrated effectiveness in improving children's safety. For example, legislative requirements to alter the environment of children to be safer include changing the packaging of poisons and medications such that the number of inadvertent poisonings was reduced; legislation for children's sleepwear to be flame retardant reduced burn injuries; crib and refrigerator safety regulations have reduced suffocation and strangulation deaths. This commission has also issued guidelines for construction of toys and places warnings on toys with small parts that might choke young children (these types of warnings have less evidence of effectiveness than the environmental interventions). Very few products are regulated or reviewed by governmental agencies, but the public erroneously believes only safe products can be sold. Structural changes are sometimes limited in the potential effectiveness when political will or power is not brought to bear on the issue. For example, because of political and car manufacturer resistance, over 30 years passed before automatic air bags were fully implemented in cars in the USA from the date they were first mandated. Other legislation mandating safety have been similarly resisted by those affected (e.g., mandatory motorcycle helmet laws, legal restrictions on handguns, speed limit laws). Indeed, while some countries have little or no commitment to safety as a cultural value or as a governmental concern, others have great acceptance (and lower injury rates across all ages).

3.2 Behavioral Modification to Achieve Safety

Behavioral research focuses primarily on those situations where structural or passive prevention is inapplicable or limited in effect (Finney et al. 1993). Behaviorally-based approaches typically involve active prevention measures in which individuals take action on their own behalf or for others in order to achieve protection. Deficient safety behaviors or excessive safety behaviors can be changed so that the injury-producing sequence is altered. In these cases, for example, safe behaviors are taught systematically to children, their parents, and adults. Empirically supported procedures include rewards and punishments, modeling, prompting, skills training, and rehearsal. For example, in one American community-wide program, school children collected reward stickers and received prize coupons for riding to school properly secured in car safety seats or seat belts. A 'safe playing' program utilizing behavioral principles was implemented in New Zealand to teach children and their parents the safe limits of outdoor activities. Research has demonstrated the effectiveness of behavioral psychology interventions for changing home hazards such as too high temperatures in water heaters and frayed electrical cords, learning fire emergency escape plans, and wearing bicycle helmets (Roberts et al. 1987).

Alexander and Roberts (in press) offered several caveats about orienting injury prevention efforts targeted to the children themselves. All too often, they noted, parents make the assumption that children are protected once they have been trained in a safety

behavior with a resulting decrease in the supervision the parents give to their children in a hazardous environment. A second problem occurs when children are assigned the responsibility for taking safety action when the adults in the children's lives should be the appropriate agents because they have greater control over changing the environment than the children do. Finally, cognitive and motoric development may determine whether children have the skills and capacity to take safety actions and recognize when situations are appropriate or inappropriate for certain behaviors. Research has shown that parents often do not have adequate knowledge to make informed decisions about safety and frequently misperceive that their children are safe in unsupervised situations in the presence of hazards.

3.3 Health Education to Achieve Safety

Much of the injury prevention effort in many countries has been devoted to providing information (see *Health Education and Health Promotion*) to parents to change their child's environment to be safer or for adults to be safer in work or recreation. This information provision may take place through lectures, pamphlets, or brochures about such things as securing storage of poisons above children's reach, safe lifting practices in adults' workplaces, using gates or locks on barriers to keep children away from stairways, buckling children into safety seats and seat belts in cars and in highchairs, and encouraging bicycle riders of all ages to wear helmets. Similarly, public service announcements are often used on radio and television to encourage seat belt use, or to swim safely, for example, or to discourage driving while drunk. There is little evidence to support injury control through providing such information as a sole intervention, although many professionals agree that information about safety is a necessary, but rarely sufficient aspect of effective injury prevention. Health education is not considered a singly effective intervention to prevent injuries, although it is typically the first approach taken. Information about hazards and what a person should do to avoid them can, however, set the stage for implementing both structural and behaviorally-based programs.

3.4 Community Interventions to Achieve Safety

Interventions made to change the attitudes and behavior of whole communities are rarely evaluated in empirical studies, but all too often are maintained because of popular perceptions of effectiveness or political support. Other community-based programs have demonstrated effectiveness when they rely on intense instruction, behavioral rehearsal, and strong community endorsement of safety and reduction of hazards through systematic rewards for safe behavior such as using seat belts and bicycle helmets (Roberts et al. 1987). Action in the community is required to achieve successful implementation of effective programs as established by research, whether directed at changing behaviors, individually or collectively, or instituting environmental modifications to be safer place for all (National Committee 1989). Increasing public attention to injury causes and changing perceptions about acceptable behavior coupled with recognition that such injuries are preventable has led to recent declines in deaths due to drunk driving and the increased use of seat belts.

4. Future of Injury Research and Control

4.1 Research Questions

The National Committee for Injury Prevention and Control in the United States (1989), reflecting international advancements, outlined the significant questions to be answered through scientific research (pp. 35–6): 'Who is being injured? How are these people being injured? Where are these injuries taking place? What are the circumstances under which these injuries occur? How serious are these injuries? How many of the injuries have occurred, and over what period of time? Which of these injuries is most significant in its personal and social consequences? Is the local injury rate from a particular type of injury higher or lower, than the national (or state) rate? What information will be needed to evaluate an intervention?'

4.2 Comprehensive, Integrated Efforts are Needed

Fragmented injury prevention programs, all too often lacking in evidence of effectiveness, are the norm. These critical questions cannot be answered through a single approach or discipline but from a combination of scientific methodologies to gain a comprehensive view of injury causes and possible prevention/control strategies. Thus, there are limitations on the effectiveness of a single approach to injury prevention whether a structural or active/behavioral intervention. The most advanced thinking views an injury control approach as optimally emphasizing comprehensive combinations of structural/passive and behavioral/active prevention.

4.3 Increased Priority for Research and Prevention

Despite the pervasiveness of injuries, professionals frequently note the lack of social outrage to motivate comprehensive injury control efforts in all countries (National Committee 1989, Roberts and Brooks 1987). Although some selected actions have been successful (e.g., in curbing drunk driving in some countries), injuries at all ages and on all continents in the world remain an enormous societal and scientific

issue for research and development of preventive interventions. Injury control needs to be made a higher priority in many countries, especially in the USA, where inadequate attention has been directed to this overall problem than to other health challenges. Enhanced injury surveillance systems or data collection can improve understanding of the nature and characteristics of injuries. Enhanced evaluation of prevention programs can improve modification and implementation of successful interventions. Related to unintentional injuries are interpersonal violence and suicide (see *Violence as a Problem of Health*). These have similar issues of required improved understanding of the causes and development and, most importantly, for prevention and intervention.

As noted by Roberts and Brooks (1987), 'injury prevention involves societal values and tradeoffs of public good versus individual freedom' (p. 8). Personal rights may be abridged when laws or regulations are passed to achieve safety benefit. Speed limits, mandatory motorcycle helmet laws, and requiring smoke detectors in residences, swimming pool fences, controls on gun ownership and use, enforcement of drunk driving laws, are examples of restrictions imposed on individuals in order to advance safer environments. Other regulations may affect economic decisions and profitability for businesses. For example, requiring cars and trucks to have seat belts, airbags, and enhanced rear brake lights restricts the automobile manufacturers. Some countries have a greater acceptance of regulation and governmental control over individuals and business. Culture and traditions play roles in the perception of the 'common good.' Affecting social attitudes are media presentations of hazardous environments and behavior. For example, risky behavior and violence are glorified and use of drugs and alcohol is portrayed as a social norm in music lyrics, videos, television programs, and movies (National Committee 1989).

Social science contributions continue to be made as methodology is applied to gain a better understanding of injury events and causes as well as to empirically evaluate the effectiveness of interventions to prevent or control injuries (Finney et al. 1993).

Injustice: Legal Aspects

What is injustice? Is it simply the absence of justice, the opposite of a utopian achievement? Or does it have a life of its own? Is it possible to disentangle the experience of injustice from the dissatisfactions and disappointments that people experience everyday? How should an understanding of injustice affect our thinking about law? These are the questions to which any student of injustice must ultimately address himself or herself.

The best recent treatment of the subject of injustice and its complex relations to justice and law is found in Judith Shklar's *The Faces of Injustice* (1990). Shklar (1990, p. 19) tries to rehabilitate injustice as a subject of study, arguing that it 'should not be treated intellectually as a hasty preliminary to the analysis of justice.' According to Shklar (1990, p. 19; also Cahn 1949, Folger 1984), 'The real realm of injustice is not in

an amoral and prelegal state of nature. It does not appear only on those rare occasions when a political order wholly collapses. It does not stand outside the gate of even the best known states. Most injustices occur continuously within the framework of an established polity with an operative system of law, in normal times.'

Shklar recognizes that injustice exists at one end of a continuum of human experience and is often confused with other undesirable conditions. To avoid such confusion, the study of injustice must be differentiated from what she calls misfortune. 'When is a disaster a misfortune and when is it an injustice?,' Shklar asks. For her the answer is to be found in the presence or absence of a responsible human agent. 'If the dreadful event is caused by the external forces of nature, it is a misfortune and we must resign ourselves to our suffering. Should, however, some ill-intentioned agent, human or supernatural, have brought it about, then it is an injustice and we may express indignation and outrage' (Shklar 1990, p. 1).

This analysis treats injustice as a matter of malevolent human action, rather than as a matter of structure or of institutional design. It embodies what Gordon (1996, p. 36) calls the perspective of 'narrow agency,' in which injustice is thought of as a wrong 'done by specific perpetrators to specific victims.' But Gordon suggests that the danger of this perspective is that it will lead us to ignore other kinds of injustices. He reminds us that injustices can be done by collective perpetrators to collective victims, such as the Nazi atrocities against the Jews. This kind of injustice involves what he calls 'broad agency.' In addition, injustice can be attributed to bad structures in addition to bad agents. An interest in this kind of injustice 'takes the form of explanations rather than a search for villains and attribution of blame.'

1. *Responses to Injustice*

Whether defined in terms of narrow agency, broad agency, or structure, some believe that in the United States people are too ready and eager to use the language of injustice and to turn to law to redress conditions which in the past would have been regarded as the uncontrollable workings of fate. Typical is Lieberman's (1981, p. xi) contention that ours 'is a law-drenched age … Though litigation has not routed out all other forms of fight, it is gaining public favor as the legitimate and most effective means of seeking and winning one's just deserts. So widespread is the impulse to sue that litigation has become the nation's secular religion.' In this view, our legal culture is today governed by two principles (Friedman 1985, p. 43). 'The first … is the citizen's expectation of fair treatment, everywhere and in every circumstance … . The second … is the general expectation that somebody will pay for any and all calamities that happen to a person … .' Together these two principles create a culture of 'total justice' (Friedman 1985) and what some believe to be a 'litigious society' (Lieberman 1981, Huber 1988).

In an article I co-authored in 1980, my co-authors and I argued that responses to injurious events are more complicated than arguments about 'total justice' or the 'litigious society' admit. These responses, we noted, could be understood as occurring in three stages (Felstiner et al. 1980–81). The first, defining a particular experience as injurious, we called 'naming.' The next step in the emergence of a claim of injustice is the transformation of a perceived injurious experience into a grievance. This occurs when a person attributes an injury to the fault of another individual or social entity' (Felstiner et al. 1980–81, p. 635). It involves 'blaming.' The third step occurs 'when someone with a grievance voices it to the person or entity believed to be responsible and asks for some remedy' (Felstiner et al. 1980–81, p. 635). This step we called 'claiming.'

It was our contention that 'only a small fraction of injurious experiences ever mature into disputes. Furthermore, we know that most of the attrition occurs in the early stages: experiences are not perceived as injurious; perceptions do not ripen into grievances; grievances are voiced to intimates but not to the person deemed responsible' (Felstiner et al. 1980–81, p. 636). Paying attention to the process through which responses to injustice are formulated and to the high rate of attrition in, or resistance to, the making of claims was, we contended, a way of putting the burgeoning argument about the litigation explosion in context. We argued that the processes through which claims emerge, or through which people decide to 'lump it,' are 'subjective, unstable, reactive, complicated, and incomplete' (Felstiner et al. 1980–81, p. 637). Most of what occurs in this domain is cultural, not legal, occurring as it does in the everyday lives of ordinary citizens and in their struggles to make sense of who they are and who they want to be in a world of risk, danger, and injury (Sarat 2000) (see *Legal Culture and Legal Consciousness*).

Since then, some scholars have studied the way in which people actually react to the injurious events of their lives (Merry 1990, Yngvesson 1993, Greenhouse 1986, Ewick and Silbey 1998). That scholarship characterizes litigation as a process of contesting meanings and adjudication as the choice and imposition of one structure of meaning over another (Merry 1990). Contests over meaning in courts or communities thus become occasions for observing the play of power. Meanings which seem natural, or taken for granted, are described as hegemonic, but because the construction of the meaning of injurious events is, in fact, typically contested, scholars show the many ways in which different people respond to injustice. They have found that the tendency to label injurious events in the language of injustice is contingent and

complex, varying from one community to the next, from one kind of injury to another.

In this process, law plays a key role. As Merry sees it, the relationship between injustice and law is not one in which law passively responds to expectations for 'total justice.' Law works, she says (Merry 1990, pp. 8–9), 'not just by the imposition of rules and punishments but also by the capacity to construct authoritative images of social relationships and actions, images that are symbolically powerful. Law provides a set of categories and frameworks through which the world is interpreted. Legal words and practices are cultural constructs which carry powerful meanings not just to those trained in law … but to the ordinary person as well.' Merry's research shows that responses to injustice involve 'a complex repertoire of meanings and categories understood differently by people depending on their experience with and knowledge of the law' (Merry 1990, p. 5). This work connects the study of injustice to the world of law and is continuous with a long history of scholarship about the connections between law and justice and about the ways law is implicated in injustice.

2. *Injustice and Law*

Commentators from Plato to Derrida have called law to account in the name of justice, scolding and chiding it for the injustices which it does, promotes, or tolerates. They also recognize that all too often law, in this culture and elsewhere, is a tool of injustice (see, for example, Cover 1975, Irons 1983). For every step taken toward realizing the good, an equal, if not greater, number have been taken in the name of evil. These commentators have asked that law provide a language for responding to injustice and demanded that it promote, insofar as possible, the attainment of a just society.

They have done so, however, in relentlessly abstract and general language, as if the demands of justice and the problem of injustice could only be apprehended accurately outside of history and context, and as if only philosophers were fit to engage in conversation about these subjects. The justice which is spoken about is, as a result, elusive, if not illusory, and disconnected from the embodied practices of law of the kind that Merry emphasizes. As one writer noted, 'there is no such thing as justice "in general," one can meaningfully discuss only fairly concrete injustices and procedures for their mitigation with existing social machinery or possible ways of improving the overall social organization' (Knight 1963, p. 1).

The turn to injustice is generally associated with an interest in context and particularity, in which attention is given to individuals and institutions and their contingent histories. In one sense, then, when scholars talk about injustice and try to connect it to law they are often reacting against the vexing difficulty that attends to the effort to examine the connection of law and justice.

In earlier days, however, speaking about law and justice was not so vexing or difficult. Justice (*jus*, meaning 'law') was a legal term, pure and simple. At the outset, then, justice was defined and constituted by laws that were 'given' and held to be unchanging and unchangeable. This ineluctable link between justice and law had the virtue of making the boundaries of justice more or less clear, but it had the considerable vice of labeling even heinous, iniquitous laws just. Attention to the problem of injustice could do no critical/reconstructive work in legal scholarship because it was impossible to think of justice as external to law.

Hobbes (1958) to the contrary notwithstanding, most natural law thinkers have resisted this result by insisting that unjust laws are not law (see, for example, Acquinas 1988, George 1992, Finnis 1890, Hittinger 1987). Doing so meant the end of any easy identification of positive or human law with 'real' or binding law. The alternative, embraced by perhaps a majority of those who do legal philosophy (Hart 1961; for an important contrast, see Fuller 1964), is to cut justice and law free from one another, to insist that justice is more than mere conformity to law and to acknowledge that even unjust laws might nonetheless be law. This has freed students of injustice to direct their attention to the practices of law itself, scrutinizing them for their contributions to injustice in society.

More recently, the distance between law and justice, and the potential for injustice in the name of the law, have been recognized in postmodern theorizing about ethics (Cornell 1988, 1992). Thus, as Douzinas and Warrington (1994, p. 23) (see also Keenan 1990) argue: 'Justice has the characteristic of a promissory statement. A promise states now something to be performed in the future. Being just always lies in the future, it is a promise made to the future, a pledge to look into the event and the uniqueness of each situation … . This promise, like all promises, does not have a present time, a time when you can say "there it is, justice is this or that." Suspended between the law and the good … , justice is always still to come or always already performed.'

Severance of the definitional tie between justice and law has left both notions free (if also bound) to acquire new identities (Balkin 1994). It has opened the way for an examination of unjust actions or conditions and for an inquiry into the ways law is implicated in them. However, this definitional separation has by no means put an end to the commonplace conviction that the principal home of justice is law and the special concern of law, perhaps its principal business, is justice. As Clarence Morris (1963, p. 170) notes, 'Though there can be law without justice, justice is realized only through good law.' In fact, law and legal theory continue to be shaped by concerns about justice and injustice, just as understandings of these notions are

shaped by an awareness of law and the concerns of legal theory (Lucas 1980).

3. *From Law to Politics in the Study of Injustice*

By what might fairly be regarded as an accident of intellectual history, concerns about injustice as a motive for studying and reforming law have been somewhat muted in some contemporary discourse which seeks to expand interest in injustice beyond the sphere of law. They have been swamped by a preoccupation with distributive justice, a subject whose contemporary pre-eminence can unquestionably be attributed to John Rawls' *A Theory of Justice* (1971). 'Justice,' Rawls (1971, p. 3) contends, 'is the first virtue of social institutions, as truth is of systems of thought.' But the justice he has in mind is almost exclusively distributive justice, not justice more broadly construed; injustice of a distributive type is not peculiarly the concern of law at all.

Similarly, the philosopher Agnes Heller (1987, p. 54) introduces the notion of a broad, though incomplete, 'ethico-political concept of justice.' In her view, justice and injustice are not simply about principles of distribution; they concern the perspectives, principles and procedures for evaluating institutional norms and rules. Developing themes in Habermas's (1987) communicative ethics, Heller (1987, p. 54) proposes that justice is 'primarily the virtue of citizenship, of persons deliberating about problems and issues that confront them collectively in their institutions and actions, under conditions without domination or oppression, with reciprocity and mutual tolerance of difference' (Young 1990, p. 33). Domination, oppression, and intolerance are thus preconditions for injustice.

Iris Young (1990, pp. 34, 37) expands on even this notion, concluding that 'the concept of justice coincides with the concept of the political,' and while it is 'not identical with the concrete realization of these values in individual lives,' it is attentive principally to 'the degree to which a society contains and supports institutional conditions necessary for the realization' of the values of equal worth as these are promoted or confined in a society's basic institutional arrangements. The study of injustice then moves from law to politics. On this account the subject is as inclusive as the political order itself.

4. *On the Continuing Significance of Procedure*

Despite these broad and encompassing views of justice and injustice, the fact remains that injustice is generally thought to be involved in matters of procedure, punishment, and recompense (Aristotle 1985, Lucas 1980). Thus, while law in its legislative moments might share with other social institutions certain distributional objectives, it is generally thought that law has a separate and distinctive commitment to doing justice, located most conspicuously, though not exclusively, in matters of form and process. This is, of course, symbolized in the universal icon of justice (and invariably associated with law): the statue of Justicia, the blindfolded bearer of sword and balance (see *Rule of Law*; *Due Process in Law*).

Despite certain ambiguities, Justicia presumably embodies law's central link to justice, impartiality (Curtis and Resnik 1987). The instrument of Justicia is a balance, not a scale, so it is only a comparative rather than an absolute measurement that is involved. She is blindfolded to prevent her decision from being inappropriately influenced or determined by forces of fear, bias, or favoritism. Moreover, she is blindfolded—not blind—suggesting a self-willed refusal of vision. If we are to avoid injustice, partial justice, or biased justice, what is required is a denial of sight though not of seeing, a regulation of information though not of knowing, a restriction on what is permissibly attended to though not a deficit of attention (Black 1989).

According to Curtis and Resnik (1987, p. 1727), 'procedure is the blindfold of Justice.' The proposition that procedure is itself an aspect of justice, and that procedural irregularities are in themselves instances of injustice, takes us some distance toward the further result that law and justice are ineluctably linked. Thus, to the extent that one supposes that the Rule of Law and the principle of legality are constituted largely by a commitment to regularized, self-limiting procedures, it is but a short step to the conclusion that procedural justice is inextricably tied to law itself.

Along some such path, it seems possible to argue further that procedures themselves must meet additional normative requirements, sounding in fairness and desert, and other dimensions of justice. As Hart (1961, Chap. VIII) has observed, a rule that is regularly, uniformly applied to prohibit certain minorities from using the town park might, despite its unfailing enforcement, be viciously unjust. Legal justice, then, involves more than general observance of the rules that regulate exercises of legal authority, the rules themselves must be fair, eschewing wholly arbitrary distinctions between and among the persons to whom they apply or on whom they finally have effect. The rules must provide suitable forms of what, in the United States, are known as requirements of due process and equal protection.

Acknowledging the relationship of procedure and justice has spawned a large and important empirical literature which explores what leads people to believe that law is just or unjust (Lind and Tyler 1988, Tyler 1989). This literature suggests that procedure is more important than substance, that the way one is treated is more important than the results one gets in determining whether people believe that they have been treated justly or unjustly in the legal system. As Lind (1998, p. 184) explains. 'If authorities seem to be

making decisions in fair ways, people assume that they can obey orders and follow rules without worrying too much about exploitation. If, on the other hand, authorities seem to be reacting unfairly, exploitation becomes a real possibility and obedience tends to be viewed with more suspicion … . Outcome-oriented theories of justice judgements err because they fail to recognize that people are generally quite ready to accept outcomes that are less than they had hoped for.'

5. *Can Law Overcome Injustice?*

Returning to the questions with which we started, we have seen that injustice is not simply an absence of justice, that it is a fact and an experience different from, though related to, misfortune, and that it may involve the relations of one person to another, of groups of people, and of the attributes of legal, political, or social structure. Though some would focus the attention of persons interested in understanding injustice fairly broadly, law seems to be at the center of any proper understanding of injustice.

Yet having envisaged ways of connecting the study of injustice and of law, it must be granted that not everyone regards the imagined association as an unalloyed good. Hayek (1982), among others, is persuaded that social justice is a mirage, a misguided affection the pursuit of which not only threatens liberty but, eventually, law itself. A somewhat more moderate concern is that the demands of distributive justice and the Rule of Law are inevitably at odds with one another, so that the effort to cure distributive injustices comes at a high price to law itself (Unger 1977, Barnett 1988). A third apprehension is that the meaning of justice is so ambiguous, expansive, and elusive that law invariably will be seen as falling short, as failing to meet justice's demands, as always, then, implicated in injustice. As Balkin (1994, p. 16) argues, laws apportion responsibility, create rights and duties, and provide rules for conduct and social ordering. Law is always, to some extent and to some degree, unjust. At the same time, our notion of justice can only be articulated and enforced through human laws and conventions. We may have a notion of justice that always escapes láw and convention, but the only tools we have to express and enforce our idea are human laws and human conventions. Our conception of the just relies for its articulation and enforcement on the imperfect laws, conventions, and cultural norms from which it must always be distinguished.

Some worry that law's legitimate authority, such as it is, will be dangerously (and unjustly) eroded (Tyler 1990). Alternatively, but with consequences no less grave, the impossibility of satisfying justice's demands may eventually be seen as the fault of justice, not of law.

Still other qualms dampen enthusiasm about the possibility of connecting law to the study of justice and injustice. Some believe that the embrace of legal justice is, at best, a rhetorically appealing device for quieting alarm about the excesses and inequities social and economic arrangements inevitably arouse (Hay 1975). So conceived, legal justice is largely a symbolic response to the incorrigible defects and injustices of liberal capitalist societies, not a positive virtue which these arrangements can promote or make possible (Marx 1978).

The fear that legal justice can be put to work in the name of legitimating social injustice, for example by 'justifying' outcomes that seem patently, outrageously disproportionate has been expressed in a different voice, and on different grounds, by Shklar (1990). She argues that the focus on justice inhibits the development of a community that both recognizes the culturally constructed quality of boundaries between the ideas of 'injustice' and 'misfortune,' and objects to passive injustice as vehemently as it abhors the active violation of rights. But Shklar's dissatisfaction with a narrow interest in legal justice is pressed even further in her contention that contemporary theory tends almost exclusively to regard injustice as 'simply the absence of justice' (Shklar 1990, p. 15, Woozley 1973).

On this view, 'once we know what is just, we know all we need to know,' Shklar (1990, p. 15) writes. Or, as Knight (1963, p. 15) observes, 'One misses a great deal by looking only at justice. The sense of injustice, the difficulties of identifying victims of injustice, and the many ways in which we learn to live with each other's injustices tend to be ignored, as is the relation of private injustice to the public order.' Scholars such as Shklar and Knight contend that we not only lack a full and coherent account of justice; even if we had one, it would not yield an equally full account of injustice, nor would it confront adequately our calloused complacency regarding vast, yet eliminable, misfortunes.

These observations call to mind a variety of uncertainties and ambivalences regarding the relationship of law and justice, but they fall far short of embracing the extreme position that justice be jettisoned from legal discourse. Rather, they remind us of the vastness of the subject of injustice, of the difficulty of constructing a single account capable of holding together its many strands, and of the space that exists to theorize anew about justice and injustice in law and legal theory.

A. Sarat

'Inner City,' The: Cultural Concerns

1. Introduction

While the growth of concentrated inner-city joblessness and poverty is, to varying degrees, characteristic of many older industrial cities in Western Europe, it is most pronounced in the central cities of the Northern and Midwestern United States (Summers 1993). As a result of fundamental changes in the national and global economies leading to the decreased relative demand for low-skilled labor, many of the USA's inner-city neighborhoods have experienced unprecedented levels of joblessness since 1970. High joblessness in segregated neighborhoods has contributed to other problems including concentrated poverty, family dissolution, welfare receipt, and declining neighborhood social organization. The net result has been the increasing social isolation of inner-city residents and therefore the crystallization of a set of habits, styles,

skills, orientations, and other ghetto-related cultural traits. Although these traits grow out of conditions of economic and social disadvantage in a highly segregated environment, they also reinforce the economic marginality of inner-city residents. The success of policies to combat inner city woes, including the problems of joblessness, will largely depend upon the extent to which they are integrated into or are a part of broader programs to enhance the economic and social health of the metropolitan region.

2. *The Rise of the Modern Inner-city Ghetto*

One of the legacies of the historic racial and class subjugation in the United States is the growing concentration of poor and minority residents in the nation's impoverished inner-city areas. The demand for low-skill blue collar workers in the North during the early twentieth century, coupled with the rise in southern blacks' economic insecurity brought about by the declining demand for farm labor due to the increasing mechanization of agriculture, helped fuel the migration of blacks to northern industrial cities. In the North, blacks found themselves increasingly segregated in ghettos that previously housed white ethnic immigrants, who themselves were gradually assimilating into US society.

In spite of the tremendous obstacles faced by African-Americans, ghetto neighborhoods, in the early parts of the twentieth century, developed a diversified social and institutional structure, characterized by a mix of poor, working-class, and middle-class blacks and viable institutions (e.g., businesses, schools, churches, and cultural organizations) that fostered a vibrant social and cultural life. This social organization of earlier ghettos helped to buffer the deleterious effects of marginalization and concentrated poverty (Dubois 1899, Drake and Cayton 1962). And despite their disadvantaged status, well into the 1960s most ghetto-dwellers resided in neighborhoods where a majority of adults were employed.

3. *The Social Transformation of the Inner-city Ghetto: Competing Explanations of the Growth of Concentrated Poverty*

Since 1970, conditions in those same inner-city neighborhoods have dramatically declined, reflecting a different social and economic environment than existed in early urban ghettos. The new urban ghetto has a much higher level of joblessness and a greater concentration of poverty (Wilson 1987, 1996, Jargowsky and Bane 1991, Jargowsky 1997). Explanations for the growth of inner-city joblessness and concentrated poverty have centered on four mitigating factors: economic changes, demographic shifts, government programs and policies, and the legacy of racial oppression.

Central-city labor markets have been altered by economic changes affecting the distribution and educational requirements of employment. Beginning in the 1970s, global competitive pressures and declining profits in manufacturing set off a wave of plant closings that decimated the old industrial centers of the USA. Many of the companies that survived moved off-shore or to the South to take advantage of lower production costs. Some employers, attracted by the cheap land and skilled labor force, moved to suburban areas. The decline in central-city manufacturing jobs was a major impetus to the growth of concentrated urban poverty (Wilson 1987, 1996).

Employment in the inner city has also been affected by the sectoral shift from goods-producing to service-producing industries and an associated increase in educational requirements of employment. Whereas most job growth has been in those industries that require higher levels of education, job loss has disproportionately affected the less educated (Kasarda 1989). Not only did the shift to higher-skilled service sector jobs reduce the demand for inner-city workers, new production technologies also eliminated many unskilled manual jobs in manufacturing. The social costs of the loss of low-skill manufacturing jobs and their replacement with more skilled jobs have not been equally shared. In particular, inner-city blacks have disproportionately felt the impact of these changes. The new spatial distribution of employment within metropolitan areas has also disadvantaged inner-city neighborhoods and residents. In the competition for jobs, suburban areas, with their cheaper land, access to highways, and other amenities, have an advantage over central city areas. Thus, the intensification of inner-city poverty is at least partly the result of the increasing suburbanization of employment that has helped to generate a growing mismatch between the suburban location of employment and the inner-city residence of minority populations (Wilson 1987). Inner-city joblessness increases as residents must contend with both fewer employment opportunities nearby and longer commutes to jobs outside the central city.

A demographic trend that has contributed to the spread of concentrated inner-city poverty is the movement of nonpoor families out of inner-city neighborhoods, first by whites and later by blacks. Beginning in the 1950s, nonpoor whites began to move out of many inner-city neighborhoods and into suburban locations. The economic vulnerability of blacks, especially the increased likelihood of joblessness, meant that neighborhoods that became predominantly black were more at risk of becoming high poverty areas. In the face of a less restrictive housing market in the post-civil rights era, many working-class and middle-class blacks also left poor inner-city neighborhoods in search of more favorable living conditions. As the proportion of nonpoor families in the neighborhood declined, the levels

of poverty increased, pushing many previously mixed-income ghetto areas into greater poverty (Wilson 1987, Jargowsky and Bane 1991, Jargowsky 1997).

Some governmental programs and policies have exacerbated the decay of inner-city neighborhoods (McGeary 1990, Wilson 1996). Policies such as the selective underwriting of mortgages, and mortgage interest tax deductions, favored the suburbanization of middle-class whites. This trend was facilitated by the construction of highway networks linking the suburbs and central cities. The construction of massive federal housing projects in inner-city neighborhoods in the 1950s and 1960s isolated poor black families for decades and helped to create some of the most highly concentrated poverty in the country. More recently, the policies of the Reagan and Bush administrations pushed many city governments to near bankruptcy under the New Federalism program that substantially reduced the federal contribution to city budgets, at a time when cities were desperate for federal help in combating escalating urban problems.

Finally, the high levels of racial segregation in American society, combined with higher rates of joblessness and poverty among blacks, helped to spread and intensify the concentration of poverty in predominantly black inner-city areas (Massey and Denton 1993). Segregated ghettos are less conducive to employment preparation and employment than are other urban residential areas. Segregation in ghettos aggravates employment problems because it leads to weak informal employment networks and contributes to the social isolation of families and individuals, thereby reducing their chances of acquiring the human capital skills, including adequate educational training, that facilitate social mobility.

4. *Concentrated Poverty, Social Organization, and Culture in the Inner City Neighborhoods*

During the 1970s and 1980s, social dislocations such as crime, gang activity, joblessness, and welfare receipt soared in many of the USA's segregated inner cities. Attempts by some social scientists to explain these trends centered on the behavior of the urban poor, behavior believed to be rooted in a cultural milieu of deviant norms and values (Murray 1984, Mead 1986).

Alternative explanations emphasized the structural underpinnings of the inner city and the extent to which macroeconomic conditions have undermined the social and cultural life of the ghetto (Wilson 1987). According to this view, ghetto-related behavior and attitudes are best understood as cultural adaptations to the lack of opportunities in the inner-city environment and the larger society (Clark 1965, Hannerz 1969, Rainwater 1970, Anderson 1990).

The social constraints faced by inner-city minorities, and their cultural manifestations, reflect their social isolation from mainstream society, especially the lack of employment opportunities (Wilson 1987, 1996). The outmigration of nonpoor blacks from poor inner-city neighborhoods contributed to this isolation by eroding the social buffer that they provided, and by making it difficult to sustain basic institutions, such as schools, churches, stores, and recreational facilities. By reducing the opportunities for contact with regularly employed adults and the opportunities for access to the social resources that higher status families provide (e.g., job networks), residents in high-poverty neighborhoods are less likely to develop the culturally shaped skills, habits, styles, and orientations so prevalent in neighborhoods organized around work (Wilson 1987, 1996).

Also, concentrated poverty and joblessness undermine the social organization of inner-city neighborhoods, or the ability of residents to maintain effective social control and realize common goals (Wilson 1996). Socially organized neighborhoods have strong and cohesive informal social networks and ample institutional resources for the preservation of neighborhood social order. Strong social networks are characterized by sustained social contacts that are based on trust, reciprocity, and normative consensus, and where there are extensive ties between parents, children, and other institutionally based adults (e.g., police, teachers, and other community leaders) (Coleman 1990). Social control is also aided by such institutional resources as effective policing, quality schools, and adequate community organizations and other locally based associations.

In contrast to socially organized neighborhoods, many segregated inner-city neighborhoods have few institutional resources and weak and less cohesive social networks. As a result residents are less able to enforce norms and control undesirable behavior in the community or to act collectively to preserve the quality of neighborhood life. When the effectiveness of formal and informal social control mechanisms drops below a certain threshold, sanctions against nonnormative behavior become ineffective and opportunities for illegitimate activities proliferate in the community (Sampson and Wilson 1995).

In sum, the cultural milieu of the inner city is embedded in the structural features of concentrated poverty, social isolation, and the lack of neighborhood social organization. Cut off from employment opportunities and trapped in neighborhoods with little access to conventional role models, social networks that contain social capital (e.g., informal job networks), and institutional resources that support families, poor inner-city families face severe obstacles in their efforts to accomplish socially desired ends such as labor force participation and family stability.

5. *The Inner-city Family: A Mediating Variable*

Since 1970, marriage rates have been declining nationally and more children are being raised in single-parent

families. Nowhere are these trends more prevalent than in the inner-city, where mother-only households are the norm in many neighborhoods. This situation has generated much public debate and, while public attention has focused on the marital disincentives of welfare policy, research has shown that a major reason for the collapse of two-parent inner-city families is the growing economic marginality of inner-city males (Wilson 1987, 1996). As male employment prospects receded, so did the economic benefits of marriage. The general weakening of social sanctions against out-of-wedlock childbearing in the larger society and especially in the inner-city ghetto further helped to undermine the foundation for stable relationships.

The high rates of single parenthood are especially troubling because of their association with persistent poverty, welfare receipt, and deleterious effects on children. Children in mother-only households are themselves more likely to be school dropouts, to have lower earnings, and to depend on welfare as adults (Krein and Beller 1988, McLanahan and Garfinkel 1989). Moreover, growing up in communities where prospects for steady employment and stable marriages are perceived as remote, young inner-city adults are more likely to engage in behavior that further jeopardizes their chances for social and economic mobility.

6. *The Inner City and Public Policy*

After years of steady urban decline, the prolonged economy recovery in the USA has recently improved situations in central cities. Unemployment has declined dramatically from 8.6 percent in 1992 to 5.1 percent in 1998. And unemployment in the nation's 50 largest cities fell from 8.6 percent in 1992 to 4.9 percent in 1998, a decline that exceeded the decreases in unemployment in the cities' surrounding suburbs (US Department of Housing and Urban Development 1999).

The positive effects of these changes are seen in even the most depressed parts of the city. A new study by the economists Richard Freeman and William M. Rodgers of low-wage workers in 322 metropolitan areas, reveals that black men aged 16 to 24 with a high school education or less—including many with prison records—are employed in greater numbers, earning larger paychecks and committing fewer crimes than in the early 1990s. Although far too many of these young men are still jobless or in prison, the rise in legitimate employment has accompanied a drop in criminal activity. Indeed, crime has fallen most rapidly in regions with the sharpest declines in joblessness. (Freeman and Rogers 1999, Nasar and Mitchell 1999). Nonetheless, the highly disadvantaged urban areas have not rebounded to the same extent as other areas in the metropolitan regions. Moreover, if the economy slows down and the country is faced with a period of economic stagnation or a new recession the problems of joblessness and poverty will become acute once again.

Any real solution to the economic and social woes of the inner city will have to address the full range of economic and social problems that currently plague them. Policies that guarantee full employment, reduce income inequality, rebuild the physical and social infrastructure of cities, and provide adequate social support for the nation's less fortunate would go a long way towards redressing the USA's urban inequalities. However, in recent years such programs have not been reflected in government policy. Indeed, as discussed above, government action has often unwittingly contributed to urban inequalities. Similarly, governmental agencies often work at cross-purposes, for example, as one seeks suburban economic development, another tries to revitalize low-income urban communities by luring businesses back to the central city. Disparate and divergent policies of this sort have 'worked to weaken the social, economic, and political strength of inner city communities' (Ferguson 1999, p. 587).

Furthermore, cross-national comparisons of urban policy suggest that the fragmented governmental structure of the USA has been, and will continue to be, a major obstacle to halting the decline of inner cities. Few Western European cities witnessed the dramatic urban decay of US cities, in part because central governments there have sought to maintain the livability of cities by controlling urban growth boundaries, implementing more effective urban renewal programs, and building cheap and efficient public transportation systems (Weir 1993, Downs 1993). In contrast, the USA has no comprehensive federal plan to influence urban settlement patterns, and most urban matters are under the jurisdiction of local governments and are heavily influenced by powerful economic actors in the private sector.

However, there is mounting evidence that the problems of jobless ghettos cannot be separated from those of the suburbs, and that the health of metropolitan regions may depend on a viable central city. For example, research indicates that the reduction of central city poverty is associated with increases in metropolitan income growth, and that central city job growth increases the value of suburban properties (Gottlieb 1998).

In the global economy, metropolitan regions continue to compete for jobs. In an era of low transportation and information costs, high mobility and intense global competition, a metropolitan region is at a severe competitive disadvantage if it lacks a healthy urban core. 'In a global economy, firms choose among regions—and the health of the central city is a key factor in deciding which region is best. Even firms that choose to relocate to the suburbs will choose areas surrounding a vibrant central city' (U S Department of Housing and Urban Development 1999, p. 19). In the USA cities and suburbs should look to the creation

of metropolitan and regional governmental bodies or city–suburban collaborative planning mechanisms to help resolve shared metropolitan-wide concerns. And paramount among these concerns should be the revitalization of the most disadvantaged neighborhoods. It would be a serious mistake to assume that efforts to enhance the economic and social health of the metropolitan region can be achieved without combating the problems of poverty, joblessness, and related woes in the inner city.

Innovation and Technological Change, Economics of

Technological innovation is the function through which new technologies are introduced into the economic system. It entails recognizing new technological possibilities, organizing the human and financial resources needed to transform ideas into useful products or processes, and carrying out the requisite activities (typically called 'research and development'). It is important because technological advances have played a paramount role in facilitating the radically improved standards of living experienced by the inhabitants of progressive nations over the past several centuries. Innovation is responsive to econ-

omic forces and the lure of profit, but their influence is complicated by uncertainty and the difficulty innovators encounter in capturing a sufficient share of the economic benefits resulting from their contributions.

1. *Acceleration and Systematization*

New technologies have been introduced into production and consumption throughout recorded history. During the eighteenth century, however, there were discernible shifts in the pace and organization of technological change through what is now called the first Industrial Revolution. Landes (1969) and Mokyr (1990). New machines reduced dramatically the amount of labor required to accomplish productive tasks, steam engines provided less costly and more reliable means to drive the machines, the machines themselves were perfected through improvements in machine-building technology, and innovations in agriculture freed workers to produce a widening array of traditional and new manufactured products. One impact of these changes was an increase in the quantity of goods and services that could be produced by the average worker, i.e., an increase in labor productivity. Higher productivity in turn meant enhanced real income or purchasing power, sometimes at first only for some segments of the population but ultimately for virtually all consumers. Landes (1969) estimates that the growth of real income per capita in western Europe increased from a rate of roughly 0.16 percent per annum between AD 1000 and 1700 to 0.4 percent between 1700 and 1750. It then soared into a range of 1.2–1.5 percent per year during the next century, i.e., doubling every 46 to 58 years.

It was always recognized that the acceleration of per capita income growth beginning with the first Industrial Revolution was coupled closely to the implementation of new technologies. Debate continues over the exact contribution of new technology as compared to increases in the amount of capital goods with which work is accomplished, efficiencies associated with increases in the scale of productive operations ('economies of scale'), and the enhancement of 'human capital,' i.e., the education and training of workers (see *Human Capital: Educational Aspects*). Full resolution of the debate is impossible, because those contributors to economic growth are intrinsically complementary. Much new technology is embodied in capital goods and implemented only when new investments are made. Similarly, technological advances and investment typically are needed to realize economies of scale. And neither technological advances *per se* nor their implementation on an industrial scale would be possible without well-educated and well-trained workers. What is clear is that advances in technology play a very important role in driving productivity improvements and hence improvements in real income per capita (Griliches 1995).

The economist Schumpeter (1912, 1934) was the first to stress a systematic functional role for innovation, or the carrying out of new combinations by an entrepreneur, in achieving economically meaningful technological advances. He wrote (1934):

> Economic leadership in particular must be distinguished from 'invention.' As long as they are not carried into practice, inventions are economically irrelevant. And to carry any improvement into effect is a task entirely different from the inventing of it, and a task, moreover, requiring entirely different kinds of aptitudes.

The differentiation of activities directed toward carrying technological innovations into practice was already evident during the late eighteenth century in the famous Boulton & Watt steam engine partnership, which included a group of workers specialized in performing what today would be called research and development (Scherer 1965). In Schumpeter's schema, the 'innovator' recognized the commercial potential of new technologies, raised the capital for and accepted the primary risks faced in implementing them, and organized the effort needed to perfect them and introduce them into the market (today, research, development, and marketing). The spread of this systematized approach to technological innovation was at first gradual, but by 1994, industrial enterprises in 25 nations surveyed by the Organization for Economic Development and Cooperation (1997) spent a combined total of roughly $237 billion (measured at 1990 price levels) on formally organized research and development activities.

2. *Endogenous Innovation*

Most of the mainstream economic writings up to the middle of the twentieth century viewed technological innovation as a function regulated by forces distinct from and independent of the supply and demand conditions through which markets for well-established goods and services reached an equilibrium. Innovation was said to be an 'exogenous' activity, not systematically influenced by economic variables (i.e., 'endogenous'). Innovations came from the efforts of 'hero' inventors who, though not immune to economic motivations, were driven at least as much by the urge to tinker and improve; or as a fortuitous by-product from the advance of scientific knowledge sought for its own sake or in the seventeeenth century, *ad majorem Gloriam Dei*.

Marx (1887) was the first to see innovation as a direct consequence of capitalists' striving to enhance their profits, but his writing had little influence on mainstream economic views. Schumpeter's insights (1912) were more influential, but only with a lag of a half-century. In Schumpeter's schema, the innovator recognized opportunities to achieve supranormal profits by introducing superior alternatives to the

products or processes embraced by the vast horde of competitive enterprises; thus, innovative activity was expressly profit-seeking. The profits realized by the innovator in turn sent a signal to other firms that their accepted technologies were becoming obsolete, but they could defend themselves and gain profits by imitating the innovator's contribution. Thus, an original innovation was followed sooner or later by a 'swarm' of imitators whose competitive efforts drove prices down until only normal returns on investment could be sustained. Further innovation was necessary if supra-normal profits were again to be gained. Schumpeter (1942) called this incessantly repeated chain 'the process of creative destruction,' adding that the organization of innovative functions in modern research and development laboratories imparted a routinization that reduced the heroic role played by Schumpeter's entrepreneur and perhaps (he wrongly feared) jeopardized the continuation of rapid technological progress.

Exactly why profit opportunities opened up for technological innovators was left unsettled by Schumpeter. Conventional wisdom held that the advance of science was the key agenda-setting influence: scientific breakthroughs or, less dramatically, the steady accretion of scientific knowledge, created an opportunity to make economically significant and profitable innovations. This view of the world was challenged by Schmookler (1966), whose qualitative and quantitative historical research pointed toward a crucial innovation-inducing role for demand-side influences. The greater the demand for a set of products, the more profitable improving upon those products was likely to be, and hence the larger was the flow of innovations aimed at satisfying consumers' (or producers') demands for those products (see also Usher 1954).

A formal model of how the economic forces of supply and demand endogenously affect the rate and direction of innovative activity can be synthesized from the contributions of Schmookler (1966), Scherer (1967), and Barzel (1969). Investing in innovation is viewed like other investment activities: a lump sum outlay is required for research, development, and introductory marketing. The innovator chooses to incur that outlay only if the investment is expected to be profitable, i.e., if the anticipated stream of quasi-rents or producer's surplus (cost savings, or new product sales revenues minus production and routine marketing costs), discounted to present value, exceeds the expected lump-sum innovation outlay. Let the lump-sum innovation outlay be RD and the discounted present value of quasirents be V. How much must be spent to realize the innovation depends upon the state of scientific knowledge and related technology. As knowledge advances, what was impossible at one time (i.e., infinitely expensive) becomes less and less costly over time. Smooth and continuous advance in the knowledge base implies that if carrying out the

Figure 1
Innovation timing with continuous demand and cost changes

innovation in year zero costs RD_o, implementing it T years later costs $RD_o\, e^{-aT}$,where $100a$ is the percentage rate at which the cost of innovation declines per year as knowledge advances. On the payoff side, let $v(t)$ be the quasi-rent or producer's surplus attainable in year $t$from an innovation. As demand grows, quasi-rents are likely to grow apace, so from an initial quasi-rent level of v_o in year zero, quasirents will grow to $v_o e^{+gT}$ in year T, where g is the annual rate of growth. Assuming for simplicity the innovation to have an infinite revenue-yielding life once implemented, the discounted present value of quasi-rents for an innovation introduced in year T is therefore

$$V(T) = \int_T^{\infty} v_o e^{(g-r)T} dt \qquad (1)$$

where r is the risk-adjusted discount rate. The innovator seeks to maximize its profits from innovation, so it will not plan to innovate if $V(T) < RD_o\, e^{-(a+r)T}$, with discount rate r added to the R&D cost term to reflect the fact that costs incurred in the future are valued less than costs incurred today. Assuming correct expectations about the future (an assumption to be examined critically later), the innovator will innovate at the earliest when those magnitudes come into equality, and perhaps (given recognition lags) not until $V(T) > RD_o e^{-(a+r)T}$.

This perspective on the innovation inducement process and important variants thereof is illustrated in Figs. 1–3. Figure 1 replicates geometrically the model of the preceding paragraph. The solid downward-sloping line labeled 'R&D Cost' shows $RD_o\, e^{-(a+r)T}$ declining exponentially from its initially high value as the time of innovation is delayed from the earliest possible date, year zero. The upward-sloping line labeled 'Benefits' shows the discounted quasi-rents from innovation $V(T)$ rising steadily as the time of innovation is delayed and the innovator taps into revenue-earning possibilities augmented by the

Figure 2
Innovation induced by technology-push

Figure 3
Innovation induced by demand-pull

growth of demand. As discounted R&D costs fall and discounted quasi-rents rise, there comes a time (14 years from the initial vantage point) at which the innovation first becomes profitable. After year 14, the innovation becomes more and more profitable, so the lure of profit becomes increasingly irresistible, making it virtually inevitable that some entrepreneur will rise to the bait and carry out the innovation. Indeed, as time advances and discounted benefits rise relative to discounted R&D cost, increasing numbers of would-be innovators are likely to recognize the opportunity, precipitating more or less simultaneous innovation by two or even more firms—a phenomenon characterized earlier by the sociologist Ogburn (Ogburn and Thomas 1922) as a response to the 'status of the material culture' (see also Merton 1961).

Nevertheless, the road to technological innovations is not always smooth, as portrayed in Fig. 1. Advances in science may occur discontinuously when there are scientific breakthroughs. This case is illustrated in Fig. 2. Up to year 9, the discounted R&D costs of innovating are well in excess of foreseeable discounted quasi-rents, so innovation is not profitable. But in year 9 a scientific breakthrough occurs, substantially reducing the cost of carrying out the developmental work needed to implement the innovation. Innovation is suddenly profitable in year 10 and becomes increasingly profitable as the knowledge base resumes its steady growth thereafter. An innovation induced in this way is called a 'technology-push' or 'science-push' innovation.

The other extreme case is portrayed in Fig. 3. Again, the innovation is clearly unprofitable up to year 9. But in that year demand takes an upward jump—e.g., because an energy shock has suddenly made energy-saving innovations attractive—and the innovation becomes profitable, the more so, the more demand continues to grow if the innovation is not undertaken immediately in year 10. Following Schmookler (1966), innovations induced in this way are called 'demand-pull' innovations.

Reality is some blend of these three polar cases. For Figs. 2 and 3, there is a clear one-sided inducement mechanism—either technology-push or demand-pull. More frequently, both demand-side stimuli and the knowledge base are changing, and it is difficult to tell which has the more powerful influence. Just as both blades of a scissors cut paper, both technology-side and demand-side changes contribute to making technological innovations profitable and thus induce (with some stochastic lag) their appearance on the market.

3. *The Appropriability Problem*

An important complication entails what has come to be called the appropriability problem. Not all of an innovation's incremental value accrues to the innovator as quasi-rents or producer's surplus. Some of the value cannot be appropriated by the innovator, but accrues instead to consumers or other producers. This happens for three main reasons. First, even when the innovator commercializes a new product under monopoly conditions, it is difficult to devise a pricing scheme that does not confer new consumers' surplus upon those who purchase the product. (Only in the implausible case of perfect price discrimination could the innovator appropriate all of the surplus from a product innovation.) Second, if multiple firms innovate more or less simultaneously or if imitation is swift, competition may drive the relevant product's price below the monopoly profit-maximizing level, increasing the amount of surplus accruing to consumers and/or competitors and reducing the amount appropriated by innovators. Third, the very fact that a successful innovation has been achieved conveys, or 'spills over,' valuable information to other economic actors (see *Social Facilitation, Psychology of*; *Information, Economics of*). They can study the innovator's technical solutions and use the insights gleaned thereby to come up with their own innovations, which

Figure 4
Divergence between social and private benefits

may either improve upon the original innovation's characteristics or provide differentiated new features. Empirical studies (Griliches 1992) have documented extensive spill-overs whose value is not appropriated by innovators.

The most influential quantitative research on the appropriability problem was by Mansfield et al. (1977). For a sample of 17 commercialized innovations, they painstakingly estimated the quasi-rents realized by the original innovator (called the private return) and the surpluses spilling over to consumers, imitators, and subsequent technology users. Converting these estimates to rates of return on the innovator's R&D investment, they found the median private return on R&D investment (i.e., the innovator's return) to be 25 percent, while the median social return (counting in addition surpluses accruing to consumers, rivals, and others) was 56 percent.

The implications of the appropriability problem are illustrated in Fig. 4. The innovator's inability to appropriate all the surplus from their innovation in effect inserts a wedge between the stream of benefits appropriable by the innovator (the private benefits) and the total benefits realized by all actors in the economy (the social benefits). The private benefits function in Fig. 4 is the same as in Figs. 1 and 2; the social benefits function is shifted upward by 80 percent. Whereas the innovation first becomes profitable to a private firm 14 years from the initial vantage point, social benefits begin to exceed R&D cost after year 7. This does not mean that the innovation should be introduced in year 7. An all-knowing decision-maker seeking an ideal solution from the perspective of all participants in the economy would choose an introduction date that maximizes the discounted surplus of social benefits less R&D costs. That date will be the same as the private sector break-even date (14 years) when $k = (a+r)/r$, where k is the ratio of social to private benefits (shown by Mansfield et al. (1977) to have a median value of approximately 2.25), a is the rate of R&D cost decline, as above, and the market growth rate g is assumed to be zero. For a proof, see Scherer (1980). If appropriability is so low that $k > (a+r)/r$, the private break-even date comes later than the socially optimal innovation date; if appropriability is sufficiently high that $k < (a+r)/r$, private break-even may precede the socially optimal innovation date.

Three main classes of remedies have been devised to lessen the innovation market failures believed to come from insufficient appropriability of innovation benefits by innovators.

A solution of particularly long standing, dating back to Venice in the Middle Ages, is the patent system. The first person to make an invention (or under some US interpretations, reduce it to practice) is granted by the government a temporary monopoly on the commercial exploitation of that invention. Patents delay the incursion of imitators and hence help innovators appropriate a larger share of the benefits from their innovations. Surveys of R&D decision-makers (Levin et al. 1987) reveal that the effectiveness of patents in achieving this result varies widely across industries. One reason for this variability is the fact that in some product lines, technological innovators enjoy substantial timing and reputation advantages over imitators even when no patent protection can be secured (Robinson et al. 1994).

Second, insufficient appropriability has been viewed as a rationale for government subsidies to support research and development investments. The relevant policy instruments range from corporate income tax credits for incremental funds spent on R&D (implemented first by Canada in 1962) to the conduct of R&D by government agencies or, more commonly, the issuance by government of contracts reimbursing more or less fully the R&D costs incurred by private firms. The contracts approach suffers from moral hazard problems and possible errors in the choice of innovators, but it is virtually unavoidable when large R&D outlays must be risked to develop high-technology products such as guided missile systems for government use. The vast array of policies chosen by governments to foster innovation in their home markets has been studied by economists under the rubric, 'national innovation systems' (Nelson 1993).

Third, firms have sought to alleviate appropriability problems by entering into joint ventures to conduct R&D and perhaps also to market the innovations achieved thereby. The cooperative R&D approach offers an added advantage of minimizing what might otherwise be costly duplication of more or less identical R&D efforts. Concomitant disadvantages include the lessening of diversity among technical approaches, where diversity enhances the prospects of achieving a successful solution, and reducing the competitive pressures that compel firms to conduct their R&D programs aggressively (see, e.g., Klein 1977).

How much competition is desirable in the pursuit of innovations is a question on which much economic research has been done (see Reinganum 1989). There are conflicting tendencies. On the one hand, competition forces firms to be aggressive and imaginative in their R&D efforts, seizing innovation opportunities at the earliest feasible moment (e.g., at year 14 in Fig. 1). On the other hand, too much competition reduces appropriability and may lead to a market failure under which no firm can anticipate sufficient quasi-rents to make its R&D investments worthwhile. This tension has led to what is called the 'inverted U' hypothesis, holding that the polar extremes of no competition at all (e.g., a secure monopoly) and intense competition are less conducive to innovation than an intermediate degree of competition, e.g., under differentiated oligopoly (see, e.g., Baldwin and Scott 1987).

4. *The Risks and Costs of Innovation*

Innovation is intrinsically an excursion into uncharted waters. The notion that costs and benefits can be predicted with precision, as assumed in the model underlying Figures 1–4, abstracts from the fog of real-world decision-making. Clearly, substantial uncertainty and risk are present. However, in early discussions concerning the economics of innovation, little was known about how much uncertainty actually pervaded innovation decisions. Mansfield made the most important clarifying contributions. In one of several such studies, Mansfield et al. (1977) obtained from the heads of 16 chemicals, pharmaceutical, electronics, and petroleum company R&D laboratories three probability estimates for the portfolio of R&D projects pursued by those laboratories: the probability that an average project would achieve its original technical goals, the probability that, conditional upon technical success, the resulting product or process would be introduced commercially, and the probability that, conditional upon commercialization, the project would yield a return on investment at least as high as the opportunity cost of the firm's capital. For all 16 laboratories combined, the average conditional probabilities were as follows:

Technical success	0.57
Commercialization, given technical success	0.65
Financial success, given commercialization	0.74

Cumulating the three probabilities by multiplication, one finds that on average 27 percent, or roughly one in four, of the projects initially undertaken eventually led to financial success as defined by Mansfield et al. (1977). To make the innovative process broadly worth while, the financial rewards from that minority of successes had to repay not only their own investments but also those made on projects that died at pre-commercialization stages. More recent research (Scherer and Harhoff 1999) has revealed that even among commercialized innovations, the size distribution of rewards (measured in absolute, not rate of return, terms) is highly skew, conforming most closely to a log normal distribution law, and that failure to achieve at least normal returns on commercialized projects may be more common than the survey by Mansfield et al. (1977) implied. The greater uncertainties appear to lie in determining the reaction of consumers and competitors to new products than in the ability of scientists and engineers to achieve success in the laboratory. So skew is the distribution of rewards that it is difficult to make profits converge toward fairly stable averages by supporting feasibly large project portfolios.

The ability to pursue portfolio policies also depends upon the sizes of individual innovation projects. There too, evidence of considerable skew exists. The median case in a large sample of prize-winning technological innovations entailed R&D outlays on the order of $2 million (Scherer 1999). However, the project size distribution has a long thin tail, including hundred-million-dollar outlays to achieve successful new pharmaceutical innovations in the United States and multi-billion outlays for new airliners. In such extreme cases, 'bet the company' risks are difficult to avoid.

How large business enterprises must be to undertake the risks of privately financed innovation has been a subject of continuing debate. Especially in Europe, the dominant belief for many decades following World War II was that large national champion enterprises were better positioned than smaller firms to sustain innovative activities. Evidence from the United States has tended to be inconsistent with this view, in part because there are thousands of companies sizeable enough to support portfolios containing numerous median-outlay innovation projects without risking financial failure. Also, beginning in the United States but spreading during the 1990s to many industrialized nations, there has been a proliferation of venture funds pooling money from wealthy investors who seek the occasional but spectacular returns that can be realized by backing an unusually successful high-technology startup firm.

Innovation: Organizational

Introduction

> There is nothing more difficult to plan, more doubtful of success, nor more dangerous to manage than the creation of a new order of things …
> Niccolo Machiavelli, *The Prince* 1961 [1513]

Despite the attention paid to innovation in the 1990s, which is evident in the increased number of books and articles, the theory itself seems to have changed little since the 1970s. Drazin and Schoonhoven (1996) concluded that research on innovation still has an adaptationist perspective. Its three basic assumptions are '(a) innovation is universally desirable for organizations, (b) once an organization increases its size beyond a critical mass it becomes more inert, less capable of meaningful organizational change, and only haltingly proficient at innovation, and (c) certain structures and practices can overcome inertia and increase the generation rate of innovation.' While this assessment may be accurate overall, it fails to take into account that the development of multilevel models and associated sophisticated statistical modeling and analysis techniques may ultimately lead to incremental or even radical change in innovation theories.

This article reviews the current state of research on innovation and points out pathways for new insights where researchers incorporate findings from learning and institutional theories into multilevel innovation models. In particular, diffusion of innovation models has much to gain from combining traditional trait with context theories and from modeling effects simultaneously. Incorporating more sophisticated theories of power and organizational memory may further revitalize research on generating and managing innovation in organizations. It is important to keep in mind that the importance of innovation for organizational success and survival may be greatly exaggerated or even mythical as von Braun's (1997) analysis of Research and Development (R&D) activities in highly industrialized nations shows. Indeed, he calls the focus on industrial innovation during the post-Cold War the *Arms Race of the '90s*.

1. Definition

Definitions vary in the extent to which they distinguish between that which is objectively or subjectively new. Some authors call only successful commercial exploitation of new ideas an innovation, while others do not distinguish between a novel idea as an invention and commercial innovation (see *Entrepreneurship*). For the latter any 'idea, practice, or object that is perceived as new by an individual or other unit of adoption … is an innovation' (Rogers 1995). Even if one were to

distinguish strictly between invention and innovation, the question to whom something is new or not, still remains. Is the exploitation of a new idea only an innovation once, when it is first discovered? Or is the pacemaker still an innovation in Germany, even though it is already widely being used in Australia or the US? Rogers (1995) prefers a broad understanding of the concept. He terms any idea or practice that is new to an adopter as an innovation. Thus, even where a practice such as activity-based cost accounting (ABC) is used within an industry, for a company that is newly adopting ABC, ABC is an innovation.

2. *Types of Innovations*

Innovations can be classified along a variety of dimensions. The most common typology distinguishes among product, process, and, more recently, also service innovations. Product innovations refer to changes in the offerings of an organization, for example, the introduction of CD and later DVD players. Process innovations refer to changes in the manufacturing or delivery of such offerings, for example, Just-in-Time Manufacturing or Total Quality Management (TQM)/(JIT). The distinctions between product and process innovations, however, seem to become blurred when it comes to service innovations, since product and process go together in the production and delivery of a service. Especially among the process innovations one could also distinguish between technological and administrative procedures. Does the change involve a new technology of transforming input into output or does it involve a new way of administering or organizing the process using existing technologies?

Another typology (e.g., Anderson and Tushman 1990) classifies innovations by the extent to which they rely on existing competencies or change existing products or processes. At one extreme are incremental, at the other extreme are radical innovations. Radical innovations are those that lead to hitherto unheard of products or processes. For example, enlarging the capacity of $5\frac{1}{4}$ inch disks to provide 20 MB of memory involved incremental changes, while developing the $3\frac{1}{2}$ inch disks represented a radical innovation. Radical innovations often involve competency-destroying changes and are associated with organizational reorientation (cf. Tushman and Rosenkopf 1996).

3. *Models of Innovation*

Brown and Eisenhardt's (1995) review distinguishes between rational plan, communication web, and disciplined problem-solving approaches to product development. The main difference among the various models concerns the underlying assumptions about the overall process, that is, whether it is rationally planned or evolves over time.

3.1 *Rational Processes*

Rational models (see *Rational Choice and Organization Theory*) assume that innovation proceeds along a strategic planning process involving information gathering, analysis and evaluation, and action. According to the rational perspective successful innovation is 'the result of (a) careful planning of a superior product for an attractive market and (b) the execution of that plan by a competent and well-coordinated cross-functional team that operates with (c) the blessings of senior management' (Brown and Eisenhardt 1995). Practitioner-oriented prescriptions sometimes list up to 16 steps in the strategically planned, rational product development process ranging from initial screening to detailed market studies, trial production, and ultimately market launch (Cooper 1993). Thus, it seems that the rational process is highly complex, especially if one were to consider turbulent or dynamic environments in the market assessments. Nonetheless, rational models can be found in many organizations and have inspired a large number of research projects. Summarizing research on successful and failed product innovations that had followed a rational plan Brown and Eisenhardt (1995) list product advantages, market attractiveness, and internal organization as the main factors for successful, rational product innovation.

3.2 *Evolutionary Models*

Underlying evolutionary theories is a repeated variation-selection-retention cycle. Evolutionary theories assume that variation—different ways of doing something—exists within any environment and that managers then selectively retain a product or process from such variation and thereby innovate within their organization. For example, organizations may selectively retain an administrative innovation such as idiosyncratic jobs (Miner 1991) and thereby change their processes and products over time.

3.3 *Linking Organizational and Industry Innovation*

Most innovation models work on two levels. At the organizational level, innovation is a means of organizational adaptation to changing environments. However, organizational innovation can also be a means of industry evolution (e.g., Anderson and Tushman 1990; Greve et al. 1995). In fact, the link between organizational innovation and industry evolution follows a well-established research tradition ranging from waves of creative destruction models (Schumpeter 1934) to organizational learning (see *Learning*: *Organizational*) and population level learning (Miner and Haunschild 1995). Even theories, such as those of population ecology, whose focus is on the population rather than individual organization level

entities, are innovation models at heart. Population ecologists argue that some new organizational forms are more likely to survive than others (e.g., Hannan and Freeman 1989) and thereby ultimately lead to innovation within a population of organizations. The linkage between organizational innovation and industry evolution is particularly evident in punctuated equilibrium and technology cycle theories (see *Technology and Organization*).

3.4 Punctuated Equilibrium and Technology Cycle Models

Proponents of punctuated equilibrium theory suggest that organizations 'evolve through alternating periods of convergence and reorientation' (Tushman and Rosenkopf 1996), that is, alternating periods of incremental and radical innovations. Instability and reorientation punctuate stable, convergent periods. Environmental change stimulates technological breakthrough innovations which disrupt stable patterns of interaction and power relations, and thereby lead to organizational or industry-wide reorientation and divergence. Empirical studies have shown that reorientation and turbulence may stem from technological, legislative or wartime jolts, or performance crises and cannot be predicted. After the implementation of radical innovations in the reorientation periods, incremental innovations dominate the convergence periods. These convergence periods can vary dramatically in length.

Technology cycle theories (e.g., Anderson and Tushman 1990) similarly point to alternating periods of radical and incremental change, but mainly operate at the industry level. Tushman and co-workers show that periods of increased discontinuities in an industry alternate with periods of increased fermentation. Periods of discontinuities experience design competition and substitution, while periods of incremental change follow the emergence of a dominant design and are characterized by elaboration of dominant designs. Decisions about a dominant design are not necessarily technology-driven but involve social or political processes which 'abjudicate among multiple technological possibilities' (Anderson and Tushman 1990). Thus, the ultimate dominant design, 'is an outcome of the social or political dynamics of compromise and accommodation between actors or unequal influence.'

Tushman and Anderson (1986) use data from the minicomputer, cement, and airline industries to study technological innovation in those industries. When they differentiate between competence-enhancing and competency-destroying technologies, they notice an interesting pattern. Apparently, competence-destroying technologies stem from new players, that is, influences exogenous to the industry, while competence-enhancing technologies are developed by existing firms, that is endogenous forces. Thus, certain variation may result from environmental change, while other variation grows out of seeds planted within the industry.

4. Diffusion of Innovation

The heterogeneous diffusion model by Strang and his co-workers (Greve et al. 1995) brings together two distinct conceptual models of diffusion processes and allows simultaneous analysis of multilevel effects. While Strang and his co-workers model organizational and network influences, the model itself could also be applicable to reconcile research streams that focus on specific traits of innovations with those that focus on contextual variables, either at the individual adopters, the organizational, or the population level.

4.1 Trait Models

One stream within the diffusion of innovation literature focuses on the traits of particular innovations. Rogers's (1995) five-factor model is a well-known example. The five factors are relative advantage, compatibility, complexity, trialability, and observability. Relative advantage refers to 'the degree to which an innovation is perceived as being better than the idea that it supersedes' (Rogers 1995). Compatibility is the 'degree to which an innovation is perceived as consistent with the existing values, past experiences, and needs of potential adopters' (Rogers 1995). Some innovations are very simple and easy to implement, while others are complex, consist of several inter-related subprocesses, and may be difficult to implement in an organization. Rogers (1995) refers to this as the complexity of an innovation, which he defines as the 'degree to which an innovation is perceived as relatively difficult to understand and use.' According to Rogers, managers are more likely to adopt an innovation after they had a chance to experiment with the innovation. Rogers (1995) refers to this characteristic as trialability and defines it as 'the degree to which an innovation may be experimented with on a limited basis.' Last, but not least, being able to observe the experiences of another organization or individual also has positive effects for the diffusion of an innovation, a concept that Rogers calls observability.

4.2 Institutional Models

Another stream of diffusion research is framed within institutional concepts. This research stream suggests that managers not only consider the traits of an innovation, but also the context. As much of the neo-

institutional research has shown, managers do not only consider the instrumental outcomes of a practice, but also the noninstrumental outcomes such as broad, increased legitimacy and isomorphism with the generally accepted practices of the industry or population of organizations (cf. Powell and DiMaggio 1991).

One of the major claims of institutional theorists is that organizational survival depends on legitimacy defined as 'a generalized perception or assumption that the actions of an entity are desirable, proper, or appropriate within some socially constructed system of norms, values, beliefs, and definitions' (Suchman 1995). Managers have an important role in building, increasing, and maintaining organizational legitimacy. For example, they may only adopt innovations that are legitimate and enhance the organization's legitimacy. Empirical research shows that managers copy innovations from large organizations or from organizations personally known to them. Moreover, managers are likely to implement innovations that have been endorsed by exogenous institutions or have become part of professional knowledge (cf. Powell and DiMaggio 1991).

Adapting Strang and co-workers' multilevel heterogeneous diffusion model may lead to new insights into the diffusion of innovation research by distinguishing the relative impact of traits and organizational or population contexts. Using such a model and the associated methodologies would also allow the incorporation of individual decision-makers' influences into the modeling, for instance, their preferences and personalities such as risk-taking or risk avoiding (see *Organizational Decision Making*).

5. *Enhancing Innovation in Organizations*

The literature on facilitating innovation in organizations falls into two streams. One stream looks at introducing and managing processes that might lead to innovation, while the other examines specific factors that may enhance or impede the innovativeness of an organization. Among those innovativeness factors one could further distinguish between factors that affect the development of particular products and those that operate on the organization as a whole. Lately, the relationship between innovation and strategy (see *Strategy*: *Organizational*) has been emphasized, for instance, in research on the effect of mergers and acquisitions, exiting certain niches or transforming an inert mature organization into an innovative one (see *Organizational Change*).

Rothwell (1994) has written comprehensive reviews on success factors, strategies, and trends for innovativeness. For example, he lists good internal and external communication, effective linkages with external sources of know-how, treating innovation as a company-wide task, high quality production, careful planning and control systems, strong market orientation, top management commitment, and long-term commitment to major projects among other critical elements of successful innovation strategies (see *Entrepreneurship*). Dougherty and Hardy (1996) reinforce Rothwell's (1994) findings, but also add the importance of managing power in product development. Going beyond the effect of powerful individuals such as powerful product champions and powerful team leaders, they introduce multi-dimensional views on power (see *Organizations*: *Authority and Power*).They suggest that generating successful sustainable innovation involves managing power on all dimensions, that is, managing resources, processes, and meaning.

Knowledge and learning theories provide further insights. In particular, applying organizational memory concepts seems fruitful. For example, Moorman and Miner (1998) consider the effect of procedural and declarative memory on improvization where improvization represents one form of creative activity in product development teams. Many novel designs consist of a recombination of existing parts, processes, and routines, that is, they result from improvization based on a recombination of knowledge stored in memory.

6. *Critical Views on Innovation*

Lately, critical views questioning the generally assumed adaptive capacity of innovation have emerged. For instance, von Braun (1997) writes that increased R&D spending in OECD countries has not necessarily led to progress, but simply to change. According to him some ancient wind-powered drainage systems may be characterized as more progressive or advanced than today's diesel or electrically-driven pumps in regard to efficient energy utilization. He especially draws attention to the *Acceleration Trap* and *R&D Spiral*. While his analyses are somewhat general, it is interesting to read that 'it proved difficult, if not impossible to discover a positive relationship between R&D growth and sales growth. This held true even if one assumed a delayed effect of R&D spending increase on sales growth' (von Braun 1997). Contrary to the generally portrayed positive image of accelerating product development and then managing product releases carefully, von Brown points out that the relationship between accelerated product development and shortened product life cycles is highly complex in competitive environments. Von Braun suggests unanticipated negative impacts on overall organizational revenue and survival and finishes his book with recommendations on how to avoid falling into the acceleration trap.

Innovation, Theory of

This article draws on the model of the diffusion of innovations in order to understand how social change occurs at the microlevel. Since the early 1940s, a large set of social scientists have investigated how new ideas, often technological in nature, spread among various types of audiences. Diffusion research provides improved understanding of technological determinism, defined as a belief that technology causes social changes in a system. The diffusion process also illuminates the social process of social determinism, defined as a belief that social forces like government regulations, social values, and human interaction shape technologies through a process of social construction. Research on the diffusion process shows the essentially social nature of the adoption of new ideas. Innovations spread in a population through a process of people talking to others. Such interpersonal communication facilitates a wide sharing of the meanings of a new idea, often leading to its adoption and use by the members of a system, but sometimes resulting in rejection of the innovation.

Diffusion is the process by which an innovation is communicated through certain channels over time among the members of a social system (Rogers 1995). Diffusion is a special type of communication process concerned with the spread of new ideas, messages that necessarily represent a high degree of uncertainty to the individuals involved. The diffusion of innovations has been studied by sociologists, political scientists, anthropologists, social psychologists, economists, and communication scholars, and by researchers in public health, education, business management, marketing, and other fields.

For instance, anthropologists might study the consequences of a technological innovation on the culture of its users (Pelto 1973). Political scientists investigate the process through which new government programs and policies spread among nations, states, or cities (Walker 1966). Marketing scholars explore how a new product or service is sold to customers by business companies (Moore 1991). Communication scholars study the diffusion of a major news event like the Challenger disaster or a presidential assassination (Deutschmann and Danielson 1960). These varied fields share a common conceptual model of the diffusion of innovations. Few other research topics have received such multidisciplinary attention as has the diffusion of innovations (Rogers 1995).

1. Perceptions of Innovations

An innovation is defined as an idea, practice, or object that is perceived as new by an individual or other unit of adoption. This definition is very broad, in that almost any kind of new idea, ranging from a new medical drug, to a new food, to the Internet, can be perceived by the members of a social system as an innovation. Most innovations that have been investigated in the some 5,000 diffusion studies to date are technological in nature.

The definition of an innovation as an idea perceived as new is consistent with the theoretical perspectives of W. I. Thomas and George Herbert Mead of the

Chicago School, which flourished in the early decades of the twentieth century. Thomas's dictum, that a situation is real to an individual if it is so perceived, suggested that perceptions count in understanding human behavior change. How an innovation is perceived on five dimensions determines its rate of adoption (as discussed later). The symbolic interactionist perspective based on Mead's theory is also involved in the diffusion of innovations model. Initially, individuals perceive an innovation with a high degree of uncertainty; they want to know how it works, whether it is safe or risky to use, where to obtain it, and its advantages and disadvantages. These uncertainties are gradually overcome as an individual obtains technical information, subjective impressions, and social support concerning the new idea.

One or more individuals in a system must venture first in adopting a new idea. These innovators are open to taking risks, are oriented outside of their local system, and have sufficient resources so that the uncertainty of the innovation is not an important barrier to its adoption. When the innovators in a system adopt a new idea, they create widespread awareness–knowledge of it, although most members of the system continue to doubt its validity until the early adopters (who adopt following the innovators), including many opinion leaders in the system, begin using the new idea. At this point, the norms of the system change, so as to support adoption of the innovation. Gradually, once a critical mass is reached in the rate of adoption of an innovation, more and more individuals adopt the new idea. This diffusion process occurs over time as those who have already adopted talk about the innovation with other individuals who adopt, and who then tell yet others about the new idea. Subjective opinions of the innovation are passed via word-of-mouth channels, as individuals who have adopted tell potential adopters about the new idea.

2. *Where Innovations Come From*

A distinction should be made between innovation and invention, defined as the process in which a new idea is discovered or created. In contrast, innovation occurs when a new idea is adopted or rejected. So invention and innovation are two different processes, although both deal with a new idea (Rogers 1995, p. 135).

An innovation, especially a technological innovation, results from a process in which a need or problem is identified, research is conducted to invent a solution, and this invention is then developed and commercialized into a product or service that is sold in the marketplace. Development of an innovation is the process of putting a new idea in a form that is expected to meet the needs of an audience of potential adopters. So the research and development process represents a transformation of an invention into a form that will be more acceptable to potential adopters.

A technology is information that is put into use in order to carry out some task (Eveland 1986). Technology transfer is the exchange of technical information between the R&D workers who create a technological innovation and the users of the new idea. Investigations and experience to date suggest that technology transfer is very difficult; many attempts at such transfer fail. A well-known case of failed technology transfer is the attempted conversion of technological innovations like the mouse, bit-mapped display, icons, and the personal computer (that is, a computer designed to be used by an individual) from the Xerox Corporation's R&D center in California into a marketable product. Instead, Apple Computer marketed these technologies as the Apple Macintosh in 1984. Appropriately, the book reporting this case is entitled *Fumbling the Future* (Smith and Alexander 1988).

Why is technology transfer so difficult? One reason is because the R&D workers who invent or develop the technological innovation perceive that it is so advantageous that it will diffuse with little effort. Such overconfidence is seldom justified. The creators of the technology are usually technical experts who fail to perceive how their customers will regard the innovation (Moore 1991). Seldom do technological innovations diffuse themselves; usually an organized effort is needed to secure the adoption of the new idea. After the critical mass is reached in the diffusion process for the new idea, however, further diffusion may be self-sustaining.

3. *Perceived Attributes of Innovations*

The rate of adoption is the relative speed with which an innovation is adopted by members of a social system. The rate of adoption is usually measured as the number of members of the system that adopt the innovation in a given time period. Certain innovations diffuse relatively slower, and other innovations diffuse faster. Why do certain innovations spread more quickly than others? The main characteristics which determine an innovation's rate of adoption are: (a) relative advantage, (b) compatibility (c) complexity, (d) trialability, and (e) observability.

3.1 *Relative advantage*

Relative advantage is the degree to which an innovation is perceived as better than the idea it supersedes. Relative advantage may be perceived in economic terms, or as social prestige, convenience, and satisfaction. Whether an innovation has a great deal of objective advantage is not so important in determining its rate of adoption as whether an individual perceives the innovation as advantageous. The greater the perceived relative advantage of an innovation, the more rapid its rate of adoption.

3.2 Compatibility

Compatibility is the degree to which an innovation is perceived as consistent with the existing values, past experiences, and needs of potential adopters. If an idea is perceived as being incompatible with the values and norms of a social system, it will not be adopted rapidly.

3.3 Complexity

Complexity is the degree to which an innovation is perceived as difficult to understand and put into use. Certain innovations are easily understood by the members of a social system. Others are more complicated and will be adopted more slowly.

3.4 Trialability

Trialability is the degree to which an innovation can be experimented with on a limited basis. Innovations that are divisible for trial represent less uncertainty to the individual, who can learn by trying out the new idea. Such trial often encourages full-scale adoption of the innovation. An early and important study of the diffusion of hybrid seed corn among Iowa farmers found that almost everyone adopted the seed corn after trying out the innovation on a few acres; several years of trial were required for most individuals before they adopted the hybrid seed on 100 percent of their corn acreage (Ryan and Gross 1943).

3.5 Observability

Observability is the degree to which the results of an innovation are visible to others. The visibility of an innovation stimulates peer discussion of the new idea, and thus more rapid adoption.

Of these five perceived attributes of innovations, relative advantage and compatibility have been found to be most important in determining the rate of adoption of an innovation. However, for certain innovations, like consumer electronics products, perceived complexity may be very important.

The diffusion of the Internet has been exceedingly rapid. From 1990 to 2000, the number of individuals adopting the Internet in North America rose from approximately five million to 200 million (some 70 percent of all US households). During the late 1990s, the rate of adoption of the Internet also reached critical mass in Asia, where the diffusion of the Internet reached about 200 million users by 2000. Perhaps the Internet has diffused more rapidly than any other innovation in the history of humankind.

Why has the Internet diffused so rapidly? The idea of computer networking began in 1969, and required 20 years (until 1989) before reaching critical mass. During this period, many unconnected computer networks arose: ARPANET, BITNET, NSFNET, HPNET, and others. The Internet provides a network of interconnected computer networks which allows an individual to communicate with many others at great distances at rapid speed for a very low cost. This 'faster, better, quicker' quality of the Internet leads to a high degree of perceived relative advantage. This innovation is also compatible with the previous idea of writing letters and using computers, so Internet use did not demand learning many new skills. Where the Internet has been incompatible with a system's values, such as in France, where the English language dominance of the Internet and the World Wide Web is incompatible with French values concerning their language and culture, the rate of adoption of the Internet is relatively slow.

4. Preventive Innovations

Certain types of innovations, even though they might be beneficial for society, diffuse relatively slowly. For instance, preventive innovations are new ideas that are adopted in order to avoid some unwanted future consequences. Because the advantages of preventive innovations are uncertain and delayed in time, their rate of adoption is particularly slow. Consider a preventive innovation like HIV/AIDS prevention. Adoption of a preventive innovation like 'safe sex' may help avoid becoming infected with HIV at some future time. But the individual might not have contracted the virus even without adopting safe sex. The rewards of adoption are delayed in time and uncertain as to whether adoption of the innovation was really needed. The unwanted event to be avoided is a nonevent, the absence of an unwelcome situation that otherwise might have happened. Such nonevents are difficult to count. Examples are noninfection with HIV, births averted by adopting family planning methods, and so forth. These behavior changes are low in visibility and difficult for individuals to perceive.

Taboo innovations, defined as new ideas that are perceived as extremely private and personal in nature (Rogers 1995, p. 237), are also difficult to diffuse. For example, national governments in many countries have launched health campaigns to diffuse condom use for the prevention of unwanted births and for HIV/AIDS prevention. In many cultures, peer discussion of condoms is taboo, and so the rate of adoption of this innovation is relatively slow. The taboo nature of certain innovations may be overcome by the use of humor, or by other strategies.

5. The Social System

A social system is defined as a set of interrelated units that are engaged in joint problem solving to accomplish a common goal. A social system may be

composed of units that are individuals, informal groups, organizations, and/or other subsystems. The social system's norms, the established behavior patterns for the members of a social system, have been found to affect the rate of diffusion of an innovation. When the new idea is introduced in the system, the norms may initially be unfavorable. But after opinion leaders, individuals able to influence informally other individuals' attitudes or overt behavior in a desired way with relative frequency, adopt, a 'tipping point' occurs, and the system's norms then encourage further diffusion.

A critical mass is the point at which enough individuals have adopted an innovation so that the innovation's further rate of adoption becomes self-sustaining. The critical mass is one reason why, after a relatively slow start (20 years in the case of the Internet), the rate of adoption of an innovation in a system takes off to form the familiar S-shaped curve. Eventually the rate of adoption of a new idea grows more slowly, and levels off, as fewer and fewer individuals remain to adopt.

Some social systems are characterized by a rapid rate of adoption of technological innovations. An example is a technopolis (technology city) like Silicon Valley in Northern California; Austin, Texas; Seattle; Tsukuba, Japan; Cambridge, UK; and Bangalore and Hyderabad in India. These technology cities are centers for the R&D to produce technological innovations, and flourish economically because of the vast wealth produced by high-tech spin-off companies. A spin-off is a new company that is formed by individuals who were former employees of a parent organization, and a core technology that is transferred from a parent organization. Spin-offs are a means of technology transfer, particularly in such high-technology industries as computers, biotechnology, and Internet-related companies. Each spin-off company uses a technological innovation as its entry ticket into a high-technology industry. If this technology can be commercialized into an innovative product that diffuses rapidly in the marketplace, the new company may expand rapidly, making its founders very wealthy.

An analysis of the economic growth by metropolitan regions in the USA during the 1990s showed that 70 percent of such growth was explained by the rise of high-tech spin-off companies, which in turn was related to the presence of research universities or other R&D facilities (Devol 1999). Thus technological innovation is the key factor in economic development.

Institutional Economic Thought

1. Introduction

As the term suggests, 'institutional economics' addresses the nature and role of social institutions in economic life. Such institutions include the firm, the state, money, property, and the family. Institutional economists have been concerned with explaining the nature and origin of these institutions, the reasons for their existence and persistence, and the ways in which they can improve economic efficiency. Other important issues faced by institutional economists include the understanding of the dynamics of institutional change, the relationship between institutions, culture and technology, and the comparative efficiency of different institutions in different cultures or contexts.

In fact, the term 'institutional economics' appeared twice in the twentieth century, each time to cover a broad and distinct stream of economic thought. However, the methodological approaches involved in the two streams are quite different.

The more recent and more familiar usage dates from Oliver Williamson (1975). He coined the term 'new institutional economics' to refer to his seminal transaction cost analysis of the nature and structure of the firm. By the end of the century, the term 'new institutional economics' was in widespread use and was associated with a vast literature. Nobel prizes were given to 'new' institutional economists Ronald Coase in 1991, and Robert Fogel and Douglass North in 1993. Coase had developed the original transaction cost concept in 1937 and was an important influence

upon Williamson. Fogel and North had developed quantitative and other methods to analyze institutional change in economic history. Other leading names associated with the 'new' institutional economics are Masahiko Aoki, Mancur Olson, and Richard Posner. There are now prominent economics textbooks dominated by 'new institutionalist' thinking such as those by Paul Milgrom and John Roberts (1992), Andrew Schotter (1994), and Eirik Furubotn and Rudolph Richter (1997).

The unifying project in the 'new institutional economics' is to explain the existence of political, legal, or social institutions by reference to a model of given, individual behavior, tracing out its consequences in terms of human interactions.

Outside economics, the term 'new institutionalism' is used in different and sometimes confusing ways. In particular there is a approach described as 'new institutionalism' in organizational analysis, associated with names such as James March, Walter Powell, and Paul DiMaggio. The methodology and assumptions involved in their works are quite different from those of the 'new institutional economics.'

The original term 'institutional economics' emanates from Walton Hamilton in an address to the American Economic Association in 1918. The 'old' American institutional economics was much influenced by the nineteenth-century German historical school, which emphasized the role of institutions in the economy and stressed that economic analysis had to take account of historically specific circumstances.

The 'old' institutionalism actually became dominant in economics departments in American academia just after the First World War. Seven out of the 20 presidents of the American Economic Association in the years 1924–43 were declared institutionalists: namely Wesley Mitchell, Thomas S. Adams, John Maurice Clark, Frederick C. Mills, Sumner H. Slichter, Edwin G. Nourse, and Albert B. Wolfe. Furthermore, the influence of the 'old' institutionalism persisted for some time even after the Second World War. At least eight institutionalists have been elected President of the American Economic Association since 1945: Calvin B. Hoover, Simon Kuznets, Edwin E. Witte, Morris Copeland, George W. Stocking, Arthur F. Burns, Joseph Spengler, and John Kenneth Galbraith. Elected sympathizers included Frank Knight, Kenneth Boulding, and Robert A. Gordon. In addition, the 'old' institutionalists Simon Kuznets and Gunnar Myrdal received Nobel Prizes in 1971 and 1974, respectively.

Other schools of thought resemble the 'old' institutional economics. For example, in the 1960s and 1970s much of the economics in Cambridge, UK had a strong institutionalist flavor, particularly in the works of Nicholas Kaldor and Joan Robinson. The more recent work of Robert Boyer, Michel Aglietta, and other members of the French *régulation* school also has strong institutionalist affinities.

A prominent and unifying theme of the 'old' institutionalism is that economic analysis had to be grounded on the specific cultural and economic circumstances of each case. In particular, it is held that individual motives and behavior are often molded by such circumstances, including the institutions involved. This contrast with the 'new' institutionalism will be discussed in greater detail below.

Characterizations of the 'old' institutionalism as purely descriptive or antitheoretical do not bear up to close scrutiny. In the writings of Veblen, Commons, Mitchell, Clark, and others there was an emphasis on the importance of theoretical explanation and theoretical development. Whatever their limitations, the early institutionalists addressed crucial theoretical issues. Some of these are discussed in Sect. 3.

Nevertheless, ever since Veblen there has been a failure of the 'old' institutionalists to agree upon, let alone develop, a systematic theoretical core. The 'old' American institutionalism bequeathed no integrated theoretical system of the stature or scope of that of Karl Marx, Alfred Marshall, Léon Walras, or Vilfredo Pareto. The reasons for this failure cannot be discussed here, save to note that it was not because of a naive and unsustainable belief that economics can proceed with data alone, and without any theory. Although several 'old' institutionalists put their faith in data, they all retained some degree of belief in the importance of an ongoing theoretical project.

The primary reasons for the failure of institutionalism lie elsewhere. In particular, the old institutionalism was partially disabled by a combined result of the profound shifts in social science in the 1910–40 period and of the rise of a mathematical style of neoclassical economics in the depression-stricken 1930s. Behaviorist psychology and positivist philosophy displaced the instinct psychology and pragmatist philosophy upon which the early institutionalism had been built. With their use of formal techniques, mathematical economists caught the imagination of both theorists and policy-makers. In comparison, institutionalism was regarded as technically less rigorous, and thereby inferior (Hodgson 1999).

2. *The Essential Distinction Between the 'Old' and the 'New' Institutional Economics*

What is the essential difference between the 'old' and the 'new' institutional economics? Answering this question is made more difficult because there is no unanimity, even among its adherents, as to what is precisely to be included in the 'new' variety. Furthermore, within both the 'new' and the 'old' institutionalism there are differences of view concerning policy matters, such as the place and role of markets. Nevertheless, an answer to this question is possible if we focus on the common theoretical core of some of

the most prominent and influential 'new' institutionalist writings, such as by Douglass North, Richard Posner, Andrew Schotter, and Oliver Williamson. Despite analytical and policy differences, there are some common presumptions behind all their works.

Examining these, it is clear that the characteristic 'new' institutionalist project is the attempt to explain the emergence of institutions, such as the firm or the state, by reference to a model of rational individual behavior, tracing out the unintended consequences in terms of human interactions. An initial, institution-free, 'state of nature' is assumed. The explanatory movement is from individuals to institutions, taking individuals as given. This explanatory approach is often described as 'methodological individualism' (Hodgson 1988).

A much earlier precedent exists for work along these lines. Towards the end of the nineteenth century, the Austrian economist Carl Menger considered the nature and origin of social institutions such as money. He is thus recognized as one of the early forerunners of the 'new' institutional economics. Menger attacked a notion attributed to the German historical school, that institutions could be explained by examining historical data alone.

Menger saw the institution of money as emanating in an undesigned manner from the communications and interactions of individual agents. Traders look for a convenient and frequently exchanged commodity to use in their exchanges with others. Once such regularities become prominent, a circular process of institutional self-reinforcement takes place. Emerging to overcome the difficulties of barter, money is chosen because it is convenient, and it is convenient because it is chosen.

Apart from the emergence of money, other examples in this literature inspired by Menger include driving on one side of the road, and traffic conventions at road junctions. For example, once the majority of car drivers stick to the right-hand side of the road, it is clearly rational for all drivers to follow the same rule. Accordingly, the emergent convention is reinforced and institutionalized by imitation, and by efficient use of the available information. The role of information in signaling information to actors is emphasized in this approach. This important core theme of an action–information loop is clearly evident, for example, in North's (1981) theory of the development of capitalism, Williamson's (1975, 1985) transaction cost analysis of the firm, and Schotter's (1981) game-theoretic analysis of institutions. This core idea is valuable and important.

However, despite its temporal adjective, the 'new' institutionalism is built upon some very old assumptions concerning the human agent, derived from the individualism of the Enlightenment. In this 300-year tradition, a key idea is the notion that the individual can, in a sense, be 'taken for granted.' Accordingly, the individual is taken as the elemental building block in economic theory. Strictly, it is not a question of whether or not a theorist is found to admit that individuals—or their wants and preferences—are changed by circumstances. Indeed, many economists admit that individuals might so be changed. What is crucial is that the individualistic economist assumes, *for the purposes of economic enquiry*, that individuals and their preference functions should be taken as given. Thus the demarcating criterion is not the matter of individual malleability *per se*, but the willingness, or otherwise, to consider this issue as an important or legitimate matter for economic analysis. The commonplace statement by mainstream economists that tastes and preferences are not the *explananda* of economics thus derives directly from the individualist tradition. Likewise, the conception of economics as 'the science of choice' takes the choosing individual and her preference functions as given. Unlike the 'old' institutionalism, the 'new' institutionalism has also taken such individualistic presuppositions on board.

By contrast, a common thread in the literature of 'old' institutionalism, from Veblen through Commons and Mitchell, to Myrdal and Galbraith, is the idea that in economic analysis the individual should not always be taken as given. The general use of given preference functions to model individuals and their behavior is rejected by these institutionalists. As well as individuals interacting to form institutions, individual purposes or preferences are molded by socioeconomic conditions. The individual is both a producer and a product of her circumstances.

Mitchell (1937) argued that the evolution of money cannot be understood simply in terms of cost reduction and individual convenience. He maintained that money 'stamps its pattern upon wayward human nature, makes us all react in standard ways to the standard stimuli it offers, and affects our very ideals of what is good, beautiful and true' (Mitchell 1937, p. 371). Accordingly, the evolution of money changed the mentality, preferences, and way of thinking of individuals themselves. This does not mean that Menger's core idea of an action–information loop is wrong, but that it has to be supplemented by an account of how institutions can change individual perceptions and preferences.

Such ideas pervade and endure through the 'old' institutional economics. They were emphasized by Veblen and Commons. They persist in the 'old' institutionalist tradition, throughout the twentieth century. For instance, writing as an 'old' institutionalist, John Kenneth Galbraith (1969, p. 152) insisted that individual 'wants can be synthesized by advertising, catalyzed by salesmanship, and shaped by the discreet manipulations of the persuaders.' Again we find an emphasis on the malleability of preferences and an abandonment of the notion of a fixed and given individual.

The 'old' institutional economics is thus distinguished from both mainstream economics and

the 'new institutional economics' precisely for the reason that it does not assume an individual with given purposes or preference functions. Instead of a bedrock of given individuals, presumed by the mainstream and new institutional economics, the old institutionalism holds to the idea of interactive and partially malleable agents, mutually entwined in a web of partially durable and self-reinforcing institutions. This distinction holds despite important theoretical and policy differences within both the new and the old institutionalist camps.

3. *The Theoretical Legacy of the 'Old' Institutional Economics*

Although it never provided a systematic theoretical legacy, the achievements and influence of the 'old' institutional economics have been considerable (Rutherford 1994, Yonay 1998).

For example, Veblen (1899, 1919) was the first social scientist to attempt to develop a theory of economic and institutional evolution along essentially Darwinian lines (Hodgson 1993). Veblen's work shares common features with the much later attempts by economists to use evolutionary metaphors from biology by Armen Alchian, Kenneth Boulding, Friedrich Hayek, and Richard Nelson and Sidney Winter. However, Veblen never regarded evolutionary processes as necessarily optimal or progressive. Although he did not use the term, his writings are replete with examples of path dependent evolution, almost a century before that concept became fashionable (Hodgson 1993).

Veblen's writings are brimming with ideas, many of which have subsequently been taken up by others. In the 1970s the Cambridge economist Joan Robinson recognized the importance of his theoretical contribution to the critique of standard capital theory. Veblen (1919, pp. 185–200) criticized the conflation of 'capital goods' with 'capital.' He rejected the 'factors of production' approach in its entirety, seeing production as much to do with 'the accumulated, habitual knowledge of the ways and means involved … the outcome of long experience and experimentation' (Veblen 1919, pp. 185–6). Veblen's emphasis on the role of knowledge and learning in economic growth is perhaps, simultaneously, his most important and most neglected theoretical contribution.

In his *Theory of Business Enterprise* (1904), Veblen discussed not only the conflict between a pecuniary and an industrial culture but also its manifestation in the separation of ownership and control, made famous later by Adolph Berle and Gardiner Means in their highly influential book on *The Modern Corporation and Private Property* (1932). Furthermore, in the same volume, Veblen (1904, pp. 46–8) hinted at the idea of transaction costs, long before Coase and Williamson.

A number of commentators have perceived similarities between the works of Veblen and John Maynard Keynes, and their joint parallels in President Roosevelt's New Deal policies. Writing after the Second World War, James Duesenberry in his *Income, Saving and the Theory of Consumer Behavior* (1949) accepted Veblen's influence in building a theory of the consumption function upon habitual behavior and Harvey Leibenstein also acknowledged the founder of institutionalism with his 'Veblen effects' in the theory of consumer behavior.

John Commons (1924, 1934) has been acknowledged as a major influence on the behavioral economics of Herbert Simon and the 'new' institutionalism of Oliver Williamson (1975, 1985). Overall, Commons made a major theoretical contribution, including the development of the concept of asymmetric information in contracts (Commons 1924). Indeed, Commons pioneered the whole modern research program in economics and law. Relevant modern ideas, such as the notion that the money supply is endogenous rather than exogenous, have also been credited to Commons. Commons and his students were also highly influential in the development of the subdiscipline of labor economics.

Nobel Laureate Herbert Simon's idea of bounded rationality was also prefigured in the writings of the 'old' institutionalist John Maurice Clark (Rutherford 1994). Clark influenced other leading economic theorists, notably Frank Knight. In fact, Clark supervised the production of Knight's classic work *Risk, Uncertainty and Profit* (1921).

Clark also shared responsibility for another important theoretical development. In a paper published in the *Journal of Political Economy* in 1917, he was one of the first to elaborate the idea of the interaction of the multiplier and the accelerator, seeing it as a driving mechanism in the generation of economic fluctuations. Paul Samuelsonand others later replicated this idea.

The Nobel Laureate Milton Friedman was a student of Mitchell. Friedman acknowledged the influence of both Veblen and Mitchell on business cycle theory, and even translated some of Mitchell's theoretical work into a mathematical model.

There are several important links between institutionalism and the development of Keynesianism. One was the innovation of national income accounting, in which the work of Mitchell played a vital part. Inheriting the German historical school view of the economy as an organic whole, institutionalism thereby developed and sanctioned the conceptualization and measurement of economic aggregates. The theoretical and empirical work involved here was of major importance in the development of twentieth-century economics.

Mitchell was thus one of the fathers of modern macroeconomics. His work is notable for its implicit antireductionist thrust and its consequent contribution to the development of Keynesianism. In the 1920s and 1930s, Mitchell and his colleagues in the National Bureau for Economic Research played a vital role in

the development of national income accounting, suggesting that aggregate, macroeconomic phenomena have an ontological and empirical legitimacy. Through the development of national income accounting, the work of Mitchell and his colleagues influenced and inspired the macroeconomics of Keynes.

The 'old' institutionalists also developed a number of theories of pricing behavior in imperfectly competitive markets (Tool 1991). Traces of the surviving influence of 'old' institutionalist ideas are found in many other areas of theoretical and applied economics.

4. *Development of the 'New' Institutional Economics*

Since the coining of the term 'new institutional economics' in 1975, this school of thought has been responsible for an enormous amount of valuable theoretical and empirical work on the nature and development of economic institutions. Institutions that were previously regarded as mysterious 'black boxes' are now opened up and examined in forensic detail. Not only have the 'new' institutionalists put institutions back on the agenda, they have prompted important and stimulating theoretical debates. With important developments such as transaction cost analysis and the economics of property rights, important insights have been gained. The face of economics as a whole has been transformed.

However, within the 'new' institutional economics there are not only important differences of approach, there are also some common and fundamental problems. In this section it is argued that attempts to explain the origin and sustenance of institutions on the basis of the assumption of given individuals have internal flaws and inconsistencies. Accordingly, attempts to explain institutions in this way may have to be abandoned. The door is opened to a more open-ended and evolutionary approach, redolent of the earlier institutionalists.

In broad terms, two opposite types of error are possible. 'Cultural determinists' place too much stress on the molding of individuals by institutions. Some members of the 'old' institutionalist school, notably Clarence Ayres, committed this error. Such 'over-socialized' views of human behavior have been widely criticized. At the opposite end of the spectrum, the 'new institutional economics' gives no more than weak stress to the processes of institutional conditioning, and focuses primarily on the emergence of institutions out of the interactions of given individuals. This section explores the problems that may arise if exclusive stress is put on the latter direction of causality.

The distinctive 'new' institutionalist project has been identified as the attempt to explain the existence of institutions by reference to a given model of individual behavior, and on the basis of an initial institution-free 'state of nature.' The procedure is to start with given individuals and to move on to explain institutions.

Admittedly, substantial heuristic and other insights have been gained on the basis of this approach. The main problem is the incompleteness of the research program in its attempt to provide a general theory of the emergence and evolution of institutions. Some moves towards an 'evolutionary' approach to solving this problem are addressed at the end of this section.

Alexander Field (1979) has exposed a key problem in the new institutionalist project. In trying to explain the origin of social institutions from given individuals alone, the 'new' institutional economics has to presume a social framework governing their interaction. In any original, hypothetical 'state of nature' from which institutions are seen to have emerged, a number of rules and cultural and social norms are already presumed. No 'thought experiment' involving an institution-free 'state of nature' has yet been postulated without them. For example, in game theoretic presentations of the emergence of institutions or norms (Schotter 1981), take the individual 'for granted' as an agent unambiguously maximizing his or her expected payoff. Yet there can be no games without prior rules, and game theory can never explain the elemental rules themselves. Even in a sequence of repeated games, or of games about other (nested) games, at least one game or metagame, with a structure and payoffs, must be assumed at the outset. Any such attempt to deal with history in terms of sequential or nested games is thus involved in a problem of infinite regress. As another example, Williamson's transaction cost theory of the firm takes its original state of nature as the market. He writes that 'in the beginning there were markets' (Williamson 1975, p. 20). This starting point is characteristic of his approach. From this original context, some individuals go on to create firms and hierarchies. He argues that these endure if they involve lower transaction costs. However, the market itself is a social institution. The market involves social norms, customs, instituted exchange relations, and—sometimes consciously organised—information networks that themselves have to be explained (Hodgson 1988). Market and exchange relations themselves involve complex rules. In particular, the institution of private property itself requires explanation. Markets are not an institution-free beginning. Hence Williamson fails to explain the firm from an institution-free 'state of nature.' In a type of comparative static approach, he assumes one institutional framework and derives another. Accordingly, the 'new' institutionalist project of starting simply from given individuals is abandoned.

There are good reasons why such a starting point is generally misconceived. Before an individual may choose, he or she requires a conceptual framework to

make sense of the world. The reception of information requires a paradigm or cognitive frame to process and make sense of it. Further, our interaction with others requires the use of the institution of language. We cannot understand the world without concepts and we cannot communicate without some form of language. As the 'old' institutionalists argue, the transmission of information from institution to individual is impossible without a coextensive process of *enculturation*, in which the individual learns the meaning and value of the sense-data that is communicated. Any communication of information *always and necessarily* involves such a process of enculturation. Information cannot be received unless the individual has been enculturated to some degree, through prior engagement with institutions. Communication requires an institutionalized individual.

In the 'old' institutional economics, cognition and habit have a central place. Knowledge and learning are stressed. There is also an insistence that the perception of information is not possible without prior habits of thought to endow it with meaning. Without such habits, agents cannot perceive or make use of the data received by their senses. Habits thus have a crucial cognitive role: 'All facts of observation are necessarily seen in the light of the observer's habits of thought' (Veblen 1914, p. 53). Such habits are acquired through involvement in institutions.

The central 'new' institutionalist project of explaining institutions from individuals alone is thus misconceived. The problem of infinite regress identified here undermines any 'new institutionalist' claim that the explanation of the emergence of institutions can start from some kind of original, institution-free ensemble of (rational) individuals, in which there is supposedly no rule or institution to be explained. At the very minimum, 'new' institutionalist stories of the development of institutions depend on interpersonal communication of information. The communication of information itself requires shared concepts, conventions, rules, routines, and norms. These, in turn, have to be explained.

What is being contested here is the possibility of using given individuals as the institution-free starting point in the explanation. It is not possible to understand how institutions are constructed without seeing individuals as embedded in a culture made up of many interacting institutions. Institutions not only constrain but also influence individuals. Accordingly, if there are institutional influences on individuals and their goals, then these are worthy of explanation. In turn, the explanation of those may be in terms of other purposeful individuals. But where should the analysis stop The purposes of an individual could be partly explained by relevant institutions, culture, and so on. These, in their turn, would be partly explained in terms of other individuals. But these individual purposes and actions could then be partly explained by cultural and institutional factors, and so on, indefinitely.

We are involved in an apparently infinite regress, similar to the puzzle 'which came first, the chicken or the egg?' Such an analysis never reaches an end point. It is simply arbitrary to stop at one particular stage in the explanation and say 'it is all reducible to individuals' just as much as to say it is 'all social and institutional.' The key point is that in this infinite regress, neither individual nor institutional factors have complete explanatory primacy. The idea that all explanations have ultimately to be in terms of individuals (or institutions) alone is thus unfounded.

We have seen that the new institutionalist project to explain the emergence of institutions on the basis of given individuals runs into difficulties, particularly with regard to the conceptualization of the initial state from which institutions are supposed to emerge. This does not mean that all 'new' institutionalist research is without value, but it indicates that the starting point of explanations cannot be institution-free: the main project has to be reformulated as just a part of a wider theoretical analysis of institutions.

In a major work, Masahiko Aoki (in press) recognizes the seriousness of the problem of infinite regress within the 'new' institutional economics. He attempts to deal with this problem both by taking individuals as given and assuming a historically-given bedrock of institutions. The focus in this approach is then on the further development of those institutions. This marks an important watershed in the development of the 'new' institutionalism. At least in strict terms, methodological individualism is abandoned. No longer is an attempt made to explain the emergence and evolution of institutions in terms of individuals alone. He adds a given institutional context to the story.

Aoki's work can be seen as a partial step in the direction of a fully-fledged evolutionary account of the growth and development of institutions. This would stress the evolution of institutions, in part from other institutions, rather than from a hypothetical, institution-free 'state of nature.' What is required is a theory of process, evolution, and learning, rather than a theory that proceeds from an original, institution-free, 'state of nature' that is both artificial and untenable.

The 'comparative statics' character of many 'new' institutionalist explanations is obvious. However, one of the reasons for the rise of 'evolutionary' thinking in economics since the early 1980s has been an attempt to break the constraints of this mode of explanation with its two fixed end points. Because there is no answer to the chicken-or-egg question, the question itself has to be changed. The question should no longer be 'which came first?' but 'what processes explain the development of both of them?' Again this implies a movement away from comparative statics and towards a more evolutionary and open-ended framework of analysis. Some moves in this direction by two prominent 'new' institutionalists have already led to a degree of convergence with the evolutionary and open-ended

ideas of the 'old' institutionalists. This is apparent, for example, in the later writings of North (1990).

Such evolutionary explanations involve the search for 'a theory of the process of consecutive change, realized to be self-continuing or self-propagating and to have no final term' (Veblen 1919, p. 37). Emphatically, abandoning the attempt to explain all institutions in terms of given individuals does not mean the abandonment of theoretical explanation. Instead, the origins and development of organizations and institutions are seen as an evolutionary process. Today, there is a substantial amount of work going on in this area, with extensive use being made of evolutionary metaphors taken from biology.

5. *A Research Agenda for Institutional Economics*

Today there are lively and growing research activities within both the 'new' and the 'old' institutional economics (Hodgson et al. 1994). Substantial benefits can be anticipated from an intensive dialog between these two schools. The 'new' institutionalists can learn from the evolutionary, historical, culturally-grounded, and technologically-oriented studies of the 'old' institutionalists. The 'old' institutionalists can usefully devote more attention to the development of a systematic institutional approach to economic theory. In this they can learn from the achievements and mistakes of the 'new' institutional economics.

The philosophical foundations of the social sciences have been shaken in recent years. Debates in philosophy and social theory have questioned many of the standard assumptions and approaches. The future development of institutional economics must address some of these underling philosophical problems, posed by philosophical realists on the one hand and postmodernists on the other. One of the tasks of institutional economics is to address some of the underlying philosophical issues—particularly those relating to the social ontology and nature of institutions (Searle 1995)—and bring useful insights into their work. Evolutionary thinking is once again on the ascendancy in economics (Hodgson 1993). However, the detailed development and explication of a theory of institutional evolution—a task envisaged by Veblen more than 100 years ago—still remains incomplete. One of the impediments to progress in this area is the lack of a consensus on key terms and methodological approaches. The solution to this problem lies through open and extended conversation and debate between the different points of view involved. Only then will it be possible to establish a sufficient consensus on key definitions and terms.

The promise for the future development of institutional economics lies in a fully interdisciplinary approach, using insights from other disciplines such as philosophy, sociology, anthropology, geography, history, psychology, and biology. Such insights have to be woven together in a well-founded theoretical structure, using insights from both the 'old' and the new institutional economics.

Institutional Investors

For organizational and management scholars interested in the political dynamics of corporations, the rise of institutional investors in the second half of the twentieth century has provided a key focal point for the analysis of organizational change and shifts in corporate control (e.g., Useem 1996). Institutional investors are organizations such as mutual funds, hedge funds, commercial and investment banks, insurance companies, pension funds, securities companies, trusts, foundations, labor unions, colleges and universities, and corporations that take major positions in publicly traded securities, and often account for a good deal of trading volume on major securities exchanges. As an indication of the growing power of institutional investors, the percentage of US stocks that such actors own has dramatically increased from around 16 percent in 1965 to over 60 percent by the mid-1990s.

In order to shed light on how the emergence of these new, powerful actors has reshaped organizational life, researchers have employed a wide variety of research foci and approaches. Research has highlighted how institutional investors can be viewed as a social movement (Davis and Thompson 1994), corporate action is consequentially shaped by lending and other intercorporate relationships (Mintz and Schwartz 1985, Mizruchi and Stearns 1994), institutional investors may shape organizational phenomena such as research and development expenditures, corporate social performance, and CEO compensation, the hostile takeover of corporations requires a good deal of cultural work by institutional investors and other powerful stockholders (Hirsch 1986), the adoption of poison pills can protect managers from corporate raiders (Davis 1991), and how the creation of investor-relations departments has enabled corporations to better manage the demands of institutional investors (Rao and Sivakumar 1999). While this work has been very revealing, it has tended to focus primarily on issues of corporate control in the US, while neglecting questions regarding how institutional investors have contributed to the reshaping of country-specific financial activities as well as global capital formation processes.

To situate this article on institutional investors, an account is provided first of the rise of pension plans that motivated the growth of the institutional investor movement in the US. Since the majority of organizational research on institutional investors focuses on problems of corporate control, there follows a discussion of how institutional investors have been conceptualized in competing theories about corporate control and argument for more research on how institutional investors are helping to remake capital formation processes around the world.

1. The Emergence of Pensions and the Institutional Investor Movement in the US

The growth of pension plans has provided one of the most significant changes in the structure of US retirement and finance in the twentieth century—providing a foundation for the rapid growth of institutional investing in the second half of the century. The first public employer-sponsored pension plan was established by the City of New York in 1850; the first private employer-sponsored plan was created by the American Express Company in 1875. Up until World War II, however, pension coverage was sparse and the plans that did exist were not guaranteed and often ownership was not vested in the pensioned person.

A confluence of factors before and after World War II fostered the development of pensions in the US. Before World War II, the Social Security Act of 1935 boosted employment-related pension insurance by institutionalizing the idea of retirement (Dobbin 1992). Subsequently, the combination of federally mandated wartime wage controls, as well as a war-related labor shortage, facilitated the development of benefits such as deferred wages as a way for corporations to compete for scarce labor. Also, due to the high corporate tax rate during war time (peaking at over 90 percent), pension plans became more attractive to employers since contributions to such plans lowered taxable income. In addition, labor union-corporation conflict became more intense after

the war. In 1948, the National Labor Relations Board ruled that pensions were to be considered as part of wages, allowing workers to initiate legally a strike over a pension dispute. Pensions became a centerpiece for management–labor negotiations.

Despite worker–manager conflict in major industries such as autos, coal mining, and steel, the emergence of pension benefits came to be associated with a system of management that valued employee commitment to and long career tenures within single organizations. In 1950, fewer than 10 million nonagricultural workers (around 25 percent of the nonagricultural workforce) were covered by private pension plans. By 1970 more than 30 million workers (approximately 50 percent of the nonagricultural workforce) were covered. As pension plans diffused and amassed a considerable amount of assets, however, the management of those assets began to change.

Up until around 1950, most pension plans were constituted as annuities and managed by insurance companies. But in the 1950s, corporate pension plans began to be managed by bank trust departments that were allowed to invest in stocks as well as bonds. At that time, insurance companies were legally limited in the extent to which they could invest in stocks. That migration of pension assets into the stock market represented a major turning point in the development of pension management as an industry. As increasing amounts of money were being directed towards the stock market, there was a corollary growth in financial intermediaries that vigorously competed for the right to manage how other people's money was to be invested in the stock market—an institutional investor movement was born.

Competition among institutional investors was largely based on performance measured by asset growth, leading to an emphasis on riskier portfolio strategies. Between 1965 and 1969, the turnover (a proxy for risk-taking) of bank managed pension portfolios rose from 13.7 percent to 25.7 percent, of internally managed portfolios from 5.5 percent to 9.6 percent, and of investment advisor managed portfolios from 27.4 percent to 55.9 percent. Corporations began to view pension assets as a profit center from which they could directly enhance their bottom line, while previously in the 1950s, pensions were viewed primarily as a way to reduce tax payments.

The shift towards viewing pension assets as a profit center led to a general restructuring of the money management industry. Bank trust departments, that had dominated pension management until the late 1960s, relied on relatively conservative investment strategies, constructing portfolios that consisted mainly of stocks of established companies that paid steady dividends. In the late 1960s, corporate pension plans began to expand beyond bank trusts, using multiple investment advisors. This effectively broke the bank trust monopoly on pension management. As a result, smaller, independent money managers, including those affiliated with mutual fund companies, became able to compete for pension dollars based on their performance record as opposed to institutional reputation and longstanding relationships.

Alongside these developments, the federal government became more involved in the protection of beneficiaries. In 1974, the Employee Retirement Income Security Act (ERISA) was enacted and the Pension Benefit Guarantee Corporation (PBGC) was created to insure qualified plans. ERISA established minimum standards for vesting, proscribed funding formulas, provided insurance for employees whose plans were terminated without adequate assets, required full disclosure of plan benefits and operations to employees, and declared that pension trustees had a fiduciary responsibility to manage pension assets with only beneficiaries in mind, not a corporation's bottom line. This federal government involvement stabilized pension practices, enabling the continued growth of pension plans while also providing more safeguards for pension beneficiaries.

Between 1945 and 1996, pension assets have grown steadily from virtually zero percent to 20 percent of all financial intermediary assets. While the growth of pensions was a critical development that facilitated the institutional investor movement, it was also supported and facilitated by broader changes in US capital formation processes. In particular, the growing legitimation of the stock market after World War II provided important momentum for a major transformation from bank lending dominated to market-based capital formation processes. Commercial banks, which had been the dominant financial actors in the US, increasingly lost their hegemonic position in the postwar era. The percentage of financial intermediary assets managed by commercial banks declined from 60 percent in 1945 to 20 percent by 1996. At the same time, new kinds of institutional investors, such as mutual funds, grew dramatically. Mutual funds began their dramatic rise in the 1980s and now constitute 14 percent of all financial intermediary assets. Hence, while the origins of the institutional investor movement are rooted in the development of pensions, the legitimation of the stock market and the concomitant shift towards market-based capital formation processes, as well as the emergence of new kinds of financial organizational forms importantly shaped the contours of that movement.

2. *The Study of Institutional Investors in Organizational Theory: The Problem of Corporate Control and other Research Possibilities*

Much of the organizational research on institutional investors has focused on the problem of corporate control, grounded in historical analyzes of the emergence and evolution of the corporate form. US Corporations emerged in the mid-nineteenth century

under government sponsorship to perform specific services such as banking and the building of railroads, turnpikes, and canals. Individually chartered public infrastructure corporations were predominant until more generalized state incorporation laws arose in the 1870s. By the turn of the twentieth century, large industrial manufacturing companies and Wall Street financiers joined forces to facilitate the broad diffusion of the corporate form (Roy 1997). This ushered in the era of 'finance capitalism' and the rise of powerful bankers such as J. P. Morgan.

Along with the birth of finance capitalism was the accelerated growth of financial intermediaries and the construction of the US field of finance. The early part of the twentieth century not only witnessed the accumulation of power by money center banks and investment bankers, but also the birth of new financial organizations such as investment and finance companies. Assets controlled by financial intermediaries grew from $19 billion in 1900 to $167 billion in 1929 and to approximately $560 billion by mid-century. It was in the first half of the 1900s that a truly national field of finance began to take shape. In the early part of the twentieth century, the field of finance was highly centralized with the most powerful actors and majority of asset flows located in New York City. This financial concentration came to be pejoratively known as the 'money trust.'

Alongside the growth and concentration of private financial intermediaries, the federal government created a central banking structure and became increasingly involved in legislating and sponsoring the formation of regulatory bodies to monitor and restrict intermediary activities. Governmental regulatory activity increased dramatically in the 1930s amid the Great Depression when explicit efforts were made to dismantle the money trust. Finance capitalism had ended.

The emergence and growth of large industrial corporations was shaped importantly by this rapidly developing capital formation infrastructure (field of finance) that supported and made possible increased corporate activity. As large-scale industrial activity became organized by the corporate form in the early part of the twentieth century, ownership became more diffuse and strategic decision-making power became vested in professional managers who had little financial stake in the firm. The publication of *The Modern Corporation and Private Property* (Berle and Means 1932) proclaimed the rise of managerial capitalism where American corporations came to be theorized as relatively autonomous entities that were unconstrained by outside owners or each other.

The shift from finance to managerial capitalism, however, was not only facilitated by the separation of ownership from control, but also the increased role of the state in capital formation processes, especially after the stock market crash of 1929 and Great Depression. Through the emergence of social redistribution programs and major war mobilization efforts, state-financing activity provided a major impetus for the creation of a stable and reliable field of financiers. In addition, a number of landmark legislative acts and finance regulatory bodies were created. For example, securities and banking legislation between 1933–35 separated commercial and investment banking and created the Securities and Exchange Commission. Also, state regulation and monitoring greatly reduced the scope and power of banks and individual intermediaries.

Up until the mid-1960s, organizational analysis had been dominated by managerial-centered theories which focused on what top executives did given certain constraints having to do with limited time and information as well as intraorganizational political dynamics. Building on Zeitlin's (1974) critique of the Berle and Means (1932) thesis that nonfinancial corporations had been freed from dependence on financial institutions, however, a number of organizational sociologists began to focus directly on corporate governance issues in the 1970s and 1980s, investigating the extent to which managerial action was indeed constrained by financial actors. In their review of the literature on corporate control, Glasberg and Schwartz (1983) argued that the notion of managerial autonomy has been challenged by four main theoretical camps: resource dependence, class cohesion, bank control, and bank hegemony.

Resource dependence theorists maintain the managerialist premise that top managers dominate corporate decision-making but challenge the notion that such autonomy is free from outside constraint. Proponents of this view argue that organizations are involved in an ongoing interdependent struggle for positional advantage, using interlocking directorates, joint ventures, mergers, diversification, and conglomeration to co-opt, internalize, or otherwise neutralize powerful external constituencies. This line of thought has been particularly prevalent in studies of interlocking directorates among financial and nonfinancial firms. The broader social theoretic imagery which emerges is conflictual and pluralistic. Scholars drawing on this theoretical orientation, therefore, tend to view institutional investors as hostile outsiders that managers need to neutralize in order to maintain relative autonomy.

Arguments drawing on class-cohesion theory, that are inspired by Marxist political economic thought, similarly accept the premise that managers are relatively free to make decisions, but claim that corporate executives comprise a unified class of actors that promote coordination and cooperation at the expense of high-powered market incentives (Davis 1991, Domhoff 1974). The orderliness of societal stratification is emphasized to counter the resource dependence conclusion that intraclass struggle best characterizes the elite strata. Recent writings in this tradition, however, have argued that elite institutional investors may be emerging as a class that controls financial flows

and corporate decision-making (Useem 1996). This revised argument seems to move class cohesion arguments closer to the pluralistic imagery of resource dependence arguments though, since institutional investors and managers are viewed as engaged in ongoing conflict over the control of corporations.

Bank-control theory, derived from twentieth-century Marxist financial capital theory, posits that banks and insurance companies, due to their centrality in controlling and allocating capital, are able to use their leverage to dictate corporate policies to serve their own interests. This approach completely rejects all theories that maintain any degree of managerial autonomy. As such, this perspective has been marginalized in organization theory. In addition, recent research has highlighted that the extent to which bank representatives have had formal positions on corporate boards of directors has decreased, indicating a waning bank influence on corporate management (Davis and Mizruchi 1999). This insight dovetails with the more general decline of bank-lending in favor of market-based capital formation processes in the US field of finance.

Bank hegemony theory may be characterized as an effort to try to synthesize bank control and class cohesion theories (Mintz and Schwartz 1985). As opposed to the overt domination proposed by bank-control theorists, power is theorized to be embedded in the relations between financial institutions and corporate producers. Hence, research affiliated with this tradition has looked primarily at direct relations between corporations and financial institutions via interlocks or lending relationships (Mizruchi and Stearns 1994) to analyze the extent to which managers are constrained by financial actors. While an underlying consonance of interest between financial and nonfinancial firms is posited, the financial sector is theorized to develop a kind of class cohesion that ultimately allows for financial institution dominance. The expression of power, however, is much more problematic and diffuse than a bank-control theorist would argue, though more coherent than predicted by class-cohesion theory (Glasberg and Schwartz 1983).

While resource dependence, class cohesion, bank control, and bank hegemony were the main perspectives used to address institutional investors and corporate control in the 1970s and early 1980s, research on these issues has since become more analytical and less overtly engaged in these broader theoretical problematics. For example, debates about the relative veracity of resource dependence approaches that envision a more pluralistic society vs. more Marxist class-cohesion arguments have been backgrounded. Nonetheless, corporate control research has continued to usefully contribute to our further understanding of the relationship of institutional investors to corporate governance and change.

One of the main limitations of this line of research, however, has been its almost sole focus on corporate control as a way to understand financial actors such as institutional investors. This has left the practice of institutional investing as well as related areas of money, banking and finance as components of a broader financial field subject to its own logic of operation woefully understudied. Since the deregulation of banking in the US in 1980, the boundaries between previously segregated financial organizational forms have begun to blur. Now insurance, commercial and investment banking, and mutual fund activities are combined under one roof. These developments call out for more detailed investigations of how financial practices and organizations are being remade as a result of these field-wide transformations.

In addition, we should also be studying how institutional investors are driving or are implicated in broader processes of social change. A first step in this direction would be to study how the activities of financial institutions and institutional investors are reshaping capital formation and corporate governance processes around the globe (Davis and Mizruchi 1999). The deregulatory 'big bang' that occurred in the US in the early 1980s subsequently has diffused to Europe and Japan and other countries around the globe. As a result of these contemporary developments, new kinds of questions have emerged having to do with whether capital formation and corporate governance processes around the globe are being remade in a way that mimics Western capitalistic countries or whether localized state–society relations exhibit more of a path-dependent quality.

As Zysman (1983) showed, the tendency towards market-based capital formation processes in England and in the US are markedly different from the more bank- and state-dominated systems in Japan, France, and Germany. Is this still the case? Recent research on Germany, France, and England indicate that those national capital formation patterns continue to persist (Mayer and Whittington 1999). We must go beyond more simplistic notions of globalization and convergence and investigate how social actors resist such convergences as well as how economy–society relations are informed by cultural logics that make the US model of finance inappropriate or unthinkable (Biggart and Guillén 1999). This may require more detailed ethnographic studies or historical research that can reveal how societal institutions are constructed locally and rooted in geographically situated meaning systems (Ventresca and Porac 2000). While there have been recent efforts to study corporate governance variation cross-nationally, we still know very little about how capital formation processes are changing in the financial systems of particular countries. There is no doubt that institutional investors are key actors in this unfolding drama.

Another important question has to do with whether the old 'money trust' is re-emerging as the boundaries between different financial organizational forms become irrelevant. The consolidation of financial

services into conglomerates has the potential to reinvigorate longstanding debates about elite class control versus pluralism, although with a global dimension. Since financial service conglomerates that are being built through mergers, acquisitions, and alliances in this era of deregulation are transnational in scope, the new, emergent money trust may not be a uniquely US phenomenon. Likewise, institutional investors are active participants in securities markets around the world and play a key role in economic development and global monetary flows. Hence, we may want to begin to study whether a new transnational class of capitalists is in the making, or at least probe how large, global investors are shaping the social organization of countries around the world.

3. Conclusion

The rise of institutional investors both in the US and around the globe is a critically important phenomenon that researchers have only just begun to investigate. While we know a good deal about how the rise of institutional investors has challenged managerial autonomy in the US, we know much less about the relationship between institutional investors and corporate governance in other, especially non-Western, countries. More generally, we know very little about how country-specific capital formation processes are changing amid the continuing globalization of financial markets and the emergence of transnational financial conglomerates. We would benefit greatly from detailed cross-national studies of how economy–society relationships may be changing as a result of these developments. Through such research, we may begin to unearth the heterogeneity of practices lumped under the category 'institutional investors' and reveal the wide variety of influences these actors have around the world.

Institutionalism

The study of political institutions has moved back into center stage in political science. Whereas only a few years ago, institutions were mostly casually mentioned in most political science research, today they are a central focus of attention. This change is not simply a change of language or the catching on of a new popular phrase or academic fad. Instead these changes represent an important development in evolution of political science theory and intellectual focus.

1. What are Institutions?

In the broadest sense, institutions are simply rules. As such, they are a foundation for all political behavior. Some are formal (as in constitutional rules) some are informal (as in cultural norms), but without institutions there could be no organized politics. Indeed absent institutions there could be no organization at

all. To understand this point, simply attempt to consider a world in which there were no rules: In this Hobbesian hell, individuals would be forced to 'invent' communication every time they encountered another individual. In this sense, then, if we study social interaction, we study institutions. This does not suggest, however, that all social scientists are 'Institutionalists.'

2. *Institutionalism*

The 'Institutionalism' specifically examines the ways in which institutions structure social and political behavior (North 1990). This burgeoning body of literature argues that policy, politics, and behavior can only be understood in the context of the institutions in which they take place. Thus, for example, Ellen Immergut argues that variations in National Health Insurance (NHI) systems are best explained by variations in national political institutions (Immergut 1992). Similarly, Bo Rothstein shows that Sweden's high union density is best explained by the 'Ghent' unemployment insurance system which gives workers powerful incentives to join Swedish unions (Rothstein 1992). Even more broadly, Douglas North suggests that the very success of Western political economic model is rooted in the peculiar institutions developed in these societies (North 1990).

The central tenet of this New Institutionalism is that institutions are not neutral to policy outcomes. As Peter Hall has suggested, 'On the one hand, the organization of policy-making affects the degree of power that any one set of actors has over policy outcomes.... On the other hand, organizational position also influences an actor's definition of his own interests...in this way, organizational factors affect both the degree of pressure an actor can bring to bear on policy and the likely direction of that pressure' (Hall 1986, p. 12).

In sum, institutions define the rules of the political game and as such they define who can play and how they play. Consequently, they ultimately can shape who wins and who loses. If politics is the study of who gets what, when and why, then institutionalists argue that institutions should be at the heart of that study.

3. *A Brief History of Institutionalism*

Institutionalism has a long established tradition among those interested in politics and political outcomes. Plato's *Republic* is a comparative study of institutions. Similarly, Aristotle's central concern in *Politics* is which kinds of political institutions will produce the best outcomes. James Madison must clearly also be seen as an early American 'Institutionalist' in that he was specifically concerned with which kinds of institutions would produce the best political outcomes and how the specific design of institutions would shape political outcomes.

Political scientists have also long been interested in institutions. Indeed, in its early years political science meant the study of political institutions (Wilson 1891). But, with some important exceptions (cf. Herring 1940, Key 1947), early political science was often more descriptive than analytical. 'Comparative politics,' in particular, consisted mostly of detailed configurative studies of different legal, administrative, and political structures (for a review and critique of this early comparative literature see Verba 1967). In the immediate postwar years a new generation of political scientists attempted to make the study of politics more 'scientific.' For many this effectively meant that political science ought to model itself on the 'hard sciences' which they believed was fundamentally a deductive process. Thus rather than studying the details of political life and inductively uncover the patterns of behavior and action, political 'science' should be a deductive science that seeks to discover of the general laws and fundamental forces that lay behind political action. Focusing on particular institutions, proponents this intellectual agenda implied, was 'a-theoretical.' Concomitant with the push for more abstract laws, political scientists were disillusioned by the failure of parliamentary institutions in Inter-war Weimar Germany (and later in post-colonial Africa) to prevent these polities from devolving into authoritarianism. Clearly, many argued, there were bigger, more important, indeed more fundamental, forces at work in politics and development than political institutions. These forces, they argued, should be the focus of political science.

Thus, behavioralist, functionalist and Marxist perspectives took leading roles in political science theory building through most of the 1960s and 1970s. As a consequence, institutional analysis diminished in prominence...particularly in comparative politics. For Functionalists, political institutions were simply seen as organizations created to fulfill the systemic needs of society. As such, political institutions were neither important nor interesting. For Behavioralists and Marxists, political institutions were simply arenas in which political battles were fought out. While Marxists saw the relevant groups as classes and Pluralists saw them as more narrowly defined, neither theoretical perspective played particular attention to the structure or character of the institutions themselves. The real meat of politics, they argued—and the keys to understanding political outcomes—was found in the articulation of group interests. Though this was rarely explicitly stated, implicit in these theories was the assertion that if politics or policies differed between societies, this difference was surely the result of different constellations of group and class interests or preferences (Almond and Verba 1963, Miliband 1969).

It was not the case, however, that all political scientists had abandoned the study of institutions. Indeed, many of the most widely read scholars in American Politics maintained an explicitly institutional emphasis (cf.

Schattschneider 1960, Greenstein 1963, Fenno 1960, Polsby et al. 1969). In Comparative Politics, as well, several political scientists continued to examine political institutions and their effects on political outcomes (Ekstein 1960, Bendix and Brand 1968, Huntington 1968), even while they sometimes had to defend their 'inductive' approach from the challenge that it was not 'scientific' (Przeworski and Teune 1970, Bill and Hardgrave 1973). For these scholars it was self-evident that if one wanted to understand what government does, one needs to specifically study the institutions through which it acts.

It was probably in Comparative Politics that the search for 'Grand Theory' had its most significant impact. It may be for this reason that a self-conscious return to 'Institutionalism' was most forcefully articulated here. Among the first group of scholars to move in this direction was Peter Katzenstein and his colleagues who sought to explain why several advanced capitalist states responded so differently to the oil shock of the 1970s. The answer, they concluded, was found in the differing institutional structures in these polities and the consequent patterns of economic policy pursued in each nation (Katzenstein 1978). Similarly, Theda Skocpol's study of social revolutions also concluded that one could not explain the course of a country's revolution without examining the nature and structure of the state against at which these revolutions were aimed (Skocpol 1979).

Soon a new 'state centered' approach emerged in comparative political inquiry. These scholars forcefully argued against the behavioralist and Marxist 'grand theory' emphasis then dominant in the study of comparative politics. Instead, they suggested, political outcomes were shaped and structured by the specific actors and their position in the state. One should not treat the state as a neutral 'black box' through which group or class interest was simply translated (Evans et al. 1985). Instead, the state had independent interests and agendas which were separate and different from the interests and preferences of classes and interest groups that made up society.

Of course it did not take long for these scholars to discover that 'the state' is too broad a concept and too varied a set of institutions to be 'taken seriously' without being broken down. To make analytic sense out of the insights, scholars began examining institutions more carefully. If state institutions 'matter,' they argued, then why should this not be equally true of institutions outside the boundaries of the executive state? With these questions 'The New Institutionalism' was born.

4. *Three 'New Institutionalisms'?*

Today three different intellectual approaches lay claim to the term 'Institutionalist' (cf. Hall and Taylor 1996). Each grows out of a different academic discipline and attempts to integrate these different analytic traditions into the understanding of politics. Sociological Institutionalism, as its name implies, grows out of sociology and the study of organizations (e.g., Selznick 1949). These scholars have been centrally interested in understanding culture and norms, as institutions. These scholars emphasize 'folkways,' 'patterns of behavior,' and 'cognitive maps' and argue that these social institutions are critical for understanding the structure of social, political, and economic interactions (March and Olsen 1989, DiMaggio and Powell 1991). Building on upon their analyses of complex organizations, these scholars show the relationship between formal institutions and the structure or patterns of behavior and beliefs. They argue that these informal institutions are core to any understanding of the nonrational aspects human communication and exchange.

'Rational Choice Institutionalism,' taking its lead from economics, emphasizes quite different sets of institutions and their effects. Rational Choice (RC) scholars attempt to apply the formal logic and methods to the study of politics and history and often explicitly eschew the more 'mushy' or less precise variables such as norms and beliefs. Instead, basic assumptions are made about human behavior and motivation in order to uncover and examine the basic laws of political behavior and action. Scholars in this tradition argue that once these laws are discovered, models can be constructed that will help us understand and predict political behavior (Levi 1988). In their deductive model, Rational Choice scholars look to the real world to see if their model is right (test the model). For these scholars, understanding real outcomes is not the first point—creating, elaborating, refining a theory of politics is (Weingast 1996).

The implications of this scientific orientation are substantial. Morris Fiorina, a highly regarded RC scholar at Harvard, put the issue in the following way: 'most PTI scholars are not as interested in a comprehensive understanding of some real institution or historical phenomenon, so much as in a deeper understanding of some theoretical principle or logic… [F]or most PTI scholars, breadth trumps depth; understanding 90 percent of the variance in one case is not as significant an achievement as understanding 10 percent of each of nine cases, especially if the cases vary across time and place' (Fiorina 1995, pp. 110–1).

The third 'New Institutionalist' approach emerges out of what might be considered a more traditional political science. Consequently, it has a quite different aim: Historical Institutionalists are primarily interested in understanding and explaining real world events and outcomes. As with the other approaches noted above, scholars working in this tradition also argue that one cannot explain particular historical outcomes without specifically examining the way in which the political institutions have shaped or structured the political process (Steinmo et al. 1992). But, unlike RC scholars

in particular, Historical Institutionalists came about their 'institutional' arguments inductively after testing a variety of alternative theories (i.e., Marxist, structural functionalist, culturalist, and rationalist) against the outcomes they observed. In other words, Historical Institutionalists are first interested in explaining an outcome (say, for example, why France and Britain have pursued such different styles of industrial Policy (Hall 1986) or why some welfare states generate more popular support than others (Rothstein 1998)); they then proceed to explore alternative explanations for the outcomes they observe.

Historical Institutionalists do not argue that institutions are the only important variables for understanding political outcomes. Quite the contrary, these scholars generally see institutions as intervening variables (or structuring variables) through which battles over interest, ideas, and power are fought. Institutions are thus the focal points in critical junctures in a historical path analysis because political battles are fought inside institutions and over the design of future institutions.

5. *Institutional Change and Evolution*

Institutionalist scholars from a variety of perspectives are currently focusing on one of the most interesting and vexing issues left hanging in the institutionalist literature—explaining institutional change. Institutional stability (or equilibrium) is far easier to explain than change: institutional change means increased uncertainty because any particular set of institutions are embedded in a variety of other institutions; it is difficult to accurately predict the long run consequences of even small rule changes. Once again, every institution favors some interests and ideas over others, and therefore the advantaged are generally loath to change the status quo. Indeed, even current losers may decide that the status quo is preferable to some uncertain future in which they could be even further disadvantaged.

Of course, institutions do change, and sometimes they can change quite dramatically. Still, we as yet have no clear theory of how and why they change (with the exception of the 'punctuated equilibrium' model derived from Steven Gould's evolutionary theory). But clearly this single model of change is inadequate. It amounts to little more than suggesting 'stuff happens.' While it may be true that 'stuff happens,' we need to have a better understanding of why even exogenous shocks get refracted in particular ways. Additionally, we need a better understanding of the role of endogenous variables in the change process.

A variety of scholars have begun to explore the dilemma of institutional change by building more explicitly on evolutionary models suggested in the life sciences (Arthur 1994, Jervis 1997). Indeed, perhaps one of the most interesting outgrowths of the 'institutionalist turn' of political science in recent years may be that political science may begin to move away from its fascination with physics and its emphasis on absolute laws that hold across time and space. An institutionalist political science may instead look more like the life sciences—with their emphasis on contingency, context, and environment. In this event, the goal will be more to explain past (evolutionary) outcomes and less to predict future ones.

Institutionalization

Institutionalization as a research topic reached its heyday in the 1970s when spates of articles featuring the 'institutionalization of (fill in the blank)' were published in major journals. The objects institutionalized included the United Nations (Keohane 1969), cultural persistence (Zucker 1977), voting patterns (Przeworski 1975) and political parties (Wellhofer 1974), among others. In the years following this explosion, there appeared other works focusing on a number of clearly political institutions such as the presidency (Ragsdale and Theiss 1997) and the California legislature (Squire 1992). An overview of these articles shows that institutionalization has meant different things to different authors. The common theme, however, was that certain institutional features had persisted and it was the continuity of the pattern which was called institutionalization. An explication of the single most cited article on institutionalization in political science serves as an example of both the concept and its application.

Building on work of Witmer (1964) and Price (1964), Polsby (1968) published 'The institutionalization of the United States House of Representatives' and, with colleagues, published a companion piece (1969) on the rise of seniority in the United States House of Representatives. In the 1968 article, Polsby cites the political development literature including Weber (1947), Durkheim (1938) and Huntington (1965). In examining the development of the US Houses of Representatives Polsby argues from organization theory (e.g., Selznik (1953) that 'the institution' of the US House of Representatives becomes separable from its environment and develops as an institution within the US political system that signals its adaptability and development. The three characteristics Polsby studies are:

(a) boundaries: the differentiation of the institution sufficiently differentiated from its environment so that members need special skills to rise to leadership positions;

(b) internal complexity: the rise of committees and a seniority system which captures the benefits of specialization, and

(c) universalism: the rise of nonpartisanship (or objectivity) in determining whom the House members will be in the case of disputed elections.

The development of the House as an institution necessitating special skills for its leaders is measured by the length of time that it takes a member to become the Speaker. Polsby shows change occurring over the nineteenth century where early in the century Henry Clay could became Speaker in his first term whereas by the end of the century the Speakers on average had served 20 years before becoming Speaker. The 'institutionalization of specialization' in the House was demonstrated by the absence of seniority violations on committees occurring early in the twentieth century. Likewise the rise of fairness is measured by the criteria applied to election disputes—that is, as bi-partisan voting behavior on contested seats rose, Polsby claims that objectivity within the House also rose to the status of a norm.

Each of these patterns of behavior shifted sharply in the 1890–1910 period—Polsby called this period the 'Big Bang period' —in the institutionalization of the House. Many articles on the institutionalization of other legislative bodies followed. The bodies studied ranged from state legislatures to the mother of Parliaments—the House of Commons (Hibbing 1988). Much of the early work treated institutionalization as though it was a full-blown theory. Polsby, however, argued more accurately that he had described a tripartite dependent variable over time to show that discernable patterns had developed. The view of institutionalization as patterned behavior is closer to sociological theories of institutions and it is to this tradition that I turn.

Institutions are at the core of sociology (Durkheim 1938) and in general one can view an institution as organized, standing procedures which taken together constitute 'the rules of the game' (Easton 1981). Such

rules are seen as exogenous to participants. This general view has not led to clear and clean usage. In the analysis that follows I take the definition of Jepperson and use his conceptual scheme:

> Institution represents a social order or pattern that has attained a certain state or property; institutionalization denotes the process of such attainment (1991, p. 145).

On this view, an institution is a social pattern that stands over time and, when there are departures from this pattern, they are sanctioned without collective mobilization. Political institutions like legislatures, bureaucracies and executives are therefore well suited to institutional analysis.

The State Department of the United States government is such an institution. Members in the organization are rewarded or punished for their behavior in regard to the 'rules of the game' and over time rules can change. Precisely because institutions can change institutionalization *per se* does not, as some have thought, necessarily require stability or survival. In fact, shortly after Polsby et al. (1969) and Abram and Cooper (1968) published their work on the institutionalization of seniority, the US House of Representatives essentially ended seniority or, at a minimum, severely constrained it by deposing four senior chairmen.

Institutional change is dependent on context, which can be cultural, environmental or structural. It is this relativity that makes pinning down the meaning of institutionalization hard to do, because the property may change. The best way to think of institutionalization is to see it as a particular state of an institution. Thus, in Polsby's classic article, differentiation and specialization in the House were institutionalized, as attested to by the increasingly lengthy career path of Speakers and the rise of a pure seniority system, both important properties of the House of Representatives at the time of the studies.

The sociological concept of institutionalization began to fall out of favor in political science due largely to two factors: first, most of what could be studied *a la* Polsby was studied and second and more importantly, the 'new' institutionalism driven by economic reasoning came to the fore in Political Science. The analytic tradition of Coase (1937), Williamson (1985) and North (1981) and others (Nelson and Winter 1982) modified the traditional maximizing assumptions of classical economics where individuals maximize behavior over stable preference orderings. Their modifications are that individuals do maximize, though they do so constrained by cognitive limits, incomplete information and difficulties in enforcing agreements. Thus institutions arise to solve a problem and to maintain the solution when the benefits derived from the extant institution exceed the costs. Institutions essentially do this by reducing the uncertainty associated with transactions.

William Riker and his students (especially Shepsle) brought this economic approach to the study of political institutions. According to this approach, the US Congress creates committees and rules in order to solve the recycling or instability problem. In Shepsle's (1986) own words, political institutions are

> *ex ante* agreements about a structure of cooperation … which economize on transaction costs, reduce opportunism and other forms of agency slippage

—thereby increasing cooperation. This view of legislative institutions is disputed by Krehbiel (1991) and Krehbiel and Gilligan (1987, 1988) who argue that Congress established committees not to solve the cycling problem but rather to solve its information problems. Both viewpoints construe the Congress as an institution where policy is dependent upon the agenda-setting powers inherent in legislative rules. In short 'the new institutionalism' sees institutions as choices made by actors for self-interested reasons and the survival of institutions and their features is cost-benefit determined. The initial problem being solved may, among others, be informational, cycling, credible commitment or coordination. Thus the costs of starting the institution are lower than the benefits conferred. Likewise, the continued existence of the institution depends upon benefits exceeding costs. On this view the process of institutionalization over time is planned, chosen and sustained as long as benefits exceed costs.

The sociological response to the inroads made by economic treatments of institutions approach has been work led by March (1981), March and Olson (1984) and Meyer (1977, 1980), which argues that, contrary to economic theory, the institutionalization process is one where organizational structure evolves over time in an unplanned, adaptive, historically determined fashion. In political science, the work of Terry Moe (1987) fits this view, as does work by Ragsdale and Theis (1997) on the American presidency. Moe argues that rational choice institutionalism overemphasizes the formal mechanisms of legislative control at the cost of neglecting more fundamental, indirect, unintentional and systemic societal causes.

The field of international relations in political science also features the conflict between rational choice models of institutionalization and sociological theories, especially in the work of Krasner (1983), Keohane (1984, 1986) and 1988), and Young (1986). The argument is essentially that the economic model cannot account for international institutions because said institutions are clearly a long way from efficient. The sociological view (especially Meyer on systems) is that international institutions do not merely reflect the preferences and power of the units constituting them; rather they shape preferences and power. Recent illustrations of this perspective include Bennett's (1997) work on alliance duration and Martin's (1995) work on firms' preferences. The historical institutionalism of Skowronek (1982), Skocpol (1992) and others also adapts to this argument, holding that the de-

velopment of the American state and its subsequent policies are not the result of a logical, chosen rational process, rather both the state and its policies are the product of exceptional events, individuals, and circumstances that at crucial historical times determine or co-determine the future of institutional development. Moreover, unintended consequences often outweigh the intended and anticipated consequences.

In sum, early work on institutionalization by Polsby (1968), Cooper (1968) and Price (1964) was already embedded in the sociological tradition. It later was overtaken by economics-based theories of institutions and institutionalism illustrated by the work of Shepsle (1986), Weingast (1988, 1995), McCubbins (1987, 1993), Cox (1993), Krehbiel (1991) and others. The sociological approach has begun to revive as March (1981) and March and Olson (1984) and in the study of American politics Terry Moe's (1987) works have come to be widely read and cited. Sociological views of institutionalization seem to dominate the field of international relations with the work of March (1981) and Meyer (1980) being most influential on scholars in this field.

Unsolved puzzles in this field include the following: first, what is an institution? The economic tradition views institutions as the product of human designs where individuals behave instrumentally in order to achieve ends. The sociological tradition views institutions as emerging from human activity, but not necessarily, or even often, the product of conscious design. This conflict will be resolved by careful historical-empirical studies that ascertain the origins of institutions such as committees, bureaucracies and so forth. Second, do institutions reflect the preferences of individual or corporate actions or do they reflect collective outcomes of group interactions? This conflict will be more difficult to resolve because, in economics, preferences are assumed, not studied and in sociology they are not variables in any individual sense. Third, and most relevant for institutionalization, do institutions respond quickly to individual interests and exogenous change as economic theory would have us believe, or do they respond glacially as sociology would have us believe?

Consider the original work on the House of Representatives where change occurs infrequently but when it occurs, it happens over a 20-year period—'the Big Bang 1890–1910'—and then is stable over another 50 years. This appears to be glacial change with punctuated equilibrium in the sociological tradition. The economic perspective leads us to believe that change is more rapid and driven by standard cost-benefit analysis. While there is no seminal work on the institutionalization of an institution in the economic tradition, Cox and McCubbins (1993) and Aldrich's (1995) work on political parties are a good beginning. Parties are created to solve problems, of coordination, distribution, etc. and, over time, parties change as exogenous shocks and members' preferences shift. A study of well-known institutions, such as the House of Representatives, that contrasts the sociological and economic views would make a major contribution by virtue of its being able to pin down the reasons for creating institutions (see Cooper (1970) on the origins of committees for an example) and the rate at which they change. At present, excellent studies of various institutions from one perspective—see Meyer (1977) on junior colleges as institutions—contribute to one perspective but the same institutions are not studied from the other discipline's perspective. Johnson and Libecap's (1994) study of the causes of bureaucratic reform in the 1880s in the USA is a classic example of institutional change studied from the perspective of economic theory which could be easily restudied from a sociological perspective. Excellent studies of separate institutions (often at different times) may enhance discipline specific research but until the same institution is examined from both perspectives over the same time period, knowledge in this area will be partial and fragmented.

Institutions

In the most general meaning of the term, 'institutions' are defined as constraints or rules that induce stability in human interaction. All human societies have developed a variety of institutions which deal with recurrent basic problems in social life, for example, institutions regulating kinship and family life or economic institutions. In this article, the concept as it is used in contemporary social science and some aspects related to the explanation of institutions will be reviewed.

1. *The Concept 'Institutions'*

In everyday language and in the social sciences, the term 'institutions' is often used in a broad and sometimes amorphous way. It is quite common to denote organizations and other corporate actors such as business firms, political parties, schools, and public administrations as 'institutions.' On the other hand, the term also, more specifically, refers to rules and other constraints of human interaction. 'Institutions' in this sense include conventions (for example, traffic rules), as well as informal and formal social norms. Furthermore the term is often used to describe complex systems of interrelated norms. For example, modern law can be considered as a set of formal norms proscribing or prescribing certain actions. Another aspect of the law is that it employs (mainly negative) sanctions to punish and prevent deviant behavior. In accordance with Max Weber's terms (1978), the law induces stable regularities of nondeviant behavior via

(threats of) sanctions that are employed by a specialized staff of actors. In this sense, the law may be conceived as an organization that enforces certain formal norms.

The concept 'institutions' is thus used in a dual way. First, it denotes rules, constraints, or norms of human interaction. Second, it describes the resulting stable patterns of interaction among a set of agents and the social mechanisms generating this outcome. This latter aspect is sometimes also expressed in the concept 'institutionalization' which plays a central role, for instance, in Talcott Parsons' theory of social systems. 'Institutionalization' means that certain cultural norms become elements of the actors' motivational dispositions, and that norm conformity is rewarded and deviant behavior appropriately punished by the application of sanctions. In Parsons' (1982, pp. 117–18) words, 'institutionalization is an articulation or integration of the actions of a plurality of actors in a specific type of situation in which the various actors accept jointly a set of harmonious rules regarding goals and procedures.'

To allude to the modern choice theoretic framework of game theory, institutions are first represented by the rules of the games actors are playing. These rules define, among other aspects, the set of possible actions (strategies) of the agents. They also specify the consequences of the actions (payoffs) and the available amount of information. Given these rules or constraints, agents choose an action (strategy) that is individually optimal. The optimal choices will, under general conditions, yield an equilibrium. An equilibrium is a combination of actions (strategies) such that no agent has an incentive to deviate from her chosen actions unilaterally, that is under the condition that the other actors choose their equilibrium actions. The stability of an equilibrium is due to the fact that no (rational) actor could gain by shifting to another strategy unilaterally. Consider now a population of actors who recurrently interact in a social situation governed by the rules of the game. Then it may happen that a certain equilibrium will eventually evolve. In other words, a stable pattern of social interactions may emerge under the constraints of the rules of the game.

An 'institution' can thus be conceived to be the set of constraints or rules which determine the opportunities and incentives of the relevant actors in a given situation. Second, interactions within these rules generate equilibria, which may be stable over time if the situation is recurrent. These equilibrium outcomes can be considered an integral component of the institution. To illustrate, consider a coordination situation. Imagine a time with considerable road traffic (e.g., horse-drawn carriages in the seventeenth century) but no universally accepted rules with respect to keeping left or right. If a central authority (the government) were to create the rule that pedestrians use the right side of the road and horse-drawn carriages use the left side, one source of potential accidents could be avoided, namely, inconsistent mutual reciprocal expectations with regard to the usage of public roads. The rule would, so to speak, 'solve' a coordination problem. A coordination problem can roughly be defined as an interaction with multiple equilibria. In the absence of any rules or 'focal points' (Th. C. Schelling), there would be ambiguity with regard to the different courses of action available to road users: should one use the right or the left side of the road? The actors probably do not have intrinsic preferences with regard to the direction of the rule, that is, whether to go right is better than to go left. But they prefer to adopt a rule that gives clear and unique prescriptions and prevents accidents if universally acknowledged, rather than ambiguous rules or rules which are not easily implemented (e.g., the rule that one should determine by chance whether to go right or left). Given that the government has publicly announced a rule, the participants easily form convergent expectations with regard to each other's behavior. In other words, an equilibrium of universal rule-oriented behavior emerges as a consequence of individually adaptive or optimizing behavior under the constraints of the rules of the game and of external constraints created by the government. This gives rise to a 'convention.' Following Lewis (1969), a convention may be defined as a behavioral regularity R in a population of agents who recurrently interact in a coordination situation if R is an equilibrium of the recurrent situation and if almost every member of the population prefers to conform to R on the condition that almost every other member of the population conforms to R too.

Conventions arising in so-called pure coordination situations (with no conflict of interest) are self-enforcing. This is so because any individual who deviates from R would punish himself. There is no incentive to break the rule. In other social situations, for example of the prisoner's dilemma type, there is an incentive to defect. A prisoner's dilemma is a social interaction such that universal cooperation is profitable to everyone, but it is even more profitable to defect unilaterally from cooperation. Cooperation is not an equilibrium situation in the single-shot prisoner's dilemma. In a population of agents who recurrently interact in a prisoner's dilemma, an institution of mutual cooperation may emerge if there is a policing mechanism such that members of the population of agents expect that nonconformity will be punished by (negative) sanctions. The policing or enforcement of cooperation could be achieved under appropriate social conditions due to sanctions that are created by the agents themselves. Of course, intervention by external, third parties (in the sense of Hobbes' *Leviathan*) would be another mechanism to enforce an institution. Generalizing Lewis' concept of convention, a social institution can be defined as a regularity in the behavior of the members of a

population that 'specifies behavior in specific recurrent situations, and is either self-policed or policed by some external authority' (Schotter 1981, p. 11; italics omitted). The self-enforcement of an institution may be due to the fact that the regularity is an equilibrium of a coordination problem. If the recurrent situation has similarities with a prisoner's dilemma, however, an equilibrium of cooperative behavior may result from self-created sanctions (e.g., of the 'tit for tat' type, cf. Axelrod 1984) or from policing by an external authority. The concept 'social institution' in this sense includes conventions as a special case, and also formal and informal social norms (see Lewis 1969, Schotter 1981, Young 1998 for sophisticated elaborations of this line of reasoning).

2. *Some Types of Institutions*

There are many different kinds of institutions. First, adopting the intuitive meaning of institutions as rules or constraints of behavior, it is useful to make the following distinctions. There are rules that regulate the personal life of human agents. These *personal* rules (e.g., the rule to go early to bed every night) resemble individual habits and individual routines. Some of these rules may be interpreted as attempts of individuals to bind themselves. Personal rules may be motivated by individuals' long-term interests to achieve self-control. But they are not social institutions in the proper sense. In contrast to personal rules, *social* rules affect social interactions, that is, recurrent situations of social interdependence. For example, it can be argued that social institutions typically regulate social dilemmas. Social dilemmas are situations where interdependent agents are faced with choices for which individual rationality does not yield a socially optimal outcome. The prisoner's dilemma and public good situations are cases in point. Furthermore, there are *formal* and *informal* institutions. Informal institutions do not rely on an external authority's monitoring and policing of the participants' behavior. These institutions include, for example, social norms of self-help among residents in rural communities (see Ellickson 1991). Other informal institutions are conventions. Though conventions are defined as self-enforcing, they often become codified in formal rules (e.g., time standards or traffic rules). Formal institutions are generally created and arranged by agents who are able to rely on third parties for monitoring and enforcement. Among the most elaborate formal institutions in modern societies one should mention the law. There are also complex formal institutions regulating political committees in political systems and collective decisions in large capitalist firms. However, it is important to notice that formal rules are embedded in informal norms. Committee power in democratic political bodies is determined to a large extent by informal norms that foster vote exchange (logrolling) (Coleman 1973, Shepsle and Weingast 1987) and only to a minor degree depends on formal rules. Thus, formal institutional constraints are often supplemented by informal rules and vice versa.

Second, it is useful to point out the different levels of rules that can be relevant in institutional analysis (see Ostrom 1990, Chap. 2). There is first the *constitutional* level. Constitutional rules define the most general context of the games agents are allowed to play. They determine the set of eligible actors and the principles used in crafting or changing more specific rules of the system. Constitutional rules are not only relevant in the arena of international and national politics but also in regional and local contexts. Second, there is the level of *collective choice*. Collective choice rules specify principles of policy-making. They help to generate unique collective decisions. Third, there is the *operational* level. Operational rules help to implement the decisions of the higher levels. They determine day-to-day decisions, for example decisions related to the monitoring and sanctioning the participants.

Third, institutions may be classified by the spheres of the society to which they belong and contribute. There are *economic* institutions regulating economic exchange, for example, property rights institutions. Other economic institutions include conventions with regard to media of exchange or the specific rules and constraints affecting economic behavior between and within firms (see Williamson 1985). *Political* institutions provide basic rules and procedures to achieve collective decisions. The most important political institutions in contemporary societies are, of course, the constitutions of nation states, for example, the constitution of the United States of America. There are also international political institutions. Besides these basic ground rules of international and national politics there are more specific institutions and laws dealing with the operation of the democratic system. Every human society has developed institutions shaping family life and kinship relations. Modern societies have created a differentiated system of educational institutions. There are also cultural and religious institutions of different kinds.

3. *Explaining Institutions*

The analysis of institutions has always been considered to be one of the most important tasks in social theory. For example, Emile Durkheim (1978, pp. 82–3) emphasized that sociology's subject was 'social facts,' in particular social institutions. A desideratum of sociological analysis, according to Durkheim, is the discovery of the mechanisms, causes, and effects of institutions in the diverse spheres of societal life.

3.1 *Effects of Institutions*

A starting point of many explanations is the study of the effects or consequences of institutions. Not only functionalist analyses in the proper sense, but also

contributions from diverse theoretical perspectives in the social sciences argue that institutions may have beneficial consequences.

Institutions regularize social life. Rule-oriented behavior reduces uncertainty and increases the predictability of others' actions in situations of social interdependence. The institutionalization of social norms in Parsons' sense is a key to the solution of the Hobbesian problem of order. In a 'state of nature' without an enforcing agency, mutual cooperation, for example, the recognition of private property rights, would be profitable, but there are strong incentives to defect from mutual agreements. The institutionalization of social norms of reciprocity and solidarity via their internalization into the actors' motivational systems would be, according to Parsons, a solution to the Hobbesian problem (Parsons 1937). Thus, institutions and the institutionalization of appropriate social norms may foster cooperation and increase efficiency (in the Pareto sense of making agents better off without harming anyone in society).

Institutions such as exclusive private property rights with respect to economic resources are prone to enhance a society's aggregate welfare because they reduce transaction costs (North 1990). If transaction costs within an economic system decrease, the economy will generally become more productive, provided the costs of creating and enforcing these institutions are not too high (see Eggertsson 1990 for a survey of the literature). To allude to a recent institutional innovation, it seems plausible to argue that global communication networks (Internet) constitute an institutional framework that reduces some kinds of transaction costs (in particular costs of acquiring information) in long-distance economic relations. Many institutions, such as property rights, can be said to be part of a society's social capital (Coleman 1990, Chap. 12). In this sense, institutions are a productive asset because they enhance the efficiency, the welfare or, in other words, the well-being of most members of a society. Furthermore, they can have the properties of public or collective goods. That is, they are goods such that it is not feasible easily to exclude agents from their consumption if these goods are available to anyone. In other words, institutions with collective goods properties can be profitably 'consumed' by all those actors who wish to benefit from them, not only by those agents who contributed to the costs of their 'production.'

This public-good characteristic of many institutions makes it clear that the potential beneficial effects of institutions cannot sufficiently explain the emergence and change of institutions. This is so because public goods create incentives to a free ride. If the formation and maintenance of an institution is costly, the amount of voluntary contributions to these costs will generally be too low, that is suboptimal (Olson 1971). At least for this reason, simple functionalist accounts of efficient institutions are incomplete.

3.2 Mechanisms of Institutional Change

There are many different types of processes that are prone to generate or change social institutions. First, there is the extreme type of institutional change by conscious design. In particular, formal institutions such as legal norms are in many cases designed purposively. Parliamentary committees in modern democracies regularly propose such changes. However, many of these changes are accompanied or supplemented by changing informal institutions in the larger society. These informal rules generally change more incrementally.

Second, institutional change may be due to evolutionary forces of an 'invisible hand' (Adam Smith). In this case, the goal-oriented actions of a large number of actors may in the long rule unintentionally produce results that seem to be due to conscious planning by a central authority. But, in fact, the institution is a byproduct of each individual's activity to locally adapt to its circumstances. Institutions of this kind are called 'spontaneous orders' (F. A. Hayek). It can be argued that many conventions have emerged as spontaneous orders (Sugden 1986, Young 1998) in the first place. Once adopted, they may be included in a cultural tradition and will be taught to children by their parents (e.g., table manners).

Invisible-hand processes of institutions and their explanation (Ullmann-Margalit 1978) are attractive because they may yield theoretical arguments with some 'depth.' They explain facts on the collective level of social institutions by principles of purposive action and by a 'generating mechanism' (Boudon 1979). Work in the tradition of evolutionary game theory has expressed these mechanisms more explicitly. It can be shown that certain institutions emerge as special kinds of (stochastic) equilibria in games played by members of a population of agents who recurrently interact in the 'long run' (Young 1998).

Obviously, most empirically observable institutions will not be explicable exclusively by one of these two extreme or ideal types of mechanisms but are probably complex combinations of different types of processes. However, the study of theoretical models representing some aspects of a complex reality in an idealized way may be understood as a theoretical 'thought experiment' (*Gedankenexperiment*). Such thought experiments enhance the clarity of theoretical arguments and provide an antidote against simplistic and empirically dubious 'conspiracy theories' of institutions (K. R. Popper) which argue that most social institutions are explicable in terms of the joint efforts of some group of powerful actors who want to foster their material interests.

3.3 Are Institutions Efficient?

Given the functionalist account, which points out that institutions are beneficial, one may ask whether in fact every institution is efficient. There is indeed some

evidence on efficient rules. Wittman (1982) has investigated various rules of thumb in certain road traffic situations and comes to the conclusion that only the most efficient rules will be used. Rules have evolved such that two types of costs are optimized, namely, costs associated with monitoring the rule and inappropriate incentives created by the rule. A similar view is expressed in Ellickson's (1991) book on informal institutions. However, there is ample evidence on the persistence of inefficient institutions (see Eggertsson 1990, Chap. 8). In the Arab world, inefficient institutions regulating economic exchange have persisted for thousands of years. For example, a form of exchange called the *suq* (C. Geertz) is characterized by high bargaining and measurement costs. These transaction costs could in principle be reduced by major institutional changes. But such changes have not been observed. Moreover, economic historian North (1990, p. 6) points out that the 'central puzzle of human history is to account for the widely divergent paths of historical change. How have societies diverged? What accounts for their widely disparate performance characteristics?' It seems safe to say, according to North, that market processes of competition did not weed out inferior institutions but that inefficient institutions have proved to be highly stable.

There are many different arguments that could explain the persistence of inefficient institutions:

(a) Some social scientists, in particular in anthropology, suggest that institutions are inexplicable by functionalist or rationalist ideas. According to this approach, (cultural) institutions mainly serve 'symbolic' functions (Sahlins 1976). A different approach, however, points out the signaling properties of certain behavioral regularities (social norms) that *prima facie* do not contribute to efficiency. These institutions may be interpreted as consequences of signaling behavior. The conformity to 'ornaments' of social life, such as clothing norms, table manners, and others, may be perceived as a signal that the actor is cooperative in the more fundamental interaction problems of family, political, or business life (Posner 2000).

(b) Inequality in bargaining power can have the effect of selecting institutions that primarily serve the interests of the more powerful agents or groups in a society. Thus, new (formal) institutions need not foster the aggregate welfare of a society or efficiency (North 1990, Chap. 6).

(c) There are many recurrent interaction situations with multiple equilibria, for instance coordination games or iterated prisoner's dilemma games. In cases like these, the outcome may be indeterminate. Furthermore, there is 'path dependence': Small differences in initial conditions and chance circumstances in structurally similar social interactions yield different paths of historical development and therefore different institutional outcomes (see North 1990, Chap. 11, Greif 1994, Young 1998).

(d) Limited rationality and incomplete information of human agents may be obstacles to attaining efficient institutions (North 1990, Chap. 3).

(e) As far as efficiency gains from institutional change are public or collective goods there may be a lack of appropriate incentives to contribute to the costs (see Olson 1971, Ostrom 1990).

4. *The Evolutionary Approach to Institutions*

Recent research on the emergence of institutions emphasizes that not all institutions are necessarily efficient. This body of work uses ideas from evolutionary game theory. It is generally consistent with all of the above mentioned arguments on the inefficiency of institutions. Historically, the roots of evolutionary explanations of institutions are ideas from the tradition of the Scottish Moralists (in particular David Hume) and the Austrian School of Economics (Carl Menger, Friedrich A. von Hayek). In constructing an evolutionary approach, one must keep in mind that there are important differences between biological and social evolution. Theories of social evolution must contain appropriate behavioral assumptions of adaptive behavior or learning processes. The evolutionary approach can be characterized by the following core ideas (see Young 1986). Institutions are the products of interactions within large populations of actors over considerable periods of time. These agents are boundedly rational and act under conditions of limited information. This means that actors may fail to figure out responses to other people's actions which are optimal. However, *under appropriate circumstances*, the *evolutionary process* may in the long run (that is, in the presence of stochastic shocks which correspond roughly with mutations in biological evolution) realize equilibrium outcomes such that efficient institutions persist. But this result may well be an exception rather than the rule. Generally, the evolutionary path will depend on initial conditions. That is, structurally similar social systems may develop qualitatively distinct institutions with considerable differences with regard to the degree of 'efficiency.' A particularly important aspect of initial conditions are 'cultural beliefs' in Greif's (1994) sense. These beliefs are embedded into a society's culture and are a product of history. They are employed as equilibrium selection devices in those interaction situations with multiple equilibria. Therefore, different sets of cultural beliefs may yield different institutional outcomes (at least in the medium run). Greif (1994) illustrates this with the help of a comparison of the cultural beliefs in 'collectivist' and 'individualistic' societies, using the historical data on Maghribini and Genoese traders in the Middle Ages. An evolutionary approach should, in principle, point out the conditions that generate distinct cultural beliefs (and other equilibrium devices such as fairness norms) and the paths of an evolu-

tionary transition from one equilibrium to another (possibly more efficient) equilibrium. The evolutionary approach is a promising research program, but much further work is needed to fully understand and explain concrete cases of empirically observed institutions.

Instructional Design

1. Instructional Design and its Relation to Instructional Technology

The term instructional design (ID) refers to the systematic and professional provisions for education or training. Considerations regarding planned instruction have been made at least as long as there have been institutions for instruction and training. The term ID itself appeared for the first time in the USA in the midst of the twentieth century.

ID and instructional (or educational) technology (IT) are related terms with an overlapping meaning. Both expressions are used in a broad as well as in a narrow sense. The term ID is used in a variety of ways with different ranges of meaning:

(a) The narrowest variant concerns only the planning of an instructional treatment.

(b) The somewhat wider usage concerns both planning and constructing of what is needed for a certain instructional solution.

(c) The even wider interpretation adds the implementation of the instructional system or program in a particular context and the evaluation of outcomes. ID is most often used with this interpretation and sometimes referred to as IT with the same broad meaning.

(d) The widest interpretation adds to the previous meaning by including maintenance and management of the instructional system or program over a period of time; this includes conducting ongoing evaluations, planning, and developing upgrades as well as managing all of these processes organizationally and economically. This broad interpretation of ID corresponds with the most comprehensive definition of IT.

ID, under any of these interpretations, can refer to these education or training processes with regard to varying degrees of scope (unit of instruction, lesson, curriculum, program, system, etc.). At the macrolevel, ID concerns instruction of whole curricula, programs, or systems that will cover months or years of instruction; this is called large-scale ID, or, alternatively, curriculum construction. At the middle or mesolevel,

the object of ID are typical lessons that cover hours or weeks of instruction. The microlevel concerns a period of minutes, or short parts of a lesson, such as giving exercises or demonstrating illustrative examples. The most frequent use of theories and models of ID refers to the mesolevel. The limits between the three levels are fluid and not always clearly defined.

Some authors tend to reduce ID to the mere planning of instruction or to restrict IT to hardware and software, but these narrower interpretations do not fulfill the conditions of providing efficient instruction, because efficient instruction has to take into account all relevant factors (e.g., learners, environmental factors) in a systematic and systemic approach.

2. *A Short Historical Overview to Characterize Relevant Aspects of ID*

In the 1930s educational scholars in the USA began to investigate questions like: will students who went through a certain, alternative high school curriculum be successful at the following college? These instructional scientists asked how to state instructional objectives more precisely by taking into account the learner's behavior. Furthermore, it was important to check if the alternative curriculum was implemented in the planned way. For this, the instructional goals were used as a benchmark and critical point of reference. Reaching the intended instructional goals was improved by continual revision of the course during the development and test phase. This cyclic process of goal-oriented checking and improvement of lessons and courses today is called 'formative evaluation.'

The development of ID as a special field of research and development was mainly stimulated by two goals to be achieved:

(a) training as many learners as possible within a short period of time; and

(b) using the most efficient available instructional means (e.g., media, such as written instructions and demonstration films, as well as practical exercises).

The Second World War introduced enormous training problems for the military in the USA. In order to address military training problems, the 'Division of Visual Aids for War Training' within the 'US Office of Education' produced hundreds of films and training handbooks. Military training became an example for the successful connection of research and development with professional practice. It started to prove to be useful that teams for instructional development should include instructional designers as well as subject matter experts and a 'producer.' From that time on, the necessity for professional ID standards and professional ID practitioners has been widely recognized.

In the middle of the twentieth century when learning psychology reached its peak, especially in North America, there was a systematic effort to apply learning research results to practice, including the design of instruction. Thus, important scholars of learning psychology implemented basic learning principles (operant conditioning in particular) in programmed instruction and teaching machines.

In 1965 Gagné published the influential book *The Conditions of Learning* which originally had a behavioristic orientation; later editions provided a cognitive orientation (Gagné 1985). Gagné's new procedure, again based on a theory of learning proposed a systematic choice concerning instructional methods corresponding to a classification of instructional goals by hierarchically ordered kinds of learning. The procedures for evaluation and control of learning success were improved in the 1960s; the term 'criterion-referenced measurement' emerged characterizing goal-oriented tests. One important addition to ID was to give precedence to 'needs assessment' as a necessary precursor to other already existing steps of the ID process. Therefore, ID models should not simply start with the establishment of instructional goals but with an analysis of which instructional goals are useful for anticipated audiences in a particular environment. In the middle of the 1970s a major 'watershed' of professionalism of instructional designers was reached in the USA. For the first time, instructional designers became responsible contract partners for course development ahead of subject matter experts. In Europe this development was delayed.

The turn from behavioral to cognitive psychology produced new approaches in learning theory. In the time of behaviorism the parsimonious theory of operant conditioning encouraged the opinion that the direct transferability of learning theories found in basic research is fairly problem-free. Later, however, criticism of these basic research theories—also of cognitive approaches—included their practical applicability as well as their theoretical coherence. As a reaction, approaches of learning psychology especially created for instructional purpose were developed. In the 1990s this type of learning theory is called 'educational learning theory' (ELT). Steiner (1997) proposed such an ELT by adding European views of learning.

In the last quarter of the twentieth century, learning psychology tended to investigate more and more complex instructional matters. The contributions of modern instructional psychology become increasingly diverse. During the last 25 years, approaches of ID have tried to take more systems thinking to ID (cf. Briggs 1977, Seels and Richey 1994, Jonnassen 1996, Dijkstra et al. 1997, and recently Richey and Fields 2000). This concerns

(a) the view on instructional systems, subsystems and its relationships to the environment;

(b) the development of highly systematic, often linear or branched design procedures; and

(c) more emphasis on systemic approaches of ID, which takes the inter-relation of all relevant factors of instruction into account.

Finally, more attention is given to the philosophical and theoretical grounding of ID principles (cf. Reigeluth 1999, Tennyson et al. 1997).

3. Present Applications of ID

The systematic application of ID generally contains the following subtasks:

(a) performing a needs assessment,
(b) identifying instructional goals,
(c) analyzing goals into subgoals and identifying prerequisite knowledge,
(d) defining what the learners have to learn to bridge the gap between prerequisite knowledge and subgoals,
(e) developing criterion-referenced tests and/or other assessment measures,
(f) developing instructional strategies,
(g) developing materials and preparing media,
(h) conducting formative evaluation, and
(i) conducting summative evaluation (a final evaluation of the whole instructional procedure).

It should be noted that these are typical tasks found in many current ID models; variations among professional practitioner models still exist. Moreover, from a systemic point of view these subtasks are interrelated and are usually not performed in a linear way or only a single time; rather, the practice of ID is interactive and responsive to individual situations (cf. Richey and Fields 2000).

ID approaches can be applied in all fields and situations that deal with education and training, including school settings, technical training, professional training, collaboration with human resource development professionals in industrial and professional organizations, higher education and university settings, as well as in distance and life-long learning situations—using all old and new kinds of media and telecommunications. In short, ID has matured into a broad profession with many connections to other professions and activities, including personnel and project management.

It is especially noteworthy that the practice of ID often involves a variety of experts, such as text designers, media designers, software programmers, subject matter experts, and learning specialists. Such a team is obviously necessary when the development involves technology-based learning or instruction since the required skills and expertise are likely to be distributed among a variety of specialists. When ID teams are involved, it is critical to have recognized standards and an established methodology.

4. Challenges for Future Theory, Research, and Development

Important challenges in the future for theory, research, and development are:

(a) Dealing with integrated sets of learning goals for teaching complex skills and higher-order skills. Such transferable skills become more and more important in our society (cf. van Merriënboer 1997).

(b) An expert can broaden his or her competency by integrating the individual knowledge *and* the resources of getting, storing, and processing information externally by computerized tools. To take this into account we need to develop more powerful, integrated techniques for instructional and task analysis.

(c) Fostering the systematic design of collaborative learning/team training, of new technological developments in distance education, in particular web-based instruction.

(d) We need models for designing media mixes instead of models for media selection.

(e) Dealing with highly heterogeneous target groups (differences in prior knowledge and skills, cultural diversity, older learners) and target groups with low motivation (e.g., 'teens at risk').

(f) Further development of effective forms of assessment. The need for assessment of efficient ID solutions is often underestimated.

(g) Automating ID processes using techniques of artificial intelligence. This can help to lower the cost, e.g., by generating tasks for a given item format and content, or to produce automatically instructional materials for a variety of products of the same type.

(h) Last but not least, a better theoretical foundation for ID, which takes into account the whole problem of providing *useful* knowledge for human beings in our world of nearly unlimited possibilities for getting immense information from everywhere.

Instructional Psychology

1. Introduction

Instructional psychology is the study of the processes and outcomes of human learning in a variety of educational and instructional settings, and of the nature and the design of environments that are appropriate to elicit those learning processes aiming at the attainment of competence and of a disposition toward skilled learning, thinking, and problem solving in a given domain. The term 'instructional psychology' was introduced in 1969 by Gagné and Rohwer (1969) as title of their literature review in the *Annual Review of Psychology* of a field of inquiry indicated until then as 'educational psychology.' Today one can say that while educational psychology is somewhat broader in scope than instructional psychology—involving, for instance, psychological aspects of childrearing in the family—both terms cover largely the same domain of research, because most work has been done on studying knowledge and skill acquisition in instructional settings. A major reason for this state of the art is that since the 1960s there has been a growing convergence between the psychology of learning and instruction on the one hand, and cognitive science on the other. As a result the mainstream of theory and research has focused on the analysis of knowledge, performance, and competence in a variety of complex cognitive task domains, and instructional psychology has during the 1980s 'become a vigorous part of the mainstream of research on human cognition and development' (Glaser and Bassok 1989, p. 631).

The question whether the tremendous amount of research in instructional psychology over the past decades has contributed to better educational practices remains controversial. In this respect the distinction between a disciplinary vs. an educational orientation in educational/instructional psychology is relevant. In the first case, instructional psychology is considered as an offshoot of psychology which mainly aims at contributing to the development of theory and methodology within the broader domain of the mother discipline. In the second case, the focus is rather on acquiring a better understanding of education as a basis for the improvement of educational practices. The disciplinary orientation has dominated for a large part of the twentieth century, especially during the associationist and behaviorist era in psychology. The prevailing type of research were laboratory studies characterized by a great concern for internal validity, and, thus, including a high degree of experimental precision. But this way of conducting research easily overlooked educationally important aspects, and has therefore been often criticized for its lack of classroom relevance. Whereas the discipline approach is certainly still alive today, the educational orientation in instructional psychology has gained more and more ground since the 1970s, and has by now resulted in an empirically underpinned knowledge base that can guide the analysis of teaching practices, but also the design of new, powerful learning environments.

A comprehensive review of this extensive field of research is outside the scope of this entry. Snow and Swanson (1992) have distinguished five essential components in a theory of learning from instruction: (a) description of desired end states or goals of instruction in a domain; (b) description of goal-relevant initial states of learners prior to instruction; (c) explanation of the transition processes from initial to desired states; (d) specification of instructional conditions that promote this transition; and (e) assessment of performance and instructional effects. This entry will focus selectively on three of these components, namely desired end states, transition processes, and instructional conditions. For a more thorough overview of the field, especially from an Anglo-Saxon perspective, the reader is referred to the series of review articles in the *Annual Review of Psychology* (especially those from 1981 on), and the first *Handbook of Educational Psychology* (Berliner and Calfee 1996). To get a more comprehensive idea of European research, one can consult the periodicals *European Journal of Psychology of Education* (published since 1986), and *Learning and Instruction. The Journal of the European Association for Research on Learning and Instruction* (published since 1991), and the volumes appearing in the series *Advances in Learning and Instruction*, recently begun to be published by Elsevier Science.

2. Toward a Dispositional View of Competence as Desired End State

During the behaviorist era learning was a prominent issue in psychological research. But with the advent of cognitive science the focus shifted toward the analysis of the structures and processes of human competence in an attempt to answer questions concerning the representation and organization of knowledge, the nature and characteristics of understanding, and the knowledge and cognitive skills involved in competent problem solving. This work, resulting in the identification of critical aspects of expert performance, is relevant from an educational perspective, because it contributes to defining the primary goals of learning in different instructional and training settings. In this respect there is now a broad consensus that becoming skilled in a given domain requires the integrated acquisition of four categories of aptitudes (for a more detailed discussion see, e.g., De Corte 1995):

(a) a well-organized and flexibly accessible domain-specific knowledge base, that constitutes the substance of a subject-matter field;

(b) heuristic methods, i.e., search strategies for problem analysis that increase the probability of finding the right solution, because they induce a systematic approach to the problem;

(c) metacognition which involves knowledge and beliefs about one's own cognitive functioning on the one hand, and skills and strategies for the self-regulation of one's own cognitive processes on the other; and

(d) affective components such as beliefs, attitudes, and emotions relating to a subject-matter field.

In the early days of cognitive science, laboratory investigations using mainly knowledge-lean tasks showed the important role of general cognitive skills in skilled problem solving. But starting in the mid-1970s expert–novice studies in rich content domains demonstrated the significant role of domain-specific knowledge in expert performance. Yet continued research in the 1980s evidenced that domain-specific knowledge could not fully account for human expertise, and showed that metacognitive, self-regulatory skills are a major determinant of successful learning and skilled thinking. Nowadays most scholars endorse the viewpoint that 'we should combine the learning of domain-specific subject matter with the learning of general thinking skills, while also making sure that children learn to monitor and control their thinking and learning' (Bruer 1993, p. 52).

However, the available evidence shows that the integrated acquisition of domain-related knowledge and general cognitive skills is not yet sufficient to overcome the well-known phenomenon of inert knowledge. In other words, expert performance entails more than the sum of the different categories of aptitudes mentioned above; it requires in addition a disposition toward skilled learning, thinking, and problem solving. According to Perkins (1995), a disposition involves, besides ability and motivation, two other crucial components, namely sensitivity and inclination. Sensitivity refers to the feeling for problem situations in which it is relevant and useful to apply acquired knowledge and skills, while inclination is the tendency to do so whenever appropriate. This dispositional conception of expertise accounts for the phenomenon of inert knowledge: students often possess the ability to perform certain tasks or to solve problems, but do not exercise them because of lack of spontaneous inclination and sensitivity.

Since the beginning of the 1990s it has been properly observed that due to the dominance of the information-processing approach, instructional psychology has studied cognition and learning too one-sidedly from a cognitive perspective. Therefore, researchers have begun to pay more attention to building connections between the affective, emotional, and motivational aspects of learning on the one hand, and the cognitive components on the other (see, e.g., Boekaerts 1992). In this respect the dispositional view of skilled learning and thinking offers a useful framework for the integration of both kinds of aptitudes, in the sense that the sensitivity and inclination aspects of the disposition can be conceived of as interfaces or mediators between the cognitive and the affective components.

Being able to transfer knowledge and skills to new learning tasks and problem situations is widely considered as an important goal of education. Therefore, it is not surprising that since the early days of instructional psychology, transfer has repeatedly been, and still is, the main focus of research on learning and instruction. The available literature shows that transfer is a very complex phenomenon, that transfer effects do not occur spontaneously, and that they are even difficult to obtain deliberately (see, e.g., De Corte 1999).

3. Constructive Learning as Lever for the Transition from Initial to Desired End State

Due to the emphasis of cognitive psychological research on the analysis of performance, the study of learning was largely unpopular in the early days of the information-processing approach. But the scene has changed since then, and many researchers working in the cognitive tradition show an active interest in learning processes. Moreover, their work has been enriched by contributions from research on learning in nonschool settings, especially anthropological studies of apprenticeships. From this research a series of characteristics of effective and meaningful learning processes has emerged, which can be summarized in the following definition of learning: it is a constructive, cumulative, self-regulated, goal-directed, situated, collaborative, and individually different process of mean-

ing construction and knowledge building. Only some of these characteristics can be briefly elaborated here (see De Corte 1995 for a more detailed discussion).

3.1 Learning is Constructive

Research has shown that learning is an effortful and mindful process, in which students actively construct knowledge and skills through reorganization of their already acquired mental structures in interaction with the environment. Some scholars—often inspired by the work of Piaget (1955)—take a radical position in this respect, claiming that all knowledge is a subjective and idiosyncratic cognitive construction; others represent a more moderate point of view that allows for the possibility of mediating learning through appropriate guidance. Notwithstanding the large variety in theoretical perspectives along the radical–moderate dimension, the constructivist view certainly implies that acquiring knowledge and skills requires active cognitive processing from the learner.

3.2 Learning is Self-regulated

This feature refers to the metacognitive nature of effective learning, and is implied in the constructive perspective. Indeed, self-regulation means that students manage and monitor their own processes of knowledge building (Schunk and Zimmerman 1998). Skilled self-regulation facilitates appropriate decision making during learning, as well as the monitoring of an ongoing learning process by providing one's own feedback and performance evaluations, and by keeping oneself concentrated and motivated. The more students become self-regulated, the more they assume agency over their learning; consequently they are less dependent on external, instructional support for performing those regulatory activities. An additional argument for promoting students' self-regulation of their learning derives from the finding that high levels of metacognition facilitate transfer: students having good metacognitive awareness and strategies are more able at using what they have learned to approach unfamiliar problems in multiple ways (Brown 1989).

3.3 Learning is Situated and Collaborative

The conception that learning and cognition are situated emerged in the 1980s in reaction to the then prevailing mentalistic, information-processing view of learning and thinking as highly individual and purely cognitive processes occurring in the head, and resulting in the construction of mental representations. In contrast, situativity theory—influenced by the work of Vygotsky (1978)—proposes a contextualized and social conception of learning and thinking: learning is enacted essentially in interaction with the social and cultural context and artifacts, and especially through participation in cultural activities and contexts (Brown et al. 1989). In other words, effective learning is not a purely 'solo' activity, but essentially a distributed one, i.e., the learning effort is distributed over the individual students, their partners in the learning environment, and the resources and tools that are available. Thus, this situated perspective strongly stresses the importance of collaboration in productive learning reflected in such activities as exchanging ideas, comparing solution strategies, and discussing arguments.

4. Powerful Teaching–Learning Environments to Promote Transition to the Desired End State

Powerful teaching–learning environments create the appropriate instructional conditions to evoke in students the learning processes that facilitate transition from their initial state toward the disposition to productive learning, thinking, and problem solving. Therefore, a challenging task for instructional psychology research consists of elaborating and validating a coherent framework of principles for the design of such powerful learning environments. Starting from our current knowledge and understanding of skilled performance in a variety of content domains (as described in Sect. 2) and of the characteristics of effective acquisition processes (see Sect. 3), but also based on observation of the practice of excellent teachers, researchers have begun to address this challenge over the past few years. A promising approach in this respect consists in the creation and evaluation in real classrooms of complex and fundamentally new instructional interventions guided by design principles that embody this present understanding of competence, of effective learning processes, and of successful teaching. Major examples of such orienting principles for the design of powerful learning environments are the following (De Corte 1995):

(a) Learning environments should initiate and support constructive and self-regulated acquisition processes in all students, thus also including the more passive learners. However, from a moderate constructivist perspective, students' construction of knowledge can be mediated through appropriate guidance by teachers, peers, and educational media. In other words, the claim that productive learning requires good teaching still holds true. But, this first principle also implies that systematic interventions should gradually be removed, so that students progressively become agents of their own learning.

(b) Complementary to the first principle, learning environments should allow for the flexible adaptation of instructional support, especially the balance be-

tween self-regulation and external regulation, to take into account individual differences in cognitive as well as in affective and motivational aptitudes. Moreover, the crucial influence on learning of motivational factors points to the necessity of balancing instructional interventions and affective support (Boekaerts 1992).

(c) Taking into account the situated and collaborative nature of effective learning, powerful learning environments should embed students' constructive acquisition processes as much as possible in real-life contexts that have personal meaning for the learners, that offer ample opportunities for distributed learning through social interaction and cooperation, and that are representative of the tasks to which students will have to apply their knowledge and skills in the future. Acquisition of a disposition to skilled learning and thinking, especially the inclination and sensitivity aspects of this disposition, will require extensive experience and practice with the different aptitudes involved, in a large variety of situations.

(d) Because domain-specific knowledge and domain-general heuristic and metacognitive strategies play a complementary role in competent learning and problem solving, learning environments should create opportunities to acquire general cognitive skills embedded in different subject-matter domains.

Cognitive apprenticeship (Collins et al. 1989) is a model for the design of innovative learning environments that is largely in accordance with those principles. The model describes four dimensions that constitute a learning environment: content, teaching methods, sequence of learning tasks, and social context of learning. With respect to content, an ideal learning environment should focus on the acquisition of all categories of knowledge that experts master, namely domain-specific knowledge, heuristic methods, metacognitive skills, and learning strategies. To help students to acquire those different categories of knowledge and skills, the teacher can apply six different teaching methods: modeling, coaching, scaffolding, articulation, reflection, and exploration. The model specifies three principles for sequencing the learning tasks: increasing complexity, increasing diversity, and performing global before local skills. Finally, five guidelines are given for creating a favorable social context for learning: situated learning, opportunities for observation of experts, enhancing intrinsic motivation, fostering cooperative learning, and comparing problem-solving processes and strategies.

Although further research is needed to validate the design principles described above, a series of intervention studies in a variety of content domains that embody those guidelines to some degree have already reported supporting empirical evidence. Often these investigations also integrate educational technology, especially computer programs and, more recently, multimedia systems, in their learning environments. One of the most representative examples of such a research-based attempt at totally changing the classroom environment is the Schools for Thought project in the USA (Lamon et al. 1996).

5. *Conclusion*

This selective, and thus incomplete, review shows that in the 1980s and 1990s research in the field of instructional psychology made substantial progress toward the elaboration of a theory of learning from instruction. Indeed, we now have a fairly good understanding of what skilled performance in a large variety of content domains involves. At the same time the research in which performance of experts and novices was contrasted has contributed to the clarification of one of the components of a theory of learning from instruction that was not explicitly addressed in this article, namely the description of goal-relevant initial states of learners prior to instruction. Considerable advances have also been made in unraveling major characteristics of effective learning processes. And a series of intervention studies has started to address basic questions relating to the design and evaluation of powerful teaching–learning environments to elicit and maintain acquisition processes that are conducive to the attainment of a disposition to competent learning, thinking, and problem solving.

Instructional Technology: Cognitive Science Perspectives

Intelligent tutoring systems (ITS) are computer-based instructional systems that are founded on the assumption that learning based on individualized instruction by a competent tutor is far superior to classroom-style group instruction. Good human tutors are 'intelligent tutors' because they are able continously to adapt the content and style of their instruction to best meet the needs of the learner. Can we achieve such a functionality using a computer program? This is, in a nutshell, the fundamental goal of ITS.

1. *Traditional Computer-based Instructional Systems*

The first generation of computer tutoring systems were developed in the late 1960s. They were essentially a kind of programmed instructions. They mostly presented pieces of information, e.g., some element of the course content to be learned, asked short-answer questions to check whether the student had learned this element correctly, and branched to further presentations depending on the answer given. The answer provided by the student, simply marked by the program as correct or incorrect, was used to determine the next step of the student's path along the course. These 'traditional' systems are often called computer-aided instruction (CAI) or computer-based instruction (CBI).

This technique already permits first steps towards the individualization of instruction, at least in principle. For example some authors try to anticipate every possible incorrect student response and to prespecify branches depending on the supposed cause of every incorrect answer. The main advantage of these traditional CAI programs is that it allows students to learn or to get trained at their own pace and in their own chosen setting (time and place). Their main drawback was the basically linear progression of the instruction. These systems were unable to explicitly take into account the learners' knowledge, learning style, and preferences, their individual progression, and the underlying cause of their errors.

2. *AI-based Instructional Systems*

The evolution beyond traditional computer-assisted instruction toward ITS has to pass three tests of intelligence. First, the subject matter, or domain, must be 'known' to the system well enough for it to draw inferences or solve problems by itself. Second, the system must be able to diagnose a learner's approximation of the knowledge to be acquired. Third, the tutorial strategy or pedagogical knowledge must be intelligent in the sense that different strategies can be implemented to reduce the difference between the knowledge to be learned and the student's actual knowledge.

The next generation of tutoring systems were based on building knowledge of the subject matter into the program (see Sleeman and Brown 1982 or Wenger 1987 for a detailed documentation and overview). There were different types of these so-called intelligent CAI or ITS. One type coached students working in open-ended learning environments to solve complex problems, such as troubleshooting an electronic circuit, writing a computer program or learning arithmetic skills. Another type attempted to have some kind of a dialog with students, e.g., in the sense of a problem monitor or as a consultant.

The first ITS-type program, Scholar, was developed by Carbonell (1970). Its subject matter was the geography of South America. What was new then was that the system's knowledge of its domain matter was explicitly represented in a semantic network utilizing AI techniques and methods. The nodes of the network stood for geographical objects and concepts. These objects and concepts were organized in a partial hierarchy with relations like superpart, superconcept, and superattribute. Inferences could be made by propagation of inherited properties via these links.

This underlying representation technique gave the system a new quality of competence.

It knew how to solve the tasks given to the student; it no longer needed a data bank of preformulated exercises together with their solutions. Such a system was capable of answering student questions as long as they were domain-related. A further consequence was that the problem-solving process itself could become part of the taught domain. Another new quality of Scholar was its capacity for mixed initiative dialogs based on a simple but robust user interface to correctly interpret the student's questions and responses and to transmit them to the inference engine. Due to the problems of understanding and generation of natural language, only a few systems of this type were built.

2.1 The Basic Architecture of ITS

ITS developed since 1970 usually contain four basic components or modules (Sleeman and Brown 1982, Wenger 1987).

(a) An environment (user interface) in which the student works on complex tasks. For instance, it might be a simulated piece of an electronic circuit that the student tries to troubleshoot.

(b) An expert system (domain knowledge base) that knows enough about the problems that the student works on to solve them by itself.

(c) A student modeling component (student model) that compares the student's behavior with the expert system's behavior in order both to recognize the student's current knowledge for solving the problem and determine what elements of correct as well as incorrect knowledge the student is probably using.

(d) A tutorial module (teaching module) that suggests tasks to be solved, responds to the student's requests for help, and points out mistakes. Such responses and suggestions are based on a library of flexible usable teaching strategies as well as on the system's model of the student's knowledge and plans.

In general, these systems try to simulate good human tutors by the integrated use of different knowledge bases. They are domain experts in the subject matter to be learned by the student, they are teaching experts using different tutorial strategies and interventions for supporting the student's acquisition of knowledge, and they are educational/psychological experts in the assessment and evaluation of the student's domain-related knowledge. Sometimes these ITS are therefore also called knowledge-based tutors (e.g., Murray 1998).

2.2 Student Modeling

The idea of the necessity of some kind of student modeling was around from the beginning. The argumentation is well known. Efficient teaching implies that the communication of the knowledge to be learned is adapted to the cognitive prerequisites and requirements of the learners, especially to their domain knowledge. The representation of domain knowledge implemented in the ITS should reflect the student's mental representation of this knowledge. In its simplest form, there may be only a list of what the student knows or should know. There may also be some techniques to model the learner's errors based on incorrect and/or incomplete knowledge. Such techniques include systematic errors, often modeled as bugs, impasses, misgeneralizations or repairs in procedural skills (Brown and Burton 1978, Young and O'Shea 1981, Sleeman 1984, VanLehn 1990), or as some kind of overlay model (Goldstein 1982). In its most complete state, the student model also contains domain-independent knowledge. In that case, the system also has to know something about knowledge acquisition based on learning processes, therefore referring to different types of students rather than to different domains. Examples of these kinds of student modeling can be found in the work of Anderson and his group (e.g., Anderson et al. 1989, Anderson and Lebiere 1998). With such information, the system is then capable of associating specific tutoring strategies to specific learning strategies.

Thanks to the complex integration of the various system modules, such an ITS is able to guide the learner as evolving to become an expert, at least in principle. Through the presentation of specific questions, tasks, or explanation requests, certain comprehension errors can be detected. Moreover, thanks to the knowledge it might thus have (or even gain) about students and their specific knowledge, problem-solving strategies, and learning mechanisms, it would be able to support a student's learning and knowledge acquisition in quite an individualized manner.

2.3 Applications

In the last half of the 1980s many ITS were developed, despite the immense costs and the complexity involved. But they were not only in use for academic purposes. ITS have moved out of the laboratory and into classrooms and workplaces, where some have proven to be highly effective as learning aides. For example, students working with an Air Force electronics trouble-shooting tutor for only 20 hours gained proficiency equivalent to that of trainees with 48 months of on-the-job experience (Lesgold et al. 1992). In another example, students using the LISP tutor (Anderson 1990) completed programming exercises in 30 percent less time than those receiving traditional classroom instruction and scored 43 percent higher on the final exam.

Although ITS were becoming more common and proving to be increasingly effective, each one had to be built from scratch at a great expense. There was also

no standardization with regard to the software and hardware used. Authoring tools for ITS have not been available until recently (Murray 1998). Although ITS show their potential effectiveness for educational purposes, there are other applications as well (cf. VanLehn 1999). A common practice is to build an open learning environment without the underlying expert system, without any student model, and without any tutorial module. The environment enables student activities that stimulate learning and may be impossible to conduct in the real world. For instance, an environment might allow students to conduct simulated physics experiments on worlds where gravity is reduced, absent, or even negative. Such environments are called interactive learning environments, microworlds, or virtual laboratories. Another new trend is to use networking to allow several students to work together in the same environment.

2.4 *ITS from a Cognitive Science Point of View*

One of the lessons learned in the development of an ITS is that it requires the knowledge and collaboration of different disciplines. But empirical cognitive studies are nevertheless particularly important in developing ITS. Developing the expert module of a tutoring system requires studying experts as they solve problems in order to understand and formalize their knowledge. Developing an effective teaching module requires understanding how students learn so that the tutor's comments will prompt students to construct their own understanding of the subject matter. An overly critical or didactic tutor may do more harm than good. A good first step in developing an application is to study the behavior of expert human tutors in order to see how they increase the motivation and learning of students. Developing the student model one needs to understand how students acquire new knowledge and how they apply their knowlege to solve problems. A good way to achieve this is a detailed analysis of the subject matter, its main concepts, and their relational structure and of important procedural skills to solve problems and tasks within the domain. An empirical study of students' errors and most typical misconceptions might also be helpful.

2.5 *Conclusions*

Many ITS have been developed since the mid-1970s and the requirements to be solved during the development of an ITS generate many fruitful interactions between academic research and application-oriented research with regard to topics like knowledge representation, computerized assessment of knowledge, learning and knowledge acquisition, expertise research. Nevertheless from a cognitive science perspective some difficult problems have not been sufficiently solved until now: First, the requirement of a quick and reliable in-time and on-line diagnosis of knowledge. Even within very complex and large behavioral spaces the system's feedback must be given immediately. Otherwise the user will not accept the system for a long time. The dynamic assessment of valid indicators and their interpretation with respect to the student's knowledge acquisition processes, goals, and problem-solving strategies still includes many open questions. Second, the systematic consideration of motivational and emotional aspects is an important question of research. Third the transitions between the content of the student model and the tutorial knowledge (system feedback, kind of help, strategic-didactical decisions, content and style of information presentation) needs more controlled empirical evidence. ITS are still an active topic of many research activities, not only because of the many problems to be solved but because of the ongoing growing requirement of computerized training and education.

3. *Current Trends*

The present research tends to be more and more interdisciplinary, slowly but surely making more effective the collaboration between course designers, cognitive scientists, computer scientists, and educators/psychologists/teachers. With regard to the uses of new technologies of information and communication in education, the main interest lies in exploiting Internet possibilities, especially the Web. Some important trends are outlined below: distance learning and teletutoring, collaborative learning, and Web-based learning. Finally, an active area surpasses them all: the evaluation of educational systems.

3.1 *Distance Learning and Teletutoring*

Distance learning and teletutoring are extremely active areas of research. Many courses are now being developed on the Web. Distance learning means that the learning material is offered as computer-based training (CBT) or as Web-based training (WBT) that can be used by students in their own learning environment at their place of work or at home. The access and interaction is completely self-organized. Teletutoring means that there is a teacher/tutor who primarily takes the role of a moderator. This teacher supports ongoing learning activities in individuals but also in groups. Communication is the most important concept. One well-known variant of teletutoring is the online seminar in which a classical teaching form is virtually imitated. Some researchers are also investigating ways to use the Web meaningfully and

effectively to develop new types of pedagogical paradigms (e.g., see the recent conferences on AI in education).

3.2 Collaborative Learning

In cognitive science, a whole area of research is striving to enhance computer supported collaborative/cooperative learning (CSCL). The basic goal is to develop learning environments in which groups of students can communicate with each other, interact with each other, and learn and solve problems together. The cooperation might take place at the same time or at different times (synchronous/asynchronous CSCL) and at the same place or at different places (local or distributed CSCL). Probably this field will play a much more prominent role in the future. It integrates the fast growing potential of new information technology (e.g., multimedia, interactivity), new learning theories (situated learning, learning as social activity, distributed learning) and the perspective of knowledge acquisition based on explanation, argumentation, and discourse. A good overview of ongoing research in this field can be found in the various contributions in Koschmann (1996) and Dillenbourg (1999).

3.3 Web-based Learning

Since the Web is the major result of the present technological progress, it can be expected that it will have a steadily growing influence on computerized training and education (e.g., Eisenstadt and Vincent 1998, Forsyth 1998, Bruns and Gajewski 2000). However, since it is only a technological evolution, it will probably act more as a catalyst than as a conceptual or theoretical leading engine. At any rate, this domain will undergo two main positive changes. The first change is the expected gain in the pedagogical capabilities of educational systems. However, this gain will be effective only through a better intercommunication and a better collaboration between educational and psychological researchers, cognitive scientists, and computer scientists. But actually to benefit from this evolution, it will be necessary to overcome several traditional but strong barriers, essentially of a cultural or administrative nature.

The second major change stems from the fast growing communication and multimedia capabilities of information technology. Owing to such capabilities, students or trainees will undoubtedly become more and more autonomous, and will feel more and more responsible for their own learning or training. The responsibility of each subject for his or her own education and training will gain increasing importance. To adapt to this evolution, teachers of all types, including university professors, will have to modify their roles by becoming rather knowledgeable guides than knowledge providers, and by becoming more student-centered. Students will be more and more engaged in their own goals, searching the Web for the information they are interested in. The drawback of these changes is that all participants in this evolution—researchers and developers, but also educators and school administrators—will have to adapt to that evolution adequately, whether they like it or not. Information technology will evolve anyway, and we should actively use the new possibilities of this evolution.

3.4 Evaluation of Educational Systems

Finally, with the variety and number of educational programs and prototypes developed, and with the variety of theories, methods, and techniques put to use in the field of computerized education, the need to better understand the pros and cons of that field gets increasingly stronger. Therefore the task of evaluating educational systems, and the methods and processes used to evaluate them, will receive growing interest.

3.5 Concluding Remarks

At the turn of the twenty-first century there are no up-to-date textbooks on intelligent tutoring. Sleeman and Brown (1982), Polson and Richardson (1988), Self (1988), and Wenger (1987) cover the basic ideas as well as the early systems. Lelouche (1999) gives a survey of the history of ITS and also a general outlook on the present trends of research. Self (1999) reviews the evolution of the ITS research, namely to make computationally precise and explicit the forms of educational, psychological, and social knowledge necessary for the design and implementation of computer-based learning systems. The latest work generally appears first in the proceedings of the conference on Intelligent Tutoring Systems or in the proceedings of the conference on AI in Education. The most relevant journals for this kind of work include the *International Journal of AI in Education* (http://cbl.leeds.ac.uk/ijaied/), the *Journal of the Learning Sciences* (Erlbaum), and *Interactive Learning Environments* (Ablex). There are also many Web-based educational systems available covering quite different subject matters. To get an impression of what is going on in the field, it might be helpful simply to use some of these systems.

Instrumental Variables in Statistics and Econometrics

The method of instrumental variables (IVs) is a general approach to the estimation of causal relations using observational data. This method can be used when standard regression estimates of the relation of interest are biased because of reverse causality, selection bias, measurement error, or the presence of unmeasured confounding effects. The central idea is to use a third, 'instrumental' variable to extract variation in the (IV) variable of interest that is unrelated to these problems, and to use this variation to estimate its causal effect on an outcome measure. This article describes IV estimators, discusses the conditions for a valid instrument, and describes some common pitfalls in the application of IV estimators.

1. The Method of Instrumental Variables

1.1 Common Problems with Standard Regression Analysis of Observational Data

In many cases in the social and behavioral sciences, one is interested in a reliable estimate of the causal effect of one variable on another. For example, suppose a mayor is considering increasing the size of the police force; what is the effect of an additional police officer on the crime rate? Or, what is the effect of an additional year of schooling on future earnings? What will happen to economic growth if the central bank raises short-term interest rates by one percentage point? What is the effect of a new medical procedure on health outcomes? These and many other questions require estimates that are causal, in the sense that they are externally valid and can be used to predict the effect of changes in policies or treatments, holding other things constant.

In theory, such causal effects could be estimated by a suitably designed randomized controlled experiment. Very often, however, as in the first three questions, such an experiment could be prohibitively expensive, could be unethical, and/or could have questionable external validity. Even when randomized controlled experiments are available, such as clinical trials of medical procedures, it is of interest to validate the experimental predictions using information on outcomes in the field. Thus, to address such questions empirically typically entails the use of nonexperimental, i.e., observational, data.

Unfortunately, standard regression analysis of observational data can fail to yield reliable estimates of causal effects for many reasons, four of which are particularly salient. First, there could be additional unmeasured effects, leading to 'omitted variable bias'; for example, the educational attainment of parents is

correlated with that of their children, so if parents' education facilitates learning at home but is unobserved then the correlation between years of school and earnings could overstate the true, causal effect of school on earnings. Second, there might be reverse causality, or 'simultaneous equations' bias; for example, more police officers might reduce crime, but cities with higher crime rates might demand more police officers, so standard regression analysis of crime rates on the number of police confounds these two different effects. Third, there could be selection bias, in which those most likely to benefit from a treatment are also most likely to receive it; for example, because ambition is one reason for success both at school and in the labor market, the measured correlation between years of school and earnings could simply reflect the effect of unmeasured ambition. Fourth, standard regression estimates of the causal effect are biased if the regressor is measured with error (see *Measurement Error Models*).

1.2 IV Regression

IV regression provides a way to handle these problems. The main early application of IV methods was for estimating the parameters of a system of linear simultaneous equations, and this remains a good expositional framework. Let y_i denote the outcome variable of interest (say, log future earnings), let Y_i denote the r treatment variables (years of education), let X_i denote K_1 additional observed control variables, and let Z_i denote the K_2 instrumental variables, where these are all observed for observations $i = 1,\ldots, N$. Also let β and γ be unknown parameter vectors, let Φ and Π be matrices of unknown parameters, and let β' denote the transpose of β. Suppose that these variables are linearly related as

$$y_i = \beta' Y_i + \gamma' X_i + u_i \tag{1}$$

$$Y_i = \Phi X_i + \Pi Z_i + V_i \tag{2}$$

where u_i and V_i are 'error terms' that represent additional unobserved effects, measurement error, etc. The coefficient of interest is β; in the schooling example, this is the percentage change in future earnings caused by attending school for an additional year.

In this notation, the four problems listed in the preceding paragraph have a common implication, that the correlation between Y_i and u_i is nonzero, and in consequence the ordinary least squares (OLS) estimator of β will be biased and, in large samples, inconsistent. It is assumed that corr $(X_i, u_i) = 0$; at this level, this assumption can be made without loss of generality, for if this is suspected to be false for some element of X, then it should be listed instead in Y. In the terminology of simultaneous equations theory, y and Y are endogenous variables and X is exogenous.

The key idea of IV methods is that although Y is correlated with u, if Z is uncorrelated with u (that is, if Z is exogenous), then Z can be used to estimate β. Intuitively, part of the variation in Y is endogenous and part is exogenous; IV methods use Z to isolate exogenous variation in Y and thereby to estimate β. More formally, consider the simplest case, in which there is no X in (1) or (2) and which Y and Z are single variables (i.e., $K_1 = 0$ and $r = K_2 = 1$). Then $\text{cov}(y, Z) = \beta\ \text{cov}(Y, Z) + \text{cov}(u, Z) = \beta\ \text{cov}(Y, Z)$. Thus, $\beta = \text{cov}(y, Z)/\text{cov}(Y, Z)$. This leads to the IV estimator, $\hat{\beta}^{\text{IV}} = s_{yZ}/s_{YZ}$, where s_{yZ} is the sample covariance between y and Z. Evidently, if these two sample covariances are consistent and if $\text{cov}(Y, Z) \neq 0$, then $\hat{\beta}^{\text{IV}} \xrightarrow{\text{p}} \beta$. The availability of the instrument Z thus permits consistent estimation of β.

If more than r instruments are available, it makes sense to use the extra instruments to improve precision. There are, however, many ways to do this, since each subset of r instruments will produce its own estimate of β. The most common way to combine instruments is to use two stage least squares (2SLS). In the first stage, Eqn. (2) is estimated by OLS, producing the predicted values $\hat{Y}$. In the second stage, y is regressed against $\hat{Y}$ and X, yielding the 2SLS estimator $\hat{\beta}^{\text{2SLS}}$. With only one instrument, this reduces to $\hat{\beta}^{\text{IV}}$ given above. Under Gaussian disturbances, this provides an asymptotically efficient method for weighting the various instruments that is easy to understand and to implement.

1.3 Conditions for Valid Instruments

The question of whether a candidate set of instruments can be used to estimate β is a special case of the more general problem of identification of parameters in multivariate econometric and statistical models. In the context of (1) and (2), when there is a single Y, the requirements for instrument validity are simple. Then a potential instrument Z must satisfy two conditions: (a) Z is uncorrelated with u; and (b) the partial correlation between Y and Z, given X, is nonzero. The first condition states that the instrument is exogenous. The second condition is that the instrument is relevant. Together, these conditions permit using Z to isolate the exogenous variation in Y and thus to identify β. For example, when $r = K_2 = 1$ and there are no Xs, if Z satisfies the two conditions then β is identified by the moment condition derived above, $\beta = \text{cov}(y, Z)/\text{cov}(Y, Z)$.

When Y is a vector (i.e., $r > 1$), the exogeneity condition (a) remains but the relevance condition (b) is somewhat more complicated. For identification of the independent effects of each Y (all elements of β), a sufficient condition for instrument validity is that the covariance matrix of Z has full rank and that Π has

full row rank. Clearly, a necessary condition for Π to have full row rank is that there are at least as many instruments as Ys ($K_2 \geqslant r$). The number of excess instruments, $K_2 - r$, is referred to as the degree of overidentification of β.

When y is a vector, so that (1) is itself a system of multiple equations, the conditions for identification become intricate (see *Simultaneous Equation Estimation: Overview*; *Statistical Identification and Estimability*). For a rigorous and complete treatment in the linear simultaneous equations framework, see Rothenberg (1971) and Hsiao (1983).

2. IV Estimators and their Distributions

2.1 Linear Models

In addition to two stage least squares, other estimators are available for IV estimation of a single equation that is linear in the unknown parameters. The leading alternative estimator is the so-called limited information maximum likelihood (LIML) estimator. The LIML estimator minimizes the Anderson–Rubin (1949) statistic,

$$F(\beta) = \frac{\tilde{\boldsymbol{y}}'(\boldsymbol{M}_X - \boldsymbol{M}_{[X\,Z]})\tilde{\boldsymbol{y}}/K_2}{\tilde{\boldsymbol{y}}'\boldsymbol{M}_{[X\,Z]}\tilde{\boldsymbol{y}}/(N-K_1-K_2)} \tag{3}$$

$\tilde{\boldsymbol{y}} = (\tilde{y}_1 \ldots, \tilde{y}_N)'$, where $\tilde{y}_i = y_i - \beta'\mathrm{Y}_i$, and $M_X = \mathbf{I} - \boldsymbol{X}(\boldsymbol{X}'\boldsymbol{X})^{-1}\boldsymbol{X}'$, where $\boldsymbol{X} = (\boldsymbol{X}_1, \ldots, \boldsymbol{X}_N)'$. This can be solved analytically as an eigenvalue problem. Many other single-equation IV estimators have been proposed, but these are rarely used in empirical applications; see Hausman (1983) for expressions for the LIML estimator and for a discussion of other estimators.

Under standard assumptions (fixed numbers of regressors and instruments, validity of the instruments, convergence of sample moments to population counterparts, and the ability to apply the central limit theorem), the LIML and 2SLS estimators are asymptotically equivalent and have the same asymptotic normal distribution. That is, $\sqrt{\mathrm{N}}(\hat{\beta}^{\mathrm{LIML}} - \beta)$ and $\sqrt{\mathrm{N}}(\hat{\beta}^{\mathrm{2SLS}} - \beta)$ both have asymptotic normal distributions with the same covariance matrix. However, their finite sample distributions differ. There is a large literature on finite sample distributions of these estimators (see *Simultaneous Equation Estimates (Exact and Approximate), Distribution of*). Because these exact distributions depend on nuisance parameters, such as Π, that are unknown and because few IV statistics are (exactly) pivotal, this literature generally does not provide approximations that are useful in empirical applications. However, some general guidelines do emerge from these studies. Perhaps the most important is that when there are many instruments and/or when Π is small in a suitable sense, LIML tends to exhibit less bias than 2SLS and LIML confidence intervals typically have better coverage rates than 2SLS.

These methods extend naturally to the case that y is a vector and (1) is a system of equations. This entails imposing restrictions on the coefficients in (1) and (2) that are implied by the model, and then using the available instruments to estimate simultaneously all these coefficients with these restrictions imposed. The system analog of 2SLS is three stage least squares, in which all the unknown coefficients are estimated simultaneously using an estimate of the variance-covariance matrix of u obtained from the 2SLS estimates. The system analog of LIML is full information maximum likelihood. For further discussion, see *Simultaneous Equation Estimation: Overview*; *Simultaneous Equation Estimates (Exact and Approximate), Distribution of*.

2.2 Nonlinear Models

Many details of the foregoing discussion hinged on the system being linear in the parameters and variables. In many settings, however, theory suggests models that are nonlinear rather than linear. A leading class of examples is consumption-based models of asset prices, in which the equations contain nonlinearities inherited from posited utility functions of representative agents. In such settings, Eqn. (1) is usefully extended and recast to incorporate these nonlinearities. Specifically, suppose that the model at hand implies,

$$E[h(y_i, Y_i, X_i, \theta) \mid X_i, Z_i] = 0 \tag{4}$$

where as before y_i and Y_i are endogenous variables, X_i and Z_i are exogenous variables, and θ is a vector of parameters. For example, in the linear system (1) and (2), (4) is implied by $\mathrm{E}(u_i \mid X_i, Z_i) = 0$ upon setting $h(y_i, Y_i, X_i, \theta_0) = y_i - \beta' Y_i - \gamma' X_i$ and $\theta = (\beta, \gamma)$.

The orthogonality condition (4) corresponds to the first condition for a valid instrument, that Z is exogenous. If in addition Z is relevant, then (4) can be exploited to estimate the unknown parameters θ. The issue of relevance of Z is equivalent to whether θ is identified. The question of identification in nonlinear models is complex and little can be said about global identification at a general level, although conditions for local identification sometimes yield useful insights (see *Statistical Identification and Estimability*).

Given a model (4) and a set of instruments, in general a variety of estimators of θ are available. Estimation is typically undertaken by minimization of a quadratic form in $h(y_i, Y_i, X_i, \theta)$, times the instruments; 2SLS and LIML estimates obtain as special cases when h is linear. In practice, the choice of the weighting matrix in this quadratic form is im-

portant, and if there is serial correlation and/or heteroskedasticity this weighting matrix (and the standard errors) must be computed in a way that accounts for these complications. Such estimators are referred to as generalized method of moments (GMM) estimators. For discussions of identification and estimation in GMM, see Newey and McFadden (1994).

3. A Brief History of IV Methods

S. Wright (1925) and his father P. Wright (1928) introduced the estimator $\hat{\beta}^{\mathrm{IV}}$ (defined in Sect. 1.2) and used it to estimate supply and demand elasticities for butter and flaxseed; this work, however, was neglected (see Goldberger 1972). The development of IV methods in the 1940s stemmed from the attempts of early statisticians and econometricians to solve what appeared to be two different problems: the problem of measurement error in all the variables, and the problem of reverse causality arising in a system of simultaneous equations that describe the macroeconomy. The term 'instrumental variables' was first used in print by Reiersøl (1945), who developed IV estimation for the errors in variables problem and extended work by Wald (1940) which, in retrospect, also can be seen as having introduced IV estimation. Concurrently, work by Haavelmo (1944) and the Cowles Commission emphasized likelihood-based methods of analyzing simultaneous equation systems, which implicitly (through identification conditions) entailed the use of instrumental variables; Anderson and Rubin (1949) developed LIML as part of this research program.

An important breakthrough came with the development of 2SLS by Basmann (1957) and Theil (1958), which permitted computationally efficient estimation in single equations with multiple instruments. Sargan (1958) introduced IV estimation for multiple equation systems and Zellner and Theil (1962) developed three stage least squares.

The extension of these methods to nonlinear models was undertaken by Amemiya (1974) (nonlinear 2 SLS) and by Jorgenson and Laffont (1974) (nonlinear three stage least squares). The modern formulation of GMM estimation is due to Hansen (1982). GMM constitutes the dominant modern unifying framework for studying the issues of identification, estimation, and inference using IVs.

4. Potential Pitfalls

In practice, inference using IV estimates can be compromised because of failures of the model and/or failures of the asymptotic distribution theory to provide reliable approximations to the finite sample distribution. Much modern work on IV estimation entails finding ways to avoid, or at least to recognize, these pitfalls. This section discusses three specific potentially important pitfalls in linear IV estimation. These problems, as well as additional problems associated with estimation of standard errors, also arise in nonlinear GMM estimation, but their sources and solutions are less well understood in the general nonlinear setting.

4.1 Some Instruments Are Endogenous

If an instrument is endogenous then $\mathrm{corr}(Z_i, u_i) \neq 0$, and reflection upon the derivation $\hat{\beta}^{\mathrm{IV}}$ and its probability limit in Sect. 1.2 reveals that $\hat{\beta}^{\mathrm{IV}}$ is no longer consistent for β. More generally, if at least one instrument is endogenous then the 2SLS and LIML estimators are inconsistent. If at least r instruments are exogenous, however, then it is possible to test the null hypothesis that all instruments are exogenous against the alternative that at least one (but no more than $K_2 - r$) is endogenous. In practice, a researcher might have at least r instruments that he or she firmly believes to be exogenous, but might have some additional instruments which are more questionable.

Testing the null that all the instruments are exogenous entails checking empirically the assumption that the instruments are uncorrelated with u_i. This can be done by regressing the IV residual (estimated by 2SLS or LIML) against Z. The R^2 of this regression should be zero; if NR^2 exceeds the desired $\chi^2_{K_2-r}$ critical value, the null hypothesis of joint exogeneity is rejected.

Although this statistic provides a useful diagnostic and rejection suggests that the full instrument list is (jointly) invalid, failure to reject is not necessarily reassuring since the maintained hypothesis is that at least r of the instruments are valid. Moreover, this test can only be implemented if β is overidentified ($K_2 > r$). The hypothesis that at least r instruments are exogenous is both essential and untestable, and thus must be contemplated carefully in IV applications.

4.2 Weak Instruments

The condition for instrument relevance states that Z and Y must have nonzero partial correlation (given X). In practice, this correlation, while arguably nonzero, is often small, a situation sometimes referred to as the problem of weak instruments. When the instruments are weak, the usual large sample approximations provide a misleading basis for inference: the 2SLS estimator in particular is biased towards the OLS estimator, and asymptotic LIML and 2SLS confidence regions have coverage rates that can differ substantially from the nominal asymptotic confidence level. When $r = 1$, an empirical measure of the strength

of the instruments is the F-statistic testing the hypothesis $\Pi = 0$ in the first stage regression (2). The risk of weak instruments is especially relevant when there are many instruments, for even if some instruments have a large partial correlation with Y, if there are many instruments quite a few of them could be weak so taken together this first-stage F-statistic could be small.

Although no single preferred way to handle weak instruments has yet emerged, one solution is to construct confidence intervals by inverting the Anderson–Rubin statistic (3). This is readily done because $F(\beta_0)$ has an asymptotic $\chi^2_{K_2}$ distribution under the joint null hypothesis that $\beta = \beta_0$ (a fixed vector) and $\text{corr}(X, u) = \text{corr}(Z, u) = 0$ (the instrument relevance condition is not needed for this result).

4.3 Heterogeneity of Treatment Effects in Micro Data

Many modern applications of IV are to microdata sets with cross-sectional or panel data, that is, data sets where the observation units are individuals, firms, etc. An important consideration that arises in this context is the role of heterogeneity in interpreting what it is that IV methods measure. To make this concrete, consider a modification of (1) and (2), where for simplicity it is assumed that $r = K_2 = 1$ and the only X is a constant. Suppose, however, that there is heterogeneity both in the responses of each individual to the 'treatment' Y and in the influence of the instrument on the level of treatment received. In equations, this can be written as,

$$y_i = \gamma + \beta_i Y_i + u_i \tag{5}$$

$$Y_i = \Phi + \Pi_i Z_i + V_i \tag{6}$$

where β_i and Π_i vary randomly across individuals. Suppose that the instrument is distributed independently of $(u_i, V_i, \beta_i, \Pi_i)$, and technical conditions ensuring convergence of sample moments hold. Then $\hat{\beta}^{2\text{SLS}} \xrightarrow{p} E[\Pi_i \beta_i]/E\Pi_i$.

Evidently, with heterogeneity of this form 2SLS can be thought of as estimating $E[\Pi_i \beta_i]/E\Pi_i$, which differs from the usual estimand $\beta = E\beta_i$ if β_i and Π_i are correlated. For example, suppose that $\Pi_i = 0$ for half the population, that $\Pi_i = \Pi$ (which is fixed) for the other half, and that the sample is drawn randomly. If β_i differs systematically across the two halves of the population, then 2SLS estimates the mean of β_i among that half for which $\Pi_i = \Pi$; this differs from the mean of β_i over the full population. More generally, 2SLS can be thought of as estimating a weighted average of the individual treatment effects, where the weights reflect the influence of Z_i on whether the individual receives the treatment. This has been referred to as the 'local average treatment effect'; see Angrist et al. (1996).

5. Where Do Valid Instruments Come From?

In practice the most difficult aspect of IV estimation is finding instruments that are both exogenous and relevant. There are two main approaches, which reflect two different perspectives on econometric and statistical modeling. The first approach is to use *a priori* theoretical reasoning to suggest instruments. This is most compelling if the model being estimated is itself derived from a formal theory. An example of this approach is the estimation of intertemporal consumption-based asset pricing models, mentioned in Sect. 2.2 in which previously observed variables are, under the model, uncorrelated with certain future expectational errors. Thus previously observed variables can be used as instruments.

The second approach to constructing instruments, more commonly found in program evaluation studies (broadly defined), is to look for some exogenous source of variation in Y that either derives from true randomization or, in effect, from pseudo-randomization. In randomized experiments in the social sciences, compliance with experimental protocol is usually unenforceable, so a subject's decision whether to take the treatment introduces selection bias; assignment to treatment, however, can be used as an instrument for receipt of treatment. In nonexperimental settings, this reasoning suggests looking for a variable that plays a role similar to random assignment in a randomized experiment. For example, McClellan, McNeil and Newhouse (1994) investigated the effect of the intensity of treatment (Y) on mortality after four years (y) using observational data on elderly Americans who suffered an acute myocardial infarction (heart attack). Standard regression analysis of these data would be subject to selection bias and omitted variables bias, the former because the decision to pursue an intensive treatment depends in part on the severity of the case, the latter because of additional unobserved health characteristics. To avoid these biases, they used as instruments the distance of the patient from hospitals with various degrees of experience treating heart attack patients, for example, the differential distance to a hospital with experience at cardiac catheterization. If distance to such hospitals is distributed randomly across potential heart attack patients, then it is exogenous; if this distance is a factor in the decision whether to move the patient to the distant hospital for intensive treatment, then it is relevant. If both are plausibly true, then 2SLS provides an estimate of the average treatment effect for the marginal patients, where the marginal patients are those for whom the effect of distance on the decision to treat is most important.

From the humble start of estimating how much less butter people will buy if its price rises, IV methods

have evolved into a general approach for estimating causal relations throughout the social and behavioral sciences. Because it requires valid and relevant instruments, IV regression is not always an option, and even if it is, the practitioner must be aware of its potential pitfalls. Still, when they can be applied, IV methods constitute perhaps our most powerful weapon against omitted variable bias, reverse causality, selection bias, and errors-in-variables in our efforts to estimate causual relations using observational data. For recent textbook treatments of instrumental variables issues see Hayashi (2000, Chaps. 3 and 4) and Ruud (2000, Chaps. 20–2 and 26).

Insurance

There is insurance when one party agrees to pay an indemnity to another party in the event of the occurrence of a predefined random event generating a damage for the latter. The most standard example is the insurance contract where the first party—the insurer— is compensated by being paid a premium by the second party, the policyholder. But many other contracts involve some forms of insurance. For example, in share-cropping contracts, the landlord agrees to reduce the rent of land in case of a bad crop. In many instances, employers agree to pay their employees more than the competitive wage in bad years. In cost-plus contracts, the buyer accepts to pay a larger price if the producer incurred an unexpected increase in cost. In the case of income taxes, the state partially insures the losses of taxpayers by reducing the tax payment when incomes are low.

The shifting of risk is of considerable importance for the functioning of our modern economies. Insurance is desirable for risk-averse agents as a risk-reduction device through the use of the Law of Large Numbers. Moreover, insurance allows for disentangling investment decisions from risk-taking decisions. Without it, there would certainly not have been the experience of the historical economic growth of the twentieth century. Ford, Solvay, Rockefeller, and the others would not have taken the investment risks that they actually took without the possibility to share the risk with shareholders and insurers. Similarly, most consumers would not purchase new expensive cars or houses if they would not be able to insure them.

However, various informational problems (observation of the risk, solvency issues, of the prevention efforts and/or of the loss by the insurer) can make competitive insurance markets inefficient by not providing enough coverage at an acceptable price.

1. The Social Value of Insurance

There is an added value to insurance only because policyholders are risk-averse, that is they dislike zero-mean risk on wealth. Consider an agent facing a random loss X to their wealth. An insurance contract stipulates a premium P and an indemnity schedule I(.) that determines the indemnity I(X) for each possible loss X. There is full coverage if I(.) is the identity function. The actuarial value of the contract is the expected indemnity EI(X). The insurance premium is said to be actuarially fair if it is equal to the actuarial value of the contract: $P = EI(X)$. Suppose that it is the case. Then, the purchase of a full insurance contract at an actuarially fair premium has the effect of replacing a random loss X by its expectation $P = EX$. The private value of such a contract is equal to the risk premium attached to the initial risk by the policyholder. It is increasing with the policyholder's degree of risk aversion and with the riskiness of the loss. As a first approximation, the riskiness of the loss can be measured by its variance.

In order to determine the social value of insurance, the effect of the transfer of the risk on the insurer's welfare should also be measured. Consider an insurer selling n fair full insurance contracts to n policyholders, each of them bearing a random loss X_i, with $X_1, \ldots, X_n$ being identically and independently distributed. The common wisdom is that the insurer does not bear any risk in the aggregate if it is able to sell enough such insurance contracts to cover independent risks, i.e., if n is large enough. This is not true, as explained by Samuelson (1963). It is a fallacious interpretation of the Law of Large Numbers which leads people to believe that accumulating several independent risks generates diversification. Indeed, the aggregate indemnity to be paid by the insurer is the sum of the X_i. Its riskiness measured by its variance equals $n\sigma^2$, where σ^2 is the variance of each individual risk X_i. If the insurer is risk-averse, the risk transfer is not Pareto-improving since it makes the insurer worse off. The classical view of modern finance on this problem is to recognize that insurance companies are not owned by a single person, but rather by a large set of shareholders. If insurable losses are uncorrelated with financial markets returns, the riskiness of insurance companies has no adverse effect on shareholders. In such a situation, the risk transfer to insurance companies is Pareto-improving, and the social value of insurance companies can be measured by the sum of the risk premia associated by policyholders to their random loss.

An alternative insurance scheme is to organize a mutual arrangement among the n risk-averse agents. Consider an arrangement in which the pool guarantees to each of its member a complete coverage of losses against an ex-post contribution equaling the average loss in the pool. In such a scheme, the random loss X_i is replaced by $(X_1 + \ldots + X_n)/n$, whose variance is $1/n$ the variance of X_i. In consequence, this mutual arrangement is Pareto-improving. At the limit, when n tends to infinity, individual risks are completely washed out by diversification.

2. Efficient Risk Sharing with Complete Markets

An important question is to characterize socially efficient allocations of risks in an economy where individuals may have very different initial risk exposures and risk attitudes. Wilson (1968) solved this question when individuals are expected—utility maximizers. Any efficient allocation of risk must satisfy two conditions. The first one is often called the mutuality principle. It states each ex-post individual's consumption only depends upon the ex-post average wealth in the economy. This means that all members raise their consumption in good states, and reduce it in bad states. There is no loser in an improving environment. Notice that this condition is satisfied in the case of the mutual arrangement examined above. The intuition for the mutuality principle is the need for diversification: all individual risks must be gathered in the pool. The second characteristic of a socially efficient risk-sharing rule deals with the sharing of the aggregate risk in the pool. As suggested by the intuition, a socially efficient sharing of the aggregate risk is such that the risk borne by a member of the pool must be inversely proportional to their Arrow-Pratt degree of absolute risk aversion. At the limit, if there is a risk-neutral agent in the economy, this agent should bear all risks, i.e., he should insure everyone else in the economy.

Whether decentralized economies can allocate risks in an efficient way is another question that has been solved by the pioneering works of Arrow (1953), Debreu (1959), and Borch (1962). Suppose that the economic system is such that it is possible to freely insure against any bet, at fixed odds, any amount wished on the occurrence of any event which will not affect the welfare of the insurers in any way. Markets are said to be complete in this case. Suppose also that there is no transaction cost on these markets, and no asymmetric information of any kind. The standard first theorem of welfare economics can then be applied to obtain that competition on these markets yields a Pareto-efficient allocation of risks in this economy. The competitive allocation must in particular satisfy the mutuality principle. At the competitive equilibrium, all households should sell their entire human and physical capital in exchange for a stake of the aggregate economy. A part of this story can be found in the Capital Asset Pricing Model in which all investors have the same composition of the portfolio of risky assets, the 'market portfolio.'

Townsend (1994) tested the mutuality principle in small rural villages in India. He did not reject the hypothesis of efficient risk sharing within each village. But he rejected the hypothesis of efficient risk sharing across villages. More generally, it is quite obvious that

the mutuality principle does not hold in large economies. Some workers may see their income reduced in a booming economy. In case of a laborsaving macroeconomic shock, workers may lose against capital owners. Some classes of retirees may enjoy an increase in their pension benefit even when there is a recession. Some countries may be in recession in a growing world economy. Shiller (1993) recommends that new institutions be created to share these society's large economic risks that are currently inefficiently shared. The welfare impacts of imperfect risk sharing are likely to be very large. In the remainder of this article, the reasons for these market imperfections are examined.

3. *Optimal Insurance with Transaction Costs*

Insurance entails transaction costs. In many lines of casualty insurance, transaction costs may be as large as 30 percent of the premium. Consider an economy with a risk-neutral insurer and consumers with idiosyncratic risks X. suppose that each euro of indemnity yields k euros of deadweight cost. In a competitive insurance market, the premium associated with insurance contract I(.) must be equal to $(1+k)EI(X)$. Mossin (1968) showed that the optimal insurance contract for the policyholder is no longer the full insurance contract. It is always optimal for him to retain part of the risk in order to reduce the insurance cost. This is because risk is a second-order effect relative to transaction costs.

Arrow (1965) examined the optimal form of the risk retention. There are various ways for policyholders to retain a share of the risk. The most standard is to accept a straight deductible, in which the indemnity is either zero if the loss is less than the prespecified deductible, or the loss minus the deductible otherwise. Alternatively, the insurance contract can contain a coinsurance rule in which case the indemnity is a prespecified percentage of the loss. Other clauses can be considered, as upper caps on indemnities, disappearing deductibles, etc. Arrow showed that the optimal insurance contract takes the form of a straight deductible. Any nondeductible insurance contract is dominated by a straight deductible contract with the same actuarial value, but yielding a smaller retained risk for the policyholder. Straight deductibles provide the best compromise between the willingness to cover the risk and the limitation of the insurance deadweight cost.

One can link transaction costs to undiversifiable risks. Obviously, many natural, environmental, or technological risks are in the class of large risks that are difficult to eliminate by using the mutuality principle. The insurer's risk-neutrality for these risks may be questioned. Insurance companies will not provide fair insurance premiums for them. Indeed, shareholders will not be able to diversify the risk associated to the dividends paid by insurance companies that cover these large risks. They will ask for a risk premium, which will increase the cost of capital of these companies. This cost will be passed on to policyholders through a larger premium rate for the component of individual risks that is systematic. It will induce them to retain part of their individual risk. In short, the fact that the risk is systematic induces insurance premiums to contain a positive loading that has an effect equivalent to a transaction cost. This is the logic behind larger deductibles for systematic risks.

4. *Adverse Selection*

Since the seminal paper by Rothschild and Stiglitz (1976), it is recognized that the fact that insurers face a heterogeneous population of consumers is a source of inefficiency on insurance markets. The classical model presented above allows for a heterogeneous population as long as the characteristics of the risk borne by each agent is common knowledge. For example, the fact that women are safer drivers than men is compatible with full insurance of every driver at the competitive equilibrium with a risk-neutral insurance industry. The premium rate for every category of risk will be fair, thereby inducing each individual to purchase full insurance at the optimum.

A problem arises when the population is heterogeneous, but the observable characteristics of the agents are not perfectly correlated to the intensity of their risk. The adverse selection problem originates from the observation that if insurance companies calculate the premium rate on the basis of the average probability distribution in the population, the less risky agents will purchase less insurance than riskier agents. In the extreme case, the low-risk agent will find the premium rate too large with respect to their actual probability of loss. They will prefer not to insure their risk. Insurers will anticipate this reaction, and they will increase the premium rate to break even, only on the population of high-risk policyholders. The literature on adverse selection is devoted to characterizing an equilibrium. Insurers will use the fact that low-risk agents and large-risk agents behave differently in the face of a large set of insurance contracts. In particular, low-risk agents could credibly signal their type by selecting a contract with a large deductible, something that high-risk agents dislike.

The presence of high-risk agents generates a negative externality to lower-risk agents who are unable to find an insurance premium at an acceptable premium rate. To illustrate, this is probably why the proportion of households that purchase life insurance is so small, despite the potential severity of the risk. People have private information about their health status that cannot be observed by insurance companies. Then, only those with the lowest life expectancy purchase life insurance.

The standard policy recommendation for improving risk-sharing efficiency under an adverse selection problem is to make public all relevant information about risks. For example, insurers should be allowed to know whether the potential policyholder has some severe illness. They should also be allowed to use genetic testing. Obviously, redistributional reasons may go against such a policy recommendation if the State is not in a position to compensate poor high-risk agents.

5. *Moral Hazard*

The population of risks can be heterogeneous not only because agents bear intrinsically different risks, but also because they do not invest the same amount of their energy, wealth, or time in risk prevention. In particular, it has long been recognized that individuals that are better covered by insurance invest less in risk prevention if the link between the premium rate and the size of these investments is weak. It will be the case if insurers are not in a position to observe the investment in risk prevention by the policyholder. In that case, the premium rate is not sensitive to the effort made by the policyholder to prevent losses. Obviously, there will be an inverse relationship between risk prevention and insurance coverage: policyholders will not internalize the benefits of their efforts. The level of risk prevention will be inefficient. This is *ex ante* moral hazard, common to all principal-agent problems. Anticipating this low degree of prevention and the higher frequency of losses that it entails, insurers will raise their premium rate. Full insurance will not be optimal for agents. At the limit, no insurance can be an equilibrium. Holmstrom (1979) characterized the equilibrium insurance contract with *ex ante* moral hazard.

To illustrate, this is why it is not possible to insure against the absence of promotion on the workplace, about failure at school or university, about the lack of demand for a new product, or about divorce. To some extent, this is also why it is hard to insure against unemployment, or against environmental and technological risks.

The policy recommendation to fight against *ex ante* moral hazard is the enforcement of norms for risk prevention. This is the case for environmental risks in which ships transporting chemical products have to satisfy various safety requirements that are imposed by regulatory agencies. Automobile driving norms are also standard, as speed limits, alcohol-free driving, etc. Why these norms are mostly organized by a regulatory agency rather than by insurers is not completely clear. One reason is due to the combination of negative externalities and limited liability. If there is more than one principal supervising the implementation of norms, the information among the different principals should be pooled to save on monitoring costs. For example, auto insurers should be allowed to get the information about driver fines by the police.

Another policy recommendation is to allow insurers to discriminate prices among different policyholders that exercise various preventive efforts. Allowing for discrimination is a way to provide incentive to policyholders to invest in risk-reducing activities. In France again, insurers are not allowed to discriminate homeowner premium rates on the basis of natural risks such as earthquake, flood, and storms. The consequences are by now notorious: many households built their houses in areas that were secularly known to be flooded periodically.

6. *Insurance Fraud*

The classical model assumed that the size of the loss is observable. There are many instances in which this is at best a crude approximation of the real world. Contracts can be made contingent only upon observable events. The problem here is to give the good incentives to the policyholder to report their actual loss. The difficulty for insurers to verify claims is at the origin of why it is not possible to insure against loss of happiness, or against some forms of suffering that cannot be measured by physicians.

There exist other types of risk for which outcomes can be observed by the insurer only at a relatively high auditing cost. Townsend (1979), Mookherjee and Png (1989), and others analyzed the optimal risk-sharing scheme in this case. If there is no limit on the penalty that can be imposed to policyholders that do not declare the actual level of their loss, the first-best solution can be attained. Indeed, insurers should announce that they will audit claims with some probability p that is very low. If the policyholder made a fraudulent claim, an unbounded penalty ('death penalty') would be imposed on him. This is enough to give the incentive not to defraud the insurance contract, even if p is very small. In this case, the fact that there is costly claim verification is not detrimental to welfare, and the risk is insurable in full.

But there are several reasons to believe that an unbounded penalty in case of a fraudulent claim is not a realistic assumption: ethics, limited liability, risk of legal errors, etc. *Ex ante*, it is then Pareto-efficient to limit the size of the penalty. In order to report their loss correctly, the insurer will have to audit claims at a high frequency. This entails additional costs on the insurance contract. If the auditing cost is high, or if the frequency of audit necessary to give the good incentive for the policyholder to reveal the truth is too high, consumers would be better off by not insuring the risk. Notice that another way to reduce the willingness to submit a fraudulent claim is to limit the indemnity. The maximal indemnity that is compatible with truth-telling is an increasing function of the penalty and of the probability of audit. Consumers would like to

announce ex ante that they will not submit fraudulent claims *ex post*. That would allow insurers to save the audit cost, thereby reducing the equilibrium premium rate, but the announcement is not credible.

Is *ex post* moral hazard an important problem? It is often suggested that the cost of fraudulent claims may well amount up to 10 percent of premiums paid for such insurance lines as automobile insurance or homeowner insurance. This estimation is the cost of unjustified indemnities to policyholders, not the auditing cost to fight against fraud. This percentage is comparable to the rate of transaction costs, whose effects on insurability have been previously examined.

The policy recommendation is clear from the discussion above: one should impose a larger penalty on policyholders that have been convicted of a fraudulent claim. Several countries in Africa, and to a smaller extent in Europe, have been weak in this area, recognizing fraud as a 'national sport' that should be forgiven. By doing so, the legal system imposes a possibly large cost to Society in terms of a loss of insurability. This weakness has been particularly clear for insurance lines where the indemnity payer does not have the good incentives to be tough on fraud. For example, one may question whether social security organizations are fighting fraudulent claims efficiently. This yields a general distrust of the system, which is detrimental to the unemployed themselves.

7. *Limited Liability*

An individual can cause damage to others, either in the course of his/her profession (medicine, surgery, house building, etc.) or because of other activities (e.g., driving a car). The same kind of external random effect occurs for firms. In most countries, the agent found liable for damage to others must indemnify them accordingly. This is done to force decision makers to internalize all costs generated by their choice. But indemnification is only possible up to the decision maker's financial capacity. Limited liability is a way to protect risk-takers against an excessive financial distress. But it has long been recognized that limited liability distorts the decision of the risk-taker in a way that is socially inefficient. The US Saving and Loans crisis is often explained by the fact that 'zombie' S and Ls adopted in the early 1980s a very risky attitude in an attempt to 'bet for resurrection' after some blows were delivered to their portfolio of (real estate) assets. This is because limited liability gives the agent the equivalent of a free put option. Put it in simpler terms, under limited liability, an insolvent agent can only benefit from taking more risk, because he does not bear the burden of losses. Therefore, if the agent is risk-neutral, he will seek to maximize the expectation of a convex function of his wealth. As a result, he will systematically exhibit a risk-loving behavior, and adopt a very risky attitude. This is a kind of moral hazard problem. Risk aversion mitigates this result, but only for agents who are well capitalized.

The effect of limited liability of the policyholder on their demand for insurance is thus unambiguous: if he is risk-neutral, it is never optimal to cover a risk of loss, even in the most favorable case where the premium rate is fair. Insuring the risk would yield a sure reduction in wealth equaling the expected loss. Not insuring the risk would yield an expected reduction of wealth that is less than it, since the agent bears only part of the risk of loss. Another way of looking at this problem is that the insurance contract creates a 'deep pocket' where victims can find compensation for their losses. This kind of problem is particularly crucial when examining the demand for insurance by firms for catastrophic environmental risks. Limited liability on the part of the insurance also reduces the demand of insurance, since it makes the indemnity dependent on solvency.

Limited liability thus raises several important questions. How to organize compensation for those who bear the negative externalities? How to build an incentive-compatible mechanism that increases loss prevention by decision makers with limited liability? How to solve the market failure of liability insurance markets? How to force firms not to under-capitalize their subsidiaries which are in charge of managing the riskiest part of the business? Two routes have been used. The first one is compulsory insurance. This solves the misallocation of risk in the economy and the organization of a system to compensate the victims. But, most of the time, compulsory insurance has been funded by a flat, non-discriminatory, non-incentive-compatible insurance tariff. The policyholder's investment in loss prevention is not observed by the fund, either because it is difficult to get information on it, or because the fund did not organize an incentive-compatible system.

The second route has been to organize a 'deep pocket' for decision-makers. For example, the hospital that employs an uninsured physician may be made liable in case of the physician's insolvency. Under the US CERCLA, when a bank has been relatively closely involved in the monitoring of a firm's activities, it may be considered by the courts as liable for cleaning up the environmental damages generated by the insolvent firm. The objective of this strategy is to force risk-takers to internalize the full cost of potential losses: the hospital will reduce the income of the careless physician, and banks will increase the loan rate of riskier firms. If there is no asymmetric information between the principal (the hospital, the bank) and the agent (the physician, the firm), the agent will select the socially efficient level of care and insurance. There would then be no insurability problem. But, there is no reason to believe that the principal can monitor the agent at no cost. The CERCLA legislation, for example, introduces more asymmetric information on credit markets. Consequently, there will be more credit

rationing, the cost of capital will be larger, and the structure of banking contracts for firms will be affected. Is insurability worth these costs?

8. *Regulation of the Insurance Sector*

Insurance markets are among the most heavily regulated ones around the world. In the Middle Ages, the Catholic Church was reluctant to recognize insurance as an ethically acceptable activity. The French revolution prohibited insurance companies in 1793. States have been very active to control insurance tariffs, in particular in life insurance. They also imposed compulsory insurance. More recently, they established solvency rules similar to those of the banking sector.

There is a European tradition to use insurance for a redistributive purpose. Insurance implements wealth redistribution if the expected profit of the insurer depends upon the observable characteristics of the policyholders. The expected profit on the low risk class of policyholders is used to cover the expected loss on the high risk class. This scheme is standard in unemployment, health, and disability insurance, but it can also be found in other insurance sectors like automobile (for young and old drivers), homeowner (for natural catastrophes), and life (for the prohibition of using health factors to price life insurance). However, the solidarity among different risk classes is difficult to organize with decentralized insurance markets without strong regulation. The absence of discrimination on the basis of policyholders' observable characteristics that are correlated with the risk introduces adverse selection. It also generates moral hazards if these characteristics can be affected by the preventive effort of the policyholder. In order to alleviate the adverse selection problem, regulators often impose compulsory insurance, as in social security systems. Pricing regulation is also necessary to react to the natural tendency of competitive markets to discriminate. Finally, insurers should be forced to supply coverage to all customers at the undiscriminating premium. Various reforms of the health insurance sector in OECD countries have been proposed to deal with the problems inherent in such heavy regulation.

There is a form of saving in an insurance contract from the policyholder's point of view. Indeed, the indemnity, if any, may be paid a long time after the premium. This is particularly true for life insurance. The lender, i.e., the policyholder, should check the solvency of the borrower-insurer. In perfect competitive markets, insurers facing a higher risk of insolvency should be penalized by collecting smaller premia, to compensate the risk borne by the policyholders. This is enough to provide good incentives for insurance companies to manage their financial reserves efficiently. However, policyholders may not be in a position to evaluate correctly the probability of failure of the insurers. This asymmetric information calls for centralized solvency regulation. It takes two forms. The first type of regulation is about solvency ratios, similar to those imposed on banks. The second type of regulation is about the kind of risks that can be taken by insurers on the investments they make with their financial reserves. Typically, there is an upper limit on the share of reserves invested in stocks and real estate. Many countries prohibit the use of derivative assets, in spite of their potential benefits for risk reduction. These constraints must be strong enough to fight against the moral hazard problem generated by asymmetric information and limited liability. It should not be too strong in order to allow for efficient Asset-Liability Management (ALM) by insurers.

Insurance and the Law

Insurance may be uniquely tied up with the law. Social insurance and other public sector insurance arrangements are creatures of statute, governed through administrative law (see *Social Insurance: Legal Aspects*).

Private sector insurance arrangements depend upon a well-functioning contract law and a regulated market (see *Contracts: Legal Perspectives*; *Markets and the Law*). Insurance thoroughly dominates the field of tort law, especially with respect to the liabilities of individuals and small business (see *Torts in Law*). Moreover, because insurance institutions inevitably exert a regulatory force over their subjects, insurance must be understood as a complement to direct state regulation. Finally, some social theorists have argued that insurance has exerted a profound ideological force on law and regulation, as activities increasingly are governed through risk (see *Law and Risk*).

1. *The Term 'Insurance'*

Spencer Kimball, one of the leading insurance law scholars of the twentieth century, once wrote 'There is no good definition of "insurance," for any purpose.' (Kimball 1992, p. 1). Kimball's admonition notwithstanding, it is useful to begin by thinking of insurance as a formal mechanism for sharing the costs of misfortune.

Contemporary insurance arrangements typically involve fixed premiums, paid in advance, and guaranteed benefits in the event that a specified loss or event occurs; but these are not necessary elements of the insurance form. Insurance arrangements typically provide protection against risks that are fortuitous from the perspective of the insured, yet reasonably predictable in the aggregate by an insurer, and which are not so catastrophic that they would overwhelm the financial capacity of insurers (as would, for example, insurance against worldwide depression). Ideas about what is and what is not insurable, however, vary widely over time and place.

Following the French social theorist Francois Ewald, it is helpful to distinguish among four aspects of insurance: technologies, institutions, forms, and visions (Ewald 1991). These categories illustrate the conceptual variety of insurance activities and, correspondingly, some of the deficiencies in analytical definitions.

Insurance, in the sense of insurance 'technology,' refers to a set of procedures for dealing with risk. Examples include the mortality tables and inspection procedures of ordinary life insurance, the incentive-based medical provider contracts and computerized claim processing procedures of managed health care companies, the payroll tax and administrative review procedures of social insurance programs, and the standard-form insurance contracts used in almost all private insurance. As a technology for managing risk, insurance extends beyond what might ordinarily be understood as the insurance field; life insurance companies were pioneers in epidemiology and public health, and fire insurance companies formed the first fire departments. More recently, health insurance companies have been behind many efforts to compare, test, and measure the effectiveness of medical procedures.

Insurance 'institutions' are the various kinds of organizations that provide insurance. Social insurance agencies (such as the German Arbeitsamt) and stock insurance companies (such as the Dutch-based ING Group) are two (very different) insurance institutions. Insurance 'forms' are the various kinds of insurance provided by insurance institutions, as well as the variations in form among them. Unemployment and property insurance are two different forms of insurance. Fire insurance and flood insurance are two different forms of property insurance.

Finally, insurance 'visions' are ideas about and images of (or, alternatively, discursive practices regarding) insurance that animate the development of insurance technologies, institutions, and forms. Three examples follow.

(a) It was once commonly believed that life insurance was immoral, because it interfered with divine providence, equated life and money, or was a form of gambling (Zelizer 1979). This vision of insurance had important consequences for the development of insurance law and institutions in the west. It slowed the growth of life insurance, and it helps to explain the American and French preoccupation during the nineteenth century with establishing the morality of all kinds of insurance. Related ideas affect Islamic insurance institutions today (Vogel and Hayes 1998).

(b) Because the primary benefit of insurance is a sense of security which, for most people, will never be tested by a catastrophic loss, much of the value of insurance rests in the imagination. Recognizing the significance of imagination to insurance, courts in the United States place great emphasis on the 'reasonable expectation of the insured.' In determining the nature of that expectation, courts invoke two distinct visions of insurance. The first mirrors the vision of insurance portrayed in insurance advertising: a promise 'to be there,' conveyed by narratives of family and the need to protect the individual against sudden misfortune. The second mirrors the vision of insurance that companies invoke when denying claims, a complicated amalgam of tough love and protecting the insurance fund, conveyed by narratives of institutional ethics and the need to protect ratepayers against fraud and abuse. In resolving insurance contract disputes, courts first decide which of these visions to employ. Who wins a dispute often depends as much on which vision the court adopts as on how the court applies that vision (Baker 1994).

(c) The actuarial vision of insurance has had great influence over the development of insurance and insurance law. In that vision, the ideal type of insurance involves premiums paid in advance, guaranteed indemnity in the event of a covered loss, and risk-based premiums based on the best available

information regarding the expected losses of the individuals insured (Abraham 1986). This vision of insurance helps explain (i) the decline of fraternal insurance over the nineteenth and early twentieth centuries, as actuarial expectations overcame values of friendship, brotherly love, and charity, (ii) also the decision to model unemployment insurance on private insurance, and the related effort to tightly link benefits to premiums, (iii) the intensity of the popular belief that US Social Security retirement benefits have been earned by the people who collect them, and (iv) the corresponding expert belief that Social Security is not really insurance (because the money to pay today's retirees comes from the contributions made by today's workers and not from the contributions of the retirees themselves). Indeed, the actuarial vision of insurance has been so successful that many well informed people would deny that it is a vision at all and would assert instead that it is the only valid model of insurance (Baker and Simon 2001).

2. *Insurance as a Form of Regulation*

Given the size of insurance institutions relative to western economies, it is surprising that social scientists have not paid more attention to insurance. Indeed, looking at the broad sweep of twentieth century social policy, it is tempting to describe insurance as the sleeping giant of power.

In setting eligibility requirements and benefit levels for social insurance, the state is obviously engaged in the regulation of populations; yet private insurance can also be a crucial form of (delegated) state power. Rather than set their own criteria for access to economic freedoms like operating an automobile or a business, states often mandate that a person obtain some form of insurance. Examples include liability insurance for automobile owners, workers compensation insurance for employers, and (in the United States) surety bonds for companies engaged in business with the state. The state leaves it to the private market to set underwriting criteria that will determine access to these privileges.

Motivated by controlling losses and assessing risk, insurance companies establish norms of conduct which they enforce by contract terms and pricing and, ultimately, through the judicial system. Whether obtained through compulsion or prudence, insurance is a form of regulation. Exclusions and conditions written into coverage for property, life, and health amount to private legislation. Significantly, this 'legislation' often acts with in the home or business, where, traditionally, the sovereignty of the King did not run (O' Malley 1991).

2.1 *Insurance as Tort Regulation*

The field of law most thoroughly dominated by insurance is tort law. Liability insurance pays the costs of claims made against the insured person. Because it is so difficult to collect money damages without insurance, liability insurance determines who is capable of being sued, for what wrongs, and for how much. The result is that tort law in action is shaped to match the liability insurance that is available. Also, liability insurance makes tort law in action more focused on managing aggregate costs and less focused on the fault of individual defendants (Ross 1970).

Other forms of insurance also regulate tort law. For example, liability commonly is limited whenever a statutory insurance regime is established. This not only creates a bar on certain types of tort claims, but also leads plaintiffs to shape their claims to avoid the tort bar, thereby shaping the tort system. In addition, people may be less likely to sue in tort when they have health, disability, or property insurance covering an injury (depressing the aggregate of tort damages). Moreover, in jurisdictions that deduct health or other insurance payments from tort damages, the existence of that insurance also reduces tort damages. Perhaps paradoxically, the existence of first-party insurance can also in some cases increase tort damages, by reducing the immediate financial need that might otherwise force the plaintiff to settle cheaply and quickly.

Insurance has also exerted an ideological effect on tort law. The existence of liability insurance helped make it possible to conceive of tort law as a risk spreading system—indeed, as a form of insurance—rather than simply as a mechanism for determining right and wrong in individual situations (cf. Ewald 1986). This concept of tort law has had a variety of consequences over the last 100 years. These include the simplification of tort doctrine, the elimination of common law exceptions to tort, and the partial replacement of tort law by statutory insurance schemes in jurisdictions such as Quebec, Israel, and New Zealand (Sugarman 2001). More recently, the concept of tort law as insurance has lent intellectual force to political efforts in the US and Britain to cap damages and to eliminate 'coverage' for pain and suffering, on the grounds that the benefits provided by the tort/insurance system should mimic the (lesser) benefits provided by first party insurance (Clarke 1997).

2.2 *Insurance and Governing Through Risk*

The ideological effect of insurance on tort law illustrates a more general phenomenon, namely the role that insurance technologies, institutions, forms, and visions have played in governing through risk (Baker and Simon 2001). Insurance institutions pioneered the use of formal considerations of risk in the direction of organizational strategy and resources. Moreover, the actuarial techniques adopted by a wide range of institutions, from police departments to social service agencies and money managers, all depend upon think-

ing about the world in the probabilistic, demographic manner that insurance has helped make possible (Ewald 1986).

For most of the twentieth century the dominant form of governing through risk was that of spreading risk, as insurance institutions increasingly assumed financial responsibility for risks faced by individuals, families, and organizations. More recently, both public and private insurance institutions may be placing a greater emphasis on individual's responsibility to embrace risk. The governmental rationales inherent in spreading or embracing risk have significant consequences for law. The spreading of risk leads to the simplification and expansion of tort law, to more expansive interpretations of the statutes regulating social insurance and the contracts regulating private insurance, and, in general, to more efforts to soften the hard edges of life. Embracing risk leads to reductions in social insurance benefits, deductibles, and benefit caps in private insurance, and links between pension benefits and market performance.

3. *Insurance Law*

Traditionally, legal scholars have divided the field of insurance law into two parts: (a) the law concerning the relationship between private insurance organizations and their insureds, which is considered a part of contract law; and (b) the law concerning the state regulation of private insurance organizations, which is considered a part of the law of regulated industries (e.g., Clarke 1997, Cousy 1999, Jerry 1996, Schimikowski 1999). (For a broader view of insurance law including the law relating to social insurance, see *Social Insurance: Legal Aspects*.)

3.1 *Insurance as a Species of Contract*

Contemporary insurance institutions grew from two distinct roots: mutual benefit associations dating back to the medieval gilds (or earlier), and marine insurance arrangements dating back to fifteenth century Italian city states (and possibly earlier, e.g., Greek bottomry loans, which were loans to merchants that were repaid only if cargo made it safely to port). Early insurance law treatises report that courts treated both these forms of insurance within the framework of contract law, adjudicating the obligations of the company or society according to the promises made in the insurance contract.

At least by the mid nineteenth century, courts in Europe and elsewhere recognized that insurance contracts differed significantly from what was traditionally understood as the ideal type of contract (a voluntary agreement, with terms that were negotiated between two parties with equal bargaining power). Because of the gatekeeper role of insurance institutions, insurance can hardly be said, in many instances, to be voluntary. Insurance companies almost universally employ standard form contracts with terms that are not subject to negotiation. And, in all but a very few cases, the parties do not have equal bargaining power. Typically, the insurance company is a much larger economic entity; competing insurance companies rarely offer significantly different terms (except sometimes price), and the insurance company has information about the meaning and value of the contract that the applicant for insurance does not. In addition, the money-for-promise nature of insurance gives the insurance company tremendous power once the insured has a claim; at that point, the insured cannot shop for a new insurance policy.

For these reasons, courts have classed insurance contracts within the general category of contracts of adhesion, and have developed somewhat more protective rules regarding the interpretation of insurance contracts (Baker 1994). Insurance contracts have long been regarded as the paradigmatic contract of adhesion (see *Contracts: Legal Perspectives*.)

Recently, the federal legislature and judicial system in the United States has acted to shift an increasingly large portion of the health insurance market away from a private contract regime to a not-yet-stable amalgamation of contract, trust, and administrative law. As private health insurance markets grow in Europe and elsewhere, there are likely to be similar efforts to create a paternalistic, yet market-oriented, legal regime governing the relationship between insurance companies and their members.

3.2 *Insurance as a Regulated Industry*

Contemporary insurance regulation dates to the nineteenth century, when a rash of insurance insolvencies in the US and Europe led to the establishment of state regulatory authorities. States limited the kinds of investments insurance organizations were permitted to make, and mandated the employment of actuaries to calculate rates and reserves, the filing of reports with state agencies, and minimum capital reserves.

In economic terms, the justifications for these and more recent forms of insurance regulation are information problems and the positive externalities of insurance. Most insurance consumers are poorly equipped to evaluate the soundness of insurance companies, to compare insurance contracts, or to evaluate the degree to which insurance companies have lived up to their promises. These information problems justify solvency, contract, and market conduct regulation. The positive externalities of insurance are the benefits that insurance provides to people other than the direct beneficiaries of insurance. Examples include the public health benefits of health insurance and the victim compensation benefits of liability

insurance. These positive externalities justify regulation directed at expanding access to insurance.

Solvency remains the primary focus of insurance regulation worldwide. Regulatory tools have expanded to include risk based capital requirements, electronic auditing of accounts, and a wide variety of limits on the ways that companies can invest the funds held in reserve to pay claims. Not surprisingly, these tools have been used for other than their express purposes. Insurance can be a powerful engine of capital accumulation, and investment regulations can be used to steer capital into preferred fields. French insurance companies, for example, are required to invest some of their funds in French real estate, with the interesting result that French insurance companies have become a major force in the French wine industry. On a larger scale, prohibitions on foreign investment in insurance in countries such as India, China, Brazil, and Argentina were long justified as a way to steer capital to indigenous insurance institutions (typically government owned or authorized monopolies), which would invest the capital locally. Recently, the International Monetary Fund and the World Bank, along with the globalization of the economy, have been significant forces in opening up capital markets—including insurance—to foreign investment (see *Globalization: Legal Aspects*).

Understanding insurance as an institution for storing and accumulating capital, it is no surprise to learn that insurance firms compete with banking and securities firms. Yet, banking, insurance, and securities traditionally have been subject to different regulatory regimes. The contemporary 'convergence' of the insurance, banking, and securities industries in the financial services marketplace places great strain on the existing regulatory institutions, as they struggle with each other and the firms they regulate, both to achieve regulatory ends and to maintain regulatory authority (Jackson 1999). Convergence and the related trend toward globalization are likely to be the primary economic forces driving the evolution of insurance regulation in the foreseeable future. This evolution will address such fundamental issues as whether, and to what extent, there will be democratic control over capital and the proper level of governmental control (local, federal, or international) over regulatory decisions.

Integration: Social

Social integration refers, in the first instance, to the extent and intensity of the interlinkages among the constituent parts of a social unit. This definition applies to all types of social units—a small group like a family; a gang or an Internet newsgroup; an organization like a firm, an administration, or a nongovernmental humanitarian organization; a community like a neighborhood, a local church community, a local business community, or a local ethnic community; or a society like a local society, a national society, a supranational society, e.g., European society or even world society (Münch 1998, pp. 27–67).

1. Actor Integration: Cohesion and Breaking Apart, Integration and Disintegration, Harmony and Conflict

What are the constituent parts of social units? On one level, we can say that these are actors as members of social units like groups, organizations, communities, and societies. On a second level, families form constituent parts of clan societies, estates of estate

societies, classes of class societies, functional units of functionally differentiated societies, organizations of organizational societies; groups and divisions are second-level constituent parts of organizations. What is then the extent and intensity of interlinkages between the constituent parts of a social unit? With regard to members of social units as individual actors or corporate actors (groups, organizations, communities, national societies within world society) it is the number of actors involved in recurrent interaction (extent) and the frequency of interactions (intensity). Such interactions can be more or less harmonious or conflictual. Actors can be extensively and intensively linked by conflict. For example, a couple could live in war from marriage to death. Such a case would be covered by our thus far outlined definition of social integration. Forces of attraction which keep them together must be stronger than forces of repulsion (Simmel 1992, pp. 312–15, Coser 1956, pp. 81–85).

Here we enter the field of explaining social integration. One explanation is that they are linked together because both of them have either no alternative at all or alternatives that are too costly so that transaction costs would be too high. For reasons of clarity, we can use the term 'cohesion' in order to denote a type of relationship between the members of a social unit which entails extensive and intensive interlinkage, as there are more forces of mutual attraction than of mutual repulsion. The opposite of social integration is not conflict but social disintegration; both are the extreme poles of a continuum with many gradations in between and a middle zone where it is difficult to determine precisely where integration ends and disintegration begins. We can say that a couple is more integrated the more they share a common life together and the more their action is mutually supportive, and it is more disintegrated the less this is the case. Just as integration has its opposite in disintegration and not in conflict, so conflict has an opposite of its own, namely harmony. Conflict means that with two or more actors, one actor's gain implies the other actor's loss. They may have different goals which cannot be attained at the same time, or they may have the same goal which, however, cannot be reached by every actor at the same time. Harmony, instead, implies that every actor's goal can be realized at the same time or that one and the same goal can be reached by every actor at the same time.

2. *Action Integration: Negative and Positive Integration*

A more ambitious notion of social integration is at stake, when we do not only look at the integration of actors as members of social units, but also at the integration of their actions. This is a second step in defining social integration. The integration of actions can be realized in two ways: negatively and positively. The negative way avoids the actions interfering with each other. The ideal-typical case of this integration of actions is embodied by two farmers who live on their own on their demarcated territory with guarded fences so that there is no chance of intrusion in either's domain of freedom. This kind of coordinated freedom can be called negative freedom. It is a freedom which results from preventing others from intruding in one's domain of free action. The corresponding type of integration can be called 'negative integration.' Durkheim used the term 'negative solidarity' for that (Durkheim 1964). It refers to the mutual acknowledgment of property rights. In the case of negative integration, the actors do not need more than the acknowledgment of their freedom to act by other actors; they do not require their cooperation and support.

The counterparts to negative freedom and negative integration are positive freedom and positive integration, which explicitly rely on mutual cooperation and support (Durkheim 1964). The most elementary form of positive freedom can be found in market exchange. As Adam Smith (1937) demonstrated, the utility maximization of one actor does not occur at the cost of other actors here, but even furthers the other actors' own utility maximization. In the founding years of sociology, it was Herbert Spencer (1972) who promoted this idea. The actors are not engaged in a zero-sum game, but in a game with a growing sum of which potentially every actor can make a profit. Their actions are in a complementary relationship to each other. Both exercising negative freedom on one's own space without interference from others and positive integration through market exchange are only possible if the actors share a minimum of rules of the game; otherwise they would end up in struggles for advantages by unlimited means including force and fraud, the Hobbesian war of all against all (Hobbes 1966). The question is, then, how it is possible that free actors come to share a minimal set of rules of the game. In a first step, cooperation in market exchange might rely on the human individual's sympathy for other people as Adam Smith, as well as David Hume, assumed (Smith 1966, Hume 1980). However, this sympathy mostly does not reach beyond particular communities and does not always guarantee the commitment to the rules of the games. Therefore, there is a need for further arrangements. Here the notion of 'positive freedom' becomes relevant. We move from the Scottish moral philosophers' individualistic theory of market integration to Rousseau's collectivistic theory of integration by the general will based on the republican spirit of citizens (Rousseau 1973). A further tradition of thought, which takes on significance here, is German idealism. It was founded by Fichte, Schelling, and Hegel in response to Kant's critical philosophy and carried on in transformed ways by Marx and his followers right through to critical theory and

Habermas's theory of communicative action (Kant 1956, Hegel 1965, Marx 1962, Habermas 1984, 1989).

3. Social Integration and Social Order

At this stage of our treatment of social integration we realize that social integration comes close to social order as soon as we ask for the integration of free action and of rights to act. Integration and disintegration then correspond to the pair of order and disorder or anomie in Durkheim's terms (Durkheim 1964). From this viewpoint, the actions of individuals are integrated, in as much as everybody can rely on normative regulations that determine the space of their actions so that negative interferences are avoided. Social order of this kind is a normative order, as Talcott Parsons has emphasized in particular (Parsons 1968). It is based on processes of regulation through collectively binding decision making. Its opposite, disorder or anomie, means that individual actors cannot count on such regulations when they encounter other actors and thus have to rely on the power available to them in order to defend their claims for space for action. As everybody has to do so, there is always the danger of the Hobbesian war of all against all.

If actors and groups are free to articulate interests within a wide framework of constitutional rules, and if the actors see themselves dependent on the tolerance and/or cooperation of the other actors, they will engage in bargaining processes in which each actor looks for the maximization of his or her interests. Such rules will have better chances of survival which allow for the growing satisfaction of a growing number of interests. Here the actors conceive of themselves as utility maximizers who learn to cooperate in a way which is beneficial for all. This is how the evolution of cooperation is explained from the point of view of utility maximization. This order is an ongoing process of steady change which serves for one interest some time and another interest at another time, or better, an always changing mixture of them. The evolutionary explanation of social order in economic terms has been particularly demonstrated by Robert Axelrod (1984). Generally speaking, this tradition of thought in sociology goes back to Herbert Spencer (1972) and is represented in contemporary sociology, for example, in the works of George C. Homans (1974), Michael Hechter (1987), and James Coleman (1990). The basic paradigm is rational choice theory. There have been many attempts to transcend the limits of economic thought, beginning with the classics, particularly Adam Smith in his work on moral sentiments (Smith 1966). One of the more prominent recent attempts is Jon Elster's acknowledgment of the noneconomic, in his view nonrational, emotional sources of norm-regulated behavior (Elster 1989).

However, there are also other settings which exert a different shaping influence on the emergence and continuation of social order. There may also be unbridgeable conflicts between the goals of major actors. In this case, social order is an outcome of a power struggle with winners who shape social order by their ideology and impose that order on the defeated through the application of monopolized physical force. This is what Dahrendorf (1958) has emphasized in his conflict theory of social order. A more complex model of conflict theory for the explanation of social order, which includes negotiation and ritual, has been constructed by Randall Collins (1975).

A completely different setting is given, when there are well-established institutions of discursive reasoning and professional legislation in the hands of legal and other types of experts. Both interest negotiation and power struggle have a more limited space for influencing the emergence and continuation of social order. This process takes place much more as the steady building up of an all-embracing, consistent, coherent, and detailed set of laws. The major question, which decides on the success of a certain proposal of legislation, is not so much as to what interests are served and what power can be mobilized, but as to what good reasons can be given and as to how it fits in the existing system of law. This type of social order is a steadily growing legal order which covers almost everything that changes in an ongoing process of adjustments to new problems and challenges. In this perspective, we conceive of social order as a norm-building process. There are different approaches to addressing this problem. The tradition of German idealism sees norm-building as a process of meaning construction. The modern version of this approach is Habermas' (1984, 1989) discourse ethics which explains norm-building as a procedure of rational argumentation. Another perspective of relevance here is phenomenology as developed by Schütz (1964), Berger and Luckmann (1966) and others. Here, norm-building is conceived of as a process of institutionalization through habitualization, sedimentation, and traditionalization as well as legitimation from rudimentary explanations to generalized symbolic. From the point of view of Harold Garfinkel's (1967) ethnomethodology and related conversational analysis, normative order is an ongoing process of ordering through the concerted action of individuals in their respective situation. For symbolic interactionism as promoted by Herbert Blumer (1969)—based on the work of George Herbert Mead (1934)—and by Anselm Strauss (1978), for example, order is negotiated in processes of mutually fitting different perspectives on the situation. In the pragmatist perspective developed in the works of William James, Charles Sanders Peirce, John Dewey, and George Herbert Mead, and revitalized by Hans Joas, order is produced and reproduced by the creative acts of individuals who cooperate in the solution of problems (Joas 1992).

A further factor which exerts an influence on the emergence and continuation of a social order is the building of relationships of solidarity in the sense of mutual support and help. The breakdown of the traditional order and its hierarchical system of privileges for estates was partly caused by lacking the inclusion of the rising bourgeoisie according to its contribution to the working of the society, particularly in terms of tax payments. There was a new class that was inadequately included in the participation in associational, political, and cultural life. The bourgeois revolutions established a new form of inclusion which was much broader. Inclusion was no longer based on inherited status, but simply on achievement (particularly in terms of market income, but increasingly also in terms of education and professional status). This new form of inclusion served as the door for every further movement aiming at participation in economic, political, associational, and cultural life and their organizations. The first one to succeed was the labor movement with the inclusion of the working class; it was followed by different kinds of movements, from the women's movement, the civil rights movement, and the movements for any kind of minority rights, right through to the movements for multiculturalism, prochoice and prolife. The sociological approach that sees the emergence and continuation of social order particularly as a process of solidarity, civic order and citizenship production, reproduction, and transformation, was founded by Emile Durkheim. This approach is carried on, in particular, in the functionalism of Talcott Parsons and in its contemporary revitalization by neofunctionalism. A further major contribution is T. H. Marshall's work on citizenship (Durkheim [1893] 1964, Parsons 1971, Münch 1998, pp. 140–65, Alexander 1998, Marshall 1964).

4. *Social Integration Beyond the Nation State*

A new level of inclusion has now been achieved in the process of transcending the system of nation-states by supranational units like the European Union or even the United Nations. A major driving force behind this transformation of social integration is the international division of labor. In Emile Durkheim's terms, the shrinking of distances through population growth, and, in the highly developed regions, much more through the increasingly faster methods of transport and communication are the major forces which promote the growing division of labor (Durkheim [1893] 1964). In this situation, competition for scarce resources intensifies and leaves specialization as the only effective means of escaping the struggle of all against all, besides suicide or emigration, which are, however, less attractive for people who love their lives and their country. Emigration is also only effective for people in poorer regions yet ever less feasible because of the crowding of the economic centers. The change from nation-state inclusion to European and worldwide inclusion is a further step from mechanical to organic solidarity in Durkheim's view. The high level of equality of results in the European welfare states can be interpreted as the most advanced level of founding the organic solidarity of labor division on much reconstituted mechanical solidarity within the boundaries of the nation-state. It reserves the equality of results for natives and excludes people in the poorer regions from its accumulated wealth. In Max Weber's terms, ingroup morality and outgroup morality are strictly differentiated (Weber 1923, pp. 303–4). Within the boundaries of the European Union, this differentiation is fading and being replaced by one comprehensive morality which is now less substantial and concrete and more formal and abstract justice as fairness within and beyond the boundaries of the nation-state (Münch 1993, 1998).

5. *The Negative Effects of Social Integration*

Social integration is not an overall positive state of affairs. In as much as it is limited to a particular unit below world society, it is always accompanied by at least some demarcation from other social units and corresponding disintegration. In this sense, nation-state disintegration is a precondition for supranational integration. Further on, social integration resides at least to some degree on processes of internal homogenization which may include not only the peaceful merging of different regions, ethnicities, and cultures, but also the imposition of a central culture on peripheral cultures, of the domination of a central ethnicity on peripheral ethnicities, of a central region on peripheral regions. Instruments for this process of 'internal colonization' are the penetration of the center's language, legal system, bureaucracy, school system, and communication system into the peripheral regions (Hechter 1975). In this way, social integration levels down differences and thus the richness of cultures and social life as well as the potential for innovation and change. Thus we can say that a balance of integration and at least some disintegration is a necessary prerequisite for preserving the potential for diversity and innovation. This was particularly emphasized by Emile Durkheim 1982). Georg Simmel 1992) pointed out the interrelation of integration and disintegration, harmony and conflict. Lewis Coser (1956) and Donald Levine (1980) revitalized this contribution by Simmel emphatically.

6. *Social Integration and Systems Integration*

Social integration becomes increasingly complex and increasingly requires a balance with elements of disintegration the more we proceed in the evolution of human societies. Clan societies in the early stages of sociocultural evolution are integrated by blood and rules of intermarriage. Traditional estate societies are

integrated by every estate serving a specific function for the living of the whole and the attribution of privileges according to the inherited status. Cohesion and the integration of actions is promoted by the hierarchical order of inherited ranks (Weber 1976 pp. 133–5, 148–55). Modern societies are integrated in a much more complex way. Their cohesion is based on comprehensive inclusion according to achievement and the constitution of citizenship with civil, political, social, and cultural rights as an abstract community beyond any primordial ties of ethnicity, color, gender, or any other kind of group.

Beyond social integration, modern societies are systemically integrated in as far as they have established functionally specified systems like economy, polity, law, science, education, the media, arts and literature, or religion. Money and democratically legitimated political power are examples of media of communication which serve as means of systemic integration in as much as they allow for the coordination of extremely differentiated economic interests or political goals, irrespective of time, place, and persons involved (Lockwood 1964, Luhmann 1988).

In the process of globalization the functionally specialized systems increasingly reach beyond the nation-state with its relatively strong social integration and produce a world society which is much more integrated systemically than socially through solidarity production and a binding social order (Luhmann 1997). It is disputed whether we approach worldwide systemic integration without social integration or whether there is a necessity and also a chance of a subsequently growing social integration on the supranational and even global levels. If we understand social integration in terms of the relatively strong positive integration of the nation-state, there are little chances for social integration on the supranational and global levels. If we realize, however, that this process involves a transformation of social integration in terms of farther-reaching and internally more differentiated solidarity of networks instead of homogeneous social units, which is accompanied by a corresponding abstraction and formalization of justice, we can imagine that supranational and global systemic integration can still be complemented by social integration.

Integrative Assessment in Environmental Studies

In this contribution we will introduce the new research area of Integrated Assessment. To this end, three questions will be addressed:

(a) What is Integrated Assessment?
(b) Why is Integrated Assessment necessary?
(c) How can Integrated Assessment be applied?

Finally, some recommendations are made for the future development of the emerging research area of Integrated Assessment.

1. *What is Integrated Assessment?*

The term Integrated Assessment (IA) was used for the first time in the early 1970s, in particular in the USA and Europe. In Europe, IA has its roots in population–environment research, developing into integrated environmental research, often practiced by doing integrated environmental modeling. During the 1980s and 1990s, many integrated environmental models were developed (Hordijk 1991, Rotmans 1990, Rotmans and de Vries 1997). In the USA, IA was rooted in economic cost–benefit analyses of environmental problems. The impact of supersonic transport on stratospheric ozone and ground level ultraviolet levels increased the awareness that human activities could disrupt the global environment.

Subsequently, there has been increasing recognition and credibility for the rapidly evolving field of IA, illustrated, for example, by the establishment of the European Forum for Integrated Environmental Assessment (EFIEA) (Tol and Vellinga 1998) under the auspices of the European Commission. Multiple definitions of IA circulate (Weyant et al. 1996, Rotmans and Dowlatabadi 1998, Parson 1996), but these definitions have three elements in common: multi- or interdisciplinarity, structuring of knowledge, and decision-support. Using these commonalities, the following definition can be given:

IA is a multi- or interdisciplinary process of structuring knowledge elements from various scientific disciplines in such a manner that all relevant aspects of a social problem are considered in their mutual coherence for the benefit of decision-making.

Metaphorically IA can be viewed as making a puzzle. Everybody sees the separate pieces of the puzzle, but the real art is fitting them together in such a manner that a logical whole arises, which is more than the sum of its parts. The essence of IA is, however, that there is no optimal solution of fitting the scientific pieces of the puzzle together. Depending on the underlying perspective, a multitude of possible solutions exists, and there is no standard-recipe available on how to arrive at this set of possible solutions. This issue explains the heuristic character of IA, being a quest in triplicate: for causalities, coherence, and commonalities.

Although active participation is no prerequisite, more and more people in the IA community are convinced of the vital importance of involvement of stakeholders in the IA process. It is generally acknowledged that involvement of nonscientific and practical knowledge and expertise, valuation and preferences in the form of direct involvement of actors will enrich the process of IA.

This process can be represented in a simplified manner through a sort of demand/supply mechanism, as depicted in Fig. 1. From society's angle there is a need for information about complex social issues, the demand side. Science delivers facts, uncertainties and hypotheses with regard to these complex issues, the supply side. Demand and supply mechanisms come together in an active dialogue, which ultimately leads to integrated visions. In consultation with decision-makers these visions can be translated into decision-strategies. However, the supply side could also be delivered by social actors in the form of nonscientific expertise and judgment, whereas the demand side could be provided by scientists, for instance through prioritizing of research themes.

One of the more successful integrated assessments achieved to date is that of global climate change. Within the framework of the Intergovernmental Panel on Climate Change (IPCC, 1996), the integrated approach has been successful in both scientific and policy terms. In science, it has proven useful in

Figure 1
Sketch of an IA process

Figure 2
A simple pressure-state–impact-response diagram of the human–climate system

addressing earth system functions and impacts, for example, the imbalance in the global carbon budget, integrated analysis of land use and land cover changes, and the climate impact on sulphate aerosols (Rotmans and Dowlatabadi 1998). In policy terms, the attempt was to underpin the discussion about the question: when do we have to undertake action and with what pace do we have to take what kind of measures?

1.1 Climate Change

An IA of climate change takes into account both the socioeconomic and biogeochemical aspects of the climate problem. The most important cause of global climate change is the large-scale increase in the demand for energy and land/food. The driving forces behind this are economic growth, population growth and changes in life-style. This all leads to changes in the composition of the atmosphere and terrestrial biosphere, resulting in changes in global and regional climate. Major social impacts are the effects on the economic sectors such as agriculture, water management, coastal defense, health care, and on natural ecosystems in terms of land degradation, erosion, decreasing vitality, and change in spatial composition.

An IA model of climate change aims to simulate the intricate dynamics of the human-climate system, in which numerous interactions and feedbacks occur, as shown in Fig. 2. Also, such a model allows for rapid calculation and evaluation of various preventive (e.g., an energy tax regime) or adaptive (e.g., infrastructural adaptations) measures.

2. Why IA?

The world around us is becoming increasingly integrated in its commercial and financial activities, while modern means of travel and communication are breaking down many of the traditional physical and cultural barriers between states. The complex dynamics of strongly interacting short- and long-term processes on various scale levels force us to think and act in a more integrative manner. This increasing complexity means that major social problems can no longer be addressed from one perspective, one country, one state, one culture, one ministry, or one scientific discipline, requiring a new conception of planning. IA tries to provide the new tools for this new way of planning, by getting more grip on the increasing complexity of society: considering problems in the light of other problems, coupling different scale levels in time and space, interrelating different themes, addressing cross-sectoral trends and developments, among others. This integration follows from the growing understanding that the various pieces of the puzzle can no longer be examined in isolation.

Opponents may argue that IA is premature, and can lead to inappropriate confidence in questionable or misleading findings. However, the complexity of the issues demands an integrated approach to ensure that key interactions, feedbacks and effects are not inadvertently omitted from the analysis, leading to surprise consequences. Another argument against IA may be that we have insufficient knowledge of the interactions and level of coherence among the social-

cultural, economic and environmental subsystems. This line of reasoning fails because the uncertainties within the subsystems are also large, and our complex society asks for studies that focus on the interface between the subsystems. Current knowledge indicates that sharp fluctuations in the dynamics of our society can be attributed to changes occurring at the cutting edge of the social subsystems, rather than within the subsystems themselves.

So overall, performing IA has a number of advantages. In general terms, IA can help to:

(a) put a complex problem in the broader context of other problems, by exploring the interrelations of the specific problem with other issues;

(b) assess potential response options to complex problems, be it in the form of cost–benefit and cost-effectiveness or some other analysis;

(c) identify, illuminate, and clarify the different types and sources of uncertainties in the cause–effect chain(s) of a complex problem;

(d) translate the concept of uncertainty into the concept of risk analysis, to assist in decision making under uncertainty; and

(e) set priorities for research topics, also by identifying and prioritizing decision-relevant gaps in knowledge.

3. *What is the Problem?*

IA deals with causally linking those social-cultural, economic and ecological processes that are relevant in the light of the problem under concern. This means integration of physical, monetary, information and policy processes. These processes are unlike, with regard to time scale, spatial scale and dynamics, e.g., many economic processes operate at a relatively short time scale, determined by the financial capital invested. Demographic processes play at a longer term of at least one generation, whereas the effect of many ecological processes becomes visible at a time scale of several generations, if not centuries. IA, therefore, seeks to couple: (a) long-term processes with short-term processes; (b) higher scale processes with lower scale processes; and (c) equilibrium processes with nonequilibrium processes.

The process of up- and down-scaling between different levels in time, space and complexity is called aggregation. The level of aggregation of an IA refers to the spatial and temporal resolution and the level of complexity used in the assessment. In general, the optimal spatial and temporal scale at which an IA operates strongly depends on the nature and scope of the problem.

The real problem of IA is that there is no unifying theory that indicates unequivocally how this analytical process of aggregation should happen. Also, the price of integration is simplification, in order to integrate disciplinary pieces into an overall framework. As a consequence, a manifold of integration routes could lead to an integrated knowledge framework. This explains why IA has been a practical, intuitive and heuristic activity so far. It also underlines the need for procedures and guidelines for testing the quality of the integration process.

4. *Methods for IA*

The methodological approaches used at this time to do IA are relatively immature. In general, two types of methods can be distinguished: analytical methods and participatory methods. While analytical methods are often rooted in natural sciences, participatory methods stem from social sciences. The group of analytical methods is reasonably well defined and basically includes model analysis, scenario analysis, and risk analysis. Their commonality is that they provide analytical frameworks for representing and structuring scientific knowledge in an integrated manner. A plethora of participatory methods, however, exist, varying from expert panels and delphi methods, to gaming, policy exercises and focus groups. They have in common the aim to involve nonscientists as stakeholders in the process, where the assessment effort is driven by stakeholder–scientist interactions. Here, we will only briefly discuss IA models and IA participatory approaches. For a comprehensive and elaborative description of IA methods, refer to Rotmans (1998).

4.1 *IA Models*

IA models are computer simulation frameworks that try to describe quantitatively, as much as possible, the cause and effect relationships of a specific issue and of the inter-linkages and interactions among different issues. Current projects in IA modeling build on a tradition started in the early 1970s, by the Club of Rome (Meadows et al. 1972).

The next generation of IA models explicitly addressed environmental issues, such as acidification (Hordijk 1991) and climate change (Rotmans 1990, Nordhaus 1992). Recent overviews of IA modeling activities in the field of climate change can be found in Weyant et al. (1996) and Rotmans and Dowlatabadi (1998). The latter distinguish between macroeconomic-oriented models, which represent relatively simple, parameterized decision-analytic formulations of complex problems, and biosphere-oriented models, which represent a more comprehensive, process-oriented description of a complex problem. Most macroeconomic-oriented models are neoclassical models based on an equilibrium framework, using traditional economic concepts regarding optimization and capital accumulation, largely ignoring environmental dynamics.

Biosphere-oriented models, however, focus on a systems-based description of the geophysical and biogeochemical processes and feedbacks, but do not adequately represent the socioeconomic system. The Dynamic Integrated Climate Economy (DICE) model is a well-known exponent of the macroeconomic-oriented school, whereas the Integrated Model to Assess the Greenhouse Effect (IMAGE) model (Rotmans 1990, Alcamo 1994) is representative for the biosphere-oriented school. Meanwhile, some attempts are underway to combine the best of both worlds, yielding a hybrid of the two categories above. Examples of such hybrid IA models are ICAM (Dowlatabadi and Morgan 1993), Global Change Assessment Model (GCAM) (Edmonds et al. 1994), and TARGETS (Rotmans and de Vries 1997).

IA models have the advantage that they are flexible and rapid simulation tools, which can easily explore interactions, feedback mechanisms, and uncertainties. Above all, they are tools to communicate complex scientific issues to decision makers, disciplinary scientists, stakeholders, and the general public.

4.2 Participatory Methods for IA

'Participatory methods' is an umbrella term describing approaches for assessment in which nonscientists, such as policy people, stakeholders or even lay people, play an active role. Participatory methods for IA differ with regard to the profile of the participants, the goal of participation and the degree of participation. Three classes of methods exist: dialogue-methods, policy exercises, and mutual learning methods. The dialogue-method is applied in cases where the intended users are considered as a source of information necessary for the analysts to perform the assessment. Within this class, we can discriminate between continuous dialogues, and cases in which the dialogue takes place in a specific phase of the assessment. In the first case, the role of the intended users can be described as that of co-designer. In case the dialogue takes place in the design phase, the role of the intended users is to contribute to the design principles by sketching their wants and needs. This type of dialogue can be described as a user-platform.

Policy exercises build upon the tradition of simulation games. A policy exercise can be described as a flexibly structured process designed as an interface between scientists and policy makers, in which a complex system is represented by a simpler one with relevant behavioral similarity, and from which decision making is part through human participants (Parson and Fisher-Vanden 1997). In general, a game is set up that represents a negotiation process in which the different teams are responsible for a certain country or region. Policy exercises quite often make use of computer support. A computer model can be used as a consulting device or as tool to convert the negotiated agreements into a new 'state of the world.'

The principle behind mutual learning approaches is that participation of stakeholders and citizens enriches the assessment by a multiplicity of perspectives, skills, and competence. The participants are considered as co-producers of knowledge. Two forms of mutual learning can be distingished: the focus group approach, in which scientists play the role of facilitator and observer, and the interactive approach, in which scientists are actively involved as participants. In the first case, special groups are composed typically consisting of citizens, policy makers or other stakeholders who are provided with scientific input. The assessments of these groups are then used in a broader IA process. The ULYSSES project involves IA focus groups with lay people (Kasemir et al. 1997).

A major weakness pertaining to participatory methods is that the use of it in IA is in its infancy, with the result that there are no (as yet) established procedures and work-packages for setting up participatory processes.

5. Quo Vadis *IA?*

In order to meet the high expectations that many people have of IA , a number of steps need to be taken. First, the existing tools and instruments for IA should be improved. Much of the criticism on IA has to do with the opaque structure of the IA methods used, and the fact that these methods are often technocratic abstractions of reality.

Second, new IA research methods have to be developed, which enable qualitative knowledge and quantitative data to be blended; but also methods that could handle different sorts and types of uncertainty; and finally methods that could operate at different aggregation levels in time, space and complexity. Regarding IA models, much attention has to be paid to actor-oriented IA models that describe the behavior of human or institutional actors in time and space by means of a set of dynamic behavior rules. Also, it is important to experiment as much as possible with different participatory methods in an IA context. In this way guidelines and procedures could be developed for the development and application of IA participatory methods.

Third, demand and supply of IA studies should be matched in a better way, as also propagated by Funtowicz and Ravetz (1994). At present, the majority of IA research is supply driven. In order to increase the number of demand-driven IA studies, the best of both analytical and participatory worlds should be combined. In this way the complementarity of both types of IA method could be used. The challenge then is to let nonscientists or stakeholders co-develop analytical IA methods.

Fourth, there is a need for IA-quality criteria to test the quality of IA research (Morgan and Dowlatabadi 1996). We distinguish here three types of quality criteria: analytical criteria, referring to calibration and validation of the used IA research methods, methodological criteria, which concern the quality of the used IA research method, and usability criteria, which refer to the extent to which the IA study is useful for policy. However, because of the rather heuristic and explorative character of many IA studies, these quality criteria should not be measured too stringently.

Finally, the time seems ripe for entering new problem areas from the perspective of IA. So far, it has been applied to only a few environmental problems, of which acidification and climate change are the most important. A real challenge for IA is now to broaden its field of application, such as transport and infrastructure issues, health care problems, technological development, the energy issue, and city planning (Rotmans 1998).

Intellectual Functioning, Assessment of

Oversimplifying somewhat, there are three applied approaches to assessing intelligence (Daniel 1997). Each rests on a different conceptualization of what intelligence is and why it should be measured. Each approach, the psychometric, the neuropsychological, and the dynamic, is reviewed below. In addition, several physiological indices—brain wave tracings, reaction and inspection times, nerve conduction velocity, and rate at which glucose is metabolized in the brain, for example—correlate with measures of intelligence. However, physiological indices are not reviewed because they have no applied utility. It is possible, though, that physiological indices will play a stronger assessment role as the twenty-first century progresses (Matarazzo 1992).

1. Psychometric Assessment

Psychometric tests have dominated intelligence testing for a century. The defining feature of this approach is its empirical foundation; 'psychometric' simply refers to the quantitative assessment of psychological states/abilities. While quantitative assessment rests on a massive measurement technology, its theoretical foundations are shallow, as reflected in its origins. The earliest tests that influenced contemporary intellectual measures directly emerged from studies by Alfred Binet and colleagues in France (Cronbach 1984). In 1904, Binet was directed to devise a means of distinguishing educable from noneducable students in the relatively new universal education system. Having

investigated cranial, facial, palmar, and handwriting indices, Binet discovered the direct measure of complex intellectual tasks involving judgment, comprehension, and reasoning most successful in distinguishing among pupils. Based on these pragmatic beginnings, Binet defined intelligence as the capacity to adopt and sustain a direction, make adaptations for the purpose of attaining a desired end, and monitor performance self-correctively. With little elaboration, this definition still directs the psychometric paradigm.

Typically, modern psychometric tests consist of varied subtests that tap diverse aspects of the loosely defined intelligence construct. For example, scales may include subtests that sample a broad range of knowledge (e.g., the names of objects, dates, historical and geographical facts) and require the examinee to assemble colored blocks such that their pattern resembles a prespecified design (Sattler 1992). Again, choice of subtests is not driven by theoretical prescription. Subtests are selected because they work—in combination, they serve to rank individuals according to how much they know and how good they are at solving certain problems. The pragmatic selection of subtests is based on Binet's conception of intelligence as a general or undifferentiated ability (*g*), so that, in principle, the tasks that tap *g* are interchangeable.

At the heart of psychometric testing lies norm referencing (Sattler 1992). Norm referenced tests are developed by administering items in a standardized manner to a representative sample of the population in question. The norm sample is considered 'representative' insofar as it is stratified within age groups for variables that might influence performance differentially, such as sex, geographic region, ethnic status, community size, etc. Scores are scaled such that each individual's derived score represents a relative standing within the norm or standardization group. In this sense, psychometric testing is an empirical endeavor in its purest sense: as a comparative construct, there is little need to theorize about the exact nature of intelligence.

As mentioned, most modern psychometric tests include varied tasks. The original intention was to ensure that *g* was comprehensively surveyed. With time, however, clinicians came to exploit the multitask construction of intelligence tests to make intra-individual distinctions (Kaufman 1990). By looking at the variability among subtests or groups of subtests, assessors hypothesized about relative intellectual strengths and weaknesses. For example, a particular respondent might prove better on tests of memory than on tasks involving conceptualization. It is important to note, though, that the analysis of intra-individual differences developed after the fact; such comparisons are driven by the practicalities of what subtests are available, rather than by a detailed theory about the structure of intelligence.

The empirical base of the psychometric effort implies both weakness and strength. With respect to its limitations, attempts to interpret intra-individual differences based on a selection of subtests that were pragmatically chosen have not been validated empirically (Reschly 1997). Furthermore, the atheoretical approach to task selection has resulted in restricted and incomplete sampling of the intelligence domain (Chen and Gardner 1997). For example, musical and interpersonal abilities are neglected. Instead, there is an emphasis on skills acquired though academic learning, a prized outcome in mainstream Western societies. Therefore, critics object to the fact that psychometric tests measure little more than achievement; they assess what an examinee has learned, not the examinee's potential to learn.

Related to this issue, and magnified by the practice of defining individual intelligence with reference to a norm group, questions have arisen about bias due to (sub)cultural, ethnic, life-experience, and motivational differences. This becomes a social issue when examinees from minority groups are compared to a norm sample whose context, values, and learning experiences are different from their own (Suzuki and Valencia 1997). Testing thereby betrays its original purpose of providing objective data on an individual's intellectual functioning and comes, instead, to discriminate against atypical examinees.

Another difficulty with psychometric tests is that although they usually correlate highly among themselves, this is not always the case (Daniel 1997). Correlations may be influenced by what tasks are included and how they are weighted. Perhaps a greater problem lies in the fact that even where test scores do correlate highly, the same individual may earn discrepant scores on different instruments due to the fact that tests are normed on different standardization groups.

A crucial criticism of psychometric tests is that recommendations derived from these instruments have not been shown to enhance remediation for the examinees (Reschly 1997). Again, this can be attributed to the fact that the content of these scales has not been selected according to any theory of intelligence, brain functioning, or pedagogy.

In other respects, psychometric testing has met with success. Although test tasks are selected pragmatically, they cluster in remarkably similar ways across tests and studies, giving insight into the structure of intelligence. Based on statistical methods that group subtests into clusters according to underlying commonalities (factor analysis), three strata of intelligence have been identified (Carrol 1997). At the highest stratum is a general factor, *g*. This factor subsumes a second stratum of broad factors, including 'fluid' and 'crystallized' intelligence. (Fluid intelligence involves the ability to cope with novelty and think flexibly. Crystallized intelligence involves the storage and use of declarative knowledge such as vocabulary or information.) Subsumed under each broad factor is a set of narrow abilities, such as 'induction' and 'reading

comprehension.' Knowledge of these distinct but interdependent strata can guide construction of new psychometric instrumentation.

Another strength of the psychometric approach derives from its emphasis on quantitative methods; psychometricians strive to ensure that their tests are reliable and valid predictors of performance (Sattler 1992). 'Reliability' refers to consistency of measurement; the more reliable a measure, the less error involved in estimates derived from it. Many psychometric tests boast extremely high internal reliability (the degree to which each component score of the test correlates with the full test score) and short-term 'test-retest' reliability (an index of stability derived by administering the test to the same group of individuals more than once). Furthermore, the long-term stability of IQ has proven impressive, with good predictions over a 20-year time-span. The validity of these tests, too, has proven strong. 'Validity' refers to the extent to which a test measures what it was designed to measure. Intelligence test scores correlate with amount of schooling, quality of work produced in school, occupational status, and performance in the work situation (although the strength of the latter prediction is controversial), both concurrently and predictively. To summarize, although there are serious limitations to psychometric measurement, the approach yields reliable and valid estimates of intellectual functioning. Psychometric tests are accurate classifiers and predictors when used with care in circumscribed contexts.

2. *Neuropsychologically-based Assessment*

In reaction to the pragmatics of psychometric assessment, several theory-based tests have been developed. These are exemplified by the neuropsychological approach to intellectual assessment. A viable neuropsychological approach emerged in the 1980s. This approach reflects an attempt to increase the validity of assessment by basing it on an understanding of brain function and brain–behavior relationships. The emphasis is not on what the examinee knows but on how the examinee reasons; not on observable abilities but on underlying capacities. Empirical considerations such as reliability, validity, and norm referencing are stressed, but they subserve theoretical relevance (Kaufman 2000).

Neuropsychological approaches to intelligence testing have been influenced by the theories of Alexandr Luria, a Russian psychologist. Luria (1980) proposed three levels of brain functioning that mediate distinct types of learning and performance. The lowest functional unit includes attention. Attention involves selectively attending to particular stimuli while inhibiting attention to competing stimuli over time. It is prerequisite to all forms of intelligent behavior. Attention can be assessed with tasks that demand sustained concentration on one stimulus and sustained inhibition of responses to distracting stimuli. The second functional unit involves encoding and processing information. According to Luria, information can be processed simultaneously and/or successively. Simultaneous processing is holistic; it involves organizing stimuli into interrelated groups. Simultaneous processing can be assessed with tasks that require an examinee to recall the spatial locations of stimuli, identify objects based on incomplete drawings, and construct abstract designs from several identical triangles. Successive processing involves integrating stimuli serially, such that each stimulus is related to the one that precedes it in chain-like succession. Successive processing can be tested with tasks requiring, for example, that the respondent repeat numbers spoken by the examiner or repeat an ordered series of hand movements made by the examiner. Planning and monitoring (executive) functions form the third and highest cognitive level, according to Luria. This level involves the integration of attention and simultaneous and successive processing, along with acquired knowledge, so as to permit the formation and execution of plans and the ongoing verification of their efficacy. Neuropsychological tests of intelligence include subtests that assess some or all of these processes. In addition, they may include subtests that are derived from research on information processing, cerebral specialization, and cognitive psychology, and subtests that reflect other theoretical orientations—the distinction between fluid and crystallized forms of intelligence, for example. Scores are derived to reflect ability in each function assessed, as well as overall functioning. These scores can be compared to derive a profile of strengths and weaknesses which, in turn, has direct educational implications.

The neuropsychological approach to intelligence testing has limitations and strengths. A central shortcoming of these theory-based tests lies in the controversy regarding whether they actually measure the theoretical constructs they purport to measure. Factor analyses indicate that subtests do not always cluster so as to confirm the neuropsychological theory on which they are based (Kranzler and Keith 1999). Furthermore, even when the subtests do cluster as expected, their underlying meaning can be ambiguous. For example, the factors that supposedly reflect sequential and simultaneous reasoning in one neuropsychological intelligence test might just as easily reflect verbal and nonverbal reasoning skills. Resolution of issues pertaining to 'construct validity' (whether a test measures what it purports to measure) is crucial; the controversy pertains to whether the theory-based tests in question are actually theory-based.

What of test bias, as discussed in the context of psychometric testing? Bias is not precluded by theoretical considerations pertinent to the neuropsychological approach. Furthermore, the neuropsychological approach relies on norming procedures, such

that the performance of a given examinee is compared to the performance of a standardization sample. While attempts have been made to reduce the discrepancies between whites and minority groups (e.g., by reducing verbal requirements, limiting/changing measures of planning, disproportionately selecting high socioeconomic representatives of minority groups), these strategies work by sacrificing breadth of intellectual sampling and minimizing the differences between whites and minority groups in the normative group artifactually. The issue of bias remains problematic in neuropsychological intelligence testing.

It has been argued that the theoretical underpinnings of neuropsychological tests of intelligence both restrain and augment the breadth of subtest selection (Das et al. 1994). Which perspective one takes depends on the neuropsychological test one is considering and what one considers the purpose of testing to be. It is true that such tests neglect areas of intelligence such as creativity and wit, but the purpose of these new instruments is primarily to aid in pedagogic planning. Hence, it is the perspective these tests afford on a given examinee's strengths and weaknesses with respect to learning that is important. If these tests can successfully divilicate the examinee's ability to plan, attend, and reason successively and simultaneously, such that a successful, deficit-related teaching approach can be developed, the breadth of neuropsychological intelligence testing will be justified. This issue has been debated, however, with some investigators arguing that the adoption of a neuropsychological approach to intelligence testing cannot or has not led to improved pedagogical success (Kranzler and Keith 1999). Others have demonstrated specific gains using carefully controlled trials (Naglieri 1999). For example, students with poor planning improved dramatically in math calculation when instructed in the use of strategies; other students who were good in planning showed more modest improvements when instructed in the use of strategies. At this point, the relative novelty of the neuropsychological approach precludes conclusive comment about treatment validity. If these instruments prove successful in directing effective pedagogy, they will have addressed the major shortcoming of psychometric assessment without sacrificing its empirical strengths.

3. *Dynamic Assessment*

Incorporating a heterogeneous set of evaluation procedures, the defining feature of dynamic assessment is that it evaluates and modifies cognitive functioning simultaneously through mediation and intervention. The product of a dynamic assessment is not an estimate of the examinee's intellectual standing relative to their peers, but an estimate of learning potential. The notion behind the learning potential construct is that individuals with similar starting competencies (e.g., similar IQs) may respond differentially to instruction; what an individual has learned does not necessarily reflect the individual's potential to learn (Grigorenko and Sternberg 1998).

Dynamic assessment represents a reaction against psychometric testing in particular (Haywood et al. 1992), with its purported: over-reliance on previously learned material; failure to consider factors other than ability in measuring IQ, e.g., the (sub)cultural, motivational, personality, and social adequacy differences in examinees; and irrelevance to remediation. The theoretical writings of Lev Vygotsky, a Russian psychologist, form the context of dynamic assessment. Vygotsky (1987) argued that what a child can accomplish when assisted by a mediator ('zone of proximal development') is more indicative of the child's mental development than what the child can do alone ('zone of actual development'). The zone of proximal development is operationalized in dynamic assessment by a collaborative examiner. This examiner provides ongoing feedback, titrated such that it is just beyond the examinee's zone of actual development, until the examinee either solves the problem or gives up. Thus, testing and teaching are joined. This is facilitated by emphasizing tasks that stress fluid, rather than crystallized, reasoning skills. The Vygotskian basis of dynamic assessment is supplemented by information processing concepts in some dynamic approaches. For example, one approach stresses the central role of working memory, the ability to hold old and new information in memory simultaneously, so as to manipulate and transform it. Dynamic instrumentation often includes standardized psychometric tasks, as described above, but they are administered interactively.

Dynamic approaches vary along two inversely related continua: individuality of assessment and psychometric adequacy. At one end of these continua, the assessor works in intensive, individualized interaction, modifying tasks freely, encouraging, prompting, and mediating between child and task at will to derive qualitative (as opposed to quantitative) diagnoses and educational prescriptions (Feuerstein et al. 1979). One commentator described the approach as 'a clinician's dream and a psychometrician's nightmare' (Lidz 1997). At the other end of the continua lies a test-train-retest sequence with standardized mediation and outcome measures. Mediation is delivered through a series of predetermined hints that vary from general to specific. Each hint is offered in response to the youngster's difficulty. Outcome is quantified as number of prompts required to bring the child to correct response and as the ability to transfer to tasks other than those on which training first occurred (Campione and Brown 1987). Some dynamic practitioners doubt the efficacy of standardized dynamic procedures, because clues are not individually modified to the child's needs. However, the method's

standard, quantifiable format renders it amenable to psychometric study.

The goals of dynamic assessment—to assess learning ability, to identify learning processes, and to teach the individual generalizable strategies for problem solving—remain its major strength. No other assessment tradition is so ambitious. Whether or not they succeed in this endeavor, dynamic assessment advocates have sharpened the focus of other assessment approaches, alerting them to the ultimate goal of intellectual evaluation. And in selecting response to remedial efforts as an outcome (as opposed to comparing an examinee with his or her age mates), dynamic assessors propose a powerful means of attenuating experiential bias in intelligence testing. The reasoning is as follows. Suppose there are two children, one biologically disadvantaged with mental retardation, the other who has experienced atypical living/educational opportunities. One might expect relatively little success in teaching the child with mental retardation. However, the educationally atypical child should make great gains, i.e., there should be a large discrepancy between this youngster's pretest and post-test scores (or the child should require relatively few clues to reach problem solution), whether or not the post-test scores approximate the average test score of this child's educationally advantaged age peers. The point is that pretest scores, conceptually comparable to conventional test results, tap a different aspect of intelligence than do difference scores; pretest scores correspond to developed abilities (and, implicitly, past opportunities to develop abilities), while difference scores approximate learning potential. It is by tapping into learning potential that dynamic assessments attenuate the biases of traditional assessment.

However, research support for the claims underlying dynamic assessment is sparse, ambiguous, and often flawed. This is more the case for approaches that emphasize nonstandardized assessment than for those that stress psychometric adequacy, but weak research foundations are common to all approaches (Grigorenko and Sternberg 1998). Little validation of the 'zone of proximal development' exists, for example, and much of what does exist has been conducted at the level of theory, ideology, and description, rather than quantitative experiment. And although change is central to the dynamic philosophy, virtually no work addresses the reliability of change scores. Little has been published on internal consistency, and there is some evidence that change scores derived from different tasks do not correlate. Although there may be reasons to expect incongruence of change scores, these reasons need to be explored and verified so that systematic predictions can be made. Questions have also been raised about variability among examiners in administering, scoring, and interpreting the less standardized assessments, and the possibility of obtaining different results for a given child as a result of this. Few studies address the issue of retest reliability of change scores, and some studies suggest that retest reliability is weak. Factor analytic studies, which are used to demonstrate that subtests intercorrelate according to theoretical expectations, are rarely conducted and do not always confirm hypotheses. Studies have shown that mediation promotes change from pre- to post-test, but it is not always clear how much of the change is attributable to mediation and how much change occurs simply by virtue of practice. Importantly, some research shows that dynamic indices augment prediction of post-test performance beyond data derived from pretest performance (Day et al. 1997). However, other studies have not confirmed the independent value of gain indices over traditional measures; results on this aspect of dynamic testing are ambiguous. From a long-term perspective, some evidence suggests a relation between ability to benefit from mediation and economic and social independence in adulthood among individuals with low IQ. However, there have been no demonstrations that dynamic assessment actually changes school or work performance or leads to recommendations that change performance (Grigorenko and Sternberg 1998). In all, dynamic approaches to assessment represent an ambitious but unproven perspective on human intelligence.

4. *Concluding Comments*

The aforementioned approaches to intellectual assessment have shared and unique strengths. With time, it is reasonable to expect an amalgamation of these strengths such that, with the addition of practical biological measures of intelligence, assessment will become increasingly reliable, valid, fair, and useful. Assuming that this synthesis will reflect current theories regarding the hierarchical structure of intelligence, a reasonable expectation is as follows. In the foreseeable future, *g* will be measured with psychometric instrumentation. The exemplary statistical properties of psychometric tests and the diversity of tasks involved in their structure render them most suitable. It is possible that biological measures will augment or replace the psychometric approach to measuring *g*, although biological paradigms remain primitive. Furthermore, because biological assessment focuses exclusively on brain functioning, rather than on brain–behavior relationships, the remedial implications of this approach will remain limited for some time to come. The neuropsychological approach to intellectual assessment can be used to delineate functional areas (e.g., simultaneous vs. successive reasoning) subsumed by *g* and provide broad remedial recommendations accordingly. Finally, the dynamic assessment approach can be used at the level of the individual by assessment-remediators. This final level addresses issues of bias most directly. However, the complexities of genetic-environmental interactions

will always dictate the need for vigilance with respect to bias. The preceding proposal does not suggest that current tests will be imported into a single paradigm holus-bolus. Nor does it suggest that such a synthesis will resolve the theoretical and empirical inconsistencies integral to each approach. The proposal suggests that the *principles* derived from each approach may be incorporated into an integrated assessment/remediation process, such that the shortcomings of each approach are attenuated. An integrated approach to intellectual assessment will permit successive classification, prediction, and remediation that encompass large groups (e.g., people with average *g*) and the smallest groups (i.e., the individual) alike.

Intellectual History

Intellectual history is the increasingly preferred English name for a discipline that was better known, during most of the twentieth century, as the history of ideas. Both names are currently in use, and the duplicity conveys one of the tensions underlying this branch of historical writing: can scholars usefully define what an 'idea' is? Yet the tension remains largely within the contours of Anglophone scholarship. Other languages have remained loyal to 'ideas' as the basic analytical unit; such terms as *Ideengeschichte*, *la storia delle idee*, *dejiny ideí*, and *l'histoire des idées*, have therefore remained unchallenged.

Intellectual history does not deal with all records of human thinking. The history of ideas has never been concerned with every idea crossing human minds. Rather, it has focused on philosophical ideas discussed by mostly well-known thinkers, primarily belonging to the Western tradition (such as Plato, Locke, and Marx), with occasional glances at non-European thinkers (such as Averroes and Maimonides). Its typical primary sources have been the 'great texts' of the European canon (from Homer and the Bible to Kant's *Critique of Pure Reason* and Mill's *On Liberty*). In recent years, intellectual history has examined a far broader range of authors and texts, reading beyond the best-known thinkers, the 'great books,' and the European canon. But its subject matter—which keeps

it apart from its neighbor disciplines, cultural history and literary studies—remains the written discussions of intellectual questions. It is interested in all records of sustained efforts to debate—within scholarly traditions—aspects of nature and human nature, knowledge and faith, society, and politics.

Historians of ideas identified several key issues that have been part of the literature of classical antiquity, Jewish and Christian thought, medieval and modern European writing: our understanding of the physical world, the applicability of its structure to human situations, faith and reason, morality and government. Broad themes (such as the role of God in the world), long-running ideas (such as 'the great chain of being'), specific concepts (such as love, reason, justice, the good life) and particular terms (such as 'libido,' 'alienation,' 'civil society') all belong to the history of ideas. But historians of ideas, unlike philosophers, do not try to 'explain' these themes and concepts. Nor do they wish, like other social scientists, to 'problematize' them and use them as analytical tools. Instead, they examine how such ideas and terms were used, transformed, transmitted, abandoned, or rediscovered, over time and across cultures.

Such examination can pose questions of continuity and change, gradual or abrupt; it can compare cultures and languages that expressed related ideas or similar terms in different ways; and it can trace the transmission of ideas and concepts. In particular, historians have looked at the passage of ideas between three kinds of interlocutors:

(a) individual thinkers reading and responding to one another, either as contemporaries or across generations;

(b) social groups—such as churches and learned academies—dealing with ideas and transforming them; and

(c) broadly shared ways of approaching ideas—such as philosophical schools, cultural movements, and academic disciplines.

The first category has been the dominant one during most of the twentieth century. Significantly, recent attempts to question the traditional approaches of the history of ideas have often focused on the individual author and reader, suggesting that we may not know as much as we think we know about their minds, intentions, and use of words.

The term 'intellectual history,' running parallel to 'history of ideas' especially in the United States during the second half of the twentieth century, denotes an attempt to depart from the limiting contours of an 'idea,' acknowledging that one may never be able to decide precisely what an 'idea' is. Intellectual history therefore moved on to analyzing texts, the uses of language, and the location of participants within the contours of intellectual discourse. It addresses the complexities of transmission, acknowledging that 'ideas' belong in texts and that texts have contexts. Inspired by neighboring disciplines, especially literary theory, intellectual history has been increasingly aware that 'meaning' and 'understanding' are neither self-evident, nor easy to trace, and can be affected by the historian's own perspective.

New intellectual history has a broader view of the nature of intellectual activity: it is no longer only about traditional scholarly debate, not only about 'great books' by towering thinkers (what the German historian Friedrich Meinecke called 'moving from mountaintop to mountaintop'). Intellectual history has broadened to include the writings of lesser-known, and even obscure, men and women. Its source material encompasses art and fiction, visual and musical ways of conveying ideas, misreception and subversion, emotions and conflicts. The intellectual historian's primary sources can include paintings and private correspondence, musical notes and prayer books aphorisms and epitaphs, poems and cinema footage, landscape descriptions and web sites. The great philosophers have not been abandoned, but they are read in new ways and weighed against new evidence.

1. *The Origins of Intellectual History*

The term 'history of ideas' first appeared in Johann Jakob Brucker's *Historia philosophica de ideis* published in Augsburg in 1723. It was taken up by Giambattista Vico who referred to his monumental *New Science* as—among other things—'una storia delle umane idee' (Kelley 1990). It was the eighteenth century, then, that marked off the history of ideas as a particular field of inquiry that differs from histories of other subjects. Eighteenth-century history of ideas also began to consider its subject matter from what the Enlightenment called a ' critical' perspective. And yet, the Enlightenment did not invent intellectual history single-handed.

1.1 *Parent Disciplines and Inspirations*

Two centuries before Brucker and Vico, the humanist historiography of the Renaissance had reached out to encompass all aspects of human thought and endeavor and aimed at writing 'the history of wisdom' (*historia sapientiae*). Europe's early modern universities developed historical accounts of their own disciplines, doctrines, and schools. The direct parent discipline of the history of ideas was the history of philosophy, which lent a particular philosophical and theological flavor to the historical accounts (Kelley 1990). Consequently, historians of ideas often asked not only the question 'what ideas did past thinkers discuss,' but also, 'what is the meaning of ideas in history,' and 'how does the history of ideas evolved.'

Another important parent discipline was Renaissance rhetoric, which offered a linguistic analysis

of the way human beings think and form their ideas. The humanist tradition of rhetoric was cast aside by major early modern philosophers, like Descartes and Leibniz who claimed to be able to describe the way things are, independent of how they are worded. But the rhetorical approach to ideas was to return, with a vengeance, in the future career of intellectual history.

1.2 Eighteenth- and Nineteenth-century Histories of Philosophy and of the Human Spirit

Enlightenment histories of philosophy, learning, literature, and the arts, which formed the nascent history of ideas, departed from former doctrinal accounts by trying to find a general meaning for the development of thought and learning though the ages. Whether God remained in the picture (Lessing) or not (Voltaire, Kant, Condorce), these histories focused on the 'progress of reason,' or on 'the history of human spirit' (Kelley 1990). The former looked at great philosophers, while the latter followed the broader dispersion of ideas different cultures and historical phases. Both these approaches to the history of ideas offered a variety of evolutionary accounts, which reflected the Enlightenment's fascination with the question of progress, the respective advantages of ancients and moderns, and models of history as a linear advance, as cyclical, or as prone to regressions.

This enlightenment fascination gave rise to two questions still haunting historians today: should intellectual history center on 'great thinkers' or on many minds? And in what sense does the history of ideas 'progress'?

The question of progress opened up a new inquiry about Europe's singularity. It led Enlightenment thinkers and their nineteenth-century heirs to create a new chronology for European history. This chronology was deeply affected by the history of ideas: Rome's grandeur and decline were considered in terms of ideas, religious and political, affecting its fate (Montesquieu, Ferguson, Gibbon). The newly minted 'middle ages' were temporarily cast aside as an intellectually 'dark' era. And, in the hands of Jacob Burckhardt, the Italian Renaissance became a focal point for an account of Europe's intellectual and cultural renewal, its leap to a great future from the springboard of a rediscovered past.

But precisely the same questions led other scholars to look beyond Europe, seeking intellectual traditions in other parts of the world and juxtaposing them against the European narrative. Nineteenth-century scholarly concern with the Jewish scriptures, Chinese religion, Indian mythology, and Islamic philosophy was partly an outcome of the Enlightenment wrestling with questions of linearity in the history of ideas.

Georg Wilhelm Friedrich Hegel saw history as a process of unfolding philosophical patterns, changing with the 'spirit' of the times and tied to the past in intelligible dialectic ways. Hegel also led the way to considering the history of the mind as categorically different from the physical world, inspiring the rise of the 'human sciences' (*Geisteswissenschaften*) in the nineteenth century. The controversial distinction between the physical and the human sciences still haunts scholars today. Intellectual historians are affected by it in their complex relationship with political history: in what sense does the 'world out there' intervene in the history of ideas? Can ideas and reality affect one another? Is their interplay an appropriate subject matter for the intellectual historian?

Another Enlightenment legacy, eclecticism, cast different light on questions of ideas and reality. Eclectics and 'popular philosophers' attempted to pick up the most interesting strands in the history of philosophy, and to compare, combine, and apply them in ways appropriate for the modern age. This approach took up the Enlightenment's key concept of 'criticism' and purported to judge, select, and rearrange contents of earlier philosophical writings. Furthermore, eclectics (notably Victor Cousin) began to suggest that the history of ideas must look to 'external' causes, cultural and environmental. Karl Marx was to follow with a more assertive theory of the dependence of ideas on economic and social factors.

The nineteenth-century views of the role of ideas in history left several unresolved questions: ought intellectual historians approach their subject matter judgementally and selectively, as eclectics and ideological thinkers have done? Or should they—as nineteenth-century historicists and twentieth-century neo-historicists argued—immerse themselves in the inner logic of the texts and the era they are studying, suspend judgement and avoid any attempts to mobilize the past in service of the present?

The Enlightenment's 'critical' approach to the history of ideas was especially interesting when it looked at language. Vico, Condillac, and Herder suggested that many alleged 'truths' of philosophy are anchored in the way thinkers use words. While philosophers like Descartes and Kant claimed to be able to grasp metaphysical truth, either about the world or about human reason, a more historical perspective disclosed that language is an unavoidable and problem-ridden medium of all human thought. Language affects individual thinkers by drawing up the conceptual lines available to their culture and era. Thus, as Christian Garve suggested in 1772, eighteenth-century Englishmen may create a political philosophy based on the concept of 'public spirit,' but their German contemporaries can not; the linguistic and conceptual apparatus is (still) missing.

The question whether language necessarily delimits thought, or may in turn be expanded by thought, is still open. Garve's claim that his German contemporaries could not understand 'public spirit' found an echo in the twentieth-century work of Hans Georg

Gadamet about the 'horizons' of cultures and languages. These horizons change and fuse, but they represent a finite range of possibilities available to any thinker at a given place and time.

And yet, thinkers have always played with language and fought against its conventions. Mary Wollstonecraft, for example, was not content with the prevalent distinction between 'male virtue' (political) and 'female virtue' (matrimonial). She chose to push the concepts around rather than succumb to her era's linguistic horizons. By applying civic virtue to women, she accomplished a theoretical breakthrough (and heralded a social one). Thus, as recent intellectual historians have suggested, language interacts with thought in more ways than one.

2. *Twentieth-century History of Ideas*

The emergence of the new history of ideas in the early twentieth century involved a conscious self-distancing from philosophy, the use of source criticism and analytical methods developed by modern historians from Ranke to the Annales school, and new sensitivity to the scope and limits of its subject matter. During the second half of the twentieth century, the history of ideas became subject to the same transformations that affected historical studies as a whole; and, due to its textual focus, it has been especially prone to critique and innovation inspired by literary theory and by postmodernist thought.

2.1 *Three Founders*

In the American context, Arthur O. Lovejoy is often seen as the founding father of twentieth-century history of ideas, a discipline closely identified with the books he wrote and the journal he edited. There were several other seminal scholars, of whom two were chosen here for representing broad European vistas and unique philosophical perspectives: the German-American Ernst Cassirer and the Russian-British Isaiah Berlin.

Arthur Oncken Lovejoy wished to consolidate the history of ideas and pare off a host of other 'histories' that had become entangled with it. The crux, he suggested, was the study of specific ideas, 'unit-ideas,' in their historical evolving. The most famous example for this approach was Lovejoy's own perusal of the history of one 'unit-idea,' the idea of the great chain of being. Lovejoy offered a historical account of the 'principle of plenitude,' starting with the early Greek notion that all possibilities would eventually be realized, and tracing the trajectory of this idea up to the modern era (Lovejoy 1936). He went on to discuss the histories of such general ideas as Romanticism, primitivism, and evolutionism.

The transformation of ideas over time was for Lovejoy by no means a linear ascent, nor 'an exclusively logical progress in which objective truth progressively unfolds itself in a rational order.' In contrast to linear progressivists, Lovejoy envisaged a perpetual historical 'oscillation' between intellectualism and anti-intellectualism (Kelley 1990). Lovejoy's legacy, especially the *Journal of the History of Ideas* he founded and edited, has affected many American historians. Recent criticism of his approach centres on the primacy of Reason in his work and on the difficulty of clarifying his notion of 'unit-ideas' as independent historical factors.

Like Lovejoy, Ernst Cassirer was a philosopher as well as a historian. Cassirer understood the rise of modern culture in terms of 'symbolic forms,' ways of cultural expressions that gradually acquired autonomous standing, including language, religion, art, and myth. As his seminal work on the Enlightenment (Cassirer 1932) shows, Cassirer's view of the history of ideas was evolutionist, but not rationalist. In the crucial era of the Enlightenment, he suggested, fields of inquiry gradually liberated themselves from the powerful matrix of natural science, creating a modern web of truth-quests leading to Goethe's literature and to Kant's philosophy. Subsequently, in the era of Romanticism, the prevalent focus on Reason transformed itself into a subtler aesthetic concept of the human search for truth.

Cassirer's work has been criticized for reasons similar to critiques of Lovejoy: he did not care to look beyond 'great thinkers,' his work centered on male European philosophers, and his progressivist master-narrative was no longer convincing to late twentieth-century historians. Cassirer, a refugee from Nazi Germany, shared Lovejoy's faith in liberal and rational responses to political evil; late twentieth-century historians did not feel his urge to reflect this moral imperative in scholarly work. On the other hand, Cassirer's approach to the history of ideas helped to broaden its horizons by seriously considering artistic imagination and religious faith as prime sources for the history of ideas, parallel but not reducible to scholarly writings.

Isaiah Berlin, who was reluctant to define himself as a historian, is one of the writers most closely associated with the history of ideas outside the American scholarly tradition. Berlin was deeply engaged with the relationships between ideas and reality. He was convinced that thinkers, especially modern European thinkers, have been able to affect leaders, revolutionaries, and hence the personal fate of millions, for better and for worse.

Berlin's works on Karl Marx, on the 'Counter-Enlightenment,' on English liberalism, and on the Russian intelligentsia convey two fundamental beliefs about the history of ideas. First, Berlin agreed with his protagonists Vico and Herder that the historian can enter the mind and reasoning of past writers, 'feel' them from within and represent their thoughts faithfully and (in Berlin's case) intensely. Second, Berlin's

writing implied that the history of ideas is adjacent to political engagement with ideas. Berlin found two traces running underground in the history of modern European thought: one associated with 'negative liberty,' associated with individual freedom from official intervention; and another associated with 'positive liberty,' a range of yearnings for communal self-fulfilment and meta-individual quests for the good life (Berlin 1958). Similarly, Berlin identified two kinds of thinkers: the 'fox' who is capable of exploring multiple ideas and possibilities, and the 'hedgehog' who creates a monolithic theory based on one type of explanation or one great idea. Berlin's history of ideas was closely associated with his own preference for negative liberty and for thinkers defined as 'foxes' (Montesquieu, Tolstoy, Mill), while exploring with great empathy the arguments for positive liberty and the thinkers who were essentially 'hedgehogs' (Rousseau, Dostoyevsky, Marx).

Criticism of Berlin has often focused on his broader-than-academic description of past writers, and on the idiosyncrasy of his style. Along with his aversion to monolithic explanations, these factors prevented Berlin from creating a historical 'school' of his own. In the last decade of the twentieth century, however, Berlin's work has been taken up by historians of ideas who wish to explore their relationship with political philosophy. Berlin's distinction between negative and positive liberty has been taken up by historians, notably Quentin Skinner, as a reference point for redefining the scope of the history of ideas.

2.2 New Approaches and Problem-setting in the Late Twentieth Century

From the early 1970s intellectual history has evolved in several directions. Interestingly, the new approaches often display 'national' schools of historical writing, banking and disparate scholarly traditions. In addition, they have been informed by innovations in cultural, linguistic, and literary studies.

2.2.1 American developments and critiques of Lovejoy's legacy. In the United States, Lovejoy's legacy has been developed by many disciples and colleagues associated with *The Journal of the History of Ideas*, founded by him in 1940. A great deal of the work has followed in Lovejoy's footsteps, looking at the historical development of themes (no longer necessarily called 'unit ideas'), mainly in European history. Even while abandoning Lovejoy's dualistic, liberal meta-history, the tradition he founded carried on what may be termed a positivist outlook on the history of ideas.

Two important new dimensions were offered by Dominick LaCapra and Hayden White, both of whom have attempted to apply methods derived from literary studies to intellectual history. According to LaCapra, intellectual history ought to benefit from the broader connections made by literary criticism between texts and the contexts of their writing and reading. Literary texts should be taken up as legitimate sources, and the mental environment of authors, both literary and scholarly, should be perused more carefully (LaCapra 1983).

According to Hayden White, structuralism can be applied to intellectual history by taking up the common denominators of realistic and fictional narratives. Texts shed light on their original 'mental climate' whether they are documents or stories, starkly descriptive or ideologically biased (White 1987).

Both LaCapra and White thus expanded both the source pool and the analytical tools of Lovejoy's tradition by appealing to literature as subject matter, historical witness and methodological pointer. Criticism of the structuralist and poststructuralist attempt to collapse the lines between literary and scholarly (or documentary) texts have focused on questions of genre, intention, evidence, and judgement: are novels really akin to philosophical tracts under the historian's gaze? Is intellectual history enriched or impoverished by identifying historical narratives with fictional ones? Are all authors equally reliable, or unreliable? Are all 'stories' equally meaningful? Are traditions irrelevant? Is 'historical truth' obsolete?

2.2.2 The British–American school of linguistic contextualism. The contextualist school, also known as the 'Cambridge school,' has maintained the traditional focus on scholarly and philosophical texts, while introducing a novel emphasis on language into the history of political and social thought.

This emphasis was in some sense heralded by the Welsh historian Raymond Williams, who held that in modern European history many important concepts—'keywords'—have undergone 'conscious changes, consciously different uses; innovation, obsolescence, specialization, extension, overlap, transfer' (Williams 1985). William's pioneering interest in the social evolution of words was, however, overtaken by a broader linguistic approach inspired by discourse theory.

Linguistic contextualism was framed by the works of J. G. A. Pocock and Quentin Skinner. While specializing in early modern Western Europe, its insights can be applicable to other periods and topics of intellectual history. Pocock and Skinner have carried 'context' beyond its traditional social, political, and economic matrices by looking at textual contexts: Sources should not be studied solely on the merits of their own contents, nor just vis-à-vis other 'great works' along the mountain-chain of traditional history of ideas. The most important context is an author's immediate textual environment. A perusal of many

contemporaneous writings, often minor or obscure, will yield a sense of a 'political language,' or what Pocock called a 'paradigm.' Pocock found several early modern paradigms, primarily in English and British history: the languages of the 'ancient constitution,' natural law, classical republicanism, politeness and civility (Pocock 1985). Many authors used more than one 'language'; Montesquieu, for example, combined natural law and classical republican elements. When the coexistence and interplay of such discourses is recognized, an author's conformity, originality and polemics are better understood. Hence the importance of minor figures for shedding new light of the major protagonists of the history of ideas. Thus, John Locke can be examined more closely as responding to his near-contemporary Robert Filmer rather than seen merely as a long-distance interlocutor of Thomas Hobbes on the one side and Jean-Jacques Rousseau on the other.

Skinner placed particular emphasis on the intentions of authors. It is precisely the understanding of contemporary textual context that allows us to identify the use an author makes when choosing particular words. Conventions can be taken up or subverted, shared vocabulary can be accepted, or expanded, or abandoned. But such intentional discursive play, with its subtle layers of allusion, criticism, and irony, can only be unearthed if the language of numerous and variegated contemporaneous texts is studied closely.

Criticism against linguistic contextualism has taken several directions. One direction is that of critical conceptual history, discussed below. From the vantage point of literary studies, Dominick LaCapra has argued that linguistic contextualism over-emphasizes 'documents' at the expense of literature, depriving poetry and fiction of their legitimacy as evidence-givers and of their status as viable primary sources in the history of ideas.

2.2.3 The German school of Begriffsgeschichte (*history of concepts*). Led by Reinhard Koselleck, the multi-volume project of *Geschichtliche Grundbegriffe* ('basic historical concepts,' Brunner et al. 1972–92) analyzes the historical semantics of key political and social concepts in German and other European languages during the 'saddle era' of modernization, 1750–1850. Like the Cambridge School, the *Begriffsgeschichte* attitude requires close contextual examination of primary sources. Authors are seen as working within a conceptual environment, where the major terms are continuously used but their meaning evolves and transforms through intellectual, social, and political changes. Thus, terms such as 'history,' 'civil society,' and 'revolution' acquire new ranges of significance as they move from their Greek or Latin beginnings, via medieval applications, to early modern times. The most crucial transformation, however, took in the decades immediately preceding and following the French Revolution.

Begriffsgeschichte was thus more committed to a strict periodization of turning points in history of ideas than its British and American counterparts. It also remained closer to political chronology. The *Geschichtliche Grundbegriffe* project was intended by Koselleck as a bridge between social history and the history of ideas. It thus maintained a commitment to social, political, and economic contexts alongside the purely linguistic approach.

Furthermore, the *Begriffsgeschichte* focus on concepts—understood as terms, sometimes accompanied by a derivative or a synonym—conveys a more formal understanding of the unit of analysis than either Lovejoy's 'unit-ideas' or Pocock's and Skinner's notions of 'political language.' The adherence to concepts has been criticized for its inflexibility; yet it also allows historians to fine-tune their understanding of conceptual distinctions, shifts of meaning, deliberate changes, neologisms and disagreements about proper usage of concepts (Richter 1990). English-speaking proponents of 'critical conceptual history' have used *Begriffsgeschichte* as a corrective to the overarching generalizations of discourse theory (Ball 1988).

2.2.4 French–American approaches to intellectual history. The intellectual history of France, centered on the French Revolution, its origins, and aftermath, has developed along lines different from the British, American, and German ones. From Daniel Mornet's *Intellectual Origins of the French Revolution* (1933) to the late twentieth-century work of Roger Chartier and the American historians Robert Darnton and Keith Michael Baker, French history of ideas has been less associated with isolating 'unit-ideas,' still lies with political discourse. Partly due to the powerful impact of the Annales school, it has been strongly tied with social and cultural history (Chartier 1982).

Consequently, intellectual history of France often appears in overlap with cultural history, especially where the history of reading, and of the book as an artefact, is concerned. From this perspective, Darnton (1980, p. 337) suggested that intellectual history includes 'the history of ideas (the study of systematic thought usually in philosophical formulations), intellectual history proper (the study of informal thought, climates of opinion and literary movements), the social history of ideas (the study of ideologies and idea diffusion), and cultural history (the study of culture in the anthropological sense, including worldviews and collective mentalités).'

3. *Major Issues, Controversies, Disciplinary Overlaps*

Intriguingly, almost all major issues and controversies associated with intellectual history during the last

third of the twentieth century were associated with its intersections with neighboring disciplines.

Social history represents claims to expand the new contextualism by placing authors and readers, as well as books, within broader social contours. (Hughes 1988). The *Begriffsgeschichte* school, in particular, attempted a social–historical approach to the history of ideas.

Cultural history poses a wide range of problems for intellectual historians, ranging from accusation of narrowness and elitism to suggestions for expanding the range of inspected authors and texts and moving beyond the written word or the individual thinker (Blake 1996).

The intellectual history of women has recently attracted growing attention. Key questions here relate to the past neglect of women thinkers, the effect of gender on the contents of thinkers' ideas and the effect of political thought on women's status and image (Kerber 1997).

The history of science, traditionally part of intellectual history, is recently posing a new set of challenges associated with novel issues such as ecology, genetics, gender differences, and animal experimentation. More fundamentally, the history of science highlights the quest for scientific truth, which provides a context for recent debates about the cultural dependency of historical truth.

Linguistics and literary theory—especially semiology, reception theory, discourse theory, structuralism, and deconstruction—have deeply affected intellectual history. They have opened up questions, as seen above, on the nature of its primary sources, their legibility and reliability, the status of writers and readers and the accessibility (or even the very relevance) of their intentions and thought processes.

Finally, philosophy, the mother discipline of the history of ideas, is still its close accomplice. Lovejoy, Cassirer and Berlin (as well as Alasdair MacIntyre and Quentin Skinner) have all pursued the history of ideas as part of a philosophical work. Richard Rorty saw intellectual history as describing 'what the intellectuals were up to at a given time' and 'their interaction with the rest of society,' therefore exempt from worries about defining philosophy and philosophers, and hence particularly helpful to philosophers in revising their own canon afresh (Rorty 1984).

Rorty's definition—seeing the philosopher as one consumer of intellectual history—incidentally raises one of its most perennial issues: whose intellect, which ideas, belong to (what) history of ideas?

4. New Directions and Future Agendas

Intellectual history is currently responding to external critiques of its narrow, selective traditional subject matter by expanding its temporal and geographical horizons in several ways. In the wake of new interest in women's intellectual history and in minor writers, it is also looking at previously marginalized European cultures and at the non-European world.

Women's intellectual history suggests that women thinkers could be analyzed in different ways than their male counterparts. It is yet unclear whether the history of non-European ideas might similarly transform itself into a non-European history of ideas, raising new conceptual approaches on top of new source materials. However, the question whether gender or ethnic groups require an intellectual history 'of one's own' remains open and is hotly debated.

Historical semantics, which has faced various critical attacks, are being partly rejuvenated by computer-based corpuses and methods of research. Linguistic conceptualism is expanding beyond its Anglophone lair, meeting up with *Begriffsgeschichte* and becoming interested in other (real) languages, political discourses, and questions of reception and interaction. Social and cultural contexts of the production of texts are gaining ever more attention. And clearly, perhaps due to the new attention to female, noncanonical, and non-European thinkers, it appears that the Author, along with her or his opinions and intentions and beliefs, is far from dead.

Intellectual Property, Concepts of

The concept of 'intellectual property' refers to ownership rights relating, for example, to a particular invention (that might be a process or product), a set of scientific research results, the written text, and increasingly so today, electronic versions of all these. Intellectual property (IP) has two forms: industrial property, which encompasses rights over inventions, trademarks, and designs, and copyright covering artistic, literary, musical, audio-visual, and photographic works. The granting of formal monopoly rights for inventions can be traced back to the medieval period in Europe, notably in England and France, though comprehensive legal protection did not appear until the mid-eighteenth century: in the US, for example, it was first enshrined in the 1778 Constitution. The granting of rights is made by IP agencies such as patent offices and patent courts at national and international levels, and the number of rights held is considerable. By 2000, for example, approximately 720,000 patents had been granted by US and European Patent offices.

The field of intellectual property conventionally is regarded as the preserve of the lawyer. However, social science also explores the social and economic processes through which people, organizations, or governmental agencies make claims to IP, and, thereby, to certain legal rights, such as copyright or patents. Social science analysis particularly has been interested in understanding how these rights are negotiated and defined, how they may change over time, their tie-in with changes in the wider economy and innovation system, and the political and ethical issues they raise. These issues have informed, for example, the debate over the patenting of national genetic registers (databases) of whole populations by major pharmaceutical companies in order to facilitate future drug development: such a step has been taken in Iceland. This review of intellectual property focuses in particular on work in the social sciences (e.g., Weil and Snapper 1989, Etzkowitz and Webster 1994, Narin et al. 1997, Etzkowitz et al. 1998) that has explored the links between IP, the innovation system, and the wider 'knowledge society' (see *Knowledge Societies*).

1. *The IP System and Contemporary Innovation*

The conventional rationale for the IP system is that it rewards creativity and innovation by providing monopoly rights to inventors for a specified period of time—typically up to 20 years. In return for disclosing or publishing something new so that others may have access to and use novel ideas, the originator receives some form of payment or recognition (such as acknowledgment in the case of prior copyrighted material). However, the pace and nature of innovation today make this process much more complicated than in the past, especially, for example, in areas such as the 'new genetics.' The question then arises whether IP law keeps up with the pace of knowledge-based innovations (Hoffman and Karny 1988) such that it can properly and coherently determine when monopoly rights are to be granted and when not, when novelty, nonobviousness, and utility (i.e., being capable of industrial application)—the three requirements of any claim to a patent—are in evidence and when not. In this regard, there has been considerable debate over the granting of patents for gene sequences whose function within the context of the human genome is still unknown. Moreover, such discoveries are regarded by many as simply the normal process of scientific investigation which should be made fully available in the public domain.

At the technical level, the laws governing what can and cannot be secured as patentable material, pro-

ducts, or processes are continually subject to reinterpretation to accommodate an ever larger range of life forms and forms of invention. The field of biotechnology has posed particular problems for IP law, not least in inventors being required to make a deposit and full description of their particular inventive step. The organic and complex structures produced through genetic engineering have meant that new arrangements have had to be made to meet this particular legal requirement. Problems, too, are found in the information technology sector where firms developing computer hardware and software promote the spread of their technologies while risking them being cloned or pirated by third parties because the security offered by copyright means very little in real terms.

Apart from the problem of handling the ever-changing demands of innovative technologies, especially those that derive from new interdisciplinary fields (e.g., agro-pharmaceuticals, or bio-informatics), the IP system must also cope with the growth of interface technologies—sometimes called 'handshaking' technologies—that enable independent systems and technical instruments to be compatible with each other. These handshaking technologies depend on competitors collaborating so that each can hook up their particular products to a wider system. Yet the question then arises of how to ensure that those firms whose innovation sets the required standard will enjoy some return on their investment (Shurmer 1996). The regulation of new technologies poses a related but distinct problem for the IP system. The need to ensure that the risks of new drugs or genetically engineered plant organisms are kept to a minimum has often led to regulatory delays on those products coming to the market. As such, one side of the 'contract' with the inventor(s) seems compromised, that is, the real value of the exclusive rights granted to an inventor will be much less because of the reduced period of patent cover once the product has come to market. In the 1990s, all three major markets of the world (the US, Europe, and Japan) extended patent term protection to pharmaceutical products by a maximum of five years to enable drugs firms a longer effective monopoly. This is a good illustration of the IP law having to adjust to meet the demands of both proprietors and regulatory agencies.

It is likely, therefore, that the IP system will encounter ongoing difficulties by the arrival of new technologies in the future as well as by the ways in which these new technologies relate to each other in the contemporary innovation system (Rothwell 1992, Taylor et al. 2000). Not surprisingly, some in the legal profession have gone so far as to argue that the IP system must adopt a technology-specific focus and develop IP law that is customized to particular technology needs (Christie 1994). For others, however, this would be to over-contextualize IP law and lead to a highly contingent interpretation of novelty and innovation (Mellor 1988).

Notwithstanding these debates, the fact that new IP rights have been granted for plant, animal, and human material raises wider socioethical issues about the patenting of life, the control over 'natural' resources, and moral concern over government's own position regarding its regulation of private sector agencies. This debate has been particularly sharp in connection with the Human Genome Project and the storage and use of genetic information (Anderson 1994, Cook-Deegan 1994) and agricultural resources (Shiva 1994). From a purely competitive position it would seem that patenting of gene sequences or indigenous germplasm would promote innovation, yet many have argued that there should be limits on what might be patented even if this constrains the development of some innovative areas of research and development (McNally and Wheale 1998).

At an international level, there has been an attempt—through GATT's (General Agreement on Tariffs and Trade) trade-related intellectual property provisions (TRIPS)—to stabilize and secure intellectual property rights (IPR) in newly industrializing countries and those of postsocialist central and eastern Europe. The GATT enables richer states to impose trade sanctions on those that fail to conform to TRIPS. This indicates that although the harmonization of IP regimes globally may be an important requirement for globalized innovation systems, the tension between global and national interests is likely to prevail. This has been especially apparent in relation to developing countries' desire to protect their indigenous natural and cultural heritage, and to control how both are translated into knowledge resources over which they have collective rights. In effect, this is to challenge the move made by global corporations and organizations to define the meaning of these resources in such a way that they become commodifiable forms of property owned by private interests. This led to the Biodiversity Treaty of 1992 that recognized the rights of countries in the poorer South to conserve and sustain their genetic resources. The impetus behind the Treaty was the growing concern over the way in which countries in the North have been exploiting the natural resources of the South—such as the fauna and flora on which new drugs might depend—and then selling these products protected by patent. The Treaty has, however, had only limited effect in addressing the poorer countries' concerns. The World Intellectual Property Organisation (based in Geneva) has sought to resolve these tensions, but with little or no success.

2. *The IP System at the Institutional Level*

Economic policy in all advanced industrial countries has sought to enhance innovation by encouraging those who produce knowledge to exploit their intellectual property more effectively. This has had an important effect in bringing a wider range of institu-

tions into closer contact with the IP system, notably small to medium sized enterprises (SMEs) and universities.

Government policy in advanced industrial states has been to favor the needs of SMEs but to regard them as poor defenders of their own interests. In part this simply reflects the dependency of many SMEs on larger corporate actors in an economic supply chain. They are unlikely to have the financial resources to defend their claims against infringement by larger companies. Nevertheless, the importance of small firms in general to innovation and employment is well established. In such circumstances, SME firms and their position within the innovation system takes on increasing importance. Evidence shows that they are much more likely to protect their IP through being faster to the market, technical encryption of know-how, strong ties with customers, and so on, rather than deploying formal IP rights (Rappert et al. 1999).

Universities and other public sector institutions engaged in research and development are also central to recent IP-related science policy. A powerful assumption since the early 1980s in both Europe and the US has been that technology transfer and innovation can be enhanced within an economy by raising the incentive within universities to exploit their own research, and to do this by devolving to them intellectual property rights that result from the publicly funded research they conduct. In the US, legislation introduced in 1980 (the Stevenson–Wydler and Bayh–Dole Acts) gave universities the rights to patents derived from federally funded research. This change (mirrored in many other countries since), coupled with increased industrial sponsorship of university research, set in train a growth in patenting such that patents filed by universities quadrupled between 1971 and 1989 in the US and continue to show rapid growth there and across Europe. (Japan has until very recently prevented its universities owning patents.) There is, however, considerable debate over whether this commercialization of university research, while generating some (often only modest) income, works against the idea of universities providing 'public good' knowledge or mistakes the real practical value of university research (Pavitt 1998). Moreover, concern has been expressed that universities are being restricted in their use of patented processes or (in the US) 'discoveries' by firms holding the IP rights to them. For example, those working in genetics research find that, to continue work on the development of new tests, they have to pay high levels of license fee to use genetic material patented by firms.

Social science research (e.g., Packer and Webster 1996, ESRC 1998) has sought to explore the way in which scientists in universities engage with patenting, how they determine the novelty and scope of their results such that they may be most effectively patented, and how this compares with practice in industry. This showed that in order to identify, take out, and market a patent successfully, academic scientists have to develop skills and knowledge that they do not get directly from their training or work experience in the public sector. These include the ability to distinguish legal from scientific novelty and utility. Scientists' judgment about novelty relates to a specific community of researchers within their field, not to the patent law's definition of 'prior art,' which assumes a global, virtual stock of knowledge. Novelty claims in patenting are distinct from those of science inasmuch as they are positioned differently to previous work in the field, by claiming discrete ownership of ideas, rather than, as is normally the case in scientific work, showing how it builds on earlier work. What this research on patenting shows is that the meaning of novelty is never self-evident but the result of a whole range of interpretive steps, negotiations, and reconstructions of knowledge claims about authorship and priority rights (Boyle 1996) by a wide range of social actors. Moreover, in engaging with the IP system to commercialize their work university scientists must also demonstrate an ability to rewrite scientific work in patent style (Myers 1995, Webster and Packer 1995). They must have access to and the capacity to search and use patent literature, an ability and preparedness to work around existing patents, the capacity to delay or alter their academic publications, and the ability to communicate effectively with patent professionals and industrial liaison staff. Patenting, in other words, requires considerable investment in the elaboration, translation, and articulation of claims through various social agents: it is never simply a matter of a purely technical adjudication of what might be deemed to be legally 'novel.' Ultimately, though, the role of law is crucial in determining whose claim to intellectual property will be upheld (Jasanoff 1995). Even so, courts themselves draw on a repertoire of interpretations relating to conventions about novelty, identity, and the boundaries between objects as the product of 'invention' and to be 'found in nature.'

New developments in multimedia technologies—such as the Internet, World Wide Web, digital communication, and broadcasting systems—are now adding even greater complexity to the interpretation of novelty and material rights. These developments are being shaped by global media groups associated with film, video, music, leisure, education, and e-commerce. International conventions that protect the IP rights of artists, composers, authors, and publishers will come under increasing pressure as copyright infringement will be more difficult to detect, or defend against, especially for smaller companies or individuals who have relied on national collecting agencies to secure royalty payments. It is clear that, here again, new technologies operating at a global level can short-circuit the protection the IP system affords.

Some new business sectors, especially the knowledge-intensive business sector covering areas such as design, accountancy, architecture, management con-

sultancy, and environmental services while sometimes using formal IP rights (such as design rights) more usually rely on informal means of controlling their core assets through working with trusted partners or establishing control over a particular area through strong networking relationships with clients and agencies. Protection through reliance on reputation and trust is regarded as equally if not more important for protecting innovation and competitiveness than are legal rights such as trademarks or patents.

The IP system has developed over the past 300 years to protect the rights of the innovator or artist and to achieve two ends: to reward the originator of the idea, yet to make that idea available to everyone else, through, for example, publication of the patent details carrying the design of the product. This system generally works well but is under increasing strain because of the more complex character of technological innovation today, the more complex patterns of research and development that may make priority claims to the inventive step more debatable, and the globalized nature of business that can create major tensions between countries, between multinational companies, and between states and companies. The globalization of interpretive debates surrounding patent claims merely echoes similar processes of the construction of and negotiation over claim and counterclaim made by social actors at more local levels, whether within the laboratory, the patent office, application, or court.

Intellectual Property: Legal Aspects

Intellectual property comprises an interrelated set of legal regimes protecting economic and in some contexts personal interests in inventions, information, works of authorship, images, symbols, and sound recordings. Intellectual property law principally embodies utilitarian precepts—such as promoting technological innovation (patents, trade secrets), spurring creative expression (copyright), and preventing confusion in the marketplace (trademark)—although strands of intellectual property law also reflect natural rights, personhood, and other philosophical perspectives. Economists and policy analysts have substantially enriched our understanding of the relationship between intellectual property protection and innovation and diffusion of new works, but the complexity of this relationship leaves many questions unanswered. The advent of various new technologies and means of distributing intellectual works during

the latter half of the twentieth century, most notably digital technology and the decoding of genetic structure, have raised fundamental questions about the rationale, implications, and appropriate scope of intellectual property protection. As a result, the premises, doctrines, and contours of intellectual property law have increasingly come into question and have sparked growing social, economic, political, and philosophical interest.

1. Origins

The modes of intellectual property law developed and have evolved in response to the rise of commerce, the shift toward industrial means of production and the development of technologies for the reproduction and distribution of works of authorship (Merges et al. 2000). The first use of trademarks can be traced back almost 4000 years to the earliest merchant societies in China, India, Persia, Egypt, Greece, and Rome where craftspeople marked their wares with distinctive symbols in order to identify the source of their goods, develop a distinctive reputation for quality, and assist in resolving ownership disputes. The roots of trade secret protection can also be traced back at least as far as the Roman empire, where courts created a cause of action for corrupting a slave through bribery or intimidation to obtain disclosure of the slave owner's confidential business information. By the time of the Renaissance, most European nation-states had laws that protected businesses (notably, the Guild cartels) from those who used their secret processes and ideas without permission. These early laws were translated during the Industrial Revolution into statutes that protected 'industrial secrets.'

The first formalized patent systems emerged during the early mercantilist period as a means for European nation-states to unify and increase their power and wealth through the development of manufacturers and the establishment of foreign trading monopolies. The term patent, derived from the Latin *patere* (to be open), refers to an open letter of privilege from the government to practice an art. The Venetian Senate enacted the first patent statute in 1474, providing the maker of any 'new and ingenious device … reduced to perfection so that it can be used and operated' an exclusive license of 10 years to practice the invention. Other nations followed suit and the granting of monopolies for inventions became the dominant means of promoting technological advance (Merges 1995).

The need for formal protection against copying did not significantly arise until the invention and diffusion of the printing press in the fifteenth and sixteenth centuries. Out of fear that this new technology would spread religious heresy and foment political upheaval, the British Crown in 1534 prohibited publication of literary works without a license and approval of royal censors. In 1557, it conferred a publishing monopoly upon the Stationer's Company, a group of London printers and booksellers. This monopoly expired in 1694, resulting in competition from new publishers and widespread counterfeiting of published works. The Stationers persuaded Parliament that such economic conditions would not support new works of authorship, leading in 1710 to the first copyright act, the Statute of Anne, 'An Act for the Encouragement of Learning, by vesting the Copies of Printed Books in the Authors or Purchasers of such Copies, during the Times therein mentioned.' By shifting protection from publishers to authors, this statute laid the foundation for a vibrant market for works of authorship and the flourishing of ideas. As technology for recording and distributing new works of authorship developed, copyright law has expanded and adapted to afford protection against copying in these new and evolving media (Goldstein 1994).

The rise of entertainment industries and celebrities in the twentieth century has led to the development of a right of publicity, which protects individuals against the appropriation of their name, image, or likeness for commercial gain. New information technologies have spurred new forms of protection for the design of semiconductor chips and databases.

2. Modern Landscape

The modes of intellectual property law have evolved into highly detailed bodies of statutory law augmented through judicial interpretation. International agreements and the globalization of commerce have harmonized many aspects of national regimes, although variations persist. Furthermore, the development of technologies that cut across the modes of protection, such as computer software, have led to more integration in the practice of intellectual property law (Lemley et al. 2000).

2.1 Patent Law

An inventor of a new, nonobvious, and useful process, machine, manufacture, or composition of matter, or improvement thereof, obtains exclusive rights to make, use, and sell the invention for a term of 20 years from the filing of a patent application. This period, during which the inventor can exclusively exploit the invention, directly or through licensing, provides strong incentives for research and development. The public benefits through the spur to innovation and disclosure of the patented invention. After the patent expires, the innovation becomes part of the public domain, free to all. In addition to utility patents, patents are available in the USA for distinctive plants and ornamental designs for articles of manufacture. Design patents have a 14-year term. A patent can only

be enforced in the nation in which the patent has been awarded.

2.2 Copyright Law

Copyright law promotes creativity in literature and the arts by affording authors and artists lengthy terms of protection (life of the author plus 70 years) against copying. Copyright law protects the expressive elements of a broad range of works—including books, graphical works, dramatic works, choreography, musical compositions, sound recordings, films, sculpture, architectural works, and computer programs—but does not extend to facts, ideas, or utilitarian aspects of such works. Copyright protection inheres upon the creation of original works of authorship fixed in a tangible medium of expression. By contrast with patent protection, copyright law employs a relatively low threshold for protection and substantially longer duration, but the scope of copyright protection is narrower and less absolute. For most categories of works, copyright owners have the exclusive right to make copies, prepare derivative works, and distribute, perform, and display their works during the term of protection. Most continental European nations, and to a lesser extent the USA and other nations, protect attribution and the artistic integrity of expressive works through inalienable moral rights. In response to the increased vulnerability of digital works to widespread piracy, the World Intellectual Property Organization (WIPO) Copyright Treaty requires signatory nations to provide adequate legal protection against the circumvention of copy protection systems and the removal or alteration of copyright management information conveyed along with a copyrighted work.

Unlike patent rights, which are essentially absolute (apart from antitrust limitations), the rights of copyright owners are constrained by the fair use doctrine, which permits limited use of protected works for criticism, news reporting, teaching, scholarship, and research. Copyright law also provides for compulsory licensing of musical compositions and television signals for cable distribution under particular circumstances. Under international conventions, works qualifying for copyright in member nations are protected in other member nations.

2.3 Trademark Law

Trademark law facilitates and enhances consumer decisions and encourages firms to supply quality products and services by protecting names, logos, words, phrases, symbols, sounds, trade dress, product configuration and other means of designating the source of commercial products or services (Economides 1988). A supplier acquires trademark protection by being the first to use a distinctive mark to identify its goods in commerce. Inherently distinctive marks, such as Kodak for photographic supplies, and suggestive marks, such as Coppertone to designate sun tanning products, receive protection immediately, whereas descriptive (or geographic) marks acquire protection only after they have acquired secondary meaning for the consuming public. Trademark protection is perpetual unless a mark is abandoned or becomes associated in the public's mind with a general category of products rather than the source of the product. For example, the terms 'escalator,' and 'thermos,' which initially referred to the products of particular manufacturers, have become generic and hence unprotectable.

Trademark owners have the right to prevent others from using their marks or otherwise confusing consumers as to the source of a product. In some jurisdictions, and now under federal law in the USA, the owner of a famous mark can enjoin and obtain damages for the dilution, blurring, or tarnishment of the owner's mark. Trademark law does not protect functional aspects of a product and allows others to use a mark fairly, such as for comparative advertising or other descriptive purposes, so long as such use does not confuse consumers.

Trademarks are territorial in nature. Unless registered, trademarks are protected only in those geographic regions in which the marked products are sold or advertised. National registration affords nationwide protection of trademarks and the opportunity to obtain foreign registration. Because the USA has not joined the Madrid Agreement Concerning the Prevention of False or Deceptive Indications of Source, the main international trademark convention, US trademark owners must prosecute trademark applications in each country where they seek protection.

2.4 Trade Secret Law

A trade secret is information that derives independent economic value from not being generally known or readily ascertainable and is the subject of reasonable efforts to maintain secrecy. Unlike patent law, information need not be novel in order to qualify for trade secret protection. Most nations protect trade secrets through national or regional regimes. Trade secret protection lasts until the information becomes publicly known. By contrast with patent protection, trade secret law does not protect against independent discovery or reverse engineering by competitors. Those who violate trade secret law are liable for damages and in some cases injunctions against use or further disclosure.

2.5 Other Forms of Intellectual Property Protection

Many jurisdictions recognize some form of unfair competition or misappropriation law prohibiting the

appropriation of some forms of information not protected by traditional modes of intellectual property law. The right of publicity, which is recognized in about half of the USA, protects individuals against the use of their name, image, or likeness for commercial gain.

With the advent of new technologies, some new specialized intellectual property regimes have emerged in recent years. Many industrialized nations, at the urging of the USA, have adopted regimes for the protection of semiconductor chip designs. In 1996, the European Union adopted a directive on the legal protection of databases.

3. *Utilitarian/Economic Theories*

Economic research demonstrates that technological advancement and increased human capital of the labor force account for most of the annual productivity increase in the USA and other industrialized nations (Denison 1985). It is not surprising, therefore, that public policy analysts and social scientists have viewed intellectual property protection principally as a means of promoting intellectual creativity. The precise role of intellectual property protection in promoting technological advancement and the optimal design of such regimes, however, have proven extraordinarily complex and elusive (Menell 1999).

3.1 *Theoretical Perspectives*

The utilitarian theory of intellectual property developed in response to the use of monopoly power to spur innovation. Adam Smith, while generally critical of monopoly power as detrimental to the operation of the 'invisible hand,' nonetheless justified the need for limited monopolies to promote innovation and commerce requiring substantial up-front investments and risk. In the terminology of modern welfare economics, information is a public good: like national defense, it is difficult to exclude those who do not pay for the good from consuming it and additional consumers of the good (e.g., the ideas in a book or improved production process) do not deplete the quantity or quality of the good available to others. Therefore, apart from the costs of distribution and incentives for creation, the optimal cost of information is zero. And in networks markets—such as telecommunications systems, computer operating systems, and standardized parts—there may be positive externalities to more people knowing and using the same information (Shapiro and Varian 1999).

3.2 *Historical, Industry, and Institutional Studies*

Studies across a wide range of industries find that technologies undergo a 'gradual, evolutionary development which is intimately bound up with the course of their diffusion.' (David 1985). Secondary inventions—including essential design improvements, refinements, and adaptations to a variety of uses—are often as crucial to the general of social benefits as the initial discovery. Many studies emphasize the critical commercial importance of linking innovation with understanding consumer needs and astute marketing.

Economic historians and industrial organization economists conclude that patents were rarely the principal means of appropriating returns in most industries (outside of pharmaceuticals and chemicals), and that trade secrecy, lead time, rapid movement down the learning curve, and marketing efforts play substantial roles in the appropriating of returns to investments in research and development (Levin et al. 1987, Mansfield, 1986, Schwartzman, 1976, Taylor and Silbertson, 1973). Saxenian (1994) finds that Silicon Valley has thrived as an incubator of technological innovation because of an extraordinary confluence of factors, including a unique culture of collaboration and sharing of know-how both within and across firms, high mobility of labor, competitive rivalry among many dynamic competitors, high density of complementary specialized enterprises, development of effective trade associations and consortia, creative use of strategic partnering, cross-licensing, a responsive, knowledgeable, and competitive venture capital financing network, close research university-industry relationships, a legal culture emphasizing informal, practical, flexible, and less litigious solutions, a management style emphasizing teamwork, openness, participation, and autonomy of decentralized engineering teams, and the use of stock options to attract, motivate, and reward innovation. Nonetheless, patents continue to play a significant role in the economy as evidenced by the steady rise in the number of patent applications and the importance of patents in the financing of technology companies.

Public funding of research, as well as university research more generally, also play substantial roles in technological advance (National Science Board 1998). Focusing upon social norms motivating scientific research, particularly in university laboratories, Merton (1973) and Eisenberg (1987) suggest that intellectual property rights may undermine scientific progress by supplanting noneconomic reward structures such as publication, reputation, and professional advancement, discouraging the sharing of research and prompt disclosure, and shifting research away from basic research toward projects with more immediate commercial returns. Rosenberg and Nelson (1994) emphasize, however, that intellectual property fosters the diffusion of academic and medical discoveries beyond research institutions into the consumer marketplace. Furthermore, many research universities now protect and license technologies developed on their campuses as a means of funding research, although the implications for scientific progress are complex (Rai 1999).

Content and entertainment industries rely significantly upon copyright protection, although some scholars have questioned whether the incentives for creativity outweigh the economic inefficiency of monopoly exploitation (Breyer 1970). While there is little question that many expressive works would be created even in the absence of copyright protection and that publishers could appropriate some reward streams through first mover advantages and price discrimination of originals, there is little question that the elimination of copyright protection would dramatically alter the incentives motivating many authors and artists and undergirding the burgeoning content industries (Siwek 1999, Tyreman 1971).

3.3 Normative Analysis

The early formal models of intellectual property rights assumed that inventors conducted research in isolation on noncompeting projects (Nordhaus 1969). As such, the models focused on the optimal reward to induce particular innovations by a single inventor. As the historical and institutional literatures reflect, however, the actual environment for innovation is substantially more complex. In particular, different innovators (and firms) often compete to invent first, thus resulting in patent races. Economists developed richer, dynamic models in order to understand the positive and normative implications of rivalrous competition (Barzel 1968, Kamien and Schwartz 1982) as well as models examining design parameters beyond duration of protection such as scope and exclusivity of protection (Gilbert and Shapiro 1990, Klemperer 1990).

Building on Barzel's model of rivalrous competition which emphasizes the inefficient duplication of research, Kitch (1977) argues that the patent system in essence provides the first to claim an invention with a 'prospect' or 'development rights,' authorizing the patent holder to 'mine' the claim exclusively or license those better able to do so. Kitch defends this function of the patent system as promoting efficient (nonrivalrous) exploitation of innovation. Other scholars reach an opposite conclusion. Drawing on a wide range of empirical evidence, theoretical models of bounded rationality, and evidence suggesting high transaction costs in technology licensing, Merges and Nelson (1990) see vibrant competition as a more positive force in spurring invention, innovation, and diffusion of technology than coordinated development by a single prospector.

The modern literature has also developed models to study the implications of cumulative innovation (Scotchmer 1991) and network externalities on the design of intellectual property protection (Menell 1987).

3.4 Positive Analysis

Notwithstanding the serious questions regarding the efficacy and complexity of intellectual property rights, the past two decades has seen a veritable intellectual property 'land grab' as new opportunities to acquire 'intangible' property have emerged. Virtually every field of intellectual property law has seen an expansion of intellectual property rights—software and business method patents (Merges 1999), extension of the term of copyright protection (Patry 1997), anti-dilution law (Port 1994)—and new modes of protection—such as the right of publicity, semiconductor chip protection, and database rights—have emerged. The rapid expansion of intellectual property, often without adequate consideration of the diffuse interests of the public at large, suggests that traditional models of political economy apply reasonably well to the intellectual property arena (Menell 1994, Litman 1989, Ryan 1998, Samuelson 1996).

4. The Expanding Social, Philosophical, and Political Significance of Intellectual Property

Although the utilitarian framework has dominated the analysis of intellectual property, natural rights, personhood, libertarian, distributive justice, and other nonutilitarian theories have played a role in justifying intellectual property, especially with regard to the protection of literary and artistic expression (Gordon 1993, Hughes 1988, Waldron 1993). Continental European nations place greater emphasis than the USA or the UK on the inalienable moral rights of authors. Digital technology and the decoding of genetic structure have raised fundamental questions about the rationale, implications, and appropriate scope of intellectual property protection, pushing the debate further beyond the utilitarian frame of reference.

4.1 The Digital Revolution

As with the development of human language, writing, printing, and industrial methods of production, computer and network technology represent a fundamental advance in the ways in which humans societies function (Robertson 1998). In just a few years, the Internet has reshaped many industries by dramatically reducing information and transaction costs and creating new opportunities and pathways for commerce to flow (Evans and Wurster 1999, Shapiro and Varian 1999). The ease with which expressive works can be created and distributed in the information age pose threats to traditional copyright-based industries as well as great opportunities (National Research Council 2000). More fundamentally, the Internet has begun to transform social and political life by unleashing a tremendous wealth of easily accessible information and enabling social and political communities to form, function, and evolve in new ways.

Intellectual property plays many roles in the new information economy, from providing incentives for new enterprises to regulating the flow of information. As a result, intellectual property protection has increasingly come into conflict with freedom of speech, privacy, contract, and with other fundamental aspects of civil society, leading scholars to reexamine the role and implications of intellectual property (Lessig 1999, Netanel 1996).

4.2 Biotechnology

The decoding of genetic structure has led to the discovery of new ways of identifying and treating human disease, increasing agricultural and aquacultural yields and the nutritional content of foods, and reducing crop vulnerability to pests. These technological advances, however, have raised a host of troubling ethical, religious, social, economic, political, and ecological questions ranging from the morality of cloning humans to the ecological risks posed by the release of genetically modified organisms. At the most basic level, biotechnology research has led some to question the morality of uncritically promoting scientific discovery and the diffusion of new products. For example, the risk-taking and commercialization ethos of the intellectual property system has increasingly come into conflict with the precautionary principle of international and environmental law. The great commercial value of many biotechnology advances has spawned a growing list of quandaries for intellectual property law, including the existence and scope of property rights in human body parts, cell lines, and waste products, whether the human genome or particular sequences of genetic information should be protectable under intellectual property law, the ownership of intellectual property derived from human material, the ownership of intellectual property derived from native plants found in sovereign nations and the rights of indigenous people to use such intellectual property (Sedjo 1992), and the use and dissemination of genetic testing information.

Intellectual Property Rights: Ethical Aspects

'Intellectual property rights' are generally understood as an instrument of economic policy providing incentives for and rewarding a broad range of useful human creativity. Despite this prevailing economic rationale, the roots of, the justification for, and some limitations of exploitation of these rights are reasoned ethically. They will be examined in the context of the notion, economic importance, and implications deriving from scientific and international policy developments.

1. *The Notion of Intellectual Property Rights*

As a generic term, intellectual property rights stand for: patents relating to inventions in all fields of human endeavor; copyright covering literary, artistic, and scientific works; neighboring rights dealing with performances of performing artists, phonograms, and broadcasts; trademarks, service marks, and commercial names concerned with signs distinguishing goods and services as well as economic subjects; industrial design protecting novel and original ornamental or aesthetic aspects of a useful article; or plant breeders' rights relating to new varieties of plants. Conceptually, intellectual property rights can be understood as rule-governed privileges that regulate the ownership and exploitation of objects which are to be characterized as intangible or incorporeal, thus abstract or intellectual. These objects are nonexclusive, since they can be in many places at once, and can be used at the same time without being consumed by their use. The possession or use of such an object by one person thus does not preclude others from possessing or using it as well. Despite their common fundamental character, i.e., being rights in intangible, abstract objects, and being territorially limited, they differ from each other in many legal details and character.

Whereas a patent also gives its owner rights against the independent creator of a similar invention, copyright confers rights against copying but does not affect the independent creation of a similar work. In other words, while patents restrict the actual usage of an idea, copyrights restrict only the copying of an expression of an idea. Necessarily, the period of protection, i.e., during which the rightful owner can prohibit unauthorized use, is tailored according to the specifics of the respective rights—for instance, 20 years from filing the application in case of patents, 50 or 70 years after the death of the author in case of copyright, or renewable at will, i.e., indefinite, in case of trademarks. However, neither patents, nor any other intellectual property right, confer on their owner a license to use the patented invention, copyrighted work, etc. Such use is prohibited whenever it would violate, for instance, laws dealing with public health, safety, environmental protection or certain ethical standards, or would infringe the rights of third parties.

2. *Economic Importance*

Due to enormous advances in science and technology, in particular in communication and information technologies, biotechnology, and life sciences in general, on the one hand, and the global economic policy developments following the conclusion of the GATT-Uruguay Round and the establishment of the World Trade Organization in 1994, on the other, intellectual property rights have gained most remarkable economic importance. They have penetrated, or are about to penetrate, new areas of economy, such as the service sector, life sciences, and agriculture. Patents have been granted for instance, for microorganisms, plants and animals, genes, as well as computer programs and

business methods. Universities and other academic institutions, primarily aimed at generating and disseminating new knowledge, have also not remained unaffected. Consequently, the new, knowledge-based economy has been characterized as 'intellectual property economy' or 'intellectual capitalism.' This trend is reflected, for instance, by the number of patent applications filed and patents issued, which in the USA almost doubled from 1988 to 1998, from 160,000 patents to 260,000 patent applications; by the amount of royalties paid for patent licenses, which increased in the USA from US$3 billion in 1980 to over US$100 billion in 1997; or by the fact that commodities constituted 62 percent of the market value of the manufacturing industry in the USA in 1980, but less than 30 percent in 1998. Also remarkable are the numbers of patents issued to US universities, which went up from 177 in 1974 to 2436 in 1997, the year in which US universities filed some 6,000 patent applications and granted around 3,000 patent licences.

3. Historic Roots and Rationale

The historic roots of patents and copyrights, as the two forms of intellectual property with the longest tradition, go back to the systems of inventors' and printers' privileges at the close of the Middle Ages. Inventors' privileges formed part of the industrial policy of regional sovereigns, being aimed at promoting domestic crafts and industry, and at transferring to their own country the production of goods which had previously been imported from abroad; thus, as expressed in a grant issued by Edward III in 1331, '*instruendi et informandi causa*.' The first statutory regulation, the Venetian Statute of Inventors, of 1474, with its time-limited protection of inventions against imitation, was also intended to stimulate 'deep thinkers and ingenious inventors from other regions to exercise their activity to the advantage of Venice.' Similar economic rationale is to be observed in the English Statute of Monopolies of 1624, under which the grant of patent monopolies of 14 years' duration was restricted to the 'real and first inventor,' and was conditional upon its not being contrary to law or 'mischievous to the state' in any way.

Following the invention of the press, the first printers' privileges were granted in the second half of the fifteenth century in Venice, later followed by Milan, and at the beginning of the sixteenth century by other Italian cities, France, Germany, and England. Whereas in Venice and France some of these privileges were granted to authors, the great majority of privileges were for publishers, or, as in England, for stationers, who acquired a work from its author and organized its printing and sale. In England, where the stationers in 1534 gained protection secured by the Crown against the importation of foreign books, and in 1556 a Charter from Queen Mary, the privileges were combined with censorship over all publications, by mandatory registration with the Stationers' Company. Although the first Copyright Act, issued in 1710 in the reign of Queen Anne (the Statute of Anne), conferred the 'sole right and liberty for printing books' for 14 years to authors and their assigns, it did not change fundamentally the economic rationale of protection.

By naming booksellers and printers as falling among the author's assigns, it demonstrated that the right 'stemmed from commercial exploitation rather than literary creation pure and simple' (Cornish 1999). Despite the remarkable influence which John Locke's theory—that all persons have a natural right to hold property, particularly the fruits of their own labour—played from the very beginning in justifying intellectual property, the economic policy of legislation has remained utilitarian. This is well demonstrated by Art. 1, Sect. 8 of the US Constitution of 1787, providing that 'The Congress shall have power…(8) To promote the progress of science and useful arts, by securing for limited times to authors and inventors the exclusive right to their respective writings and discoveries.' This is equally true for the first modern patent laws. which were passed in 1790 in the United States and 1791 in France, although they strengthened the position of the inventor and awarded him a property right to his ideas. The same rationale controlled also the first US Copyright Statute of 1790.

The doctrine of intellectual property developed in eighteenth-century France, advocated primarily by D'Héricourt, Diderot, and Voltaire as a weapon against extended privileges of publishers. A first true statutory shift of the emphasis from the publisher to the author can be observed in the Decrees of the French revolutionary legislation of 1791 and 1793, which extended the term of protection to the entire life of the author and beyond; first for five, then for 10 years after the author's death. In the course of the nineteenth century France further extended the term of protection to cover also the lifespan of the author's widow, and 20 (later increased to 30) years for the benefit of the children. Eventually, in 1866, the duration of French copyright was extended generally to 50 years after the author's death. Even this shift of emphasis, however, did not add to the economic rights of the author any 'personality right' or *droit moral*, which had been first mentioned by Immanuel Kant. Kant stated that the right of the author 'is not a right in an object (*in re*), i.e., in the copy (for the owner can burn this up before the author's eyes), but an innate right, inherent in his own person, which implies the possibility of opposing the attempt of another person to compel him to speak against his will.' Kant characterized copyright as a supremely personal right (*jus personalissimum*) (Strömholm 1983).

French and German legal doctrine and French case law in the second half of the nineteenth century

eventually paved the way for *droit moral*: first, into the case law, and then into copyright statutes of the principal Continental countries. Although *droit moral* was introduced into the Berne Convention for the Protection of Literary and Artistic Works of 1886, as revised in 1928 in Rome, with a new Article 6 bis—which at present guarantees an author independent economic rights, and even after their assignment, 'during his whole lifetime the right to claim authorship of the work and to object to any distortion, mutilation or other alterations thereof, or any other action in relation to the said work, which would be prejudicial to his honour or reputation'—the common law countries of the United Kingdom and USA remained reserved in this respect. In general, therefore, one distinguishes between 'author's rights' of civil law countries, with their emphasis on the principles of natural rights, and the 'copyright,' rooted in the idea of utilitarianism, of common law countries. However, on balance, it was neither human rights nor copyright doctrine that decisively shaped the law, but economic interests of copyright owners, because: 'In the world of copyright policymaking, a Canadian book publisher has far more in common with a Japanese book publisher than it does with a Canadian librarian who wants to make free copies for library patrons' (Goldstein 2001).

4. *International Legal Developments*

The very nature of the objects to which intellectual property rights relate, and the development of international trade combined with the progress of transportation and communication technologies, already by the nineteenth century revealed the need for international instruments for protecting intellectual property rights. What started in 1883 with the adoption of the Paris Convention for the Protection of Industrial Property, followed by the Berne Convention for the Protection of Literary and Artistic Works in 1886—which established the principles of national treatment or nondiscrimination and minimum rights as binding standards for the contracting states–subsequently developed into a true network of international conventions and treaties covering the entire range of intellectual property rights under the administration of the World Intellectual Property Organization (WIPO).

However, membership in many important conventions long remained limited, and minimum rights incomplete or, as in the case of patents, nearly nonexistent. The turning point came when, during the GATT-Uruguay Round negotiations, issues of international trade, including membership in the World Trade Organization (WTO), were linked directly to an effective protection of intellectual property rights, and the International Agreement on Trade Related Aspects of Intellectual Property Rights (TRIPS) was adopted in 1994. Under this new umbrella for international protection of intellectual property rights, all members of WTO accepted unified high standards of protection, including protection requirements, content, and limitations and duration of rights, as well as their enforcement. Developing countries, countries in transition and the least-developed countries were granted transition periods.

5. *Old and New Ethical Aspects in Intellectual Property Rights*

Traditionally, ethical aspects in intellectual property rights have been discussed in the broad context of justification of these rights. Lockean theory of natural rights to the fruits of one's labour, the doctrine of intellectual property, as well as Hegel's personality justification suggesting that the best way of progressing science and the arts is to protect scientists and artists from theft, so as to become the basis for learning by others, are such examples and had some lasting influence on legal developments, reflected, *inter alia*, in broad acceptance of *droit moral*. Modern critics of intellectual property rights also put emphasis on ethical aspects when, for instance, claiming that increasing scope of patentable subject matter or legislatively creating new forms of abstract objects, such as plant variety rights, constitutes effectively the creation of capital, which has the danger that it can act as an enormous power resource for a select few. Furthermore, a global protectionist scheme for intellectual property would help to promote the formation of global factions, resulting in the danger of global rent seeking, and perhaps providing temptation to multinational elites to increase their profits through the simple stratagem of persuading a supranational body to elevate levels of protection for abstract objects already in existence (Drahos 1996). With such reasoning, neither the ethics of the controlling doctrine nor the ethical aspect of attempts to take care of the developing world and the unprivileged in general can be overlooked. The same is true for the debate on intellectual property rights in genetic resources and benefit sharing. Although clear empirical evidence whether intellectual property rights confer a net benefit or a net loss upon society is still missing modern law makers seemingly accept a limited and flexible intellectual property rights scheme as a reasonable and, as revealed by the adoption of TRIPS, internationally necessary effort to maximize benefits while minimizing costs. This attitude is demonstrated by the adoption of statutory rules or acceptance of case law, creating new objects such as DNA sequences, monoclonal antibodies, or for instance, business methods as subject matter of protection. In their overall positive attitude toward exclusive intellectual property rights modern law-makers might have been in part influenced by the negative experience with some alterna-

tive protection found in the former socialist states such as 'investors' certificate' which did not provide for exclusivity and had no beneficial macro-economic effects.

Special attention is paid to ethical aspects when patentability of inventions is at hand, the commercial exploitation of which would be contrary to '*ordre public*' or 'morality.' Under the TRIPS standards, members of the WTO 'may exclude from patentability inventions, the prevention within their territory of the commercial exploitation of which is necessary to protect *ordre public* or *morality*, including to protect human, animal or plant life or health or to avoid serious prejudice to the environment, provided that such exclusion is not made merely because the exploitation is prohibited by their law.' Thus such exclusions may only apply for ethical reasons, first, if commercial exploitation is prohibited, and, second, if they are prohibited for specifically qualified reasons, which need not necessarily be set out in statutes, however. European patent law reflects these ethical considerations by excluding from patentability the human body, at various stages of its formation and development, including germ cells, processes for cloning human beings, processes for modifying the germ line genetic identity of human beings, uses of human embryos for industrial or commercial purposes, processes for modifying the genetic identity of animals, which are likely to cause them suffering without any substantial benefit to man or animal, and in general all therapeutic methods. By declaring, explicitly in principle, that biological material, even that of human origin (provided the prior informed consent of the source person is obtained), as well as animals and plants (except varieties) is patentable, European law makers demonstrated clearly that they do not share respective ethical objections against patentability of life forms. This ethically reasoned approach, which differs in particular from that applied in the USA, where no such exclusions exist, however itself raises ethical concerns. On the one hand, it seems consistent that inventions, which for reasons of ethics may not be commercialized, should also not be patented, although an issue of a patent does not confirm more than that the usual patentability requirements of novelty, inventiveness (nonobviousness), and industrial applicability (utility) were met and the invention adequately disclosed. It does not contain any other value judgment. On the other hand, the invention under such circumstances cannot be commercialized in any case, as long as its exploitation is prohibited. However, if such a ban were to be lifted, anybody could use the invention, and the inventor would remain empty-handed. As history demonstrates—for instance, with contraceptives—this is not a far-fetched scenario and could easily happen again, e.g., with regard to specific uses of stem-cell technology, germ line gene therapy, etc. Empty-handed inventors, and at least to the same extent the lack of incentives for investment in potentially useful research, may be viewed as ethically doubtful results.

Intellectual Transfer in the Social Sciences

1. Intellectual Transfer as a Basic Process

Intellectual transfer is one of the least researched and most common processes in the social sciences. It is defined as the importation into a social science discipline of formal procedures or substantive insights developed in another social science discipline or in the natural sciences, in such a way that those procedures

or insights not only provide suggestive metaphor or imagery, but define a coherent conceptual universe. Such importation may result from a conscious search for more rigorous modes of analysis than those which the practitioners of a discipline currently have available to them; the geographical displacement of a significant body of scholars; an intellectual milieu providing for interdisciplinary cross-fertilization; or the actions of scholars acting as intellectual import–export agents. For much of the twentieth century the first mode of importation was the most common, exemplified by the borrowings made by sociology and anthropology of procedures from biology, physics, cybernetics, and linguistics. The second is best exemplified by the influence of psychoanalysis on a range of disciplines. The last three decades of the twentieth century saw the emergence of a different form of intellectual transfer—interdisciplinary hybridization—the culmination of which is the proliferation of departments of cultural and other 'studies,' in which the 'same' object of inquiry may be addressed by a range of—often epistemologically contradictory—procedures.

2. *Transfer of Procedures*

Whether the classics of modern social science owe their achievements to a spirit of nineteenth century humanism which pervaded them all (Nisbet 1967) or to their location between literary and scientific modes of perception (Lepenies 1988), the subsequent history of sociology, anthropology, economics, political science, and psychology is pervaded by the widespread if intermittent quest for methods and results whose rigor would be comparable to those of the natural sciences. This has entailed a readiness among social scientists to look beyond their own disciplinary boundaries not only for (philosophical) clarification of existing assumptions and procedures, but also for tools which would place social science knowledge on firmer foundations and generate a significant corpus of findings. Within sociology, anthropology and political science, functionalism, structuralism, systems theory, and rational choice theory, are only the most prominent results of intellectual transfer based upon this foundationalist impulse. Functionalism's conception of society as an organic unity is rooted in conceptions of the organism drawn from biology; structuralism's exploration of social codes and messages deploys methods first developed in linguistics; the systems theory of the later Talcott Parsons or Niklas Luhmann is unthinkable without the conceptual apparatus of cybernetics; rational choice theory applies individualist models of utility maximization drawn from economics to all domains of the social and political world; and within mainstream empirical social science the persistent classification and subclassification of social phenomena owes much to the taxonomic procedures of eighteenth century natural history (Foucault 1974). More recent moves to apply chaos theory to society have added a twist to this quest for foundationalist respectability. Here, theories of uncertainty and nonlinear dynamics appear to warrant claims that the natural and social worlds are both marked by the absence of law-like regularity.

Since the intellectual transfer of a formal apparatus entails an initial abstraction of its core components, their uprooting from their original home, and translation into an idiom recognizable to the social science discipline in which they are to operate, the blessings of these efforts have been mixed. All display a tension between the descriptive power of a rigorous theoretical apparatus and the need to adapt it to circumstance, most notably the absence of an isomorphism between the natural and social worlds. A number of consequences of this may be noted:

(a) Techniques and conceptual schemes imported into the social sciences from outside have produced genuine semantic innovation and enhanced the descriptive vocabularies of practicing social scientists.

(b) At the same time, it remains doubtful whether they have added significantly to collective social scientific knowledge of the sources of social order, social change, and human motivation that emerged in the late nineteenth century classics.

(c) While intellectual transfer of this type has increased the theoretical sophistication and rigor with which 'results' or 'findings' are presented, it has produced little if any innovation in empirical research techniques or methodologies.

(d) In cases of a more explicit embrace of natural science models social scientists' understanding of natural science knowledge may be incomplete/inaccurate, as witnessed by the 'Sokal affair' of 1998.

(e) The very success of well-defined approaches such as systems theory or rational choice theory—descriptive power, volume of findings, size of intellectual following—has produced paradigm multiplication—intellectual closure, the progressive internal differentiation of disciplines and disciplinary vocabularies—rather than disciplinary unity.

As a result of this last consequence, histories of disciplines such as sociology or anthropology are forced to combine an in-house relativism/ecumenism with a vaguely felt evolutionism. Here, the more extensive the importation of natural scientific paradigms into social science disciplines, the less any of them taken as a single entity appears describable through Kuhn or Lakatos' accounts of the development of natural science disciplines: scientific revolutions, or the growth of knowledge through criticism.

3. *Transfer of Substantive Insight*

In contrast to the considerable development of formal techniques and conceptual vocabularies in the twentieth century, the history of substantive innovation in

the social sciences is less impressive. Since the turn of the nineteenth century the anthropological claims which grounded the identities of the various disciplines or subdisciplines at their inception have proved remarkably robust. Within social science disciplines with more porous boundaries these models of humankind have continued to define the terms in which the nature of social being is debated and researched. The images of humans as producing animals, as the maximizers of utility, as altruists, as fabricators of a meaningful universe, still dominate mainstream social science at the beginning of the twenty-first century. Some notable additions, however, in which a 'migration of insight' has occurred, may be mentioned. Most marked are the claims of psychoanalysis concerning the basic structure of the psyche, which have exerted widespread influence on a range of disciplines, particularly sociology and anthropology. The work of the archaeologist Uexküll on the relationship between humans and the environment influenced the theory of social institutions developed by a whole generation of conservative German social scientists from the 1930s to the 1950s.

4. *Interdisciplinarity*

If one product of open disciplinary boundaries is a form of intellectual transfer based on a quest for certainty, foundation, and intellectual closure, then another is interdisciplinarity, the mutual influence of two or more disciplines. A major stimulus to this process has been a change in the status of natural science knowledge from being an explicit model or implicit standard for social scientific inquiry, to being a topic of it, subject to the same scrutiny as other realms of human action. This breaking out of the shadows of natural science has left the social science disciplines both on their own and with room to explore their relationship to humanities disciplines such as literary criticism. Three forms of interdisciplinarity may be distinguished:

(a) The combination—common throughout the history of the social sciences—of the major building blocks of two or more disciplines in order to throw light on a clearly defined element of the human condition. Examples of such an approach are the combination of literature and anthropology in Rene Girard's account of violence; of sociology and economics in Talcott Parsons' account of the nature of action; and of sociology and history in Barrington Moore and Skocpol's accounts of democracy and revolution.

(b) The eclectic hybridizing of a variety of discipline-specific conceptual devices and methods as part of an effort to generate a new field of inquiry. Notable examples are 'area studies' which developed in the 1950s and 1960s out of an effort to apply Western social science to Third World and developing societies, and the contemporary phenomenon of cultural studies, which has mushroomed in new universities throughout the Western world.

(c) The utilization of the results and findings of the different social science disciplines in order to develop a comprehensive anthropology (Gehlen 1988).

5. *Mechanisms of Transfer*

The transfer of formal or systematic procedures into a social science discipline depends partly upon the degree of systematization already prevailing within it. Social science in France and Germany—where all-embracing terms such as *Wissenschaft* know no English equivalent—developed at its inception a series of systematic, conceptually rigorous theories of social wholes. The relative immunity of these social sciences to pressure from natural science or the humanities may be attributed, ironically enough, to the fact that many of their founders were trained in jurisprudential modes of reasoning. It is arguable that by contrast, in the English-speaking world the division between the arts and natural sciences has made the social sciences more open, yet also more vulnerable to the rival claims of both a natural science model of good knowledge and a hermeneutic or culturalist inquiry based upon procedures drawn from literary criticism or, after World War II, semiotics. The coexistence of rational choice theory and postmodernism within the same departments of sociology is an index of this.

Yet social science in the English-speaking world is not wholly torn between the importation of scientistic models of explanation and the adoption of literary models of textualist interpretation, sharing much with the social science of the continental European tradition. That this is so owes much to the exile and migration of that tradition's representatives and their presence within Anglo-Saxon higher educational institutions. If Anglo-Saxon sociology, political science, psychology, or anthropology have held their own as *sui generis* and self-confident disciplines, or if political sociology or economic anthropology have later produced systematic interdisciplinary inquiry, it is on the basis of the work of Marx, Weber, Durkheim, Schumpeter, Malinowski, Freud, and Levi-Strauss, much of it mediated by the European intellectual diaspora of the 1920s and 1930s (Anderson 1992). By the same token, the Anglo-Saxon world has become the protective home of a generic 'European' or 'continental' tradition of social science inquiry, based upon and promoting an intellectual transfer between national traditions which contrasts with the entrenchment and mutual suspicion frequently displayed by their native practitioners.

6. *The Future of Intellectual Transfer*

In the 30 years following Lakatos and Musgrave's (1970) *Criticism and the Growth of Knowledge*, the

philosophy of the social sciences has lost much of its appeal to the social sciences themselves. The mirror in which reflection on the identity of the social sciences occurs is no longer that of the epistemological status of social scientific knowledge but, increasingly, that of the social responsibility of both natural and social scientific practitioners (Wallerstein 1996). Natural science models continue to prove attractive, but in doing so contribute only to the internal differentiation of disciplines. The more significant contemporary version of intellectual transfer for the foreseeable future will continue to be that which produces interdisciplinary departments of 'X studies' drawing on a variety of epistemological assumptions and asking few questions concerning the status of the knowledge produced therein. The reflexive apotheosis of this development is the emergence of departments of 'interdisciplinary studies.'

Intellectuals: History of the Concept

The noun 'intellectuels' appeared in France in the 1890s and was largely diffused thanks to the polemics around the Dreyfus Affair (in particular the so-called '*Manifeste des intellectuels*,' published after the famous *J'accuse* paper by Zola issued on January 13, 1898, in *L'Aurore*). This diffusion not only occurred in France but also, sooner or later, in the whole of Europe and even in America (North and South) (Drouin 1994). There are two exceptions to this large diffusion of the new concept: Germany and Russia where there existed former and akin notions, *Intelligenz* and *intelligentsia*, already used as social or political denominations (Müller 1971). Previous uses of the English translation, 'intellectuals,' are attested too before the 1890s, but they seem to have been too rare to have known a broad social circulation (Williams 1976). In the same way, in America, 'intellectuals' became a common notion only in connection with newspaper commentaries about the Dreyfus Affair (Bender 1987).

To understand why this new terminology received a European or even international diffusion, it is necessary to recall the issues of this historical moment. What was at stake in this crisis was not only a political problem but also the affirmation of a new group, defender of universal values against the reason of State (Charle 1990). These values justified the fact that writers, artists, scholars, students, members of liberal professions, and so on, intervened on a collective basis in the political debate, although they were not themselves, for the main part, professional politicians. The other specificity of this moment was that, in other countries, this same cause or other similar ones favored the intervention of intellectuals, but generally in various patterns and with different contents. Since that period, social sciences have debated at a theoretical level, in order to find universal characteristics underlying this new vocabulary (Shils 1972). As a matter of fact, the emergence of intellectuals cannot be assimilated to the apparition of a new permanent social group as some historians or sociologists suggest regularly, wrongly mixing intellectuals, intelligentsia and professions (Bell 1973, Perkin 1989). To know in reality what is meant by the words, intellectuals, *intellectuels, Intellektuelle, intellettuali, intelectuales,* and so on, it is necessary to define them within their specific cultural, social, and historical contexts.

1. The French Case

In France, even before the Dreyfus Affair, the neologism '*intellectuels*' was used by avant-garde circles as a social mark. The *intellectuel* was some kind of mandarin, who despised politics and wanted to distinguish himself from middle class, dominant writers and academics. *Intellectuel* was a sort of superlative of what Flaubert meant by the word '*artiste*' (Bourdieu 1992). But, since the neologism was widely used during the Dreyfus Affair, the initial cultural meaning was replaced by a strong emphasis laid upon the political

acception. In the first phase of the Dreyfus affair, the *intellectuels* were an equivalent of '*dreyfusards*' and, afterwards, when *antidreyfusard* intellectuals also intervened in a collective way, the word *intellectuels* began to define a special category of people who defended political positions based on arguments of social authority, i.e., their competence as thinkers, historians, scientists, professors, writers, or artists.

In France, the birth of *intellectuels* may be first explained by a growing inadequacy of former cultural patterns confronted to the buoyant cultural expansion of the last decades of the nineteenth century. Intellectual professions, far more numerous now, defended their social and symbolic status at once so that collective attitudes appeared, breaking with older individualistic habits. But this defense may be argued on two different grounds: with intellectual and pure values or on professional and pragmatic issues. Against avant-garde writers or academics, generally militating for the first option, professional associations appeared during the same period that were more attached to material interests. The first use of the term *intellectuels* was reserved for the first type of elitist fraternity. It was to be the germ of its political transformation as for the Russian *intelligentsia* diffused a bit earlier in the 1870s. As in Russia too, reformed universities played a major role in the process of emergence and mobilization of nonconformist intellectuals.

The second paradoxical factor of ideological and political change, was the early crisis of parliamentary democracy in France. After the stabilization of the Third Republic, apolitism predominated among intellectuals as if the end of history was already reached. A new politicization occurred with the crisis of official parties and the emergence of extremist factions, which had a large echo among avant-garde writers (in particular anarchism and, to a lesser degree, socialism). This new trend prepared what is the specificity of the Dreyfus Affair, the invention of a new relationship with politics outside the official political scene. Intellectuals in this new terminology pretended to practice politics in a different way. This was possible because the legitimacy of Republican elite laid on the same bases as the legitimacy of intellectuals themselves, i.e., upon merit and individual talent. But in so far as these elite appeared incompetent or corrupted after different crises and scandals (Boulangism, Panama scandal, and so on), intellectuals preserved from these faults might pretend to offer an alternative elite necessary to lead any genuine democracy.

Students, avant-garde writers, and even younger generations of academics, before and during the Dreyfus Affair, expressed these new revendications of being the true representatives of the people against politicians. The State itself, with its growing intolerance towards literary innovations or extremist parties (especially anarchism) contributed to the mobilization of authors against juridical prosecutions through collective manifestos just before the Dreyfus affair.

The Dreyfus affair presented both a true continuity with preceding years and a break due to the scale of mobilization. Afterwards, the main following mobilizations of intellectuals obeyed the same collective rites and values (Ory and Sirinelli 1986). Its founding importance was to prove that this type of mobilization might lead to real political consequences. This twofold mobilization (of *dreyfusards* and *antidreyfusards*) was new and defined, on both sides of the political scene, a general definition of intellectuals, which was not limited to leftist intellectuals. On the contrary in other countries, the equivalents of *intellectuels* are, generally speaking, confined to one side of the political spectrum.

2. *The Peculiarities of English Intellectuals*

In contrast with France, it is generally argued that no intellectuals exist at all, in the continental acception, in the UK. Since around 1980, British historians and sociologists reacted against this strong and vulgarized anti-intellectual bias. Some authors speak of an intelligentsia (Allen 1986, Heyck 1982), i.e., an elitist avant-garde, others of '*public moralists*,' which enhances the role of dominant and academic intellectuals (Collini 1991) or of a '*professional class*' which assimilates intellectual professions to a new class (Perkin 1989). A comparative approach shows that two specific factors may explain the strong difference with the French situation, in spite of the proximity of economic and political conditions in intellectual life, the persistent elitism of English academic life and the relative proximity between intellectual professions and political elite. Established elites, even if they were obliged to reform and enlarge the political system at the end of the nineteenth century, were not contested as an illegitimate power elite, to the degree they were in France. In fact, English dominant intellectuals mainly shared the same values and background as gentlemen and political leaders because they were largely issued from the same public schools and universities.

In front of these dominant intellectuals, appeared, in the last decades of the twentieth century, new types of intellectuals who presented outsider profiles. The best known were the Fabians who could not attend the best colleges and universities and had to find their way through journalism, literature, new academic institutions (e.g., the London School of Economics) or militant politics. But these avant-gardes were very different from contemporary French avant-gardes. They limited their intervention to one main field: for the Fabians, social and political questions, for aesthetes, aesthetic life, and so on. They pretended to create a voluntary structure and to indirectly influence the official sphere indirectly, not at all to destroy or affront it directly.

Even when mobilization occurred on a larger scale, as during the Boers war, English intellectuals used the official means of actions and respected legal frameworks. Finally, the main difference lay in the very different function of the State in England and in Continental Europe. In England, militant intellectuals endeavored to enlarge its role to correct social injustice, whereas, in France and even more in Germany, intellectuals tried first to weaken its authoritarian trends.

3. The German Case

Even if the word *Intellektuelle*, derived from French, continues almost until now to bear a derogatory nuance (Bering 1978), the German genuine equivalents *Intelligenz*, *Gebildete*, and *Geistige*, have been used for a long time but do not imply, as the French term, the same political or social behaviors. This early appearance of the question of 'intellectuals' may be shown through the recurrent discussion about the academic proletariate (first in the *Vormärz* period, then in the 1880s, and finally in the Weimar period: Titze 1990), with the ideological debates within the social-democratic party about the place of *Intelligenz* (Gilcher-Holthey 1986), and also with the *Antisemitimusstreit* in 1879. This last famous polemic about the role of Jews in German society between the conservative historian Treitschke and his liberal colleague Mommsen, a former Forty-eighter (former participant to revolutionary troubles of 1848 in Germany), appears very near, in its arguments, to the debate between opposing French *dreyfusards* and *antidreyfusards*. The rights of minorities and, in particular, of individuals and Jews, lay at the center. Other affairs concerning academic freedom (Arons case or Spahn case), or freedom of creation, like the mobilization against the lex Heinze (1900), show too that the debates about intellectual autonomy were as crucial in Germany as in France and that they succeeded several times to mobilize some groups of intellectuals (Charle 1996).

But, in all cases, mobilization was limited to specific groups and to particular issues which did not put into question the whole structure of State itself as in France. A mere political explanation (an Empire opposed to a Republic) does not suffice. What was specific and new in the Dreyfus case was the convergence of different intellectual groups about common values. In Germany, the corporatist ethos remained stronger even about general issues; free intellectuals and State intellectuals (mainly university professors) despised each other. Academics began at that time to live apart from the political sphere and preferred a general cultural function as State or *Bildung*'s defenders through different associations. Only a small minority of free intellectuals and very few in the Academe put into question dominant elite or national causes.

The *Gebildete* assumed that they represented the true public opinion and that they were the best interpreters of general causes, but they intended to remain in their own field in order to serve their country best. This German intellectual and geographical fragmentation hindered the linkage between local or professional struggles for autonomy (Engelhardt 1986, Hübinger and Mommsen 1993, Ringer 1969, 1992).

4. Southern Europe

In Spain as in Italy, the local equivalent of *intellectuels* seemed also to be in use in the 1890s in connection with, or even before, the Dreyfus case. The French example was very influential for the Spanish and Italian intellectuals because French cultural influence, in the two peninsulas, was already very strong since the French Revolution. Also, the inner social and political situations of Spanish and Italian intellectuals presented some analogies with the French context. As their French homologues, they thought that their countries went through a deep crisis (economic backwardness, military defeat in Spain, emigration, social riots and parliamentary corruption in Italy), which implied some sort of public intervention to find solutions. The strong anticlericalism and antimilitarism, the link between intellectuals and extreme left movements, the emergence of a new nationalism in both countries, also recalled the French debates at the turn of the twentieth century (Serrano and Salaün 1988). Obvious differences also existed: the weaker public audience of intellectuals depending on the cultural backwardness of popular classes (high level of analphabetism) and the persistence of a large sector of opinion among Catholics, hostile to the cultural inheritance of Enlightenment, very influent in both countries, and an overproduction of *laureati* in Italy which could explain a strong commitment of academics to extremist parties (Barbagli 1974, 1982, Michels 1921).

5. Twentieth-century Changes of Meanings

The intertwining of the sociological and the political or ethical viewpoints was perpetually renewed during the history of French intellectuals after the Dreyfus affair. A new sociologization of the word occurred with the attacks against previous *dreyfusards* in the pre-world-war period. The '*parti intellectuel*,' to use Péguy's phrase, was charged by their former allies (for example Georges Sorel) for having used the political struggle in order to conquer eminent positions of power. For their critics, this political party in fact

constituted a social cluster of arrivists, a new elite of mandarins backing upon leftist politicians (Prochasson 1992).

Between the two World Wars, there was a revival of the political and ideological emphasis on the meaning of the word during what has been called the 'Franco-french war' between the right-wing '*parti de l'intelligence*' and the left-wing '*intellectuels de gauche*.' This trend is enhanced because, at the same time, extreme left movements tried to restrict the notion to a sociological sense. The influence of Soviet Marxism may be found here in which *intellectuels* become a mere synonym for the Russian word *intelligentsia* which is nearer a sociological concept after the October revolution than the term *intellectuels* is in French. *Intellectuels* in the phraseology of the Communist Parties are assimilated to a social group in order to deny them any political autonomy and oblige them to define their political attitude within the limits of the Marxist-Leninist orthodoxy and to renounce to their own vision which is, in the French political tradition, far more linked with the French Revolution legacy and the defense of Human Rights (Benda 1927). This intertwining of two traditions after the 1930s explains why leftist intellectuals used social concepts to attack their rightist opponents, while in contrast, rightist intellectuals laid the stress on the idealist conception of the intellectuals' role; they opposed themselves to materialism (i.e., leftist intellectuals influenced by Marxism) instead of only taking the defense of tradition as before (Sapiro 1999).

The decline of Marxism in the *intelligentsia* and the excess of sociological terrorism in intellectual struggles during the 1950s and 1960s (Boschetti 1985) explain why French contemporary intellectual life is dominated by some sort of revival of the primitive meaning of the word *intellectuel*. This complete historical cycle is one of the origins of the renewed interest for the study of intellectuals as political and social actors by French and foreign scholars in the 1980s and 1990s (Bourdieu 1992, Jennings 1993, Judt 1992, Julliard and Winock 1996, Sirinelli 1990, Trebitsch and Granjon 1998).

Anti-intellectualism, which was so frequent in England and Germany before World War I seemed to somewhat decline after the mobilization of all types of intellectuals (scholars as well as writers or journalists) during the *Union sacrée* for propaganda or practical applications devoted to National Defense. It conferred on them a new importance in all political contexts. After World War I, the democratization of politics, in both the UK and Weimar Germany, now placed intellectuals in a political context quite similar to the French one. The growing influence of left parties, of Marxist ideas, of international questions (communism, fascism, pacifism, fear for a new world war) gave birth to international debates among European intellectuals (or even American, if the case of New York intellectuals may be included: Wald 1987). Nevertheless, this did not mean that the specific national traditions were forgotten. Even if notions like *Intellektuelle* or *intelligentsia* were present more than before in the German or English public debate, they never obtained the general influence or consensus which their equivalents enjoyed in France, Italy, or Spain (Bering 1978, Stark 1984). Even innovative sociologists such as Karl Mannheim continued in general to use the older lexis even to propose their new conceptions of a free-floating intelligentsia (*freischwebende Intelligenz*: Mannheim 1929). Debates about the social decline of 'intellectual workers' in Germany or Central Europe used too old phrases such as *geistige Arbeiter* (Jarausch 1990, Titze 1990). The anti-intellectualism of the Nazi movement and the huge migration (after 1933) of progressist or Jewish intellectuals out of Germany and Central Europe stopped, for almost two decades, this timid convergence with the Latin tradition of intellectuals.

The decline and fall of the different fascist or communist regimes in the second half of the twentieth century gave a new actuality to the oppositional figure of intellectuals, in particular in Central and Eastern Europe (the 'dissidents' who recalled the nineteenth century meaning of intelligentsia). In Southern Europe, in Africa, Asia, or Latin America, revolutionary intellectuals or militants for the Human Rights also rejuvenated the nineteenth century European tradition of intellectual youth mobilized for the nation or populist projects. All these convergences or political cycles explain why the historical notion of intellectuals continues to be at the center of many historical, sociological, or philosophical reflexions, trying until today to find general or transhistorical definitions of this term.

Intellectuals, Sociology of

1. Origins

Intellectuals are people whose main activities involve producing, evaluating, and distributing culture. Their role often involves endorsing or criticizing the cultural objects of their attention.

The intellectual role has been performed in all but the most primitive human societies. However, the Renaissance humanists (circa 1300–1600 CE) were the first influential group resembling today's intellectuals. Renaissance scholars thought they lived in a golden age of virtue and learning. To emphasize the point, they invented the term 'Middle Ages' to refer to the dark gulf separating their era from the glories of the ancient world. Promoting the study of poetry, grammar, rhetoric, history, and moral philosophy, the humanists from Petrarch in the fourteenth century to More, Erasmus, and Rabelais in the sixteenth century influenced the Reformation, the scientific revolution, and the Age of Reason.

Only since about 1600, however, have intellectuals become a large, moderately well-defined, and occasionally self-conscious group. The chief factors that helped to distinguish them were the rise of commerce and industry since the late Middle Ages, the spread of literacy, the growth of markets, and the proliferation of social contexts for intellectual discussion and debate. Flourishing commerce and industry permitted the accumulation of economic surpluses. They were used to expand state and private institutions employing intellectuals. Public education and mass literacy increased demand for intellectual services. In turn, the evolution of markets for these services allowed intellectuals greater freedom to define their political allegiances. The interests of aristocratic and church patrons no longer constrained them.

Finally, a host of modern social settings—ranging from universities to political movements, professional societies to coffee houses, academic journals to mass-circulation newspapers—provided contexts within which intellectuals could formulate their social and political identities.

It was not until the second half of the nineteenth century that 'intellectual' and the kindred 'intelligentsia' entered common parlance. The term 'intellectual' was first employed on a wide scale in France. In 1898, Georges Clemenceau referred to the leaders of the anticlerical and antimilitary camp that opposed the conduct of the Dreyfus trial as *les intellectuels*. Soon the political right was deriding the self-proclaimed conscience of the French nation. Because of the resulting public debate, the term intellectual stuck. The term intelligentsia was popularized in Central and Eastern Europe a few decades earlier. It, too, denoted liberals, socialists, and other critics of authority. Only gradually since the end of the nineteenth century has the term intellectual gained widespread acceptance and succeeded in unwrapping itself from quotation marks.

2. *Theories*

Many normative or moralistic treatments of the problem of intellectuals may be found in the literature. They make a case for what intellectuals *should* do. In contrast, this article focuses on the analytical literature, which seeks to explain *why* intellectuals do what they do. Three main analytical traditions inform the sociological study of intellectuals. Sociologists have regarded intellectuals as (a) members of a class or as a class in their own right; (b) relatively classless; and (c) embedded in a shifting network of class and other group affiliations.

Class theory. Early Marxists asserted that intellectuals are bound to become members of the proletariat under capitalism. Later Marxists, disappointed with the failure of many intellectuals to become radicalized, claimed they are part of the *petite bourgeoisie*. Both Marxists and non-Marxists updated these assertions in the 1970s. The middle of the class structure had expanded enormously over the preceding century. People with university degrees filled many of the middle ranks. Reflecting on this change, some social thinkers argued that the intellectuals form a class. Alvin Gouldner held that the intellectuals form a new 'emancipatory class.' Barbara and John Ehrenreich maintained that intellectuals form part of a new 'professional-managerial class.' Irving Kristol called intellectuals the 'new class of knowledge workers.' These and other scholars disagreed about the political interests of the intellectuals. However, they shared the view that intellectuals form a large, rising, and ideologically quite homogeneous class.

Theories of classlessness. In contrast, Karl Mannheim held that modern intellectuals form neither a class nor part of a class. Instead, they are 'members of a relatively classless stratum which is not too firmly embedded in the social order.' Intellectuals are typically recruited from various classes. However, because they participate in a common educational milieu, their class differences, and the variations in outlook normally associated with them, tend to be suppressed. Others echoed Mannheim's conclusions. Talcott Parsons asserted that intellectuals put 'cultural considerations before social ones.' Everett C. Ladd and Seymour Martin Lipset wrote that the capacity of intellectuals for social criticism, creativity, innovation, and attention to facts enables them to overcome their class socialization—and, for that matter, the influence of many other groups and communities to which they belong.

Theories of shifting social networks. Both class theories and theories of classlessness ignore some crucial issues. For example, intellectuals may be found at all points on the political spectrum. Yet class theories briefly note ideological heterogeneity, dismiss it as an uninteresting side issue, and leave it unexplained. Meanwhile, theories of classlessness minimize the significance of social influences on the shaping of ideas. Thus, they deflect attention from the very issue that the sociology of intellectuals is supposed to analyze.

A third approach seeks to overcome both these problems by focusing on the intellectual's web of shifting group affiliations. According to Pierre Bourdieu, cultural fields tie individual and organizational actors together in various social institutions. These cultural fields are structured as social networks. Different positions in a social network are associated with different endowments of economic, social, and cultural capital. Network position is also associated with cognitive structure. Thus, intellectuals in similar network positions share tastes, ideas, and values. Randall Collins' analysis of philosophical schools takes this argument a step further by showing how intellectuals gain reputations by successfully competing for attention, fame, and influence in intellectual networks.

Bourdieu's and Collins' mesolevel theories are compatible with Robert Brym's macrolevel approach. Developing themes in Antonio Gramsci's essay on intellectuals, Brym argues that the ideologies and political allegiances of intellectuals depend on their social origins and the structure of opportunities for education, employment, and political involvement they face during their careers. These opportunity structures are, in turn, shaped by the relative power of major classes and other groups. Accordingly, to explain intellectuals' ideologies and political allegiances, one must trace their paths of social mobility as they are shaped by the capacity of classes and other groups to expand the institutional milieux through

which intellectuals pass. To the degree these milieux are imprinted with the interests of the classes and other groups that control them, they circumscribe the class and other group interests reflected in intellectuals' ideological and political allegiances. From this point of view, it is an oversimplification to say that intellectuals form a class, are members of a class, or are classless. They are embedded in social networks whose ties to various classes and other groups shift over time and help account for their ideologies and political allegiances. This theme has also been taken up by Jerome Karabel. It is illustrated in the remainder of this article.

3. *Social Origins and Institutional Opportunities*

3.1 *Social Origins*

In Weimar Germany, professors were largely anti-republican and Right-wing. Mostly their fathers were military officers, state bureaucrats, and academics: members or handmaidens of the aristocracy. In contrast, nonacademic intellectuals were inclined to the left. They tended to be children of successful participants in the Industrial Revolution: members of the upstart German bourgeoisie. Similarly, in the middle of the nineteenth century, Russia's conservative and politically moderate intellectuals were recruited overwhelmingly from the aristocracy. On the other hand, the first generation of truly radical Russian intellectuals dates from the 1860s, and it contained in its ranks a large mixture of commoners. Their fathers were merchants, peasants, and petty officials. These examples illustrate that support for the traditional social order is common among intellectuals who have been reared in upper-class families that are threatened by social change. Being born into a less advantaged class has usually been associated with greater potential for intellectual radicalism.

But not always. In North America, rates of upward social mobility are higher than in Europe, and historically class has been a less important social distinction. As a result, class origin has less bearing on the ideologies and political allegiances of North American than European intellectuals. Especially in the United States, ethnic and racial origin, educational background, field of expertise, professional and institutional status, and generational experience matter more. Accordingly, American surveys show that professors in small provincial universities are more likely to be politically conservative than professors in prestigious Ivy League universities. African-American and Jewish intellectuals are usually more liberal than non-Jewish white intellectuals. Young intellectuals who work in the social sciences and cultural fields are more likely to be Left-wing than older intellectuals in industry and business.

3.2 *Economic Opportunities*

As intellectuals reach adulthood, the structure of markets for intellectuals' skills can modify their early political socialization. An abundance of secure jobs that allow free expression can dampen intellectuals' early radical impulses. A lack of such jobs often exerts a radicalizing effect. Some intellectuals may continue to express radical political sentiments after they have taken jobs that suit them professionally. Still, the rate and intensity of radicalism are generally greater when the number of such jobs is fewer.

For example, the Quebec educational system began to produce substantial numbers of highly educated French-speaking graduates in the 1960s. The new graduates found that an English-speaking minority controlled the larger and more efficient businesses in the private sector of the economy. Many highly educated *Québécois* were shut out of good jobs. This, among other factors, encouraged some of them to develop the idea that to become 'masters in their own house' Quebec must become a sovereign state. Surveys show that intellectuals became separatists in disproportionately large numbers and were a driving force leading to the election of separatist governments in 1976 and 1994.

3.3 *Political Opportunities*

The patterns of political opportunities intellectuals face also profoundly affect their ideas and loyalties.

At the level of social organization, political opportunities are structured by the availability of historical agents: workers, peasants, ethnic collectivities, and other groups that intellectuals may demarcate as the chief instruments of social change. Whether intellectuals become, say, socialists, populists, or nationalists is determined partly by which historical agents are mobilized for political action and which are relatively politically dormant at a given time.

At the level of the political system, the capacity of party organizations to absorb new talent is also important in shaping intellectuals' allegiances. For example, before the 1920s, the German Social Democratic Party had attracted most of the country's radical intellectuals. In the 1920s, however, it became (to use the then-current catchwords) 'bossified, ossified, and bourgeoisified.' Old men remained incumbents in the German Social Democratic Party for many years, and young men and women had little hope of rising in its ranks. Lack of opportunity was one reason the young generation of radicals turned in large numbers to the Communist Party of Germany.

If historical agents are largely unmobilized and no party organization is available to sustain the intellectual's beliefs, a process of political disillusionment is likely to set in. The lack of a historical agent combined with the presence of a party organization, however, is likely to lead to intellectual elitism.

4. Intellectual Elitism

Ever since Plato envisaged an ideal society ruled by 'philosopher-kings,' some intellectuals have been politically motivated or subconsciously driven by the conviction that they are better suited than nonintellectuals to create and maintain a just society. For example, in 1816 Hegel referred to Prussia as 'the state of the intelligentsia.' Both he and Comte characterized historical epochs in terms of the accomplishments of the human mind. Moreover, they saw the human mind as the driving force of history and its personification as the intellectual.

Other intellectuals have spurned such elitist views. The degree of elitism expressed by intellectuals varies independently of their position on the left–right dimension of politics. One finds democrats and elitists on both the left and the right. Two sets of circumstances promote intellectual elitism: weak participatory demands by the masses and lack of competition from other elites.

The history of Latin America illustrates how weak mass demand for political participation encourages intellectual elitism. For example, in the 1950s, Cuban revolutionary intellectuals were faced with a small and reformist working class and a politically inert peasantry. Consequently, they took matters into their own hands, forming guerilla bands in the countryside to seize state power. The low level of popular political participation in, and mass control over, the Cuban revolutionary party diminished the likelihood of subsequent democratic development.

The history of socialism and communism in Russia reveals a similar pattern. However, the Russian case is also instructive because it illustrates the opposite tendency. Even apparently unyielding elitists can democratize if they are pressured from below. Thus, when ties between workers and Russian Marxist intellectuals were dense—during the strike wave of the 1890s, the 1905 revolution, and the period of labor militance in 1912–14—most intellectuals wanted their parties to operate according to democratic principles. In contrast, when working class political participation fell—due to labor quiescence caused by troughs in the business cycle, strong government and police reaction to radical activities, and enormous losses in World War I—intellectuals returned to elitist principles of party organization.

A second precondition of democratic practice among intellectuals is vigorous elite competition. Aristotle argued that justice can be maximized not if philosopher-kings rule, but if constitutions are divided against themselves—if, in other words, there exists what is now called a separation of powers between the various branches of government. Following Aristotle, scholars now commonly believe that tyranny and arbitrary rule by an elite can be prevented if the branches of government hold each other in check. One may invoke a broadly similar principle in analyzing intellectual elitism. Nonintellectual elites need to keep intellectuals in check if they are to prevent the political and social dangers that can result from intellectuals taking Plato to heart.

The most compelling case for the benefits of elite competition derives from the history of communism, the epitome of intellectual tyranny in the twentieth century. Yet the dangers of intellectual elitism have hardly subsided now that the communist era has virtually ended. In much of the world, intellectuals are making bolder claims than ever about their ability to forecast and plan social and scientific change. Governments are respecting those claims by seeking the advice of intellectuals, awarding them research contracts, and employing them by the legion. Emboldened by their growing numbers and prestige, some intellectuals, particularly in the United States and Eastern Europe, have proclaimed themselves the ruling class of the future, the real holders of power in an era when knowledge allegedly means more than capital in determining status.

One should not take intellectuals' claims about their accomplishments too seriously. Economists, the 'hardest' of the social scientists, have failed to forecast and regulate economic trends. Natural scientists have arguably helped to create nearly as many social problems as they have solved.

On the other hand, the dangers of too much intellectual influence on political life should be carefully heeded. Individual intellectuals have proved to be exemplary political leaders, but when intellectuals are in a position to impose their blueprints on society the result is often more harm than good. The 'shock therapy' advocated by the academics who formed the core of the Russian government late in 1991 caused tremendous social dislocation and political reaction that undermined reform in that country. This is only the latest example of what can happen when intellectuals rule. It seems reasonable to conclude that the practice of politics is much too serious a matter to be left only to the intellectuals.

Intelligence: Central Conceptions and Psychometric Models

1. Lasting Debates in Intelligence Research: The Elusive Concept of Intelligence

Given its practical importance in individual lives and societies, the topic of 'intelligence' attracts much attention and debates both among the researchers and the general public. The research of intelligence has been pursued by psychometricians, cognitive psychologists, and developmentalists (see Sternberg et al. 1994 for comprehensive reviews; see also *Intelligence: Historical and Conceptual Perspectives* and *Intelligence: History of the Concept*). However, not many other terms in psychology are so elusive as 'intelligence' escaping consensual definitions over more than 100 years of research. Tracking chronologically the reports of three representative forums, each participated by experts in the field, sheds some light on the changing terrain of intelligence research during the twentieth century.

In 1921, a classical symposium convened by the editors of the *Journal of Educational Psychology* was held to discuss three questions: (a) What is intelligence?; (b) How can it be best measured?; (c) What are the most crucial next steps in research? (Thorndike et al. 1921). Among the 17 leading researchers who participated, 14 different answers were given! About one fourth of the participants suggested elementary processes (i.e., perception, sensation, and attention) as primary attributes of intelligence. Another fourth of the experts thought that physiological mechanisms of the brain should be the determining factors, and there were still others who contented that overt adaptive behavioral responses are the key features of intelligence. Sixty-five years later, a succeeding effort with 27 experts was arranged to address the exact same questions (Sternberg and Detterman 1986); however, the degree of lack of consensus remains similar to that was in 1921. Experts of the 1986 forum offered two dozen definitions.

Aside from the diverse conceptions among researchers, two popular books also sparked heated debates in the general public. The views range from renouncing the idea of 'measuring' individuals along the dimension of psychometrically-defined intelligence (S. J. Gould, *The Mismeasure of Man*, 1981) to the belief in a general intelligence factor (R. J. Herrnstein and C. Murray, *The Bell Curve*, 1994). Reacting to these controversial debates, in 1995 the Board of Scientific Affairs of the American Psychological Association called for an another authoritative report from a dozen experts in the field to discuss the 'knowns and unknowns' of intelligence (Neisser et al. 1996). The diversities and controversies surrounding conceptions of intelligence led some researchers to contend that the multiple determinants (and their relations) contributing to individual differences in intelligence could only be understood within integrative frameworks.

2. Some Lasting Trends and an Attempt of Integration

In order to highlight a few continuing trends hidden behind the overwhelming diversities, organizers of the 1986 forum compared the main issues raised in their discussions with those that were discussed in 1921 and showed that there were some general agreements across the two efforts (Sternberg and Detterman 1986). Specifically, conceptions including attributes such as *adaptation to the environment*, *basic cognitive processes*, *and higher-order thinking* (i.e., reasoning, problem

solving, and decision-making) were prominent in both discussions. In addition, the recurring themes of central debates seemed to surround issues about (a) whether intelligence is unitary or manifold, (b) the relative contributions of nature and nurture to individual differences in intelligence, and (c) the relative emphases on the process, content, and product aspects of intelligence.

As an attempt to compile the two dozen different views, an integrative framework (Sternberg and Detterman 1986) with multiple levels was also proposed in the report of the 1986 forum. At the behavioral level, theoretical conceptions that originated within the psychometric tradition focus on measuring the 'products' of information processing and on identifying the structure(s) of intelligence. These theories could be compared mainly in terms of whether the structure of intelligence is, more or less, considered to be unitary or pluralistic. At the processing level, the theories attempt to integrate psychometrically-defined 'products of intelligence' with various concepts of information processing. In this regard, the various conceptions differ in terms of their differential emphases either on elementary cognitive processes or higher-order cognition involving metacognition, planning, and decision-making. At the contextual level, some theories of intelligence stress the dynamics of human-ecology interaction and the concepts of situated intelligence. Another version of the contextualist theories emphasizes the dynamic contexts of lifespan development from birth into old age (see *Lifespan Theories of Cognitive Development*). These contextualist theories evolved primarily in conjunction with a focus on the nature of intelligence as adaptive capacity.

Still there have been other theories focusing on genetic and neurobiological influences on intelligence, which are not within the purviews of this article (see *Intelligence, Genetics of: Cognitive Abilities*; *Intelligence, Genetics of: Heritability and Causation*). In the following sections, we review and compare main theoretical conceptions of intelligence with respect to their differences along the cross-level product-process, the contexts of human-ecology, and the lifespan developmental orientation; as well as their relative emphases on interactions across these dimensions.

3. *Measuring the Products of Intelligence: From Unitary to Pluralistic and Hierarchical Views*

Ever since Alfred Binet's (see *Binet, Alfred (1857–1911)*) success in devising tests to distinguish mentally retarded children from those with behavioral problems, the psychometric approach to quantify individual differences in cognitive competence using standardized intelligence scales (e.g., the Stanford–Binet test or the Wechsler test) played a dominant role in intelligence research. These scales tend to measure scholastic performance with tasks over broad areas (e.g., memory, analytical reasoning, numerical skills, verbal fluency, and practical knowledge). Thus, overall sum scales of such tests predict school performance well. Perhaps not surprisingly because of their emphasis on school-related performances, their predictive validity drops when predicting task performance outside of the classroom, such as everyday problemsolving, vocational competence (Dixon and Baltes 1986), or other more expertise-like outcomes of real-world intellectual functioning (Ericsson and Smith 1991).

With a more general aim to capture a broader spectrum of human cognitive abilities and their interrelations in addition to the applied orientation of predicting academic performance, a number of psychometric theories have been proposed over last century. Scholars such as Burt, Cattell (see *Cattell, Raymond Bernard (1905–98)*), Guilford, Spearman, and Thurstone were the main proponents. At the methodological level, these theories differ with respect to the type of factor analytic methods they adopt and whether these methods are applied on the empirical-exploratory or theoretical-confirmatory basis. At the substantive level, they differ in terms of whether they orient more towards the general factor or multidimensional views of intelligence.

3.1 *Two-factor Theory*

Although subtests of the intelligence scales are often designed to measure specific domains of cognitive performance (like numerical skill and verbal fluency), performances across different tests tend to be positively correlated with each other (i.e., the so-called *positive manifold*). Spearman (1904) first presented a theory of general intelligence which he later expended into what is now known as the two-factor theory. He developed the first statistical model for explaining the positive manifold among task performances. The underlying assumption of this model is that individual differences in a given test can be decomposed into two components. One variance component is common to all other cognitive tasks—a general factor of intelligence (commonly known as *g*), whereas the other component is specific to each task (Spearman 1927). With this method, Spearman showed with several data sets that *g* accounted for all positive correlations among the test performances (see Jensen 1998, for a modern review on *g*). Since then, hundreds of other studies have also found that *g* accounts for rather large portions of the common variance among a broad selection of cognitive tasks.

3.2 *The Primary Mental Ability Theory*

Since the discovery of *g*, a main issue in psychometric intelligence research has been whether the structure of

intelligence is unitary with one general common factor or pluralistic with multiple specific factors reflecting domain-specific abilities. Among the first to question the unitary view was Thurstone, who developed multiple factor analytic techniques and conducted studies that included a broad range of paper-and-pencil items found in most other intelligence scales. In these studies, Thurstone (1938), for instance, was able to identify seven distinct factors reflecting spatial, perceptual speed, numerical, verbal, fluency, memory, and reasoning abilities. However, his assumption of these primary mental abilities being completely orthogonal to each other was not empirically supported. Instead, multiple common factor models later proposed by others showed that the positive manifold emerges again at the level of higher-order factors.

3.3 The Gf-Gc Theory and Related Theories

Building on the multiple primary abilities identified by Thurstone, one influential conceptual model since then has been the *Gf-Gc* theory (Cattell 1971, Horn 1982). Based on results from higher-order factor analyses, this theory distinguishes general fluid (*Gf*) abilities reflecting the individual's basic problem solving, reasoning, learning, and selective attending capabilities from general crystallized (*Gc*) abilities reflecting the acquired knowledge and their utilization. Unlike Thurstone's theory, which assumes independent primary mental abilities, Cattell proposed the ontogenetic *investment theory* to specify a possible mechanism relating *Gf* to *Gc*. He postulated that the culture-, experience-, and knowledge-based crystallized abilities arise, in part, as a result of a process in which the more biology-, maturation- and process-based fluid abilities are been *invested* into suitable learning experiences and contexts as the individual develops. The *Gf* and *Gc* distinction is often compared with Hebb's (1949; see *Hebb, Donald Olding (1904–85)*) differentiation between innate potentials for information processing (Intelligence A) and the acquired level of performance and comprehension (Intelligence B), and Baltes' (1987) juxtaposition of the cognitive mechanics and the cognitive pragmatics (see more details in a later section). Besides these two central broad factors, Cattell and Horn were also able to identify several other factors reflecting visual processing ability (*Gv*), short-term memory (*Gsm*), quantitative abilities (*Gq*), associative storage-retrieval (*Glr*), novel reasoning (*Gr*), and processing speed (*Gs*). These factors have been further verified and captured by comprehensive psychometric test batteries developed by others, such as the Stanford–Binet, Wechsler, and Woodcock–Johnson batteries.

3.4 The Structure of Intellect Model

Moving even further away from the unitary pole of *g* and working towards better delineating the process and product aspects of intelligence, Guilford (1967) proposed the structure of intellect (SOI) model, which specifies the (a) operation, (b) content, and (c) product components of intellectual abilities. The component of mental operation contains five general intellectual processes: cognitive, memory, divergent production, convergent production, and evaluation. The content component encompasses four broad areas (i.e., figural, symbolic, semantic, and behavioral) of information to which operations are applied. The product component entails six possible results (i.e., units, classes, relations, systems transformations, and implications) of applying particular operations in particular contents. Applying factor analytic techniques in a confirmatory manner to test this model deductively, Guilford expected the structure of intellect to result in 120 single independent factors of different operation $\times$ content-$\times$ product ($5 \times 4 \times 6$) combinations. However, in later modifications he acknowledged that the first-order factors could be correlated, therefore giving rise to multiple higher-order factors, but he still denied the existence of a general factor (Guilford 1982). On the one hand, the strength of the SOI theory is its more specific and refined definition of ability structure across dimensions capturing three distinct aspects of information processing. On the other hand, the main critiques of the model targeted at the fact that this model was derived through the use of a certain factor rotation technique (i.e., the procrustean rotation) which later was criticized to be subjective to confirmatory bias and lacking empirical support for most of the factors specified.

Another theoretical model akin to Guilford's facetted conceptualization is the Berlin model of intelligence structure (BIS) by Jäger (1984). This model cross-classifies each cognitive test with respect to an (a) operation and a (b) content facet. Operation is further categorized into four ability groups (reasoning, memory, creativity, and speed), whereas content is divided into three groups (figural, numerical, and verbal). Conceptually, the 12 operation $\times$ content (4×3) combinations taken as a whole represents general intelligence. However, by factoring groups of variables that are homogeneous within one of the two facets but are heterogeneous in the other facet, one can either extract the four operational or the three content factors. Specified as such, methodologically this model implies that any given mental ability is a linear combination of the two factors, and conceptually it simultaneously specifies a mental ability with a process and a content aspect.

3.5 The Three-stratum Theory

Reanalyzing 477 available covariance matrices of cognitive ability tasks, Carroll (1993) integrated the findings from the different theoretical schools into a hierarchical structure with three stratums. At the

lowest stratum, more than 60 narrow first-order abilities could be found. Given these narrow abilities are positively correlated with each other to varying degrees, a second stratum of broad abilities, ich closely resemble the primary mental abilities identified by Thurstone and by Cattell and Horn, could also be extracted. At the highest stratum, a general factor of intelligence captures the positive manifold among the broad ability factors at the second level. The hierarchy with all three stratums then describes the overall structure of intelligence. In terms of empirical breadth, this model comprehensively integrates the empirical basis of human cognitive abilities observed at the behavioral level. In terms of theoretical integration, it shows that diverging psychometric views of intelligence can be understood in terms of their differential focus on one of the stratums within the overall structure, selections of indicator tasks defining the lowest level of the structure, and adoptions of factor-analytical techniques.

Regarding the behavioral psychometric approach to intelligence research as a whole, a key issue that remains is whether factors derived by factor analysis are entities with causal status or organizational concepts capturing a system of the products of intelligence. Defining the structure of intelligence with multiple levels, going from multiple low-level specific abilities to intermediate broad abilities, and, finally, to a general factor at the highest level, has advantages for relating to other theoretical conceptions. Various conceptual connections from psychometric measures of intelligence to other theoretical conceptions that either emphasize inward cross-level integration with information-processing mechanisms and their biological correlates, outward integration with real-world everyday knowledge and problem solving skills, or lifespan developmental integration can be more easily drawn.

4. *Integrating Psychometric Intelligence With Cognitive Processes*

Starting from late 1970s, there has been a development towards specifying the processing aspects of intelligence in hierarchical models within the psychometric tradition and the development of investigating information-processing mechanisms in cognitive science in general. With the parallel developments in both fields, researchers of intelligence started to integrate information-processing concepts into the theoretical conceptions of intelligence. Some theories focus on integrating the measurement and explanation of intelligence by looking inwardly and downwardly within the individual for elementary information-processing correlates (e.g., processing speed and working memory) of intellectual abilities (e.g., Hunt 1980, Resnick 1976) and their neurobiological correlates (Eysenck 1982, see Deary 2000 for recent overview). Other theories focus on relating intelligence with aspects of information processing that are more closely related to real-world competence, such as complex reasoning, metacognition, planning, knowledge, vocational skills, and expertise (e.g., Ackerman 1996, Sternberg 1985, 1999).

4.1 *Mental Speed Theory*

The notion that information-processing speed may underlie individual differences in intelligence goes back all the way to Galton (see *Galton, Sir Francis (1822–1911)*), who tried to measure intelligence by simple sensory and reaction time tasks. Researchers dedicated to the mental speed approach have taken up Galton's initial idea to investigate the relation between intelligence and reaction times measured in a broad range of simple elementary cognitive tasks (see Jensen 1998, Vernon 1987 for reviews). Performances in these tasks tend to be perceptual based and do not require any semantic or practical knowledge. Thus, it is perhaps no surprise that the correlations between the reaction times measured with such simple tasks and intelligence have proven to be only moderate (i.e., hovering around the so called 0.3 barrier, Hunt 1980). Proponents of the elementary information processing theory in general and the mental-speed theory in particular admit that simple reaction time measures are inferior to more complex composite measures derived from mental tests for the measurement and prediction of intelligence. However, they argued that the moderate but consistent correlations between measures derived from simple elementary information-processing tasks and performance on mental tests may be important for unraveling the information processing aspects of intelligence. Variations in the observed correlations across studies and their theoretical interpretations have been the issues of much discussion. The interpretations range from proposing nerve conduction velocity as the basic biological parameter for all cognitive functioning, to several alternative explanations postulating higher-level constructs like attention, motivation, personality factors, or speed-accuracy trade-offs, to be the causes for a spurious relationship between intelligence and mental speed measured with simple de-contextualized tasks.

4.2 *Working Memory Theory*

Another aspect of cognitive function that has been deemed as a likely candidate information-processing correlate of intelligence is working memory (Baddeley 1986). Working memory reflects people's ability to briefly maintain information, while simultaneously carrying out other mental operations on the same or other information. Empirical evidence suggests that tasks requiring greater working memory loads tend to

correlate more highly with intelligence. Furthermore, it has also been found that working memory capacity correlates highly with psychometric reasoning (Kyllonen and Christal 1990). Taken these findings together, proponents of this theory suggest that working memory might be a better candidate process for explaining fluid intelligence than mental speed (Engle et al. 1999, Süß et al. in press).

4.3 The PPIK Theory

Staying with the general sentiment of relating intelligence with information processing, but orienting more towards issues on knowledge representation in artificial intelligence systems rather than the experimental cognitive approach, Ackerman (1996) proposed an integrative framework characterizing adult intellectual development as complex interactions between cognitive processes, personality traits, broad interest and knowledge domains. This framework can be seen as a starting point for disentangling the complex relations between the different aspects of intellectual functioning and personality-motivational modulators (Ackerman and Heggestad 1997). For instance, there is initial evidence indicating that personality traits, such as degrees of openness to experience and typical intellectual engagement, are correlated with the crystallized knowledge, but not with the general fluid abilities. Such findings motivate further intelligence research to explore the roles of broad domains of occupational and avocational knowledge in adult intelligence, which has not been captured sufficiently by the traditional assessment of *Gc*.

4.4 The Triarchic Theory

Sternberg's triarchic theory of intelligence (1985) is another example of an integrative theory that seeks to combine traditional psychometric approach with information-processing perspectives at the level of higher-order cognition, rather than elementary cognitive processes. Three different kind of information-processing components are distinguished in the triarchic theory. *Metacognitive components* are higher-order control processes used for executive planning, monitoring, and evaluating task performance. *Performance components* are lower-order processes that deal with the execution of a task itself. For instance, in an inductive reasoning task, the performance components may involve encoding the test word pairs, comparing the word pairs, and retrieve from memory information about the test items. The *knowledge-acquisition components* are processes involved in learning, retaining and integrating new information with old experiences. More recently, Sternberg (1999) had extended his original theory to encompass a broader spectrum of issues regarding successful everyday real-world competence. For instance, in everyday context, successful intelligent individuals are likely to invoke metacognitive higher-order regulatory thought processes to discern their own strengths and weaknesses, and device strategies to maximize their strengths but compensate for their weaknesses. While this theory is more integrative and ecologically valid in nature, details of many components of the theory await further specification and empirical testing.

5. Bioecological and Lifespan Theories of Intellectual Development

Traditionally, developmentalists have also been among the researchers of intelligence. Piaget, the pioneer of modern developmental psychology (see *Piaget, Jean (1896–1980)*), studied the development of mental processes through which knowledge is constructed during ontogenesis (Chapman 1988). The Piagetian view of intelligence focuses more on the processes of intelligence, rather on the products of intelligence and the individual differences therein. Specifically, central to Piaget's theory of intelligence (1960) is the view that adaptive behavior and knowledge are constructed through an intimate interplay between the child and the environment. Intellectual development results from the child generalizing her current behavior and knowledge to new situations (assimilation) and also adaptively modifying her current behavior and knowledge through new experiences (accommodation). Influenced by Piaget's conceptions, two main variants of later theories of intellectual development share common endorsements of gene-environment (or biology-culture) co-constructivist and contextualist views.

5.1 The Bioecological Theory

With its main focus on understanding the complex interactions between biology and ecology in shaping child development, the bioecological theory (see *Human Development, Bioecological Theory of*; Bronfenbrenner and Ceci 1994) proposes that aside from genetic effects individual differences in intellectual functioning are the result of variations in the bioecological interactions a child experiences during development. The theory has three main tenets. First, there are multiple innate abilities, as opposed to a single ability. Second, innate abilities serve as a range of possibilities that may develop, or fail to develop depending on their interactions with mechanisms and processes in the proximal developmental contexts (e.g., such as parent–child interactions and schooling). Third, motivation plays important modulatory roles in determining how much the environmental context aids the actualization of the individual's innate potential for intellectual development. The notion that

interests and motivational factors play a role in intellectual development has also recently been considered in the PPIK theory (see above).

5.2 The Dual-process Theory of Lifespan Cognitive Development

While also being co-constructive and contextual in nature, the dual-process theory of lifespan cognitive development focuses on understanding the biology–cultural interplay in the gains and losses of intellectual development across the lifespan from early childhood into old age (e.g., Baltes et al. 1999; see also *Lifespan Theories of Cognitive Development*). The lifespan developmental theory has been developed by combining both the psychometric and lifespan developmental approaches.

Combining Hebb's Intelligence A and Intelligence B distinction (see above) and the Cattell–Horn *Gf-Gc* framework with perspectives from cognitive and evolutionary psychology, the dual-process theory of lifespan cognitive development highlights two distinct but interacting aspects of intellectual functioning: the biologically-driven cognitive mechanics of basic information processing, and the contextually-driven cognitive pragmatics of culture-based bodies of acquired factual, procedural, and profession-related skills and knowledge. Furthermore, with an emphasis on the dynamic of lifespan development, the dual-process theory also focuses on how these two aspects of intellectual functioning interact with each other, develop, maintain, and decline throughout the lifespan. In line with Cattell's investment theory, the dual-process theory proposes differential lifespan trajectories for the cognitive mechanics and pragmatics. The biologically-driven cognitive mechanics display an early growth pattern which is then invested into the acquisition of pragmatic skills and knowledge. While most abilities of the cognitive mechanics start to decline in midlife, the efficacy of culture-, experience-, and expertise-based pragmatics remain, well into old age; or, as suggested by Ackerman (1996), lifelong occupational and avocational knowledge could still be maintained or even increase up to late adulthood. However, in old age the role of biology-based cognitive mechanics in regulating the culture-based cognitive pragmatics increases.

6. Concluding Remarks

As reviewed above, there is a continuing effort in intelligence research at evolving its subject matter in terms of which mental representation and phenotypic behavioral expressions of intelligence are part of the theoretical conceptions. A few other themes, although deviating somewhat from the more traditional conventions, have been evolving in parallel with the theoretical conceptions reviewed thus far, and merit acknowledgements. For instance, there have been growing emphases on various forms of expertise, such as professional skills or cognitive skills associated, e.g., with chess, medicine, or computer programming, as part of the core of intelligence (see Ericsson and Lehmann 1996, Newell and Simon 1972 for reviews). Other examples are the various lines of research on extending the predominately cognition-oriented conceptions of intelligence to social intelligence, emotional intelligence (e.g., Davies et al. 1998, Ford 1992, Mayer and Geher 1996), and other presumably separable intelligences, such as musical, spatial, and interpersonal intelligence (i.e., the Multiple Intelligence Theory, Gardner 1993).

As it is evident from the debates and controversies since Galton and Binet, it is not fruitful for intelligence research to continue into the new millennium with questions such as: is intelligence unitary or pluralistic? Is the goal of intelligence research to measure the end product of intellectual functioning and to predict performance, or is it to explain the processes of intelligence? Which plays a greater role in the development of intelligence, nature or nurture? Looking at the terrain of current intelligence research and its related fields, it is probably more fruitful to ask questions that highlight the differential utility of the various conceptions of intelligence in furthering our understanding of the complex dynamic interplay between neurobiology and sociocultural contexts in shaping intellectual development. For instance, given existing data at the different levels, which facets of intelligence maybe more biologically-driven and which are more context- and culture-based? Which aspects of intelligence are primarily implemented through elementary information processing mechanisms and their genetic and neurobiological correlates, which other aspects are open to influences from metacognitive, personality and motivational factors? Which aspects of intelligence are of more direct relevance to real-world problem solving? What are some aspects of intelligence that might be culture-invariant, and which other aspects are culture-dependent?

Integrating most of the central conceptions of intelligence developed over the last century reveals that intelligence as a phenomenon has multiple facets and levels, and is dynamic both in terms of information processing and in terms of the varying contexts in which it is expressed during individual ontogeny. Couched within an integrated framework, intelligence may be viewed as biologically-implemented information-processing capabilities together with knowledge and expertise giving rise to adaptive behaviors in different domains of functioning that are co-constructed through the interplay between socio-cultural contextual influences and the genetic and neurobiological mechanisms across lifespan development. A

growing Zeitgeist is more and more in the orientation of biocultural co-constructivism.

Intelligence, Evolution of

Intelligence is defined as a special form of biological adaptation (see adaptation and evolution). It is a trait that generates adaptive behavior by altering brain

states, the configuration of which corresponds to memory and is related to some specific feature(s) of the environment. The phylogenetic distribution of intelligence is uncertain, but is likely to have first evolved hundreds of millions of years ago. The intelligence of any species is characterized by the intelligence of the species from which it evolved, and possibly also by special features of intelligence specific to that species. This applies to *Homo sapiens* as to any other species. Intense interest has centered about the notion of intelligence from the time Darwin contrasted intelligence with instinct, thus setting the stage for the nature–nurture controversy, which has created a schism in the behavioral and social sciences since the 1870s. The relatively recent notion that intelligence itself is an adaptation, closely interwoven with instincts, has gone a long way to resolving this long-running dispute.

1. *Defining Intelligence*

Intelligence is notoriously difficult to define in any brief and simple way. One reason for this is that whilst intelligence gives rise to adaptive behaviors, adaptive behavior is a ubiquitous phenomenon, most of which is not a consequence of intelligence. The first requirement, then, is to distinguish between behaviors that are a consequence of the action of intelligence and those that are not. A second reason for the difficulty in defining intelligence is that it has generic meaning in all animals that have the trait of intelligence; but it also has specific meaning in that intelligence may, and often does, manifest itself differently in different species. The problem is made more complicated by the commonly held view on intelligence in our own species, which is partly a manifestation of the problem of extending the generic definition to its species-specific manifestation in *Homo sapiens*. Given the fundamental tenet of evolutionary theory (see *Evolution, History of*) that living forms have a common origin based upon descent with modification, at least some aspects of human intelligence must be related to intelligence in non-human species.

1.1 *A Generic Definition*

Unlike plants that can incorporate and utilize the energy of the sun to fuel their needs, animals must indirectly gain access to the sun's energy by consuming plants, or other living forms, including other animals that eat plants. In order to do this they must move about and act on the world, that is they must behave. Most behavior is the result of inherited patterns of central nervous system (CNS) functions that have evolved as efficient ways of exploiting such energy resources and avoiding damage. Such adaptive behaviors may be described as innate or instinctive in that they are solely caused by genes expressed by appropriate and necessary conditions of development to result in relatively invariant species-typical behavior patterns. Such behavior neither is generated by, nor results in, long-term changes in CNS states. However, in some animals, adaptive behavior is the result of enduring changes to the state of their CNS that arise from experience. This capacity to generate adaptive behavior resulting from within-lifetime experiences leading to changes in CNS states is the generic definition of intelligence. Thus defined, intelligence is identified with psychological mechanisms and processes such as learning, memory, and forms of internally manipulated CNS state changes referred to as thought and problem solving. Most intelligent animals are confined to relatively simple mechanisms of learning and memory.

1.2 *Specific Definitions*

Intelligence is often defined in terms of specific, often species-specific, manifestations. The reduction of response to irrelevant events (habituation) and associative learning (classical conditioning and instrumental learning) are widespread and common means of generating adaptive behavior in most intelligent species. There are also a host of more restricted forms of intelligence which include the ability of honey bees to learn about the position of food resources from other members of their hive, the ability of some bird species to acquire species-typical bird song, and tool use in chimpanzees. The human capacity for acquiring language, doing arithmetic, and forming abstract concepts are other examples. Very little is yet known about the psychological and neurological mechanisms that are the basis of any forms of intelligence. They may be similar if not identical in some cases, but are clearly different in others. For example, most psychologists agree that there has been a singular failure to identify language acquisition with associative learning. Nonetheless, all are forms of intelligence conforming to the generic definition given above.

2. *The Origins of Intelligence*

One of the few things that Darwin wrote about with uncharacteristic lack of clarity is the origin of intelligence and its relationship to other forms of behavioral adaptations. It is now believed that intelligence originates in the limitations of instincts in dealing with changes in the world that occur at certain rates. However, it must be recognized that the difficulties faced by Darwin and later writers is that evolution is an historical process. The traits that are seen in living forms now are the result of selection forces acting on variations in the past, often millions, or hundreds of

millions of years before the present. This applies to all adaptations including intelligence. Beyond the reach of empirical verification, one can never be certain about the reasons why adaptations originally evolved. The strength of any analysis rests upon the extent to which conjectured past selection forces are still present.

2.1 The Uncertain Futures Problem

Nothing in the world is constant. Change and flux are pervasive, giving rise to what C. H. Waddington called the uncertain futures problem. All problems of survival concern coping with change, and all extinctions are caused by the inability of species to cope with uncertain futures. One of Darwin's great contributions to modern thought was his recognition that explaining the dynamic, not the static, is the aim of science. Change, however, takes different forms and occurs at different rates. Intelligence is one of a family of processes that make up biological responses to dynamically changing circumstances (Plotkin 1994).

All adaptations have three characteristics. The first is they increase individual fitness (that is, the chances of survival and reproduction). This is why they are selected and become widespread in a population or species. The second is they are heritable (that is, they are part-caused by genes and hence inherited from parents by offspring). The third is they constitute a relationship between parts of organismic organization (for instance, the existence of an enzyme, or a limb of specific form) with a particular feature of the environment (for example, a nutrient, or the form of terrain). Behavioral adaptations possess all these characteristics. They increase fitness; they are genetically part-caused, finding expression in behavior through development in an appropriate environment; and they have matching relationships to specific features of the environment.

2.2 Adaptations to Different Rates of Change and the Evolution of Intelligence

Adaptations constitute matching relationships to rela tively enduring features of the world, that is, whose change is so slow that they appear to be enduring. This is why they are present in most members of a species and endure as species-specific traits over long periods. The information for the construction of the trait is present in the gene pool of that population or species. However, features of the world that change more rapidly than can be tracked by the main evolutionary program have also to be adapted to if they constitute significant features of the environment. Some behavioral adaptations show developmental flexibility (see *Genotype and Phenotype*) such that different ranges of environmental experience will result in different forms of behavior (for example, living as solitaries or swarming in locusts). Such developmental adjustments to adaptations, however, are bound to the temporal restrictions of the developmental process. Other fluctuations in the environment are so fleeting and pervasive, like non-seasonal temperature changes, that flexible development cannot provide appropriate adaptations. In such cases, short-term responses like shivering or sweating provide a means of tracking such changes.

An important and different class of change is those which occur rapidly and possibly repeatedly throughout a lifespan, but which may constitute features of the world that endure for significant periods. Neither developmental plasticity nor short-term physiological adjustments can furnish adequate adaptations to such forms of change. Examples are the position of a food resource or the identity of an ally or enemy in a social species. Such short-term stabilities concern the relationship between organisms and their environments that are central to the social and behavioral sciences. It is the need to adapt to such short-term stabilities that constitute the evolutionary origins of intelligence. Hence, the definition of intelligence as the capacity to alter CNS states because of experience now extended to the notion that such changes in short-term stabilities be tracked and matched by neural network states that generate adaptive behaviors to such short-term stabilities.

One important feature of the environment is cause-effect relationships. Some of these are so constant that adaptations in the form of innate or instinctive behaviors of approach or avoidance will evolve. Others are transient. For example, the characteristics that identify food that causes illness may and do change and such changes must be tracked. A sensitivity to such changing cause–effect relationships and the ability to conserve these in the form of changes in CNS states (that is memories) that direct appropriate behavior were likely to have been amongst the earliest forms of intelligence to have evolved.

3. The Phylogenetic Distribution of Intelligence

There are no reliable reports of intelligence in non-animal forms such as plants or fungi. Depending upon classificatory system, the animal kingdom is made up of about 25 major divisions (phyla), with reports of intelligence being present in species belonging to seven of these.

3.1 Intelligence in Vertebrates

Vertebrates comprise much the greater part of the phylum Chordata, the comparative evidence indicating that intelligence in the form of associative and other relatively simple forms of learning is widespread

throughout this subphylum, which ranges from cartilaginous and bony fish, through amphibia, reptiles, and birds, to mammals. The comparative study of intelligence, in any phylum, has never been undertaken in any systematic fashion. Most laboratory-based animal learning studies have used just two species of animal, the domesticated laboratory rat and the pigeon. The poor status of this work as comparative scholarship is attested to by few texts on animal learning carrying an index of species. That said, and noting that negative studies are seldom published, it is probably the case that positive results on simple learning have been reported in all studies undertaken in different vertebrate species.

In addition to associative learning capacity, intelligence in the form of the ability to acquire knowledge of complex spatial arrays, complicated sound patterns being incorporated into vocal signaling, problem solving, transitive reasoning, and tool use have been demonstrated in a variety of species of bird and non-human mammals. The existence of imitation learning and the ability of apes, especially chimpanzees, to attribute mental states to others and to be able to learn and use language are highly contentious issues.

3.2 Intelligence in other Phyla

The most complete review of invertebrate intelligence is to be found in three volumes edited by Corning et al. (1973a, 1973b, 1975). In general, the evidence is either weak or disputed. The unicellular Protista (for example, amoeba) may show habituation, but lacking a nervous system, the mechanisms underlying the ability to cease to respond to non-significant events will be entirely different from multicellular animals that have evolved nervous systems (see *Science and Industry*). Claims for the existence of habituation in Coelenterate species (e.g. hydra, medusa) are also disputed, though such animals do have nerve-net nervous systems. Platyhelminthes (flatworms) have received considerable study. These animals have a CNS, occupy a pivotal position in the evolution of multicellular animals, and may have been demonstrated to have simple associative learning. The evidence for associative learning in members of the phylum Annelida (earthworms, leeches) is stronger. The great majority of animals are members of the phylum Arthropoda, which includes crustaceans, spiders, and insects. The behavior of honeybees is the most extensively investigated of all invertebrates. There is no doubt that they have associative learning, which shows remarkable similarities to the learning of the laboratory rat. Gastropod molluscs (like snails) can habituate, and possibly condition. There are extensive reports of Cephalapod molluscs (octopods and squids) demonstrating associative, instrumental, and discriminative learning. Given that these are active predators with highly developed sensory and nervous systems, this might be expected. However, it should be noted that claims for learning in these species have been vigorously contested.

In general, the evidence for habituation in a number of non-chordate animals is strong. Honeybees apart, the status of work on other forms of learning is poor. There is much to be done on invertebrate intelligence in the future, an area of research that for some years now has been moribund. It should be noted that centralized nervous systems with neural networks evolved around 500 million years ago. The selective advantages of being able to detect conserved cause–effect relationships and other short-term stabilities must always have been very strong. It would be surprising if high quality research into non-chordate learning in the future did not prove positive.

3.3 Intelligence, Ecology and Life-history Strategies

The nature of the short-term stabilities that are significant for the survival and reproduction of animals will vary with the life-history strategies and ecologies of different species. This view has led to a conceptually powerful approach in recent years which seeks to place intelligence within the context of the natural history of any intelligent species, where intelligence is seen to be interwoven with instincts (Gould and Marler 1987). It is likely that much of the ambiguity of findings on animal intelligence, especially that of invertebrates, will be resolved by research carried out within this framework.

4. Human Intelligence

Intelligence has been a central area of human psychological research throughout the twentieth century. Much of it has revolved around the seeming dichotomy between general intelligence (*g*) and specific intelligences (*s*) such as verbal and numerical skills. In recent years, *s* has come to be identified with computationally specialized cognitive modules (Fodor 1983). There is, however, no reason to think of *g* and *s* as being exclusive properties of human intelligence (Plotkin 2002). It is entirely conceivable either that some property of the brain's information processing capacity is common to all computational modules, or that the outputs of individual modules are subject to further common processing which is reflected in *g*.

4.1 Current and Future Research

Since the early 1980s there has been a remarkable advance in understanding the emergence of intel-

ligence in the child. The findings are relatively uniform in supporting the existence of discrete intelligences (*s*) that appear to be largely innate cognitive systems (Hirschfeld and Gelman 1994). The notion of human intelligence as a *tabula rasa* has been shown to be wrong. Furthermore, there is a move towards relating such individual cognitive skills to more basic mechanisms, for example showing the connections between language, gesture, and manual skills (Wilson 1998). This conceptual marriage between viewing intelligence as a collective of specific, innate, cognitive devices, and yet relating it to more basic mechanisms like information processing and memory mechanisms (Deacon 1997), is likely to be the dominant form of research into human intelligence in the coming decades.

It should be noted that lineages maintain many of the features of ancestral species. For this reason, human intelligence certainly comprises evolutionarily older forms of intelligence, such as associative learning because of the continuing need to be sensitive to conserved cause–effect relations, as well as more newly evolved forms of intelligence such as numerical and linguistic competence.

4.2 Intelligence and Culture

Culture (see *Cultural Evolution: Theory and Models*) is at once an extraordinary manifestation of, and an extension of, human intelligence. The appearance of culture is one of the major evolutionary transitions in the history of life (Maynard Smith and Szathmary 1995). An important focus of research into intelligence in this century will concern the essential psychological mechanisms of culture, especially those features of intelligence that allow humans to enter into culture (Plotkin 1998), as well as the interrelationship between culture and human cognition (Donald 1991) and between culture and biological evolution (Laland et al, 1995) (see also *Genes and Culture, Coevolution of*). Intelligence will be seen as an evolved adaptation with specific manifestations in *Homo sapiens* that make it central to understanding human culture. Understanding the relationships between biological evolution, individual intelligence, and human culture delineates one of the most important developments in the social sciences in the decades to come.

Intelligence, Genetics of: Cognitive Abilities

Far more genetic research has been conducted on intelligence than on any other behavioral dimension or disorder. Most of this research consists of family, twin, and adoption studies (see *Behavioral Genetics: Psychological Perspectives*) that investigated the rudimentary questions of whether and to what extent genetic factors are associated with individual differences in intelligence. This research will be reviewed briefly followed by new directions for genetic research that go beyond these rudimentary questions, including molecular genetic research that aims to identify specific genes responsible for genetic influence on intelligence.

1. Genetic Perspectives on Intelligence

Nearly all genetic research on human intelligence focuses on individual differences within our species. In contrast, cognitive psychology generally considers species-typical cognitive functioning, asking questions

such as the involvement of working memory and a central executive in processing information. Imaging research asks what parts of the brain are engaged during particular tasks. Such research is more concerned about universal themes of human cognitive functioning rather than individual variations on these themes, which is the provenance of genetic research. These represent different perspectives and entail different levels of analyses. Perspectives are not right or wrong, merely more or less useful for asking particular questions. Genetic research cannot address the etiology of species-typical behavior but it is well suited to investigate the etiology of individual differences within a species.

Genetic research to date is also largely limited to a particular model of cognitive functioning called the psychometric model that considers cognitive abilities to be organized hierarchically (Carroll 1993) from specific tests to broad factors to general cognitive ability (often called *g*). There are hundreds of tests of cognitive abilities. These tests measure several broad factors (specific cognitive abilities) such as verbal ability, spatial ability, memory, and speed of processing. These broad factors are not independent—they intercorrelate modestly, about 0.40. That is, in general, people who do well on tests of verbal ability tend to do well on tests of spatial ability. General cognitive ability, that which is in common among these broad factors, was discovered by Charles Spearman nearly a century ago. It has been suggested that *g* is preferable to the word intelligence because the latter has so many different meanings in psychology and in the general language (Jensen 1998).

Most people are familiar with intelligence tests, often called IQ (intelligence quotient) tests. These tests typically assess several cognitive abilities and yield total scores that are reasonable indices of *g*. For example, the Wechsler tests of intelligence, widely used clinically, include ten subtests such as vocabulary, picture completion (indicating what is missing in a picture), analogies, and block design (using colored blocks to produce a design that matches a picture). In research contexts, *g* is usually derived by using a technique called factor analysis that weights tests differently according to how much they contribute to *g*. This weight can be thought of as the average of a test's correlations with every other test. This is not a statistical abstraction—one can simply look at a matrix of correlations among such measures and see that all the tests intercorrelate positively and that some measures (such as spatial and verbal ability) intercorrelate more highly on average than do other measures (such as nonverbal memory tests). A test's contribution to *g* is also related to the complexity of the cognitive operations it assesses. More complex cognitive processes such as abstract reasoning are better indices of *g* than less complex cognitive processes such as simple sensory discriminations (Jensen 1998).

Although *g* explains about 40 percent of the variance among such tests, most of the variance of specific tests is independent of *g*. Clearly there is more to cognition than *g*. Moreover, there may be more to *g* than can be seen from the types of psychometric tests used to assess it at the end of the twentieth century. There are other ways to study cognitive processes than psychometric tests such as information-processing approaches that typically rely on reaction time. Especially exciting are neuroscience measures that directly assess brain function such as evoked potentials, positron emission tomography (PET) scans, and functional magnetic resonance imaging (fMRI). As new tests of cognitive abilities are developed and their reliability and validity established, their relationship to *g* and their genetic and environmental origins will be investigated. However, few genetic studies have as yet used these other cognitive measures.

Just as there is more to cognition than *g*, there is clearly much more to achievement than cognition. Personality, motivation, and creativity all play a part in how well someone does in life. However, it makes little sense to stretch a word like intelligence to include all aspects of achievement such as emotional sensitivity and musical and dance ability that do not correlate with tests of cognitive ability.

Despite the massive data pointing to *g*, considerable controversy continues to surround *g* and IQ tests, especially in the media. There is a wide gap between what lay people (including scientists in other fields) believe and what experts believe. Most notably, lay people often hear in the popular press that the assessment of intelligence is circular—intelligence is what intelligence tests assess. To the contrary, *g* is one of the most reliable and valid measures in the behavioral domain, its long-term stability after childhood is greater than for any other behavioral trait, and it predicts important social outcomes such as educational and occupational levels better than any other trait (Gottfredson 1997). Although a few critics remain, *g* is widely accepted by experts. It is less clear what *g* is, whether *g* is due to a single general process such as executive function or speed of information processing, or whether it represents a concatenation of more specific cognitive processes (Jensen 1998).

2. *Historical Context*

The relative influence of nature and nurture on *g* has been studied since the beginning of psychology. Indeed in 1865, a year before the publication of Gregor Mendel's seminal paper on the laws of heredity, Francis Galton published a two-article series on high intelligence and other abilities, which he later expanded into the first book on heredity and cognitive ability, *Hereditary Genius: An Inquiry into its Laws and Consequences* (1992; originally published in 1869).

The first twin and adoption studies in the 1920s also focused on *g*. Highlights in the history of genetic research on *g* include Leahy's (1935) adoption study, in which she compared IQ resemblance for non-adoptive and adoptive families. This study confirmed an earlier adoption study that showed genetic influence, in that IQ correlations were greater in non-adoptive than in adoptive families. The first adoption study that included IQ data for biological parents of adopted-away offspring also showed significant parent–offspring correlation, suggesting genetic influence (Skodak and Skeels 1949). Begun in the early 1960s, the Louisville Twin Study was the first major longitudinal twin study of IQ that charted the developmental course of genetic and environmental influences (Wilson 1983).

In 1963, a review of genetic research on *g* was influential in showing the convergence of evidence pointing to genetic influence (Erlenmeyer-Kimling and Jarvik 1963). During the 1960s, environmentalism, which had been rampant until then in American psychology, was beginning to wane, and the stage was set for increased acceptance of genetic influence on *g*. Then, in 1969, a monograph on the genetics of intelligence almost brought the field to a halt, because the monograph suggested that ethnic differences in IQ might involve genetic differences (Jensen 1969). Twenty-five years later, this issue was resurrected in *The Bell Curve* (Herrnstein and Murray 1994) and caused a similar uproar. The causes of average differences between groups need not be related to the causes of individual differences within groups. The former question is much more difficult to investigate than the latter, which is the focus of the vast majority of genetic research on IQ. The question of the origins of ethnic differences in performance on IQ tests remains unresolved.

The storm raised by Jensen's monograph led to intense criticism of all behavioral genetic research, especially in the area of cognitive abilities. These criticisms of older studies had the positive effect of generating a dozen bigger and better behavioral genetic studies that used family, adoption, and twin designs. These new projects produced much more data on the genetics of *g* than had been obtained in the previous 50 years. The new data contributed in part to a dramatic shift that occurred in the 1980s in psychology toward acceptance of the conclusion that *g* is significantly associated with genetic differences between individuals (Neisser et al. 1996).

3. *Genetic Influence on* g

Dozens of studies including more than 8,000 parent-offspring pairs, 25,000 pairs of siblings, 10,000 twin pairs, and hundreds of adoptive families all converge on the conclusion that genetic factors contribute substantially to *g* (Bouchard and McGue 1981, Plomin et al. 2001). Correlations for first-degree relatives living together average 0.43 for more than 8,000 parent-offspring pairs and 0.47 for more than 25,000 pairs of siblings. However, *g* might run in families for reasons of nurture or of nature. In studies involving more than 10,000 pairs of twins, the average *g* correlations are .85 for identical twins and 0.60 for same-sex fraternal twins. These twin data suggest that genetic factors play an important role in the origins of familial resemblance in *g* scores. Adoption studies also indicate substantial heritability. For example, in two recent studies, identical twins reared apart are almost as similar for *g* as are identical twins reared together, with an average correlation of 0.78 for 93 such pairs (Bouchard et al. 1990). Adoption studies of other first-degree relatives also indicate substantial heritability, as illustrated by recent results from the longitudinal 25-year Colorado Adoption Project (Plomin et al. 1997).

Estimates of the effect size of genetic factors, called heritability, vary from 40 to 80 percent but estimates based on the entire body of data are about 50 percent, indicating that genes account for about half of the variance in *g*. Even a meta-analysis that attempted to ascribe as much variance as possible to prenatal effects estimated heritability as 48 percent (Devlin et al. 1997). It is not of much importance whether heritability is 30, 50, or 70 percent because few implications would follow from one or the other estimate being correct. The point is that genetic influence on *g* is not only statistically significant; it is also substantial. Although heritability could differ in different cultures, moderate heritability of *g* has been found, not only in twin studies in North American and western European countries, but also in Moscow, former East Germany, rural India, urban India, and Japan (Plomin et al. 2001).

Most of the genetic variance for *g* is additive; that is, genetic effects add up rather than interact across loci—offspring resemble their parents genetically for additive genetic effects, not for interactive effects among genes. The additivity of most genetic effects on *g* may be due to the fact that there is greater assortative mating (nonrandom mating) for *g* than for other behavioral traits. Spouses correlate about 0.10 for personality, about 0.20 for height and weight, but for *g* spouses correlate about 0.45. Because bright women are likely to mate with bright men, this double-barreled effect makes their offspring likely to be brighter on average than would be expected if mating were at random. In this way, assortative mating spreads out the distribution of additive genetic effects on *g* in the population (Plomin et al. 2001).

These same genetic data provide the best available evidence for the importance of environmental factors independent of genetics. If genetic factors account for about half of the variance then non-genetic factors account for the rest of the variance. Environment clearly is important. This is suggested as well by the

steady rise in IQ scores during the past several generations, which would seem too short a time to allow genetic explanations (Flynn 1999), and by studies in which children from abusive families show gains in IQ when adopted (Duyme et al. 1999). However, little is known about specific environmental differences as they relate to *g* independent of genetic factors.

4. *Beyond Heritability*

The answers to the rudimentary questions of whether and how much genetic factors contribute to *g* now seem sufficiently clear—the answers are, respectively, 'yes' and 'a lot.' Genetic research on *g* has moved beyond heritability, for example, to investigate developmental changes, multivariate relations among cognitive abilities, and specific genes responsible for the heritability of *g*.

4.1 *Genetic Influence on* g *Increases During Development*

When Francis Galton first studied twins in 1876, he investigated the extent to which the similarity of twins changes during development. Other early twin studies of *g* were also developmental, but this developmental perspective faded from genetic research until the late twentieth century. One of the most interesting findings about *g* is that heritability increases steadily from infancy (20 percent) to childhood (40 percent) to adulthood (60 percent). For example, a recent study of twins aged 80 years and older reported a heritability of about 60 percent (McClearn et al. 1997).

The 20-year longitudinal Colorado Adoption Project (CAP) confirms this finding using the adoption design (Plomin et al. 1997b). CAP is a 25-year study of 245 children adopted away from their biological parents at birth and adopted into adoptive homes in the first month of life. CAP includes 'genetic' (biological) parents and their adopted away children, 'environmental' (adoptive) parents and their adopted children, and 'genetic-plus-environmental' (non-adoptive or control) parents and their children who have been matched to the adoptive families. Correlations between non-adoptive parents and children increase from less than 0.20 in infancy to about 0.20 in middle childhood and to about 0.30 in adolescence. The correlations between biological mothers and their adopted-away children follow a similar pattern, indicating that parent-offspring resemblance for *g* is due to genetic factors. In contrast, parent–offspring correlations for adoptive parents and their adopted children hover around zero, which suggests that family environment shared by parents and offspring does not contribute importantly to parent–offspring resemblance for *g*. Because CAP is a parent–offspring design with adult parents and young offspring, these results can be interpreted more precisely as showing that genetic effects on adult *g* do not come on line just in adulthood, but also to a considerable extent in adolescence, to a lesser extent in childhood, and even to some slight extent in infancy.

Why does heritability of *g* increase during the life span? Perhaps completely new genes come to affect *g* as more sophisticated cognitive processes come on line. A more likely possibility is that relatively small genetic effects early in life snowball during development, creating larger and larger phenotypic effects, perhaps as individuals select or create environments that foster their genetic propensities.

4.2 *Genetic Effects are Broad (Molar) Rather than Modular*

In the widely accepted hierarchical model of cognitive abilities mentioned earlier, *g* consists of what is in common among specific cognitive abilities such as spatial, verbal, speed of processing, and memory abilities. Less is known about the genetic and environmental origins of individual differences in specific cognitive abilities, but they also appear to show substantial genetic influence, although less than *g* (Plomin and DeFries 1998).

To what extent do different sets of genes affect these phenotypically different abilities? A technique called multivariate genetic analysis examines covariance among specific cognitive abilities and yields a statistic called the genetic correlation, which is the extent to which genetic effects on one trait correlate with genetic effects on another trait independent of the heritability of the two traits. That is, although cognitive abilities are moderately heritable, the genetic correlations between them could be anywhere from 0.0, indicating complete independence, to 1.0, indicating that the same genes influence a variety of cognitive abilities. Multivariate genetic analyses have consistently found that genetic correlations among specific cognitive abilities are very high, close to 1.0 (Petrill 1997). In other words, the same genetic factors largely influence different abilities. What this finding means concretely is that if a specific gene were found that is associated with verbal ability, the gene would also be expected to be associated with spatial ability and other specific cognitive abilities.

These genetic results have major implications for current theories of cognitive neuroscience. According to one theory, the brain works in a modular fashion, that is, cognitive processes are specific and independent. Implicit in this perspective is a bottom-up reductionistic view of genetics in which modules are the targets of gene action. In contrast, the findings from multivariate genetic analyses suggest a top-down view in which genetic effects operate primarily on *g*,

rather than a bottom-up view in which genetic effects are specific to modules. Given that the brain has evolved to learn from a variety of experiences and to solve a variety of problems, perhaps it makes sense that the brain functions holistically. However, finding genetic correlations near 1.0 does not prove that genetic effects are limited to a single general cognitive process that works in a top-down way. Another alternative is that specific cognitive abilities as they are currently assessed might involve many of the same modular processes that are each affected by different sets of genes. This alternative hypothesis could be tested by multivariate genetic research on measures of more modular processes such as neuroimaging measures of brain function.

4.3 Specific Genes are Beginning to be Identified

Heritability of complex dimensions such as *g* seems likely to be due to multiple genes of varying but small effect size rather than a single gene that has a major effect. Genes in such multiple-gene systems are called quantitative trait loci (QTLs) (Plomin et al. 1994). Unlike single-gene effects like PKU that are necessary and sufficient for the development of a disorder, QTLs contribute interchangeably and additively like probabilistic risk factors. Traditional methods for identifying single-gene effects are unlikely to succeed in identifying QTLs.

It is interesting that the two best-replicated QTLs are both in the cognitive domain. Apolipoprotein-E was first reported in 1993 to be related to late-onset dementia using allelic association (Corder et al. 1993) and has since been replicated in scores of studies (Rubinsztein 1995). QTL sib-pair linkage designs were used to identify a linkage between chromosome 6p21 and reading disability (Cardon et al. 1994), a linkage that has been replicated in several subsequent studies (e.g., S. E. Fisher et al. 1999). The QTL perspective suggests that both dementia and reading disability are likely to be the quantitative extremes of continuous distributions.

If additive genetic factors are important for complex traits, then it should be possible to identify the genes responsible if we have sufficient power to detect QTLs of small effect size. The critical question is the distribution of effects sizes of these QTLs: What is the average effect size of QTLs and how are QTL effect sizes distributed? If the average effect size is 1 percent we will eventually detect many QTLs given a heritability of at least 50 percent. However, if the average QTL effect size is 0.1 percent, we will detect very few QTLs and they will be difficult to replicate.

A QTL study applying new genetic approaches to *g* yielded a replicated association in a study comparing groups of children of high *g* and children of average *g* (Chorney et al. 1998). The gene is insulin-like growth factor-2 receptor (IGF2R) on chromosome 6, which has been shown to be especially active in brain regions most involved in learning and memory. The frequency of one of the alleles was twice as high in two groups of children with high *g* as compared to two groups of children with average *g* (about 30 percent vs. 15 percent). Combining these results yielded a highly significant result ($\chi^2 = 12.41, p < 0.0004$). An ongoing systematic scan of the genome using these techniques has begun to identify several other QTLs associated with *g* (P. J. Fisher et al. 1999).

5. Implications of Identifying Genes Associated with g

Identifying replicable QTLs associated with *g* will make it possible to use measured genotypes rather than indirect inferences about heritable influence based on familial resemblance in order to address issues such as developmental change and continuity and the multivariate relationships among cognitive abilities. Replicated QTL associations with *g* will also provide discrete windows through which to view pathways between genes and *g*. Functional genomics, understanding how genes affect traits, is generally viewed in terms of bottom-up molecular biological analyses of cellular function in which the gene product is identified and its effects studied at a molecular and cellular level. However, other levels of analysis are also likely to be useful in understanding how genes affect *g* such as anatomical neuroimaging, functional neuroimaging, electrophysiology, psychophysiology, cognitive processing, and psychometrics. As an antidote to the tendency to define functional genomics at the cellular level of analysis, the phrase 'behavioral genomics' has been proposed (Plomin and Crabbe 2000). The grandest implication for science is that the functional (behavioral) genomics of *g* will serve as an integrating force across diverse disciplines with DNA as the common denominator, opening up new scientific horizons for understanding learning and memory.

As is the case with most important advances, identifying genes for cognitive abilities and disabilities will also raise new ethical issues. Finding QTLs for *g* will have important implications for society as well as science (Plomin 1999). In terms of implications for society, it should be emphasized that no policies necessarily follow from finding genes associated with *g* because policy involves values. For example, finding genes for *g* does not mean that we ought to put all of our resources into educating the brightest children. Depending on our values, we might worry more about children falling off the low end of the bell curve in an increasingly technological society and decide to devote more public resources to those who are in danger of being left behind.

Many ethical issues related to DNA are being broached at the level of single-gene disorders that are

hard-wired in the sense that a single gene is necessary and sufficient for the development of the disorder. This will benefit ethical deliberations about the genetics of *g*, which seems less pressing because genetic effects on *g* are probabilistic rather than deterministic for two reasons. First, heritability is closer to 50 percent than to 100 percent, which means that non-genetic factors make a major contribution. Second, because many genes contribute to the heritability of *g*, the system is inherently probabilistic. Potential problems related to finding genes associated with *g* have been discussed such as prenatal and postnatal screening, discrimination in education and employment, and group differences (Newson and Williamson 1999).

The fear lurks in the shadows of such discussions that finding genes for *g* will limit our freedom and our free will. In large part such fears involve misunderstandings about how genes affect complex traits like *g*. Finding genes for *g* will not automatically open a door to a genetic version of Huxley's brave new world where babies are sorted out at birth (or before birth) into alphas, betas, and gammas. Although the balance of risks and benefits to society of finding genes for *g* is not clear, basic science has much to gain from functional genomic studies of brain functions related to learning and memory. We need to be cautious and to consider carefully societal implications and ethical issues. There is also much to celebrate here in terms of the increased potential for understanding our species' nonpareil ability to think and learn.

Intelligence, Genetics of: Heritability and Causation

In theory, the 'genetics of intelligence' describes the extent to which, and manner by which, an individual's mental abilities are influenced by his or her genes. In practice, there is a lot of debate and no universally accepted description of the genetics of intelligence. Intelligence is regarded as a complex trait, meaning that many genetic and environmental factors are thought to influence it. Nevertheless, we know little about the number or nature of genes that influence cognitive abilities. We know even less about how the expression of these genes depends on other genes or on environmental factors. To complicate matters even further, there are numerous facets of intelligence, each of which may be influenced in different ways by genes and the environment. This article focuses on the genetics of human intelligence and on the problems of assessing the genetic and environmental contributions to intelligence. To begin, definitions and measures of intelligence will be described. The effects of genes known to influence intelligence will then be mentioned. Finally, the degree to which variation in intelligence among humans may be genetically based will be discussed.

1. *Intelligence is a Multifaceted Trait*

Before one can study the genetics of a trait, one has to define precisely what the trait is and how it can be measured. Once a measure has been defined for a trait, then one can begin to tackle the question of how an individual's score may be influenced by genetic and environmental factors. Specifying an appropriate scale for intelligence is complicated by the fact that intelligence is a multifaceted trait. That is, there are several aspects of intelligence, involving reasoning, abstraction, problem solving, memory, linguistic aptitude, artistic ability, etc. Abilities in these different areas tend to be correlated to some extent within a population, which has led some authors to posit the existence of an underlying general intelligence factor, *g* (Spearman 1904). It is argued that the *g* factor directly influences many different aspects of intelligence, causing them to be correlated. Another possibility is that

Figure 1
The frequency distribution for an idealized IQ test. Raw scores from a test are rescaled to fit the shape of a normal curve with mean at 100 and standard deviation of 15. Consequently, when the test is devised, 95 percent of the population will have IQ scores that fall between 70 and 130 by construction

different aspects of intelligence interact with one another and that these interactions generate the observed correlations (Hunt 1997). For example, strength in one area of intelligence (e.g., memory) might compensate for weakness in another area (e.g., linguistic ability), causing a person's abilities in these areas to be more similar than would be expected for uncorrelated traits. A compelling reason to believe that the various facets of intelligence are not just alternate manifestations of some underlying *g* factor is that they respond in different ways to aging and education. For example, Horn (1985) noted that measures of 'fluid intelligence' (the ability to solve new problems) generally declines with age among adults whereas 'crystallized intelligence' (the ability to apply known problem-solving methods to a problem at hand; see Cattell 1971) tends to increase with age and experience. A final possibility is that there are both general and specific cognitive factors that interact in a myriad of ways for different aspects of intelligences (e.g., Spearman 1904, Vernon 1979, Carroll 1993).

In most genetic studies, some variant of the Intelligence Quotient (IQ) is used as a single measure of intelligence, ignoring the multifaceted nature of intelligence (for exceptions see Cardon et al. 1992, Cardon and Fulker 1994, Pederson et al. 1994). The IQ measure grew out of studies by Alfred Binet on the ages at which children display skills of varying difficulty. Binet (1905) developed a series of age-scaled tests to assess the mental age of children. Wilhelm Stern (1916) used these tests to devise the IQ, defined as the mental age of a child divided by his or her chronological age multiplied by 100. Similar scales have been devised for adults, such as the Wechsler Adult Intelligence Scale and the Stanford-Binet Inte-

lligence Scale. These scales have been plagued with controversy over the degree to which the measures are biased in favor of certain classes, cultures, races, or sex (Gould 1996, Schiff and Lewontin 1986, Wahlsten 1997). It is argued that there can be no completely objective measure of intelligence, since what it means to be intelligent and who is perceived to be intelligent are social constructs subject to change.

Scores on IQ tests are adjusted so that they follow a normal distribution, or a 'bell curve,' with a mean of 100 (Fig. 1). An indication of the importance of environmental factors on IQ is that these scales must constantly be readjusted over time, a phenomenon known as the 'cohort effect.' In many countries, the average IQ score has risen over time (Flynn 1987, Wahlsten 1997). For example, the average IQ score based on Ravens Progressive Matrices of 18-year old males from The Netherlands has increased from 100 in 1952 (when the test was developed and standardized) to 106 in 1962, 112.4 in 1972, and 121.1 in 1981/2. This time-span is far too short for genetic changes in the composition of the population to account for the increases. Rather, these data are evidence that changing educational and social environments can have a dramatic effect on whatever aspects of intelligence were measured by this IQ test.

2. *Genes Known to Affect Intelligence*

Intelligence, like any human attribute, is partly a product of our genes, simply because we would not be living human beings without these genes. However, human intelligence is partly a product of our environment, because mental impairment can be caused, for example, by exposure to toxins such as lead during development. Between these two trivial statements lies an entire spectrum of possibilities, and a heated 'nature versus nurture' debate has grown over the extent to which individual differences in intelligence are genetically based (Devlin et al. 1997b, Fraser 1995, Herrnstein and Murray 1994, Jensen 1969, Lewontin et al. 1984, McInerney 1996).

The human genome contains between 30,000 and 100,000 genes. Although the number of genes that affect intelligence is unknown, there is reason to believe that the number is large. Measures of intelligence, such as IQ, are most likely quantitative genetic traits influenced by hundreds or thousands of genes. Most of these genes will not be 'intelligence' genes, *per se*, but rather genes that are critical to normal development. Severe mutations in such genes would affect several traits, not just mental ability, causing a disease syndrome with multiple symptoms. These severe mutations are the most studied, in large part because they are the easiest to detect.

Geneticists have compiled over 10,000 genes and genetic disorders affecting humans into the database, *Online Mendelian Inheritance in Man* (http://www3.ncbi.nlm.nih.gov/Omim/). A search for entries describing intellectual impairment, mental retardation, or dementia turned up almost 1,000 syndromes, although many of these might not be genetically independent. Familiar examples include Down's syndrome, Parkinson's disease, Alzheimer's disease, fragile X syndrome, Prader–Willi syndrome, Tay-Sachs disease, Wolf–Hirschhorn syndrome, and Rubinstein syndrome. Through the human genome project, more genetic details will be uncovered for these and other human traits and diseases.

Even in those cases where a mutation has been identified that 'causes' a disorder affecting intelligence, the mental development of patients carrying the mutation can be greatly improved by environmental conditions. A classic example of the interplay between genes and the environment in mental development is phenylketonuria (PKU). PKU is a recessive disease caused by a mutation at the phenylalanine hydroxylase gene (PAH) on chromosome 12. People with PKU do not produce enough of the enzyme, PAH, which oxidizes phenylalanine and converts it into tyrosine. Without this enzyme, phenylalanine levels increase to poisonous levels in the body, giving rise to a number of symptoms including mental retardation, a 'mousy' odor, light pigmentation, unusual posture, eczema, and epilepsy (Paine 1957). All of these manifestations of the disease may be prevented, however, by a straightforward change in the environment: a diet low in phenylalanine.

It is crucial to remember that understanding the genetics of severe mental disorders may reveal little about how intelligence develops normally and how this development depends on genetics. By analogy, understanding the environmental risk factors associated with brain damage from severe meningitis (inflammation of the tissues surrounding the brain) reveals little about environmental influences on normal brain development.

3. *Population-based Estimates of the Genetics of Intelligence*

Although severe mutations at many genes may affect intelligence, it does not follow that the majority of differences observed among individuals within a population are due to genetic differences. In fact, genes that, when disrupted, have large effects on mental abilities may not be responsible for any of the more minor differences seen among individuals. An entirely different approach must be taken to assess the extent to which variability in a trait is based on genetic differences within a population. In animals and plants, one would raise individuals in controlled environmental conditions and measure trait differences among these individuals. Assuming that the environmental variance has been minimized in the experiment, the remaining variability is attributed to genetic dif-

Figure 2
The attributes of an offspring may not be predictable on the basis of parental attributes with epistasis. As an illustration, consider a poker game where two parent hands are used to provide the cards for two offspring hands. In this example, the trait is 100 percent genetically determined, because all cards in the offspring hands come from either the father's hand (2/5 cards) or the mother's hand (3/5 cards, with the fifth card representing maternally inherited mitochondria). Nevertheless, an offspring's hand may be much worse or much better as a poker hand than expected based on the parents' hands. In the example shown here, the father's hand (ace high) and the mother's hand (pair of threes) are fairly poor, as is the first child's hand (ace high), but the second child has a fantastic hand (full house). Poker is a game with a large amount of epistatic interactions among cards in a hand. That is, a winning hand depends less on any particular card than on a good combination of cards. Similarly, even if a complex trait such as intelligence depends on the genes that an individual carries, it may do so in such an idiosyncratic way that only individuals with the same combination of genes are similar.

ferences among individuals. This controlled approach cannot be used for humans, however, and instead correlations based on family measures are used to infer the influence of genetic variation on the observed variability in a trait such as IQ.

3.1 Heritability

Heritability is a quantity used to measure the extent to which individual differences in a trait can be attributed to genetic differences. We must first define a few terms. The phenotype (P) of an individual constitutes the visible and/or measurable properties of that individual. In the following, for concreteness, we will take the phenotype to be an individual's score on an IQ. Therefore, our discussion will focus narrowly on the heritability of IQ rather than the heritability of intelligence. Different measures of intelligence are influenced in different ways by genes and the environment and consequently have different heritabilities (Cardon et al. 1992). Nevertheless, the difficulties described below in estimating heritability apply to any measure (or measures) of intelligence in humans.

In the simplest genetic models, phenotype is imagined to be a sum of genetic and environmental effects. Specifically, the genotype (G) of an individual is the total effect of his or her genes, and the environment (E) of that individual is the total effect of all non-genetic influences (e.g., education, diet, stress) on his or her phenotype. These effects will vary among individuals, and the differences are measured by the phenotypic (V_P), genotypic (V_G), and environmental (V_E) variance in a population for a given trait. Broad-sense heritability (H^2) measures the proportion of variance in phenotype that is attributed to genotypic variance: $H^2 = V_G/V_P$. This formulation assumes that the phenotype can be neatly partitioned into two parts and ignores genetic-by-environment interactions (GxE). All treatable genetic disorders, such as PKU, exhibit strong GxE, since symptoms depend on both predisposing mutations and insufficient treatment. Interactions between genes and environment may take on many forms and may well be important in the development of complex traits such as intelligence.

Broad-sense heritability estimates the degree to which differences among individuals are genetically based, but not all genetically based differences can be passed from parents to offspring. For example, whether a parent is homozygous (e.g., $++$) or heterozygous (e.g., $+-$) at a gene is entirely a genetic attribute (broad-sense heritability is 100 percent), but this state cannot be passed on faithfully from parents to offspring. Even if both parents are heterozygous at a gene, their offspring will only be heterozygous half of the time. In other words, there are genetic attributes of an individual that depend on the particular ways in which genes combine and interact and that cannot be inferred from the additive effect (A) of each gene

Table 1
Estimated correlations between the phenotypes of relatives[a]

Relationship	Estimated correlation in phenotype
Monozygotic twins	$V_G/V_P = H^2$
Siblings	$1/2\ V_A/V_P + 1/4\ V_D/V_P$
Half-siblings	$1/4\ V_A/V_P = 1/4\ h^2$
Parent–offspring	$1/2\ V_A/V_P = 1/2\ h^2$
Aunt/uncle	$1/4\ V_A/V_P = 1/4\ h^2$
Grandparent–offspring	$1/4\ V_A/V_P = 1/4\ h^2$

a This simple genetic model ignores epistasis, correlations among parents (assortative mating), cultural inheritance, maternal effects, and common environmental effects (due, for example, to attending the same schools). V_D equals the variance in dominance effects. See text for remaining definitions.

considered over all possible genetic backgrounds. There are two main types of genetic interactions. Dominance (D) describes interactions between the two copies of a gene (one inherited from the mother and one from the father), and epistasis describes interactions among different genes. With dominance and epistasis, knowing the phenotype of parents can sometimes provide little information about the phenotype of offspring. This point is illustrated in Fig. 2.

With genetic interactions, broad-sense heritability does not predict the extent to which offspring resemble their parents. Instead, narrow-sense heritability is used to measure how variation among individuals is influenced by genetic differences that are, on average, passed from parents to offspring. Narrow-sense heritability is defined as the fraction of phenotypic variance that can be attributed to variation in the additive effects of genes (V_A): $h^2 = V_A/V_P$. Narrow-sense heritability is always less than or equal to broad-sense heritability.

Neither heritability measure can be calculated directly since the genotypic (G), additive genetic (A), and environmental (E) scores for human individuals are unknowable. Instead heritability is inferred from formulae relating it to correlations among relatives. This creates an immediate problem, because the expected formulae depend strongly on the model one chooses. If one assumes that there is no epistasis, no social or cultural inheritance, no assortative mating (i.e., no correlation between parents in a trait), no sex differences, and no GxE interactions, then correlations among relatives can be derived in a straightforward manner (Table 1; see e.g., Lynch and Walsh 1998). With such a simplified model, heritability can be estimated from familial correlations. For complex traits such as IQ, however, we know that many of these assumptions are violated. Estimates in the literature for broad- and narrow sense heritability differ widely, depending in large part on what set of assumptions are made.

3.2 Heritability Estimates

Bouchard and McGue (1981) summarized a large number of studies measuring the correlations between relatives in IQ scores (Table 2). Heritabilities have been estimated from these data using different models and different subsets of the data (Table 3). The heritability estimates described in Table 3 have an extremely broad range, from 0.26 to 0.72 (out of a maximum range of 0 to 1). Although a large number of models appear to be included in Table 3, most of these models share several assumptions. Consequently, the range of heritability estimates is even smaller than

Table 2
Familial correlations in IQ from Bouchard and McGue (1981)

Relationship	Symbol	Number of pairs	Correlation
Spouses	M	3817	0.33
MZ twins (together)	r_{MZT}	4672	0.86
MZ twins (raised apart)	r_{MZA}	65	0.72
DZ twins (together)	r_{DZT}	5546	0.60
Sibs (together)	r_{SST}	26473	0.47
Sibs (raised apart)	r_{SSA}	203	0.24
Offspring–parent	r_{OPT}	8433	0.42
Offspring–midparent	r_{OMT}	992	0.50
Offspring–parent apart	r_{OPA}	814	0.22
Foster offspring–parent	r_{FOP}	1397	0.19
Foster offspring–midparent	r_{FOM}	758	0.24
Midoffspring–midparent	r_{MMT}	410	0.72
Adopted/biological sibs	r_{SFB}	345	0.29
Adopted/adopted sibs	r_{SFF}	369	0.34
Half-sibs	r_{HSS}	200	0.31
Cousins	r_{CZ1}	1176	0.15

Table 3
Heritability estimates based on correlations in IQ between relatives[a] (see Table 2)

Estimator	Estimate	Simple expectation	Assumptions
Estimates of broad-sense heritability			
r_{MZA}	0.72	$(V_A+V_D)/V_P$	(D, E, F[b], G; requires A, B to estimate h^2)
Estimates mixing broad-sense and narrow-sense heritability			
2 (r_{MZT}–r_{DZT})	0.52	$(V_A+3/2\ V_D)/V_P$	(B, C, F; requires A to estimate h^2)
2 r_{SSA}	0.48	$(V_A+1/2\ V_D)/V_P$	(B, C, D, E, F[b],G; requires A to estimate h^2)
2 (r_{SST}–r_{SFF})	0.26	$(V_A+1/2\ V_D)/V_P$	(B, C, D, F; requires A to estimate h^2)
Estimates of narrow-sense heritability			
2 r_{OPA}	0.44	V_A/V_P	(B, C, D, E, F[b])
2 (r_{OPT}–r_{FOP})	0.46	V_A/V_P	(B, C, D, E, F[b])
DP model	0.29	V_A/V_P	(A, B, D)
IP model	0.33	V_A/V_P	(A, B, D)
IS model	0.42	V_A/V_P	(A, B, D)
Devlin model[c]	0.34	V_A/V_P	(B, F)

a The first six estimates are described in Plomin and Loehlin (1989). The next three estimates are based on different published models of cultural and genetic inheritance with assortative mating from the analysis of Otto et al. (1994). The DP model assumes direct cultural transmission of IQ with assortative mating based on IQ (Cavalli-Sforza and Feldman 1978, Feldman and Cavalli-Sforza 1979, Martin et al. 1986). The IP model assumes indirect cultural transmission of IQ through social factors (e.g., socio-economic status) with assortative mating based on IQ (Cloninger et al. 1979a, 1979b, Feldman and Cavalli-Sforza 1979, Rice et al. 1978). The IS model assumes indirect cultural transmission of IQ through social factors and assortative mating based on social grouping (Morton and Rao 1978, Rao et al. 1976, 1979). The last estimate is from Devlin et al. (1997a), which uses a model that includes maternal effects and other pre-separation influences on siblings and twins. 'Simple expectation' is the value for the estimators under the restrictive genetic model described in Table 1. Assumptions made by the estimators include: (A) no dominance, (B) no epistasis, (C) no assortative mating, (D) no pre-separation effects on adopted offspring, (E) no correlation between biological and adoptive environments, (F) no cultural inheritance, (G) no allowance for siblings experiencing common environments (e.g., same schools).
b Cultural inheritance would affect the phenotypic variance in a way that is not accounted for in these estimates based on offspring raised apart (Otto et al. 1994).
c Devlin et al. (1997b) examined a slightly different data set, which excludes the last five rows in Table 2.

would be seen if models based on completely different sets of assumptions were included. For example, all estimates except the first one based on identical twins raised apart (r_{MZA}) ignore epistasis. Genetic interactions are difficult to include in models because the forms of these interactions are generally not known. Without this knowledge, one cannot accurately predict correlations among relatives, just as one cannot accurately predict the winnings of the poker hands in Fig. 2 without knowing the rules of poker. Furthermore, all models ignore GxE interactions. Finally, even those models that include cultural inheritance cannot capture the intricate and diverse ways in which social structures influence IQ and the many ways in which family members can influence one another's social context.

There is no consensus about the most accurate value for heritability. There are essentially two camps: those who argue that heritability lies between 0.5 and 0.8; and those who argue that heritability lies between 0.2 and 0.5. The first camp tends to focus on estimates based on twins, especially identical twins raised apart. Such estimates include dominance and epistatic interactions to some extent and therefore tend to measure broad-sense heritability. The correlation in IQ between identical twins raised apart is indeed high (0.72), but there are several nongenetic reasons to expect that identical twins raised apart may be similar. Twins raised apart tend to be placed in similar homes (Bouchard et al. 1990). They also have a certain amount of contact before and after separation (Bouchard et al. 1990). In particular, twins share the same womb and environmental influences during gestation, including any maternal effects (Devlin et al. 1997b). Furthermore, strikingly similar twins may be more easily recognized as identical twins raised apart and may be more likely to enter twin studies. The second camp, which argues for a low heritability of IQ, tends to use a wider variety of familial correlations and more explicit models. Such models have incorporated inheritance of social and cultural influences, similarities among parents (assortative mating), selective placement of adopted children, and/or maternal effects. Although narrow-sense heritability is most often reported in these expanded studies, the difference between broad-sense and narrow-sense heritability is often small when it is measured. For example, Devlin et al. (1997a) estimate a narrow-sense heritability for IQ of 34 percent and a broad-sense heritability of 48 percent. Heritability estimates are sensitive enough to the assumptions made to warrant skepticism towards any particular value.

3.3 The Limits of Heritability

Despite the fact that a lot of effort and scores of publications have been devoted to estimating the

heritability of IQ, heritability provides very limited information of relevance to human society. Heritability is a descriptor of the variability currently within a population and how this variability is partitioned into genetic and nongenetic influences. Even with an estimate of heritability, we know nothing about the reasons for the IQ of any given individual. Furthermore, heritability depends entirely on the set of environments in which it is measured. If one changes the environment, heritability may change in unpredictable ways, both because the phenotypic variance depends on the variance in environmental effects and because genotypic effects may depend on the environment (GxE). One cannot say on the basis of heritability whether or not a trait will change in response to an environmental manipulation (e.g., improved parental support and training, dietary supplements to pregnant women, different methods of schooling).

If heritability for IQ were 100 percent, one might be tempted to conclude that environmental factors are irrelevant and that there is little point in embarking upon social programs to improve the environment. This conclusion would, however, be entirely wrong. Consider the following fictitious example: imagine that there are only two types of people in equal frequencies, those with PKU and those without it. Imagine that no treatment is known, and that there are no environmental/cultural/social/maternal effects on IQ. Let the IQ of those without PKU equal 100, and the IQ of those with PKU equal some number less than 100. Under this scenario, 100 percent of the variability in IQ within the population is genetic ($H^2 = 1$). If the link between dietary phenylalanine and mental deficits in people with PKU is then discovered, and if people with PKU start controlling their diets, the average IQ would rise towards 100, despite the fact that, originally, there was only genetic and no environmental variation within the population. In short, heritability says nothing about how IQ might change in a new environmental context.

Estimating heritability will not help us know how to improve a trait, be it IQ or health or happiness. Detailed studies about how changes in social, educational, medical, and economic opportunities affect intelligence are required to determine what programs would be effective in permitting individuals to attain their highest potential.

4. *Race, Gender, and IQ*

Nowhere has the debate over the genetics of intelligence been fiercer than in the literature discussing differences in IQ between genders or among races (see, for example, the debate over *The Bell Curve* (by Allen et al. 1996, Devlin et al. 1997b, Fraser 1995, Herrnstein and Murray 1994, McInerney 1996). In those cases where a mean difference in IQ is observed between two groups, it is very difficult to determine the root causes of the IQ difference. One problem is the inherent bias in IQ tests favoring those individuals that come from the same cultural milieu and social class as the scientists that developed the tests (for examples, see Schiff and Lewontin 1986, pp. 21–3). A further problem is that the basis of differences among groups need bear no relationship to the basis of differences within groups. Even if IQ were entirely genetically heritable within groups, IQ differences among them may be entirely cultural or environmental. For example, the difference in average IQ score between a group of children exposed *in utero* to high levels of alcohol and a control group would be primarily environmental in origin (due to alcohol exposure), regardless of the heritability of IQ in either group.

Perhaps the greatest hurdle to understanding the root causes of IQ differences, however, is that it is difficult to eradicate the many socioeconomic differences faced by individuals of different ethniciticies, cultures, or genders. Nevertheless, transracial adoption studies have shown that differences in IQ among racial groups largely disappear when children are adopted into caucasian families, presumably because the children are then reared in 'the culture of the tests' (Weinberg et al. 1992). Furthermore, those programs that have enriched the educational environment of disadvantaged children have had great success in boosting their mean IQ score. For example, Wahlsten (1997) reviews two studies of children from disadvantaged homes with few financial and educational resources; a majority of these children were African American. In the studies, children were randomly assigned to a group receiving no additional educational resources and a second group receiving educational day care prior to public schooling. The average IQ score at four years old was 13.7 and 12.1 points higher in the two studies for the children receiving additional educational resources. Considering the average IQ gap between African Americans and Caucasians in the USA is about 15 points (Devlin et al. 1997b), these studies suggest that most if not all of the differences could be eradicated by providing quality educational opportunities for all children.

5. *Concluding Remarks*

Nearly the entire sequence of the human genome is now available. This genetic database will make it easier to find genes associated with human traits, including aspects of intelligence. It will be essential to remember, however, that genes do not cause intelligence. The developmental process that led to who we are today is a complex one involving the expression and repression of tens of thousands of genes in a manner that both depends on environmental conditions and alters these environmental conditions. The specific form of a gene that may enhance IQ in one family in one set of environments may be irrelevant in other families and in other environments. If future

genetic studies of intelligence are able to identify genes that enhance (or reduce) IQ under certain circumstances, then we may be able to mimic (or counter) the effects of these genes. Attempts to improve the educational and nutritional environments of children are, however, much more promising and immediate. Yet we should remember that linear, one-dimensional scales such as IQ mislead us into thinking that there are better and worse intellects. In reality, human thought is much more complex and multi-dimensional, which we must keep in mind if we are to preserve and encourage the rich intellectual diversity that characterizes human society.

Intelligence: Historical and Conceptual Perspectives

1. *Introduction and Brief History*

The term *intelligence*, as it is used in modern psychology, refers to individual differences in the ability to acquire information, and to use that information to solve new problems. The emphasis on individual differences distinguishes theories of intelligence from theories of cognition. Theories of cognition try to explain how the brain–mind system works in general, while theories of intelligence attempt to explain how people vary in their cognitive ability.

Comments on intelligence have a long history. Homer's *Odyssey* repeatedly refers to the hero's superior thinking. In the 1500s the Spanish philosopher Juan Huarte de San Juan wrote extensively on the difference between people who solve problems through their memory and those who rely on imagination. Huarte also speculated that the differences were due to differences in biological capabilities, but his investigations were restricted by the limited (and often erroneous) biological theories of his time. Truly scientific theories of intelligence had to wait until the nineteenth century, when Francis Galton proposed that individual differences in mental capacity were reflections of individual differences in the efficiency of the central nervous system. This lead Galton to try to develop tests of 'nervous functioning,' such as the speed with which a person could make a motor movement in response to a signal, and then to try to relate performance on these tests to performance in complex activities, such as success in college courses. At the time this effort was not seen as a success, and it was abandoned. Subsequently more sophisticated statistical analyses have shown that this conclusion may be premature. Some of our modern theories of intelligence can be traced to Galton's ideas. Shortly after Galton's proposal Alfred Binet, a French scientist, was asked to develop a test that could be used to identify children who were likely to fail in the French public school system. Binet took a pragmatic approach. He assumed that (a) mental competence grows as a child ages and (b) that children who are ahead or behind normal development at one age are likely to be similarly ahead or behind at a later age. Accordingly, Binet developed an intelligence test that was actually a 'battery' of subtests, in which children were asked to perform a variety of tasks that were 'typical of their age.' For instance, an average four-year-old child was supposed to be able to repeat back three digits: an eight-year-old should repeat back five digits.

The most widely used modern versions of intelligence tests, such as the Stanford–Binet test (derived from Binet's original work by Lewis Terman, a professor at Stanford University) and the Wechsler adult and child intelligence scales, retain Binet's emphasis on a battery of tasks, rather than relying on a single task to measure intelligence. Tests that are used to evaluate candidates for jobs and academic programs also use the battery approach. The Scholastic Assessment Test (SAT), widely used in the USA for college admission, for instance, consists of separate batteries evaluating linguistic and mathematical skills. So does the Armed Services Vocational Aptitude Battery (ASVAB), which is used as a selection device for the United States Armed Services.

There has been concern that tests such as these, which assume that all examinees have had certain experiences, are simply evaluating a person's exposure to different cultures. This is unlikely, at least for the range of countries represented by modern industrialized society, for testing seems to serve the same purpose in European, North American, and industrialized Asian nations. However there have been numerous attempts to develop tests that used the same type of problem (but at different levels of difficulty) rather than to take the test-battery approach. The most successful of these tests require the examinees to find patterns in observations, and especially in geometric patterns.

2. *One Intelligence or Many?*

As different tests were developed a surprising finding emerged. Although tests of vocabulary, paragraph comprehension, arithmetic problem-solving, or pattern recognition involve different processes on their face, in practice there are moderate to high correlations between the various types of tests and subtests. The correlation coefficients, r, usually lie in the range 0.6 to 0.9. This suggests that there is a single individual difference, 'general intelligence,' that determines a person's mental competence almost independently of the way in which that competence is expressed. While this turns out to be a reasonable approximation for

many purposes, research in the 1990s demonstrated a more complex picture. The following facts seem to be a more accurate statement of the situation:

(a) In the range from normal to high mental competence there appear to be three factors of intelligence. One is *Fluid Intelligence* (Gf), which can be thought of as the ability to see new patterns in data and develop new solutions to novel problems. The second is *Crystallized Intelligence* (Gc), which reflects the ability to apply previously learned information to the current problem. The third is *Visual–Spatial Intelligence*, which reflects the ability to manipulate visual images and see visual relationships.

(b) Measures of fluid and crystallized intelligence are correlated (r about 0.6) in most studies, suggesting but not proving that they may be partly a reflection of a general intelligence (*g*) factor. An alternative explanation for the correlation is that the Gc and Gf depend upon different combinations of elementary abilities, such as pattern recognition, short term memory, and ability to maintain attention. At the present time we do not know which of these interpretations is correct.

(c) Visual–spatial reasoning has a much lower correlation with Gc and Gf than the two intelligences have with each other. This indicates that visual—spatial reasoning is a somewhat different ability than intelligence, as indicated by Gc and Gf.

(d) The above remarks apply in the normal–above normal-gifted range. Test scores are much more highly correlated at the lower end of the scale than at the upper end. Put a slightly different way, unusually high scores in one type of test (say, Gc) may be associated with a fairly wide range of scores on a different test (say, Gf). However unusually low scores on one type of test are usually associated with low scores on another type of test. Put somewhat crudely, the case for general intelligence is weak, but the case for general stupidity is strong.

There are a few exceptions to statement (d). Turner's syndrome is a genetic disease that affects women. Turner's syndrome patients have low visual–spatial intelligence test scores, but score in the normal range on tests requiring verbal reasoning. People who have suffered damage to specific areas of the brain may lose mental competence in one area, such as memory, without necessarily losing competence in other areas. (People who suffer widespread brain damage, not surprisingly, show widespread deterioration of functioning.) These exceptions aside, statements (a) to (d) above are a reasonable summary of the distributions of test scores in normal populations.

3. *Do Test Scores Matter?*

A person's score on an intelligence or aptitude test is of little difference in itself. It becomes interesting only if test scores predict performance in some socially important arena, such as schools or the workplace. There has been considerable controversy over whether the tests (a) predict nothing at all, (b) predict performance in academic settings only, or (c) predict performance in both academic and workplace settings. The facts are fairly well known. The disagreement is over what to make of them.

In university settings the correlation between test scores and grades is in the range 0.3 to 0.4. The correlations are somewhat higher for students going through technical training, such as Armed Services technical training schools, at least partly because these students represent a wider range of abilities than university students. These correlations do not allow for the fact that performance scores can only be obtained for those people who have a high enough test score to be enrolled or employed in the first place. When statistical adjustments are made to allow for this selection effect the correlation rises to about 0.5. Moving outside of academics, similar scores are obtained in industrial settings. For instance, one study found a correlation of 0.38 between scores on an SAT-type test given to management trainees and the level of management position that the trainees achieved 20 years later. Similar correlations have been observed in many studies relating test scores to industrial performance, although the range of obtained correlations is generally higher in industrial than academic studies. This may be because it is difficult to obtain accurate measures of personal performance in many industrial settings.

Mathematically, a correlation of 0.35 indicates that about 10 percent in the variance of one score is predictable from knowledge of another. In this case, it means that 10 percent of the variance of academic or industrial performance would be predictable from knowledge of a cognitive test score. The higher 0.5 estimate raises the variance effect to 25 percent. Both of these values are some distance from perfect prediction. However, 'variance' is a statistical term whose meaning does not easily translate into the everyday concept of 'variation.'

There are three other ways of looking at the situation. One is to consider what sorts of correlations are typically found between different aspects of human variation. For instance, the correlation between adult height and weight (within sexes) is about 0.5, not far from the estimated population value for test-performance relations.

A second way to look at the issue is to ask whether there are alternative predictors that do as well as tests of cognitive competence. The evidence here is striking. The typical personality test has a correlation of about 0.20 with indices of workplace performance, just slightly more than one-half of the value for a cognitive test. However, it is important to note that the personality and cognitive tests appear to predict different aspects of workplace performance, for prediction from a combination of cognitive and personality tests is

higher than the prediction from a cognitive test alone. If just one measure of prediction of performance is to be used, a cognitive test will be a better predictor than a personality test. However, the ideal selection system would use both types of predictor.

A third way to try to evaluate the importance of intelligence is to ask how much workplace or academic performance is improved by using a test as a screening device. The answer to this question depends upon the correlation between test scores and performance and the extent to which the academic or workplace institution can select candidates. If all applicants are to be accepted, then there is no point in using any test. On the other hand, if only 10 percent of the applicants are to be accepted, then a test that has a correlation of 0.3 with performance can be used to select a workforce (or student body) that, on the average, will outperform an unselected group by more than 150 percent. This shows that the use of cognitive tests for selection is most justified when (a) the selection is rigorous and (b) there is a substantial difference between the benefits of good and poor performance.

Finally, there are interesting observations about the distributions of test scores in the population. It is well established that people who have high test scores as adolescents or young adults will, on average, tend to get better jobs and do better economically. It is even true that people with high test scores tend to live longer than those with low test scores! However, it is very difficult to establish cause and effect from such studies, because education, health, and economic success are themselves positively correlated.

4. *What Causes Intelligence?*

When we ask 'what causes intelligence?' it is important to distinguish between two different ways that this question can be asked. At the individual level, we can ask what characteristics of a person cause them to be or not to be intelligent. At the population level, we can ask what measurable demographic variables are associated with intelligent performance. We look first at the individual level and then the population level.

4.1 *The Individual Level*

At the individual level, it becomes important to distinguish between physical and social causes of cognitive competence, and between fluid and crystallized intelligence (Gc and Gf). People who perform well on tests of fluid intelligence and reasoning are, to a very large extent, people who are adept at keeping track of several things at once, and who can manage fairly large amounts of information. This ability is known as an ability to manage 'working memory' for information relevant to the problem currently being worked on. It is contrasted with 'long-term memory,' which refers to memory for information about how the world works and information about biographic events that happened some time ago. Working memory, in turn, appears to be related to the functioning of the frontal and prefrontal areas of the brain. There is now a good deal of evidence suggesting (but not yet proving) that individual differences in the ability to activate information in these areas of the brain is related to scores on tests of fluid intelligence. Just what these relations are, and how they relate to individual differences in neural functioning in other parts of the brain, is an important topic in research on intelligence. While individual differences in fluid intelligence are related to individual differences in brain functioning, it is important not to exaggerate the relationship. Statistical analyses suggest that individual differences in brain functioning can account for only a part of the wide individual differences in the ability to deal with 'new and unusual problems,' that is, fluid intelligence. By default, the remaining influences must be social (e.g., education, early training that might set a particular style for problem solving), but as of this article psychologists have been unable to determine what these environmental influences are.

The situation is quite different for tests of crystallized intelligence, that is, the ability to recognize and apply previously acquired solutions to new situations. In part this ability appears to depend upon generalized pattern-recognition abilities in the brain. However, it is also extremely responsive to education and training. This is seen most clearly by studies of *expertise*, individual differences in solving problems within a particular domain. Study after study has shown that specialized problem-solving depends upon the acquisition of schematic forms of reasoning appropriate to the domain at hand. Furthermore, these schema are very largely acquired by extensive practice. This has been shown in domains as far apart as chess, physics, and economics. Fluid intelligence appears to be one determinant of how efficiently information can be acquired during the schema-acquisition period. (This may partially account for the correlation between measures of fluid and crystallized intelligence.) However, knowledge builds on knowledge, so soon the expert has an advantage over the novice in learning how to learn within a particular field. Whether or not there is a generalized ability to learn to learn, regardless of the field being studied, is an open question. If there is, this ability is probably quite closely related to fluid intelligence.

As would be expected, any influence that causes a deterioration of brain structure is likely to have a deleterious effect on intelligence. In modern industrialized society alcoholism is undoubtedly the biggest single effect; repeated studies have shown a negative correlation between excessive alcohol use and intelligence test performance. Once again, whether or not this is causal is hard to determine, as excessive alcohol use could either produce or be produced by

low intelligence. However, the effect can be transgenerational. A major cause of mild mental retardation in children is excessive alcohol use by the mother during pregnancy. Other negative influences on intelligence include prolonged malnutrition (primarily in the developing nations) and exposure to atmospheric lead.

Aging has a paradoxical effect on intelligence. Fluid intelligence test scores drop. This is not surprising, as there is considerable evidence for an age-related drop in performance in tasks involving working memory. However there are very large individual differences in the extent of the drop. If we compare the fluid intelligence test scores of otherwise comparable individuals in their 20s and 60s we find that the top scores of the older group are only slightly below the top scores of the younger examinees, but the lowest scores in the older group are considerably below the lowest scores in the younger examinees.

Crystallized intelligence, in the sense of scores on such things as vocabulary and knowledge tests, may rise slightly during the adult working years, and declines only slowly until people reach their 70s or beyond. Because we live in a specialized society this may actually underestimate the abilities of older people. People become quite competent in those things that they practice, so during their working years people may become 'cognitive specialists' in the tasks that they encounter every day. Perhaps for this reason, general cognitive tests, such as the Department of Labor's General Aptitude Test Battery (GATB), seem to underestimate the out-of-laboratory performance of older workers. Of course, these statements apply only so long as the workplace and social environments remain the same.

4.2 Population Level Variables

Another way to answer the question 'what causes intelligence?' is to look at the correlations between intelligence test scores and various other measures of individual differences. This sort of analysis can be quite informative, although it only indirectly provides an indication of the mechanisms that produce cognitive competence at an individual level.

One of the oldest questions in the study of intelligence is whether intelligence is inherited or acquired through experience. The answer, not surprisingly, is that it is partly inherited and partly acquired. Very many studies have been conducted in an attempt to estimate the percentage of variance in a population that is due to genetics. This is called the *heritability coefficient*. Conceptually, the clearest experiment is to examine the correlation between monozygotic (MZ) 'identical' twins raised apart to the correlation between MZ twins raised together. Such situations are rare but they do occur, usually in cases of adoption immediately after birth. Correlations as high as 0.8 have been reported between MZ twins raised apart. By contrast, the test scores of dizygotic (DZ) 'nonidentical' twins raised apart is usually in the range 0.4 to 0.5. If one believed that the environments for each of the adoptees were chosen randomly this data is consistent with a heritability coefficient of 0.8. However there are a variety of reasons to believe that these correlations are inflated to some unknown degree by common environmental factors (e.g., sharing a common uterine environment prior to birth). Other studies of correlations between family members of varying degrees of relation (e.g., parent–child, siblings, grandparent–grandchild), using statistical techniques too complicated to be easily explained, have lead geneticists to conclude that the heritability coefficient is somewhere in the range 0.4 to 0.6. It is important to realize that this value applies to a modern industrialized society, where the difference between the well-to-do and the poor in terms of nutrition, disease, and schooling are not large. In a society in which there were very wide differences in living conditions and educational opportunity we would expect environmental effects on intelligence to be large, and hence the heritability coefficient would decrease.

Notwithstanding these qualifications, one fact is clear. Within the range of environments found in a modern postindustrialized or industrialized society, the single most important influence on intelligence is heritability. It accounts for slightly over one-half of the variance in intelligence test scores, on a population basis. This does not mean that you can say that one-half of an individual's mental competence is due to genetics: the variance referred to applies only to the population as a whole. Given advances in understanding the human genome it may be possible, in the future, to associate specific genes with intelligence. When this is done it will be possible to discuss genetic effects on an individual basis. As of the year 2001, such research was in its infancy.

What in the environment determines intelligence? Three effects have been noted. One is schooling: people who receive formal instruction (and especially people who are literate and read a good deal) do better on intelligence tests. Another is the physical environment: certain diseases, environmental hazards, and pathogens can cause reductions in intelligence. The most notable are alcoholism, exposure to atmospheric lead, and any disease or physical insult that harms the brain. The last influence is not inevitable. Some brain injuries lead to a drop in intelligence, others do not.

A third, and particularly puzzling, environmental influence is the 'cohort effect' phenomenon. In industrialized nations the population average on intelligence tests rose throughout the twentieth century. (We do not have comprehensive data for nonindustrialized nations.) The rise was particularly marked at the low end: on a percentage basis there are fewer people with very low scores (IQ below 80) than there used to be. The cause for this rise is unknown. However, it is

clearly an environmental effect, for the change is far too rapid to be due to genetic changes. Understanding genome patterns for intelligence (see above) and understanding the reason for the cohort effect are perhaps the most interesting questions in research on intelligence as we progress through the twenty-first century.

5. *Who Has Intelligence? Demographic Variables*

The question of whether or not different demographic groups differ in intelligence is one of the most hotly debated, socially contentious issues in the social sciences. It turns out that the facts are relatively clear. The reasons for those facts, however, are far from clear.

Male–female differences present a fairly straightforward case. While absolute equality cannot be proven, there are no marked differences between men and women in either fluid or crystallized intelligence. It is possible that women exhibit a slight advantage on some verbal tasks, but the size of the effect is not large. Men, on average, do considerably better than women on visual–spatial reasoning tasks that involve visualization or perceptual judgments of motion. This is important, because such judgments are required in tasks that involve spatial orientation, such as walking around a building and then trying to imagine what it would look like from above. The difference between population means on such tasks is about 0.5 standard deviation units. In less statistical terms this means that about 70 percent of the male population scores above the median score for the female population. Because visual–spatial reasoning has been shown to be correlated with achievement in mathematics, it has been suggested that the female difference in visual–spatial reasoning is one of the reasons that women are not proportionately represented in jobs that depend on mathematical reasoning. While this is a reasonable conjecture, with some evidence to support it, social factors are also responsible for this difference in occupational achievement.

There are racial and ethnic differences in intelligence test scores. This statement is largely based on studies in the USA, although a few studies from Europe (where there is less ethnic diversity) show generally the same pattern. In tests carried out in the late 1990s, 'African-Americans' scored about 0.8 standard deviation units below the 'White' mean (and it should be noted that this latter social category includes many disparate groups), while 'Asian-Americans' scored approximately 0.3 units above the 'White' mean. People identified as 'Hispanic-Americans' (who may be of any race) scored between the 'African-American' and 'White' mean, and there were differences between particular groups of 'Hispanic-Americans'. Furthermore, there was no evidence that the tests were unfair to particular groups, in the sense that the tests predicted performance more accurately in one group than another. The correlations between test scores and academic or job performance (and other relevant statistics) were substantially the same across all groups. This indicates that the cognitive skills that are (a) tapped by the test and (b) required in academics and the workplace are not equally distributed across racial and ethnic groups in the USA.

These statistics do not provide a reason for the differences. Environmental effects are clearly involved, for greater opportunity for social equality has been accompanied by a lessening of the difference between groups. For instance, the 'African-American' vs. 'White' difference was about 1.2 standard deviation units prior to the end of legal segregation and separate, usually inferior, educational opportunities for African-Americans. This clearly indicates a social influence. However the rate at which the gap is closing has slowed since about 1980. This and other evidence has led some individuals to claim that ethnic differences are partly due to genetic differences between groups. The claim has been strongly challenged by other researchers. The controversy is impossible to resolve at this time, largely because genetic differences between ethnic groups are confounded with social differences in economic status, living conditions, family structures, and a host of other environmental variables. To make the situation even more confusing, it is logically possible that differences between groups A and B are genetic, while the differences between A and C are environmental. Perhaps some day advances in molecular biology will make it possible to trace genetic influences on intelligence at the single-gene level. It is also possible that in the future a better understanding will be obtained of the way special environmental factors, such as childrearing practices or schooling, influence intelligence. Until this research is done any causal 'explanation' of racial and ethnic differences in cognitive competence will be highly speculative.

6. *Final Comment*

A century of modern research on intelligence has led to a great many interesting conclusions. Perhaps the most important is that individual differences in cognitive competence are the best single predictors of success in industrialized and information-age societies. This does not mean that intelligence is the *only* thing that is important, but it does mean that it is important. The changes in population levels of intelligence throughout the twentieth century are not yet understood. When they are, though, they may well lead to ways of improving human cognitive potential in the twenty-first century.

Intelligence: History of the Concept

The direct antecedents of the word 'intelligence' lie in the Latin '*intelligentia*' or '*intellegentia*' meaning 'the action or faculty of understanding,' itself derived from the Latin '*intellegere*' meaning 'to understand.' As one of the traditional divisions of the human soul (along with the emotions and the will), intelligence was a concept that had long been of importance to Western philosophers and theologians, especially in their attempts to differentiate human beings from other species in the animal world. Nonetheless, until the eighteenth century, it was not a word that piqued much general interest on either side of the Atlantic. Intelligence began to attract attention in the West as growing curiosity about the nature of human differences meshed with the turn to scientific methods as a privileged form of explanation. This essay will explore some of that history and suggest how the development of the concept was intimately related to the particular cultural circumstances in which it was formulated and used.

1. Species, Groups, and Intelligence

Although human nature had become a topic of hot concern in the eighteenth century, of relevance not only to the emerging human sciences but also to many of the most important developments in political philosophy as well, this did not at first spur much interest in intelligence. Rather, the focus tended to be on other concepts, on 'faculties,' 'talents,' 'sensations,' and, most especially, 'reason' and 'virtue.' While it is clear that there was widespread agreement that human beings differed in their mental powers, the origin, significance, and even the sheer number of those differences were all issues that elicited either a multitude of opinions, or no particular view whatsoever. In general, single all-encompassing approaches to understanding mental capacity, such as 'intelligence,' tended to be used only in limited and very particular contexts.

Intelligence began to become an object of direct scientific investigation toward the end of the eighteenth century, when such naturalists as Linnaeus, Buffon, and Blumenbach developed taxonomic schemes that compared human beings systematically with the rest of the animal kingdom, often focusing in part on differences in overall levels of mental ability. The Dutch anatomist and artist Peter Camper, for example, proposed in the 1760s that a scale of intelligence across the animal kingdom could be erected on the basis of a particular physiological feature, the facial angle, which first allowed intelligence to be converted into a type of measurable characteristic, though one operating primarily at the level of species or groups. Over the next century and a half, a number of other physical features were also evaluated as stand-ins for direct determinations of degree of intelligence, with most physical anthropologists according particular significance to cranial capacity and brain weight. Elaborate programs of measuring hundreds of skulls were carried out throughout Europe and the United States, with the results frequently used to provide scientific sanction for common beliefs about the intellectual inferiority of certain groups, most especially Africans and women, on the basis of the greater proximity of their mean skull or brain sizes to those for the non-human primates. As more data were collected, however, extreme variations were found both within and between groups, rendering group-level rankings in the eyes of many largely meaningless. At the same time, the efforts of women in feminist movements and blacks in anti-slavery campaigns produced powerful denunciations of the entire project of creating hierarchies of intelligence based on physical characteristics.

At the level of individuals, until the latter part of the nineteenth century intelligence as a personal characteristic distinguishing one individual from another generated little systematic interest, save for medical concern with diagnosing the profoundly mentally deficient. Mental philosophy and the emerging discipline of 'scientific' psychology were preoccupied with the universal characteristics of human reason and, in the case of psychology, with the process of subjecting mental features to new laboratory techniques being imported from physiology. As the evolutionary theories of Charles Darwin and Herbert Spencer became more broadly accepted, however, interest grew in the overall mental power of an organism, because it was deemed to be a critical characteristic shaping the organism's adaptation to its environment. Greater pressure to understand the nature of individual differences was also developing as the result of a number of institutional and social changes occurring throughout the West. The spread of universal primary education, the increase in urban concentrations of workers, and

the expansion of factory methods of production, along with the rapid growth in asylums for the mentally deficient, all provided many more opportunities to engage in systematic comparisons at an individual level, and thus helped to make intellectual differences much more visible and socially meaningful.

2. Intelligence and Its Tests

During the late nineteenth century, a number of investigators began to explore the meaning of individual differences, including those associated with overall level of intelligence. In England, Francis Galton carried out an extensive program of quantifying human mental and physical characteristics (anthropometrics) toward the goal of identifying superior members of the human stock. His *Hereditary Genius* ([1869], 1972) argued that innate differences in overall superiority existed within human groups, that those differences were mental in origin, and that they were inheritable. Galton's work helped to initiate widespread enthusiasm for anthropometry, one that persisted until the end of the nineteenth century. It was also a basis for his promulgation of the science of eugenics, which conceived of human progress in biological terms and advocated improvement in the quality of the breeding stock through encouraging marriages and child bearing among the most 'fit' (i.e., most intelligent) and restricting them among the least.

On the other side of the English Channel, psychologist Alfred Binet, one of the pioneers in the development of *psychologie individuelle* in France, conducted a wide range of investigations at the turn of the twentieth century into the nature of human mental ability. As one of these projects, in collaboration with Théodore Simon, Binet developed the initial version of what would become the first successful individual intelligence assessment instrument, the Binet–Simon Intelligence Scale (1905), a group of age-related tasks whose purpose was to reveal whether an examinee's overall intelligence was developing at a 'normal' rate. The measuring aspect of the scale was enhanced following its 1908 and 1911 revisions, when results from the testing were reported in terms of mental age (MA), which facilitated conceiving of intelligence as a physical and quantifiable object.

Binet's death soon after the publication of the 1911 scale robbed the Binet–Simon of its most effective champion in France and interest in intelligence testing there soon waned. Such was not the case elsewhere in the West, however, most especially in the United States. With the help of American psychologist Henry Herbert Goddard, who introduced the 1908 version of the scale to his fellow US psychologists in 1910, the Binet–Simon was adopted with enthusiasm. Rival versions of the test were soon produced in great numbers and a vogue for testing developed that never completely vanished.

Stanford University psychologist Lewis M. Terman's 1916 revision of the scale, his Stanford–Binet (Terman 1916), did much to cement the place of intelligence testing within the American intellectual and cultural landscape. Thoroughly overhauled for an American population, the Stanford–Binet provided clearer age demarcations and popularized a new way of quantifying mental ability, the Intelligence Quotient (IQ), a ratio of mental age to chronological age (times 100) designed to remain constant over time. Terman celebrated this feature of IQ, argued that it provided a measure of an individual's innate mental ability and suggested that a range of social decisions, including the nature of the occupation an individual should take up and whether or not he/she should be institutionalized, could be made on the basis of this number.

While not every mental tester was as certain about the implications of IQ as Terman, during the 1920s use of intelligence tests in a variety of contexts spread widely, facilitated by the creation of a group mental test for the World War I war effort that allowed 1.75 million US army recruits to be assessed without needing the time-consuming one-on-one methods of the Stanford–Binet. Terman's individual scale, revised in 1937 and 1960, however, remained the gold standard for measurements of intelligence, though its preeminence began to be challenged starting in the 1940s with the creation by David Wechsler of the Wechsler Intelligence Scale for Children (WISC) and the Wechsler Adult Intelligence Scale (WAIS), instruments that generate assessments of verbal and nonverbal intelligence as well as an IQ.

3. The Nature of Intelligence

Concomitant with the rise of intelligence testing came a series of debates over the characteristics of the object being measured. In 1904, British psychologist Charles Spearman used early test data to argue for the unitary nature of intelligence, explaining performance on mental tests in terms of general intelligence (*g*) and specific abilities (*s*). While numerous researchers—including Karl Pearson, Goddard, and Terman—accepted his analysis, others were skeptical, insisting instead that intelligence was composed of a number of primary independent abilities. Edward L. Thorndike in the United States was among the first to articulate this position, and he was soon joined during the 1920s by two statistically sophisticated psychologists, L. L. Thurstone in the US and Godfrey Thomson in the UK. In the period after World War II, psychologists continued to put forward a range of interpretations of the composition of intelligence: while Hans Eysenk remained convinced of the reality of *g*, for example, Philip E. Vernon proposed a hierarchical model of intelligence that inter-linked specific skills, general abilities, and overall intelligence, and Joy P. Guilford contended that intelligence was composed of as many as 150 independent factors. Later influential additions

to these models included Howard Gardner's theory of the existence of seven discrete types of intelligence and Robert J. Sternberg's triarchic conception of intelligence.

Overshadowing all of the arguments over intelligence, however, has undoubtedly been the nature–nurture question. Figures such as Galton, Spearman, Pearson, and Terman argued early in the twentieth century strenuously for the nature position, with Galton producing studies on identical twins that have served as a model for investigations into the relative weights of heredity and environment. During the 1900s to 1930s, when eugenics was at the apex of its popularity, arguments in favor of intelligence as an inheritable biological entity ran strong and were used to justify calls for immigration restriction and for the sterilization of the mentally 'unfit,' as well as for the creation of multi-tracked secondary schools. At the same time, however, anthropologists were beginning to put renewed emphasis on culture as the primary determinant of human behavior, claims strengthened during the middle of the twentieth century by studies carried out especially at the Iowa Child Welfare Research Station, where IQ was found to change depending on nutrition and educational environment. The post-war period continued to see the debate pressed from both sides, with increasingly sophisticated twin studies showing high IQ correlations between identical twins separated at birth, while at the same time other researchers were teasing out ever more complicated connections between intelligence development and such factors as nutrition, family child-rearing practices, socio-economic status, and quality of education received.

While few experts would deny the influence of both genes and environment, the vociferous debate in the mid-1990s over *The Bell Curve* (Herrnstein and Murray 1994), with its claims that IQ is hereditary and a prime determinant of an individual's future, indicates that broad disagreements persist about intelligence and show little likelihood of quick resolution. What they reveal as well is that the language of native intelligence has remained a powerful vehicle for discussions of a range of social issues, from the organization of the educational system to the value of affirmative action programs to the just allocation of social resources.

Intelligence: Organizational

For Weber (1978) and his heirs the intelligent organization was a bureaucratic organization. The files served as the repository of knowledge. Intelligence resided in the institutionalization of routines (see *Organization: Overview*; *Bureaucracy and Bureaucratization*). Later it became seen as functionally specific to positions at the apex of the organization or in the technostructure. Today, it is necessary to rethink the concept in terms of virtuality and knowledge management.

1. Organizational Intelligence as a Historically Situated Term

Organizational intelligence—defined as the questions, insights, hypotheses, evidence that were relevant to policy—enters organizations through their strategic apex as clear, timely, reliable, adequate, and wide-ranging strategic information that informed embedded organizational routines. Wilensky (1967), from whom this definition is taken, regarded organizational intelligence as a variable that was directly dependent upon the degree to which there was, organizationally:

(a) Conflict or competition in relation to the external environment—typically related to the extent of involvement and dependence on government (see *Conflict: Organizational*);

(b) Internal support and unity;

(c) A belief in the rationalization of internal operations and external environment; and

(d) A contingent development of size and structure, goal and member heterogeneity, and the centralization of authority (structural contingency).

Wilensky's (1967) view was that the more organizations were developed in these terms the greater would be the need for and existence of organizational intelligence, embodied in specific types of functions, such as 'contact men,' 'internal communications specialists,' and 'facts-and-figures men.' His views were very much informed by the experiences of the military, defense, and intelligence agencies of the US in the Second World War and Cold War eras. In particular, he was concerned with the way that organization routines, embedded in discursive patterns, would often dictate policy long after it should have been evident that it was failing. He found examples in both the British and US strategic bomber commands of the Second World War as well as in the Vietnam War that raged at the time that he was writing. Were he writing more recently, he would, no doubt, have had something similar to say about the NATO offensive against Serbia that occurred in 1999. Organizational routines and discursive patterns can often mean that even where strategic intelligence is available it may be unattended to or, if it is, not understood. Thus, organizational intelligence involves more than merely information: it involves also its application, even against discursively established routines. Organizational intelligence marks the ease with which such routines are abandoned.

2. *Contemporary Views of Organizational Intelligence*

Wilensky's (1967) view of organizational intelligence was informed largely by big, US military-industrial complex organizations. The picture changed dramatically during the 1980s, as learning from Japan became the watchword. Japanese organizations were still bureaucracies—but learning bureaucracies. What they were oriented to learning was continuous improvement of quality—and it was this that became seen as the nub of their specific organizational intelligence—learning not only to do existing things better but also to be better at innovation. The key involved unlocking total organizational intelligence rather than refining strategic intelligence (see *Innovation: Organizational*). Thus, the metaphors of intelligence shifted from defense to commerce (see *Organizations, Metaphors and Paradigms in*).

Using smart machines and robots for more routine work, Japanese manufacturers tried to create smarter workers for better products (see *Technology and Organization*). Organizations sought to develop relational contracts based on similar philosophies of continuous improvement as were applied in manufacturing (see *Alliances and Joint Ventures: Organizational*). Intensified global competition and the development of new digital technologies became the drivers that saw the lessons from Japan become widely distributed in existing industry, especially in the United States and Europe, by the end of the 1980s. The knowledge based information economy had arrived in which creativity, intelligence, and ideas were the core capability for sustainable success.

New information and communication technologies are crucial to such innovation processes, helping to globalize production and speed up the diffusion of technology. Information technology and globalization are transforming organizational concepts of time and space. The convergence of computing power and telecommunications reach is providing new technological and information resources in a global, digital world. As Hamel and Prahalad (1994) insisted, against Wilensky's (1967) view of entrenched structures, size, and centralization as strategic assets, such assets become liabilities when organization competitiveness is based on radical, nonincremental innovation (see *Strategy: Organizational*).

3. *Intelligent Information*

The development of information and communication technologies not only provides the means to process and transmit vast amounts of information but also determines the shape of organizational intelligence. If information and knowledge is to be used productively and intelligently by organizations then organizational intelligence rapidly translates into knowledge management rather than contacts, internal communications, and facts-and-figures (Wilensky 1967). Too much information is too easily available so that the key issue is not gaining information but being able to manage available knowledge.

Increasingly, knowledge and information is created and used as binary digits and transported electronically, rather than in physical forms. Ultimately, digitalization creates new structures of electronically networked organizations, replacing both individual market-based relations as well as bureaucratic structures whose resource base, in terms of size, comprises their chief strategic asset. Galbraith (1967), writing in the same year as Wilensky, although he did not foresee a digital economy, was one of the first to recognize how profound the organizational implications of the knowledge economy were in his prophetic statement of the arrival of the technocracy in *The New Industrial State*:

> With the rise of the modern corporation…the guiding intelligence…(passes to)…a collective and imperfectly de-

> fined entity…(that)…embraces all who bring a specialized knowledge, talent, or experience to group decision-making. I propose to call this organization the Technostructure (1985).

The new digital technostructure allows knowledge to be developed more readily as well as to be stored, accessed, and distributed more easily, thereby simplifying organizational transactions and allowing them to be conducted remotely. Hierarchical and centralized organizations of functional specialists applying standard procedures give way to flatter, more decentralized firms with flexible arrangements by professionals who rely on real-time information, catering for specific markets or customers.

Information technology is central to each stage of this transformation, potentially enabling global coordination of enterprise networks, distributed processing, portable work, and constant access.

Enthusiasm for information technology led to a fragmentation of technologies and approaches in many organizations around local networks. Incompatibility of software, computers, and systems undermined networking capability, provoking a determined search for open systems interconnection. Integration became the driving force as organizations attempted to coordinate all operations. Constantly improving information technology promotes changing conceptions of the role of information systems. What was originally an impenetrable device of limited utility has become the main strategic resource upon which operations and strategy are founded. It is the core of contemporary organizational intelligence.

Organization intelligence involving distributed knowledge, technology, and networks focuses attention on management control. Contemporary organizations create a growing variety of linkages along the value chain by developing extensive electronic and contractual relationships with networks of suppliers, customers, and partners. The intelligence created in these systems 'is not simply about the networking of technology but about the networking of humans through technology…not just…linking computers but…internetworking human ingenuity' (Tapscott 1996).

How is 'intelligence' to be exercised in line with managerial objectives in networks? Increasingly, the rules of organization bureaucracy give way to the patterning and design of organization culture. Unlike routines produced according to formal rule, there is more scope to innovate and establish experimentation around norms. The interaction of members in a group makes it possible to exchange information on successful practices. Under these conditions groups formulate similar patterns of perception, similar interpretations of some subjects, and similar evaluation of alternatives. There is an adaptation function whereby groups arrive at successful results to satisfy their needs. By following the norms of the group, people gain acceptance from the group. Acceptance by a group signifies affiliation or cohesiveness. From the organizational viewpoint, culture aids adaptation to the environment. 'Quality first' is an example. If members accept such a slogan and internalize it, it can become a pattern for decision-making. This is not to suggest a culture dreamscape where resistance and conflict have been eliminated in favor of boundless creativity. Such a picture rarely corresponds with empirical evidence (DeCieri et al. 1991). Instead, it suggests a world in which obsessive self-surveillance becomes the norm—a neurosis at the core of organizational intelligence in a digital world.

Information technology is used extensively to make performance and quality standards visible and accountable to employees in organizations. For instance, large-scale video screens can express quality-related information in a simple code that all can understand, alerting people to their degree of success in meeting standards. Two aspects of this are important. First, everyone's intelligence is enrolled to organizational effect through their becoming a constantly self-regarding subject. It is not only others who will hold one accountable—such as bosses and colleagues—but also one must hold one's self-accountable. The fact that others are able to see, transparently, what one is accountable for, helps focus one's energies on this enormously. One becomes a specialist in self-regarding behavior that helps to ensure that the need for external surveillance and exercise of power is minimized as the functions of control become internalized in oneself as a neurotically normal organism.

Second, this modeling of organizational intelligence in terms of individually reflexive self-control breaks down both collective strength and enhances individual isolation. The union function of articulating plural and countervailing power in the workplace becomes less relevant when, formally, unions either directly (as in Japan) or indirectly through their members are involved in the quality processes that define organizational intelligence. Where everyone is assumed to have an interest in quality to oppose it can be seen only as bloody-mindedly against the interests of employees whose jobs depend on continually improving quality—including oneself. Here is another significant discontinuity with Wilensky: organization intelligence becomes embodied in everyone, not just the 'contact men,' 'internal communications specialists,' and 'facts-and-figures men.' In these new forms of organization, structure loses its historic role of managing power relations at a distance. For one thing, distance disappears electronically; for another, power relations flatten as teams proliferate, work becomes a series of projects, and the supervisory gaze is both internalized and becomes part of peer pressure.

Davidow and Malone (1992) identified *The Virtual Corporation* as a distinctive model premised on new technologies making old assumptions irrelevant. Organization design becomes virtual, enabling time and space to be collapsed and the informational

Table 1
Modern and virtual organization compared on Weber's criteria

Modern Organization	Virtual Organization
Functionality in design structure	Defunctionalized project-based design held together by network capabilities
Hierarchy governing formal communication flows and managerial imperative the major form and basis of formal communication	Instantaneous remote computer communication for primary interaction; increase in face-to-face informal interaction; decrease in imperative actions and increased governance through accountability in terms of parameters rather than instructions or rules
The files	Flexible electronic immediacy through IT
Impersonal roles	Networking of people from different organizations such that their sense of formal organizational roles blurs
Specialized technical training for specific careers	Global, cross-organizational computer-mediated projects

Source: Nohria and Berkely, 1995

controls inscribed in bureaucracy which sought to manage across them, superseded.

> [T]he file cabinets of bureaucratic ritual disappear, replaced by devices that shatter the traditional physical instantiation of information and knowledge … When employees … use electronic mail or build reports from network databases, there is no original physical reality to which this information refers (Nohria and Berkely 1994).

Some find the virtual organization an attractive, if challenging, prospect, because it will have no '(P)re-established boundaries, and it will be conspicuous by the absence of hierarchy. It will be completely horizontally structured and geographically distributed organization … (with) … small cluster groups that are distributed throughout the world in network-intensive, computer mediated, interactive environments' (Estabrooks 1995).

Others are less sure that intelligent technologies necessarily make organizational intelligence. Groth (1999) presents a less sanguine, and probably more accurate, perception of the human emotional and organizational implications of information technology in which there is a continual acceleration in the rate of obsolescence of organizations' and individuals' knowledge base and skills—their intelligence. To counter this would require provision for the continual upgrading of skills and life-long learning: whether states or organizations will deliver this or whether it is left to markets, will be a core issue of future organizational intelligence.

The virtual organization is almost the exact opposite of the modern organizations that Weber (1978) first identified (see Table 1 in which we contrast Weber's modern organization with its 'virtual' counterpoint).

Virtual organizations are invariably networked organizations (see *Network Analysis*; *Interorganizational Relationships and Networks*). Networks may be characterized in terms of the strength or intensity of linkages, as well as the symmetricality, reciprocity, and multiplexity of their flows. The strength of a network linkage depends on the extent to which it is an 'obligatory passage point' in the network: can information flow elsewhere or must it route that way? The greater the amount of information, affect, or resources flowing through the passage point, then the more powerful will be those whose knowledge decodes it (Roberts and Grabowski 1996, Clegg 1989). The relations of different knowledge around these obligatory passage points embodied in different people, may be more or less symmetrical, that is, some will be more or less dependent or independent within the flow of relations. Reciprocity refers to the degree of mutual or nonreciprocal obligation that occurs in the relationship. Multiplexity refers to the degree to which those who relate to one another do so more or less exclusively. Finally, the content of the linkages is important, in terms of its degree of 'classification' and 'framing': how strongly or loosely framed or bounded it is, and how tightly or loosely coded is its classification. These notions of classification and frame serve to replace the earlier emphasis that Wilensky (1967) placed on variables of organizational structure and resources as key variables in the understanding of organizational intelligence.

4. *The Recursive Nature of Organizational Intelligence*

One hallmark of organizational intelligence is its fundamentally recursive character: learning transforms the existing stock of organizational know-how contained in existing normative routines and competencies. Within such a framework 'learning is no longer … objectified in norms, procedures, routines

and standards. Rather it is the cognitive activity which produces images, representations, causal links, and which is sensitive not only to human passions but to the social and organizational conditioning of thought as well' (Gherardi 1997) (see *Learning: Organizational*).

Organization learning occurs as a result of individuals learning becoming institutionally embedded in organizational ways of doing things. Where it is not, then learning will remain at the individual level. For organization learning to occur there has to be a culture that is conducive as well as management devoted to intelligence gathering, as Wilensky stressed. Many traditional tasks of management are now undertaken by computer-based technologies: managers thus must possess diagnostic, interpersonal, creative, and systems-thinking skills rather than be fact-finders. Management needs to enact interpretation, particularly where radical technological innovation creatively destroy or reduce existing competencies. Increasingly, such managers will seek to practice exploratory learning to increase organizational intelligence.

Exploratory learning is associated with complex search, basic research, innovation, variation, risk-taking, and relaxed controls. The stress is on flexibility, investments in learning, and the creation of new capabilities. Exploratory learning characterizes more intelligent organization, where radical innovation, rather than refining what already exists, produces creative discontinuities. Levinthal and March (1993) propose that the survival of any organization depends upon being sufficiently exploitative of what it already knows as to insure current viability and sufficiently exploratory as to insure its future viability. Too much exploitation risks organizational survival by creating a 'competency trap,' where increasingly obsolescent capabilities continue to be elaborated. Too much exploration insufficiently linked to exploitation leads to 'too many undeveloped ideas and too little distinctive competence.'

The digital interlinking of organizations allows for learning to be distributed globally, immediately, virtually, if the intelligence acquired in one location is potentially portable to others. To do this, breakthroughs must be standardized and exploited. Standardized information is a commodity. By making tacit knowledge a commodity the dependence of exploratory insights on the individuals who produce it is eliminated. Where management can reduce individual dependency by rendering knowledge into artifacts it is possible to manipulate and combine knowledge with other factors of production in ways that are impossible if it remains a human possession. Abstract properties need to be developed for the phenomena to become a standardized commodity—so that it becomes alienable, like a property title—entailing a shift from knowledge-workers to knowledge as a pure factor of production, usually embodied in systems and software.

It is easy to transmit exploratory learning embedded in innovation throughout the world when it is embedded in a systems and software. But these may not capture the embedded tacit knowledge involved in making exploratory innovation work. A solution is at hand: work processes can be videotaped, scanned on to computer, and downloaded instantly by the globally networked organization, thus disseminating it globally, instantly, to individual desktops and workstations. Thus, we are all potential 'contact-men' now and anyone connected to the World Wide Web, intranet, or Internet, can be an 'internal communications specialist' and 'fact-finder.' Organizational intelligence no longer belongs to a specific organizational entity or to its apex: it can be virtually everywhere.

Intelligence, Prior Knowledge, and Learning

Intelligence test scores can account for interindividual achievement differences in many content areas to a considerable extent but they lose their predictive power when measures of prior content-specific knowledge are added. When controlling for differences in prior knowledge, medium correlations between intelligence and learning outcome are found. However, it is still far from clear exactly what kinds of learning activities are affected by intelligence. Education stimulates the emergence of intelligence but does not decrease the variance in intelligence test scores.

1. Intelligence: A Valid Predictor of Achievement Differences

Individuals with similar cultural, social, and educational backgrounds differ from one another in the time they need to process certain information, in their ability to understand complex ideas, in the efficiency with which they can deal with novel, transfer-demanding tasks, and in the learning outcome that results from attending certain instructional environments. The construct of psychometric intelligence attempts to clarify what is behind such achievement variations that cannot be explained by differences in learning environments or in amount of practice.

1.1 Measuring Intelligence

About a century ago Alfred Binet constructed problems designed to determine whether children who did not meet certain school requirements suffered from mental retardation or from behavioral disturbances. Since then many psychologists have been quite successful in developing reliable verbal and nonverbal intelligence tests for children and adults. Intelligence tests contain items composed of verbal, numerical, and pictorial material, and they require various mental operations, among them inductive and deductive reasoning, pattern recognition, and memorization. So-called speed tests contain items that are comparably easy for everybody; individual differences in the numbers of correctly solved problems only occur because of time limitations. In power tests the items are ordered according to their difficulty, and limits in intelligence become apparent if people do not solve all problems despite having sufficient time.

The distribution of achievement scores in all intelligence test scales follows the bell curve (normal distribution). This reflects the fact that the majority of people resemble each other quite a lot with respect to their cognitive capabilities, and only a few people show extraordinarily low or high competencies. Normal distribution is the statistical prerequisite for measuring intelligence on interval level by indicating deviations from the mean score. To determine the intelligence quotient (IQ), test scores are converted to a scale in which by convention the mean is 100 and the standard deviation is 15. The reliability of IQ tests, revealed either by correlation coefficients based on repeated measurement or by figuring out internal consistency, is between 0.80 and 0.90, which is higher than for most other psychometric measures. Nonetheless, a reliability lower than 1.0 only allows us to interpret a range rather than a single value. For example, if a person's tested IQ is 110, and if the reliability of the test is 0.90, the IQ of this person is between 101 and 119 with a probability of 95 percent. A test reliability of 0.80 reveals a range of 97–123.

Despite broad variations in the content and the form of presentation of intelligence test items, all tests have in common that they do not presuppose knowledge that can only be acquired in particular learning environments not accessible to everybody. Moreover, differences in test scores within a group only reflect differences in intelligence between these persons if all of them have had access to similar learning environments. In other words, each member of the group must have had, in principle, the opportunity to acquire the knowledge necessary to solve the problems. Intelligence test scores can be raised considerably by practicing the respective types of items, while individual differences do not disappear but rather remain quite stable at a higher level. The Flynn effect, named for its discoverer, is the observation that mean IQ scores have increased considerably in the past 50 years. This may be at least partly due to training effects caused by widespread exposure to intelligence test items in various media. Interindividual differences in intelligence test scores between persons can only be interpreted as differences in intelligence if similar amounts of practice can be presupposed. Attempts to construct so-called culture-free or culture-fair tests, which were supposed to be unaffected by prior experience, have failed because it turns out that different cultures are not prepared in the same way even for dealing with nonverbal material and mental operations that are not part of institutional schooling. Although some studies reveal ethnic differences in mean IQ, hitherto there is no convincing evidence that these differences are genetically affected.

Within a fairly homogeneous cultural context intelligence can be considered as a personality trait mainly for two reasons. First, performance on intelligence tests that are based on different contents and mental operations show significant correlations. For

instance, correlations between tests on inductive reasoning with pictorial material and with verbal material are around 0.50, and correlations between tests that measure basic visuospatial competencies such as mental rotation and tests of verbal fluency are about 0.30. In numerous studies run all over the world, multivariate statistical methods such as factor analysis have revealed that a single factor, called factor *g*, can account for 30–40 percent of the variance in IQ-test batteries composed of various scales covering a range of content knowledge and mental operations. Second, longitudinal studies have revealed that IQ is a fairly stable measure across the life span. Long-term stability of IQ for adolescents and adults comes close to the reliability of the tests, and even in early childhood long-term correlations are around 0.50 for both verbal and nonverbal tests.

Overall, intelligence test scores predict academic performance fairly well: the correlations between IQ and grades in school and university are about 0.50. The correlations between intelligence test scores and measures of outside-school success such as income or professional status are lower but still significant. That intelligence cannot account for a larger amount of achievement variation is not at all surprising, given the importance of numerous other factors, among them social background, motivation, and effort.

Because verbal and nonverbal intelligence tests are good predictors of how well an individual will succeed in school and university, they are quite helpful for making recommendations for different educational trajectories. They allow educators to identify children who cannot be expected to gain from normal schooling and therefore need special education, or children who might benefit from an advanced learning environment. According to Guthke (1993), the validity of intelligence tests can be increased if they are presented as learning tests, which means that all test-takers practice the items in several trials by getting feedback and thinking hints so that individual differences in familiarity with tests are compensated for. Particularly for children from disadvantageous social environments, learning tests are a more reliable and valid measure of intelligence than conventional IQ tests.

Attempts to extend the construct of intelligence by including social and emotional competencies as well as striving for success are controversial because the theoretical background of these concepts is still vague, and, more importantly, because the tests designed to measure these aspects do not meet the strong diagnostic criteria that have been established in psychometric research.

1.2 Factor g, Specific Abilities, and Knowledge Acquisition as Determinants of Cognitive Development

What cognitive capabilities are behind factor *g* is still a controversial question in psychology (Neisser et al. 1996). According to low-level theories, *g* reflects individual differences in basic brain functions, for example, neuronal speed. These theories are supported by results from studies that reveal 10–25 percent common variance between intelligence test scores and simple reaction time measures. However, the search for a single brain function that determines differences in cognitive capabilities has not, as yet, met with much success.

Anyhow, the heterogeneous pattern of correlations between the range of intelligence subtests leaves no doubt as to the fact that human abilities vary beyond general basic brain functions. Though significant, many correlations between intelligence subtests are low, indicating the involvement of independent mental resources. Even between tests on inductive reasoning which are based on different forms of representation (i.e., pictures, numbers, words), only medium correlations are revealed, suggesting that cognitive processes are to a large extent guided by specific verbal, visual-spatial, or numerical abilities, among others.

Among the several attempts that have been made to integrate general and specific abilities into broader theories of intelligence is the hierarchical model developed by Cattell (1971). The author proposes two major subfactors, which are related to one another. Fluid intelligence (Gf), which describes basic information processing and reasoning is measured by content-poor nonverbal tests. Crystallized intelligence (Gc), which is particularly revealed in content-rich verbal tests, represents the accumulation of higher order knowledge over the life span of an individual. Both kinds of intelligence are closely interrelated in childhood because Gf partly guides the development of Gc. From the age of about 25 years on, however, Gf and Gc take different developmental trajectories. While Gf starts to decrease at the age of 25, first slightly and from about 50 years on more quickly, Gc is unaffected by age and even has good chances to increase until the age of around 70. It is worth noticing that because of the large individual differences, the given age information is only a rough estimation.

Developmental changes also occur with respect to the structure of intelligence. The prominence of Gf decreases during childhood while Gc as a function of repeated enlargement and rearrangement of knowledge becomes more useful. When people from their adolescence on, at the latest, start to specialize in different areas, general cognitive resources have to be completed by specific abilities. This process of differentiation is characterized by decreasing correlations between intelligence subtests from childhood over adolescence to adulthood. Only in old age is a process of dedifferentiation observed which is characterized by a growing impact of Gf (Baltes et al. 1999).

After years of controversial debate, researchers now agree that part of within-group differences in IQ is determined by genes. Twin and adoption studies conducted in North America and Europe suggest that

about 50 percent of performance variation in intelligence tests is due to genetic differences. In general, the amount of variance in intelligence test scores to be explained by genes is higher the more members in a society have access to school education, health care, and sufficient nutrition. Findings which suggest that heritability increases during the life span and is not lower for Gc than for Gf are contra-intuitive only at first glance. To understand these results one has to realize that societies which provide access to a broad variety of cognitive activities in professional as well as in private life enables adults more than children to actively select special environments which fit their genes. People who have found their niche can perfect their competencies by deliberate learning.

Genes, however, not only indirectly guide learning and knowledge acquisition via general and specific abilities, rather, there is growing evidence that during evolution the human mental architecture has been equipped with quite specific knowledge structures for instance about visual or auditory patterns, physical objects, language use, and social situations. Such knowledge structures, called input systems or modules, allow appropriate cognitive and behavioral functioning beyond learning. Moreover, the representational redescription of innate modules may provide the basis for acquiring higher order domain-specific knowledge which only emerges during cultural development (Karmiloff-Smith 1992). By integrating the differential perspective of psychometric intelligence research and the universal approach of mental modularity, Anderson (1992) presents a new theory of differential cognitive development in his very informative book. According to this approach individual differences in cognitive capabilities start to increase from birth onwards because the speed and efficiency with which modules are redescribed into higher order knowledge structures is determined by general and, to a lower extent, by specific cognitive abilities. Despite its general plausibility, however, several central claims of this theory are in conflict with some well-established and appreciated theories of cognitive development and psychometric intelligence.

2. *Prior Knowledge: The Best Predictor of Learning Outcome but not a Substitute for Intelligence*

In three lines of research domain-specific knowledge has become an important variable that has challenged the value of intelligence tests as a diagnostic instrument.

2.1 *Research on Outstanding Professional Expertise*

Nobody would challenge that most of the people who have contributed in an outstanding way to an academic domain score in the upper third on intelligence tests. However, one should note that this claim is almost all that intelligence research can contribute to explaining expertise. For outstanding expertise in various fields, among them chess, medicine, and physics, having access to an elaborate domain-specific knowledge base was proven to be necessary and sufficient. For detailed treatment of this topic and for further references see *Expertise, Acquisition of*.

2.2 *Comparisons between Intelligent Novices and Less Intelligent Experts*

When entering learning settings, learners often differ from one another with respect to prior domain-specific knowledge and IQ. Studies that have investigated the learning effects of attending mathematics lessons at school and reading texts about sports have revealed much better outcomes for persons with high prior knowledge levels (experts) and low IQ than for persons with little prior knowledge (novices) and high IQ (Weinert and Helmke 1998). Note that it was novices, rather than laypersons, who were considered. In contrast to laypersons, novices possess the necessary domain-specific knowledge in terms of rules and core concepts but differ from experts in their lack of practice.

2.3 *Domain-specific Determinants of Cognitive Development in Childhood*

Research on cognitive development suggests that variations in prior domain-specific knowledge can often better account for achievement differences between younger and older children than general cognitive capabilities. For detailed treatment and for further references see *Cognitive Development: Child Education*. Moreover, longitudinal studies suggest that within-age-level achievement differences in core elementary school subjects are to a remarkable extent determined by domain-specific prior knowledge obtained in the preschool years. Early numerical competencies could account for achievement variations in mathematics after partialing out general intelligence, and early indicators of letter identification and phonological awareness predicted later performance in reading and writing (Weinert and Schneider 1999).

The reported results are important because they show that at least in complex knowledge domains a high IQ cannot compensate for a lack of prior knowledge, and moreover, that there is no direct connection between intelligence and achievement in content domains based on rich specific knowledge. However, regression analyses based on longitudinal studies reveal that the confounded variance of prior knowledge and intelligence predicts differences in learning outcome better than each single variable. This means that prior knowledge and intelligence are to a certain extent inextricably linked with each other.

Intelligence may guide the selection of learning environments and thereby determine the acquisition of prior knowledge. A person with a low IQ will hardly follow courses on theoretical physics even if he or she is credited with extra time. Moreover, intelligence may influence in how many content areas a person is able to acquire a profound amount of prior knowledge.

3. *Intelligence and Learning*

Since Sternberg (1985) claimed in his pioneering book that research on intelligence has to focus on different aspects of information processing, as there are meta-components, performance components, and knowledge-acquisition components, several attempts have been made to find out what kinds of cognitive activities are affected by intelligence during learning and problem solving. Creative assessment paradigms and stimulating ideas will be discussed in the following section.

3.1 *Efficiency in Constructing and Accessing Knowledge: Few Knowns and Many Unknowns*

At first glance it sounds plausible that, given that individual differences in prior knowledge can be controlled, intelligence affects the speed of mastering complex systems as well as competencies in dealing with novelty. Intelligence may affect the efficiency with which a knowledge base is constructed and moreover it may determine the means of accessing it. For instance, from an early age intelligent persons may represent certain problem-solving strategies in a more abstract way so that they can be easily transferred to novel situations. In addition, efficient metacognitive strategies for accessing and combining knowledge may increase the lead of the intelligent persons. Such general claims have been somewhat supported by research on complex problem solving (Frensch and Funke 1995). In this paradigm learners are presented with complex computer scenarios that, for example, require them to maximize the profit of a company, increase the supply of water in the desert but at the same time avoid an ecological collapse, or organize a city as a mayor. Tests and interviews make sure that prior knowledge about the content of the scenarios as well as experience with the computer are the same for all learners. To reach a certain goal, learners have to manipulate various variables that show a complex pattern of interaction with each other. Correlations of 0.30–0.50 between IQ and speed of mastering a complex scenario have been obtained in various studies. Moreover, contrary to a long-held scientific opinion, the impact of intelligence on learning outcome does not decrease with practice.

Although such results are somewhat promising, they often encourage the establishment of rash and arbitrary definitions of intelligence, such as speed of information processing, working memory capacity, ability to abstract, ability to deal with novelty, or metacognitive competencies. It is, however, often difficult to distinguish between such concepts, and moreover, they often lead to inconsistent conclusions. For instance, those learners who are thought to acquire information quickly may do so at the expense of profoundness. Given the controversies in cognitive psychology about modeling general working memory capacity, this construct is hardly ready for describing individual differences. Also the plausible claim that intelligent persons represent their knowledge in an abstract way that facilitates transfer does not hold (Detterman and Sternberg 1993). On the one hand, as mentioned above, research on expertise indicated that an elaborate knowledge base is not characterized by abstraction but rather by the efficient organization of specific elements. On the other hand, one of the most consistent results of psychology is that even persons with an IQ above average only rarely show spontaneous knowledge transfer even when they are presented with problems with an isomorphic formal structure. Moreover, because novelty is a combination of hitherto unrelated knowledge, the construction of completely new demands has turned out to be unattainable. The enthusiasm about metacognition, which was appreciated as a synonym for IQ by some researchers in the 1980s, has died down considerably after it has turned out that metacognitive competencies can rarely account for achievement differences in the normal and upper performance range. In sum, despite the many attempts to identify components of information processing as sources of individual differences, hitherto more questions have arisen than have been resolved.

3.2 *Educational Implications of Differences in IQ*

Comparisons between schooled and unschooled groups reveal a strong effect of education on intelligence test scores even on nonverbal tests. Only by systematic education can individuals' intelligence emerge and approach an optimum. However, given that a basic level of education has been encountered, schooling in general and special training programs in particular increase intelligence only very modestly, if at all (Perkins and Grotzer 1997). IQ differences remain quite stable over time in groups who have been attending stimulating learning settings. Education highlights individual differences in intelligence rather than compensating for them.

Broad variance in intelligence is a challenge for designing educational environments. The question arises of whether learners of different intelligence levels gain more if they are assigned to different learning environments. A few studies have revealed so-called Aptitude-Treatment Interactions. Less intelligent students gained more from structured than from open instruction, while for more intelligent learners the reverse pattern occurred. However, most studies have

failed to reveal interactions between intelligence and educational treatment, some of them probably because they lacked the statistical power necessary for revealing interaction effects. In general, when assigning learners to different learning treatments according to their intelligence, one must remember that IQ follows the normal distribution. This means that 68 percent of the population do not differ by more than one standard deviation in either direction from the mean—they are quite similar. Therefore, assigning an unbiased group of learners to two different learning environments by median split of IQ scores is not useful at all. Moreover, research has shown that similar educational environments can equip learners with a broad range of IQs with necessary prior knowledge in various areas. Eventual deficiencies in intelligence can be compensated for by effort and deliberate practice to a considerable extent. However, given the relationship between intelligence and efficiency in learning and information processing, a higher IQ facilitates the exploitation of learning environments, leading to the acquisition of knowledge that is broad as well as deep enough to master many of the as yet unknown demands of the future.

Intelligent Tutoring Systems

The main aim of intelligent computer-aided instruction (ICAI) systems or intelligent tutoring systems (ITS) is to provide sophisticated instructional advice on a one-on-one basis that is comparable to that of a good human tutor. Research on ITS also serves a second aim: to develop and test models about the cognitive processes involved in instruction. Although these two aims are closely related, they may lead to different emphases concerning the priorities dealt with in relevant research (see below).

The first ITS were built in the 1970s (for an overview of these early systems see Wenger 1987). They were a response to the rather inflexible conventional computer-aided instruction (CAI) systems which were (and are) mostly built on the principles of reinforcement learning. Whereas the reactions of CAI systems follow predetermined paths, ITS aim to provide instructional interventions that are custom tailored to the strengths, weaknesses, and the actual knowledge of a given learner. This flexibility of ITS which in theory also extends to unexpected situations and which is the justification for calling them 'intelligent' is achieved by using techniques from artificial intelligence (AI) research (see *Artificial Intelligence in Cognitive Science*). The most salient property of ITS which takes them apart from other AI applications such as expert systems (see *Expert Systems in Cognitive Science*) is the diagnosis of the current state of the student knowledge. This diagnosing facility and the other parts of ITS are described next. Then follows a description of how ITS work. After that, several problems are pointed out that have led to discrepancies between theory and practice of ITS. Finally, several new developments are mentioned.

1. System Architecture

In the classical view ITS consist of three modules that contain domain knowledge, a model of the learner's current state, and teaching knowledge. These modules have been given slightly different names by different authors. Here, using Dede's (1986) terms they will be called *knowledge base, student model*, and *pedagogical module*, respectively. The importance of the com-

munication between learner and system has been increasingly recognized and this *user interface* (see *Human–Computer Interface*) is now widely recognized as the fourth module of ITS.

1.1 Knowledge Base

The knowledge base contains the domain knowledge, both declarative (knowing what) and procedural (knowing how). For instance, in ITS that deal with geometry proofs, the declarative part may contain the fact that the three angles of a triangle add up to 180 degrees; and the procedural part may contain the 'side-angle-side' rule, that is, the rule that if two triangles coincide in two corresponding sides and the angle in between one may conclude that the triangles are congruent. To represent the domain knowledge many different kinds of representational schemes have been used such as semantic networks, frames, constraint satisfaction networks, logic, propositional representations, and variations or combinations thereof (see *Propositional Representations in Psychology*; *Schemas, Frames, and Scripts in Cognitive Psychology*). However, the most common technique used to represent domain knowledge seems to be production systems (see *Cognitive Theory: ACT*; *Production Systems in Cognitive Psychology*) which consist of a memory buffer (working memory), a set of production (if–then) rules (procedural memory), a collection of facts (declarative memory) and an interpreter that decides what to do next. Production system architectures are often used in expert systems and indeed, expert systems have served as the knowledge base in early ITS. The best known example is GUIDON which used the expert system MYCIN as its knowledge base (Clancey 1987). In more recent ITS, production systems form the basis of an ideal student, who knows how to perform the task the student is expected to perform (e.g., Anderson et al. 1995).

1.2 Student Model

The student model should represent the student's current state of knowledge. That includes a representation of the knowledge, concepts, and skills the student has acquired either fully or partially. It also includes the representation of a given student's special skills and needs. Moreover, there should be a mechanism to represent misconceptions, bugs, or erroneous information which the student might have acquired. For instance, in ITS that deal with geometry proofs, the student model might represent that the student has understood the side-angle-side rule, that the student (erroneously) thinks there is also an angle-angle-angle rule which allows one to conclude that two triangles are congruent, and it may have inferred that this given student prefers delayed over immediate feedback. All this information should be used to provide optimal teaching interventions. To come up with such a student model one needs assumptions about how people learn and how they represent in memory what they have learned. Specific contents of the student model are inferred by asking the students questions and analyzing their reactions toward prompts of the system or the way they are going to tackle a problem posed by the ITS. For the student model, basically the same AI techniques are used as for the knowledge base.

1.3 Pedagogical Module

Teaching can be considered a knowledge-based skill, guided by strategies and techniques which are selected and combined dynamically in reaction to the student's actions. The pedagogical module incorporates just this skill. It should determine the presentation method, the balance of tutor and student control, and it should give feedback when necessary. One important task of the pedagogical module is how to deal with student errors, for instance, when to interrupt and what to say. Pedagogical strategies may include presenting increasingly complex concepts or problems, Socratic tutoring, simulating phenomena, and modeling of expert problem solving via coaching. The teaching strategies and techniques used should have proved successful for the particular content matter. The pedagogical module should also be able to answer student questions.

1.4 User Interface

The user interface is essential for the success of an ITS: even if the three other parts were perfect, a weak user interface could make the ITS nearly useless. The best solution would be for the student to communicate with the ITS in natural language. This, unfortunately, is not possible to date, despite huge advances in the AI field of natural language comprehension and generation. Solutions to this problem include 'canned language,' multiple choice selection, and the almost exclusive use of graphical interfaces. The user interface must take into account attentional and memory constraints of the student but it should also use the strengths of human information processing. In many earlier ITS, the user interfaces have been constructed more or less ad hoc, but recently, theoretical considerations about transfer and domain specific issues have increasingly influenced the construction of interfaces (e.g., Anderson et al. 1995, Sedlmeier 1997).

2. How do ITS Work?

The four components of ITS described above capture the different aspects included in ITS and give a good

idea about how ITS might work in principle. Although parts of real ITS can be mostly assigned to one of these four parts there are not usually four independent modules at the level of implementation that interact with each other on equal terms. Usually one of the three classical components can be regarded as playing the central part in the teaching process.

2.1 Expert-centered Instruction

In most ITS, the knowledge base plays the central part in the teaching process. Usually, the knowledge base is conceptualized as a domain expert or an ideal student and the course of action taken is dependent on the deviations of the student model from the expert or ideal student. In an *overlay model* the knowledge of the learner is seen as a subset of the expert's knowledge (e.g., Clancey 1987) and if a deviation between the current student model and the expert knowledge is diagnosed, the system tries to remove that discrepancy by suitable instructional measures. It has been found that the student's knowledge is not just a subset of the expert's knowledge but may contain nonexpert ways to arrive at the solution of a problem. Extensive research on how students solve problems correctly and what kinds of errors they commit led to the model of an ideal student and to 'bug libraries,' that is, to possible explanations for errors (Brown and Burton 1978). This approach has been elaborated into the technique of *model tracing* (e.g., Anderson et al. 1990). In this approach, a performance model specifies how, for a particular problem, a student's current knowledge will map onto performance. Instructions address diagnosed confusions and keep the student on the right solution path. A learning model specifies how the student's current knowledge will change as a result of problem-solving experiences and this learning model can be used to trace the student's knowledge over time.

2.2 Teacher-centered Instruction

One might argue that the most natural choice of an ITS component to control the instructional process should be the pedagogical module. Unfortunately, the pedagogical module is the most neglected component of ITS. This might in part be due to still existing deficiencies in instructional theory but it might also be the result of a practical problem: Teachers or education scholars are seldom involved in the construction of ITS. One approach that puts the teacher into the center of the instructional process is to use planning techniques that make it possible to develop and flexibly adjust global teaching strategies (e.g., Peachey and McCalla 1986, Sedlmeier and Robles de Acuña-Ponseti 1992).

2.3 Student-centered Instruction

In expert and teacher-centered instruction, the learning process is fully dominated by the tutor. This contrasts with the current emphasis in instructional theory on *learning by doing* and *situated learning* (see *Situated Cognition: Contemporary Developments* and *Situated Cognition: Origins*). One way to put the student into the center of the instructional process would be to use techniques of *machine learning* (Self 1985). Research on this kind of instructional process is still in its infancy.

3. The Practice of ITS

Whereas ITS seem to be ready to be used for specialized applications on the commercial market (Norton et al. 1998), to date, by far the most ITS did not pass the status of prototypical systems and there are very few ITS employed in the classroom. One important reason for this state of affairs is probably the diversity of researchers involved in the construction of ITS. A second might be that there is still no convincing evidence of ITS's superiority over more conventional teaching procedures, and finally, there are severe problems with constructing good student models.

3.1 Diversity of Interests

Constructing ITS is a multidisciplinary endeavor, including computer scientists, mathematicians, cognitive psychologists, and educational researchers, to name the most important groups. With some notable exceptions (e.g., Anderson et al. 1995), researchers are usually most interested in those aspects of ITS that are closest to their own field of research: Educators are most interested in effective tutors but often do not know how to write computer software, and researchers in cognitive science are more interested in developing and testing theories about how humans learn than in the sometimes tedious process of implementing computer software in schools. Another problem was that many ITS were developed on workstations and Lisp machines that schools could not afford and maintain.

3.2 How Effective are ITS?

There is still a lack of thorough evaluation studies in which the effectiveness of ITS is compared to that of conventional teaching techniques. Keeping in mind that the development costs for ITS are quite high, ITS have to achieve noticeably better learning results than conventional CAI systems. One motivation to use ITS in the classroom has been the assumption that individualized instruction is much more effective than group instruction and that ITS can provide such an individualized instruction. However, a collection of

meta-analyses shows that overall, the benefits of individualized instruction are almost indistinguishable from those of group instruction (Fraser et al. 1987). This is in line with the conclusion which Legree and Gillis (1991) reached in a survey of evaluation studies: For the majority of the ITS analyzed, there was no noticeable advantage over the learning success achieved with group instruction.

3.3 Problems with the Student Model

Research on student models since the early 1970s has shown that even for relatively small and well-defined domains such as simple arithmetic it is not possible to construct a complete cognitive model (e.g., Elsom-Cook 1993). One reason is that the representation of everyday knowledge which is needed in addition to domain knowledge is an almost insurmountable task. Another reason is that the basis for diagnosis, the student's behavior, is often not clearly interpretable. A given student error encountered by the system may have many potential causes. However, the underlying misconceptions and not the observable behavior should be the basis for corrective procedures. Even if it were possible to construct an optimal student model, could it be used effectively? All available evidence suggests that it could not: Good teachers often have incomplete and even wrong 'student models' but are nonetheless very successful. They achieve their success not by a thorough diagnosis but by moving through a curriculum script, that is, a loosely ordered but well-organized and sequenced set of skills and concepts they expect students to learn, and by using adequate activities and strategies for teaching this material (Putnam 1987). Thus it seems that, at least for the purpose of effective instruction, the student model in its present state has severe deficiencies and might be discarded without much loss as far as teaching efficiency is concerned (Gugerty 1997).

4. Perspectives: Cognitive Science Research vs. Educational Practice

Research in ITS is still flourishing (e.g., Goettl et al. 1998) but the emphasis is more on the second aim stated in the beginning of this article, that is, to develop cognitive models about the components of the instructional process. This could eventually also lead to the achievement of the first aim, that is, to provide effective instructional devices for all kinds of domains. It seems that for highly specialized industrial applications, this first aim has already been reached, at least in part. The deployment of ITS in the classroom is, however, only in its starting phase. For practical purposes it might be worthwhile in the short run to de-emphasize the reliance on the problematic student model and put more effort into the construction of theory-guided flexible interfaces. Such flexible interfaces could be the front-end to existing computer tools, simulations, games, or microworlds (Cumming and Self 1990) or could take part in guiding the teaching process (Sedlmeier 2000). Technological advances and the possibility of using the Internet will greatly facilitate the deployment of ITS in schools but ultimately whether or not schools will profit from the potentially huge benefits of ITS depends on successful collaboration among educators and system builders.

Intensification and Specialization, Archaeology of

Many of the major transitions studied by archaeologists—the development of agriculture, urbanism, institutionalized inequality, and markets; processes of imperial incorporation, colonialism, and political collapse—either consist of, or are accompanied by, significant changes in the organization of production. As such, these changes, their causes, and consequences have been pivotal research issues. Studies of intensification and specialization build on archaeological approaches to production, and must be understood in the light of this broad construct, which differs significantly from its use in economics.

1. *The Archaeology of Production*

Archaeological concepts of production are typically situated in the anthropological perspective that productive activities are embedded in larger cultural and social systems. Production—the creating, constructing, and tending of artifacts, structures, human-modified plants and animals, even entire landscapes—is a fundamental focus of the study of the archaeological record. Production, as one dimension of human economy is both responsive to and constitutive of other domains such as processing, distribution, and consumption. This perspective is a legacy of the formalist–substantivist debate in anthropology, which centered around whether nonindustrial economies could be understood in the same terms as industrial capitalism (the formalist position), or whether the economies of nonindustrial societies typically studied by anthropologists were, in Polanyi's (1957) words, more fundamentally 'embedded and enmeshed' in social institutions. However, this picture is complicated by important strands in archaeological thinking which draw on economistic approaches or on those approaches as modified by ecology and evolution.

Research has not focused evenly on all arenas of production. Although agriculture and animal husbandry constitute important areas of research, there is a longer history of emphasis on durable goods or artifacts, objects made or modified by humans. Artifact manufacture is often termed craft production. While changes in the organization of craft production are generally conceived in terms of specialization, food production is more often viewed in terms of intensification. Part of this divergence may relate to the different kinds of information available about each arena of production. Students of craft production typically work with artifacts themselves and with evidence from production locales such as kilns, workshops, even dumps. Food production research does involve products such as seeds and animal bones, but these are often conceived as objects of consumption, with production studies focused primarily on locales of production such as fields.

2. *Intensification*

Archaeological studies of intensification have focused primarily on agriculture. In some sense, the historical trajectory of agricultural change can be viewed as a long, although variable, history of productive intensification, concomitant with the rise in global population, its clustered distribution on the planet, and the entrenchment of economic and social inequality.

2.1 *The Concept of Intensification*

The difference between intensification and simple increase is analogous to the difference between concentration and amount. Intensification of production refers to attempts to increase the concentration of production, or productive output per unit of land, labor, or some other fixed quantity. The focus on production effort in this definition highlights the salience of input, allowing failed efforts to increase productivity to be included in studies of intensification. In archaeology, the variable held constant almost always refers to land in reference to agriculture (getting more from a given area), and labor in reference to craft production (increasing efficiency of production). Situations in which both land and labor are held constant while capital inputs are increased, as in industrialized agriculture, are more rarely discussed.

2.2 *History of Approaches to Intensification*

The model of intensification set forth by economist Ester Boserup (1965) has been the most influential

formulation of the problem, and was widely adopted in archaeology (e.g., Cohen 1977). Boserup's model was parsimonious, general, and comprehensive; however, like other unilineal models of cultural evolution, it greatly generalizes and simplifies this complex process. Boserup's view of population pressure as an independent variable driving intensification inverted the earlier Malthusian formulation. While Malthus saw arable land as limiting increases in production, Boserup optimistically asserted that constantly increasing population (an assumption shared with Malthus) acted as a motor, driving technological changes in land use along an extensive–intensive continuum.

The most contested aspect of Boserup's model was the causal efficacy of population pressure, a view resting on several related assumptions. First, producers are assumed to exert the minimum effort required to meet their needs (the law of least effort). Thus, the most labor-extensive regime possible will always be employed. Second, Boserup argued that there are diminishing marginal returns to labor (declining efficiency) with increasingly intensive forms of production. The disadvantages of intensive agriculture—increased labor inputs and declining efficiency of that labor—ensure, for Boserup, that more intensive forms of production will be adopted only when strictly necessary. These assumptions have been criticized on empirical grounds, as has the prime-mover status of population pressure. There is now a vast literature considering such causal factors as population density and distribution; sedentism; market-driven, prestige-driven, or politically-driven demands for produce; risk, climate change; and many others (reviewed by Morrison 1994). Contemporary approaches to intensification tend to stress multiple and cascading causes which may be locally contextual and historically contingent (e.g., Kirch 1994).

2.3 *Consequences of Intensification*

In a proximate sense, the most common consequence of intensification is increased productivity. More significant, however, are less-proximate consequences, such as the restructuring of human labor, possibilities for differentiation of nonfood production, and the support of nonproducers. It is in this sense that intensification has been seen as underwriting social and political complexity, by which archaeologists generally mean the existence of institutionalized inequality and/or the presence of complex polities such as states or chiefdoms. Historically, intensified food production has also had dramatic ecological consequences, leading to landscape modification on a large scale, the worldwide movement of plant and animal taxa, and the existence of artifactual landscapes such as cities.

2.4 *Methodological Issues in Intensification Studies*

The study of intensification poses serious methodological challenges. The investigation of past agriculture, in particular, is difficult because of its large spatial scale and ephemeral material remains. For this reason, archaeologists consider numerous indicators of land use, including agricultural implements, historical documents, settlement distributions, agricultural facilities, and botanical remains. Identifying intensification in the archaeological record depends on the definition adopted; views which stress output require some measure of productive success, a difficult requirement for archaeology, where agricultural productivity can rarely be quantified. Output-based models are more popular in craft production studies, where such measures may be more reasonably inferred. Production effort is usually postulated on the basis of inferences about the overall form of production, using clues such as technological forms, products, or cultigens with special productive requirements, as well as knowledge of specific environmental conditions.

2.5 *The Future of Intensification Studies*

Three promising trends in the archaeology of intensification may be identified. The first is increased attention to the process of intensification itself, a process incorporating a great degree of variability. Kaiser and Voytek (1983) for example divide intensification into three components: specialization, diversification, and intensification proper. These involve changes in the amount and organization of labor and its application through technology, and require measurement of multiple variables. The second trend is increased attention to actual historical trajectories of change and the variable paths intensification may follow. Finally, in accord with moves toward a more inclusive view of production, many studies now weigh cultural meanings of food products alongside concerns of labor efficiency or energetics.

3. *Specialization*

The origins and development of specialized production have always been major concerns in archaeology. If intensified food production is often seen as undergirding social complexity, then specialization has been regarded as its index. Students of specialization draw on Marxian traditions which integrate concern for the means and social relations of production with anthropological attention to culture. This research tradition, however, draws equally from Adam Smith in its attention to the division of labor and focus on exchange, as well as its often embedded assumptions about the nature of economic behavior. In their concern for social and political implications of

specialization, archaeologists have also drawn on Durkheimian notions of solidarity and integration.

3.1 The Concept of Specialization

Specialization may be defined as the channelling of resources and/or labor into restricted ends, a definition focusing on the products and process of specialization. Other definitions stress the role of specialization in setting apart people, technologies, and production locales, both physically and socioeconomically. Most literature on specialization in archaeology focuses on craft production; such studies have been dominated by a concern for technological process, interest in the organization of production, and, more recently, an expanded interest in the social relations of production, including issues such as identity and meaning. Specialization implies exchange on some level and as such, is not intelligible outside larger political/economic contexts.

3.2 History of Approaches to Specialization

Most early studies of artifacts emphasized typology, using morphology and manufacturing technology to classify objects, creating the chronological and spatial systematics that still underlie disciplinary practice. Despite pioneering studies such those of V. Gordon Childe that stressed the social and political roles of craft specialists in early stratified societies, most observations on artifact variability were oriented toward defining the cultural/temporal units which were themselves the goals of research. With moves toward functionalism in the 1950s and 1960s however, technologies of production commanded greater attention as areas of study in their own right; this focus on technology continues into recent materials science approaches.

With the 1960s and 1970s came concerted efforts to delineate the organization of production and especially the integration of specialized producers into larger political economies. Growing from this interest, much effort has been spent investigating the scale (household production, workshops, factories) and tempo (full- vs. part-time specialists) of specialized production and the material correlates of organizational forms. Also of concern were forms of control over production, strategies of labor and resource mobilization, and the disposition of manufactured goods. Several classifications have attempted to capture some of these contextual dimensions of production, distribution, and consumption (Costin 1991). Studies of exchange have been particularly important, congruent with a focus on regional economies and with the development of new analytical methods for determining source areas of raw materials.

Specialization studies have been marked by a concern for the initial causes of specialization, although here explanations often stress socially-based demands, perhaps because many artifacts are clearly not biologically necessary for survival. More recently, archaeologists have begun to stress processes of production, especially agent-based approaches which focus on structured chains of culturally-inflected decisions made by producers (Lemmonier 1986) and on interrelations between technology and meaning. A new focus on producers, too, has followed from concern for more finely-divided aspects of producer identity, including gender and ethnicity and from recognition that multiple organizational forms of production often co-exist, even where the producers are the same.

3.3 Consequences of Specialization

From the time of Childe, archaeologists have explicitly linked specialized production with complex political forms and social inequality (Brumfiel and Earle 1987). The very existence of elites is typically inferred, in part, from sumptuary objects identified by their elaboration, restriction, and sometimes exotic provenance. Curiously, specialization in craft production (sometimes cast as intensification) is generally viewed as promoting efficiency, while intensified agriculture is depicted as producing declining marginal returns. Recent work on the meaning of production, especially its ritual context, draws more fully from an anthropological tradition de-emphasizing efficiency.

3.4 Methodological Issues in Specialization Studies

Recognizing specialized production begins with the objects and by-products of manufacturing and their distribution. The definition of specialization allows for certain ambiguities, as issues of scale and context impinge. For example, the production of artifacts in one region and exchange to another may be considered regional specialization, although artifacts were manufactured by every household. Locations such as quarries are specialized places without necessary associations with producer specialization. Although the goal of archaeological research is usually to identify producer specialization, because archaeological data are fundamentally spatial, determining the organization of production is inevitably inferential. Much of the methodological development of specialization studies grew around this dilemma. Complex technological requirements or high levels of producer skill are sometimes assumed to index specialist manufacture; another criterion advanced for identifying specialization and its scale is standardization, mass-production being thought to promote standardization (for reasons of efficiency).

3.5 The Future of Specialization Studies

The trends identified in intensification studies also hold for studies of specialization. Concerns for process are implicated in perspectives that draw specialized production into the larger field of the anthropology of technology; this concern is sometimes expressed in the language of 'crafting' and the ways in which crafting both draws from and creates social relationships (Costin and Wright 1998). Recent developments in the archaeology of both intensification and specialization tend to stress process over cause and explore the consequences of productive organization for differently situated social actors rather than classify productive forms along an evolutionary continuum.

Intentionality and Rationality: A Continental-European Perspective

1. The Text

There is an objective interrelationship between 'intentionality' and 'rationality.' As a rule, intentionality is considered to be a necessary, although not a sufficient, condition for rationality. This means that one is usually convinced that something or someone can be called rational only when the predicate 'intentional' can be applied to it or to him or her first. In addition, both concepts can be applied both in the sense of an expression of disposition and to describe specific manifest qualities. Thus, intentionality is attributed to living beings when they have the ability to produce something that can be described as intentional: actions, psychic occurrences, or linguistic utterances. Conversely, the intentional has always been understood as the actualization of the disposition 'intentionality.' Similarly, in the case of 'rationality,' that which can be seen as rational, can be traced back to the activation of rational competence which itself presupposes intentionality. Both can be applied only to people. If one considers institutions, systems, or even machines and their achievements to be rational, one uses this expression in a figurative or derived sense.

2. Intentionality

2.1 Intentionality From the Standpoint of the Theory of Action

This artificial philosophical term does not have an equivalent in colloquial language except to characterize something that someone has done as intentional, i.e., deliberate. Thus, it made sense that the theory of action use this predicate in a defining sense as well, and speak of actions only when there is sufficient reason to assume that the action or behavior took place intentionally. For the social sciences in so far as they conceive of themselves as sciences of action, but also in a court of law or in morally relevant situations, it is important to know what it is that makes occurrences in the world actions. Reflex movements or forms of instinctual behavior certainly do not belong in this category; they are objects neither of social scientific research nor of normative judgment. The specific difference of actions is usually seen in the fact that they took place deliberately, and only under this condition is responsibility taken for them. The question, then, is how this relation to intentions fits together with the causal interpretation of all world events: are intentions causes? If so, then they themselves would have to have been caused, and this is considered incompatible with our self-understanding as subjects acting freely and spontaneously.

In opposition to the neo-positivist concept of a physicalistic unified science, which also ties the social sciences to behaviorism—that is, to the description and explanation of observable behavior only—the attempt has been made since the 1950s, above all in Anglo-Saxon analytical philosophy, to place the theory of action on its own foundation. In this attempt, special meaning was attached to the concept of 'intention' (cf. Anscombe 1957). Related concepts were grouped around it, all of which were explicated more precisely with the goal of countering the physicalists' causal manner of speech with an intentional vocabulary that also enabled one to speak in scientific terms about the intentions, motives, and reasons for actions. The central differences became clear above all in the extensive debate that took place in the 1960s about causes and reasons. According to the intentionalist camp, two characteristics above all distinguish reasons, as the clearest intentions or motives for action, from causes. First, reasons are not events that are followed by other events according to general laws of nature, but rather, they are subjects' dispositions to bring about specific events under specific circumstances. Second, reasons, like intentions or motives, relate to what follows from them, and not, like cause and effect, to each other. According to Hume, one can speak of causality in the strict sense of the word only when cause and effect are two events that can be described as logically independent of one another. This is not the case here, as one cannot ascribe to someone a reason for any action without making reference to this same action. Thus, someone who did not take a specific action also cannot have had a reason for this action. (This is referred to in the literature as the 'logical connection argument': cf. Melden 1961, p. 78ff.)

The reference to the special status of intentions and their meaning for the description and explanation of events as actions also led to attempts at opposing the causal explanations of the natural and behavioral sciences with another explanation type: that of intentional or rational explanations (cf. Schwemmer 1973), which are to be determinative in the sciences of action. (When speaking of rational explanations, 'rational' refers to the reasons (*rationes*) that someone has for doing something specific.) In this context, recourse is made to Aristotle's practical syllogism, which can be considered an elementary form of practical rationality in general (cf. von Wright 1963).

The thesis 'what we call causes in the case of physical events are, in the case of actions, intentions (reasons, motives, aims)' does admittedly lead to the problem that actions are also physical events—for example, bodily movements—and in this respect, of course, also have causes. Thus, when the thing–event language and the action–reason language are used in parallel, they are simply two different descriptions of one and the same occurrence in the world, and the problem arises of how these two kinds of description can be reconciled with each other. The same holds for the compatibility of causal explanations of action with intentional explanations of action: it can be ensured only by accepting that the intentional explanation type is not a sub-type of causal explanation forms, but something else with a completely different aim. Additionally, Donald Davidson (cf. Davidson 1980, p. 7ff.) showed that it is very sensible to view not the reasons themselves, but rather the complex intentional disposition of having reasons as a causally effective factor.

2.2 Intentionality from a Psychological Standpoint

In the late scholastic period, the expression *intentio* was used as a generic term for concepts and ideas, whereby a distinction was made between *intentio prima* and *intentio secunda*. *Intentio prima* applied to things and facts, while *intentio secunda* had other *intentiones* as its object: as thoughts about thoughts. In this case, *intentio* thus has an object which itself is an *intentio* and which only exists within it. Franz Brentano characterized consciousness using this figure of the intentional inexistence of the *intentio prima* in the *intentio secunda*. According to Brentano it is always consciousness of something, and intentionality, in this sense of being directed at an inner object, was considered by him to be the specific characteristic that differentiates mental states from all others. Brentano's student Edmund Husserl adhered to his teacher's model, although with several changes, and thus also to 'intentionality' as a fundamental concept of his phenomenological philosophy. The same is true of the phenomenological schools that broke with Husserl (including Scheler, Heidegger, Sartre, and Merleau-Ponty). Furthermore, the work of Alfred Schütz is important (especially *Der sinnhafte Aufbau der sozialen Welt* 1974): he took up the ideas of Husserl and, using phenomenological means, undertook to lay the foundations of sociology as an understanding (*verstehende*) and at the same time explaining (*erklärende*) science of action in Max Weber's sense. Weber was interested in defining the difference between mere behavior and action with a 'subjective meaning,' that is, action to which agents attach their own meaning (Weber 1974, p. 542). The phenomenological concept of intentionality opened up the opportunity for Schütz to explicate more precisely what could be meant by the term 'subjective meaning.' The phenomenological tradition found its way into the discussion of the foundations of social sciences through Schütz above all, and here provided an important additional stimulus to the methodological programs of symbolic interactionism and of ethno-methodology.

2.3 Intentionality from the Standpoint of Linguistic Philosophy

In contrast to Brentano and the phenomenologists, linguistic philosophy maintains that thoughts cannot

be discussed independently of their expression in language. In this field, Rudolf Carnap in his *Logischer Aufbau der Welt* (1966) was the first to study 'intentional relationships,' that is, the logical relationships between sentences beginning with 'X thinks,' 'Y believes,' or 'Z assumes' and the clauses which, as a rule, follow the word 'that.' In designating such verbs as 'intentional,' Carnap expressly followed Brentano and Husserl, but with an important difference in interpretation: he held that an entire sentence must always follow the 'that.' The idea that intentional attitudes always relate to something that exhibits the form of an entire sentence and, only in this context, to objects has been disputed ever since. For this reason, such attitudes are also known as propositional attitudes. The grammatical forms in which we present such attitudes do admittedly have the unpleasant characteristic of not conforming to the demand of extensionality. This means that the truth value of sentences such as 'X believes that *p*' is not a function of the sentence parts contained within them, since it could be true that X believes *p*, even if *p* is false. This connection between intentionality and intensionality, which means that sentences expressing intention are extensionally opaque, has prompted many philosophers to follow the example of W. V. O. Quine in banishing the intensional context from scientific language—although admittedly at the cost of having to bring the intentional into compliance via a purely behavioral interpretation of physicalistic–extensional description and explanation.

Today, the intentional is no longer threatened by reductionism. At least since Wittgenstein's late work and Gilbert Ryle's classic, *The Concept of Mind* (1949), the philosophy of mind has striven to provide the intentional attitudes their grammatical right as well, but without falling back into the pre-lingual self-observation or introspection with which Brentano and the phenomenology of Husserl operated. Daniel Dennett (1991) in particular made important suggestions for an answer to the question of what it means to ascribe intentionality (intentional stance) to organisms or machines. His most formidable opponent for many years was John R. Searle, who does not hold intentionality to be merely something ascribed by an observer, but rather, a natural quality of specific organisms. The question of the naturalizability of consciousness (cf. Dretske 1995)—that is, the possibility to describe and explain intentionality exclusively by natural scientific means—has been debated heatedly since then.

In language theory as well, the topic of 'intentionality' has been discussed in depth, particularly in connection with the thesis of Grice (1957) which states that linguistic meaning can be understood and reconstructed exclusively from that which a speaker means and expresses in communicative actions. In simpler terms, this intention-based semantics (cf. Meggle 1994) refers back to what a speaker wants to give a hearer to understand through his or her speech act. Thus, it brings together the semantic aspect of intentionality with the aspect of intentionality represented in theory of action. In his work *Intentionality*, Searle (1983) submitted a superior version of this approach to Grice's, with the central thesis that intentionality is a basic state of mind that 'gives' the mind its linguistic expression. With this, suddenly Searle's earlier theory of the speech act appeared as a branch of the philosophy of mind. The opposing position to this intentionalism in semantics is conventionalism (e.g., Wittgenstein), according to which all that we can mean and communicate is already set out according to linguistic conventions and rules. The conventionalist asks 'How can I know what I mean before I hear what I say?' (Black 1977). The strength of the conventionalist position is that it refers to what a speaker means and can give a hearer to understand, even before the speaker has to be present in verbal or just symbolic form (cf. Schnädelbach 2000, pp. 204ff.), because 'X means that' and 'X wants Y to believe that' always needs a propositional object which is itself written in grammatical form. Not only is the relationship between intentionality and conventionality (Strawson 1971, pp. 174ff.) interesting from the point of view of language theory; it also applies to a wide variety of types of action—for example, to ritual or institutional actions—and not merely to speech acts.

3. *Rationality*

The word 'rationality' is currently used mostly in the sense of means–ends rationality (*Zweckrationalität*), which takes as its own example the economic conception of rationality. What it means is always the optimal balancing of ends and means while giving primacy to ends, which can either not be rationally justified at all or only incompletely. However, this model cannot adequately express all that is connected historically and objectively with the *rationalitas* of the *animal rationale*. The philosophical tradition, admittedly, seldom used the expression 'rationality' and always gave preference to other terms such as 'reason' or 'understanding.' Therefore, the concept of rationality has only returned to modern philosophical discourse via the detour of discussions in the social sciences and in the theory of science. It is well known from common experience with unreasonable rationalizations that a distinction can be made between the rational and the reasonable; thus, a philosophical theory of rationality should be defined broadly enough to encompass such intuitions.

3.1 *A Narrower and a Broader Concept of Rationality*

The predicate 'rational' is most often used in a normative or evaluative sense, whereas the opposite

appears as 'irrational' in the sense of being contrary to reason. Thus, we judge actions, institutional rules, and also people by means of a criterion of rationality, and discover that what is being judged is inadequate to the criterion. The fact that we are dealing here with the narrower concept of rationality becomes clear when we recall that we are also talking about the opposite of the rational even when such a judgment does not come into question at all. In this case, we use the 'irrational' to designate that which is lacking reason or is arational. This broader concept of rationality thus serves to separate from the wide variety of things and events those things which we could view as candidates for a normative or evaluative judgment according to the narrower concept of rationality. Rationality, as the opposite of unreasonableness, is probably the same thing as understandability; we use the narrower, normative concept of rationality only for behavior patterns and expressions where there is something to understand about the causal or functional explanation (cf. Schnädelbach 1992, pp. 79ff.). The relationships between this broader concept and the normative concept of rationality were the topic that was debated following the theses of Winch (1958) among philosophers and social scientists on 'rationality and relativism' (cf. Hollis and Lukes 1982, Wilson 1970). The question, then, is whether rationality as understandability simply coincides with intentionality. What is certain is that intentionality is a necessary condition for rationality qua understandability, but it is not certain whether it is a sufficient condition. The concept of the rule appears to decide this question: it is to be assumed that the understandability of behavior patterns and expressions presupposes the capacity to follow rules which the person understanding them is also in a position to follow. There is much evidence suggesting that intentionality exists below the level of following rules as well, although here the condition of understandability would not yet be fulfilled.

3.2 Types of Rationality

The fact that we always have to reckon with different types of rationality (cf. Schnädelbach 2000, pp. 256ff.) has been known to philosophy since its beginnings. Plato's differentiation between *nóesis* and *dianoia*, which was passed down into the modern age via the difference between *ratio* and *intellectus* or between reason (*Vernunft*) and understanding (*Verstand*) can be mentioned in this context, as can Aristotle's doctrine of the five dianoetic virtues, Scientific Knowledge, Art, Prudence, Intuitive Reason, and Wisdom. Even when one assumes the usual, but much too narrow, interpretation of rational competence as the capability of establishing reasons, one must make further differentiations. Because of the fact that Aristotle defined the capability of establishing reasons—which according to him constitutes the specific characteristic of scientific knowledge—in general terms as the ability to answer why-questions, we have had to clearly differentiate between causes (*causae*) and reasons (*rationes*) since the seventeenth century. Therefore, at the beginning of the twenty-first century we regard answers to questions about causes as explanations, and only answers to questions about reasons as 'the establishing of reasons' in the strict sense. We can differentiate between cognitive and normative types of explanations: while cognitive (causal, final, functional, historical, etc.) explanations tell us why something is the case, normative explanations inform us about why something should be the case. Establishing reasons, on the other hand, relates in the epistemological case to reasons that indicate why one could believe something to be true, and in the intentional or rational case, to what—within the bounds of what we can possibly know—can be said for doing or not doing something specific. The intentional or rational establishing of reasons is the locus of the social scientific model of rationality, since neither in the case of economic rationality nor in the case of Weber's means–ends rationality does it play a role whether subjective calculations correspond to reality to the best of one's knowledge or not. Thus, someone who made a mistake was not irrational but simply unlucky. This is also the locus of those intentional or rational explanations for action mentioned in Sect. 2.1 which cannot be interpreted as a special type of causal explanation because of their relation to the subjective perspective of the agents.

Often, 'establishing reasons' is used in the sense of the Latin *rationem reddere* or the Greek *lógon didónai* to mean argumentation. However, this usage often fails to recognize that argumentation, as a reflection of critique and justification, relates not directly to things, occurrences, or actions—after all, nobody criticizes or justifies the fact that the sun will rise tomorrow—but to the claims to validity that are connected with assertions about things, occurrences, or actions. The most important of these claims to validity are those of truth and rightness. The question whether or not an occurrence took place is not the theme of argumentation, but rather, the assertion that this occurrence did take place. Here, as well, the issue is not primarily whether or not an action is good, but whether the thesis that this action is good can be justified or not. In simpler terms, the rationality type 'argumentation' is to be located on the meta-level of speaking about assertions that apply to things and occurrences or actions. There is much evidence to support the idea that when Kant and Popper among others defined reason as essentially a critical faculty, they had this type of rationality in mind. However, in order for something that can be the object of argumentation—that is, of critique and justification—to come about at all requires rationality in the broad sense, that is, qua understandability. Thus, understandability is the more fundamental type of rationality.

3.3 Incompleteness of Every Theory of Rationality

The idea that it is probably impossible to explicate rationality all at once, as a whole and for all contexts is supported by the fact that every explication of rationality must itself have a claim to rationality. Therefore, it cannot discuss its own medium of explication and the implicit standards of explication contained in it as long as it makes use of them itself. Admittedly, this is possible in other contexts, but then as well something outside the theme of discussion is left behind (cf. Putnam 1981, Chap. 5). From this emerges an argument against the radical skepticism regarding rationality that has come into fashion under Nietzsche's influence; if it really takes itself seriously, it forgoes the opportunity to present itself as a serious position.
