and, though still in its beginnings, to liaison psychiatric services with nursing home populations. For primary care settings, studies show that inclusion of a psychiatrist in primary care treatment teams, e.g., on the basis of regularly performed visits of a psychiatrist, leads to a marked improvement in the symptoms of patients with somatization disorder or depression than provision of services by primary care physicians alone (APM 1997). For nursing home populations, the need to consider psychopharmacological as well as nonbiological interventions such as talking therapies, recreational therapies, and so on, in combined treatment plans tailored to specific residents and specific nursing home settings, stress the need for psychiatrists to oversee the implementation of such integrated approaches. Hence, liaison models with more intense involvement of psychiatrists working with other nonpsychiatric physicians, as well as administrative and nursing staff in addition to care for residents and their relatives will be developed in the near future. The latter holds especially true for people with mental retardation (or learning disability) living in nursing homes, as diagnostic and treatment approaches in this clientele will require special expertise not necessarily familiar to primary care physicians, or even psychiatrists themselves. Especially in patients that are not able to communicate verbally, 'cooperative' and 'uncooperative' behavior may reflect an underlying psychiatric disorder, which in turn may be treatable, as in the case of hostile behavior in demented patients with dysphoric depression that may well respond to pharmacological treatment with, for example, selective serotonin reuptake inhibitors. C-l psychiatrists working in such settings are ideally placed to teach nursing staff and primary care physicians that expert assessment of behavioral and psychological symptoms in nonverbal patients may lead to more specific management and better patient care. Thus a patient with dementia whose delusional experiences lead to bizarre behavior should be treated differently from a demented patient who suffers from pain, or a depressed nonverbal patient who refuses aggressively to accept food (Reichman and Katz 1996).

Despite the increasing interest in models of collaborative care in the outpatient, as well as nursing home sectors, it has to be borne in mind, that, at least at this point in time, many patients with somatopsychic comorbidity are seen for the first time by a psychiatric specialist after having been admitted to a general hospital. Thus, psychiatrists as well as planners of health services will have to bear in mind the importance of the general hospital as a pathway to specialist psychiatric care.

2.3 Evaluation of C-l Psychiatric Interventions

Psychiatric care leads to improved management of medically ill patients with psychiatric comorbidity. This is the rationale of the practice of c-l psychiatry, whose benefits can be demonstrated within a value matrix, taking into account treatment outcomes in medically ill patients with psychiatric comorbidity, as well as economic savings by adding specialist psychiatric treatment to standard medical treatment. Cost–benefit issues of consultation psychiatry service delivery have been demonstrated initially in general hospital inpatients, with primarily US studies showing a trend to reduced length of hospital stay with corresponding reductions in cost of treatment in medical patients after a psychiatric liaison service was inaugurated, compared with control groups without such an intervention program (APM 1997). However, as other studies failed to show such an effect, the overall conclusion was that this research approach had to be judged as inconclusive in the face of a sharp decrease in lengths of hospital stays worldwide due to secular trends in shifting the provision of healthcare into the outpatient sector in order to reduce the escalation of overall healthcare costs. Consequently, research on the efficacy of psychiatric intervention strategies in patients with psychiatric (co-)morbidity in the primary care sector has increased. Studies showed that integrated c-l psychiatric approaches, but not those that only offered screening strategies to identify patients with psychiatric disorders, has led to improved outcomes in patient care (Katon and Gonzales 1994). In the inpatient setting, models of integrated medical and psychiatric care also are being proposed.

3. Future Developments in C-l Psychiatry

Future developments will see an increased emphasis on the education of psychiatrists in collaborating with primary care practitioners in the treatment of medically and psychiatrically ill patients, the development of models of integrated care, and the need to develop and implement guidelines and standards of care in quality assurance programs.

3.1 Education

The education of physicians working at the interface of medical–surgical and psychiatric medicine has to be twofold. Psychiatrists have to learn how to treat medically ill patients with psychiatric comorbidity. Psychiatric training cannot remain restricted to gaining experience predominantly with patients with schizophrenia or manic-depressive illness, but has to take into account the needs of patients suffering from medical illnesses and comorbid psychiatric illness, for example, depressive patients suffering from cardiac disease or stroke, who require somatic as well as

psychological treatment. To achieve this goal, c-l psychiatric curricula are being developed within specialist psychiatric training, e.g., in Europe and the USA. Psychiatrists will have to become proficient in mastering diagnostic and treatment problems arising from somatopsychic comorbidity, e.g., address problems of diagnosing depressive disorders in the medically ill, and adjusting psychological as well as psychopharmacological treatment issues for patients suffering form both medical and psychiatric disorders.

On the other hand, c-l psychiatrists will have to expand the education of primary care physicians, in order to broaden nonpsychiatric doctors' knowledge of and experience in diagnosis, referral, and treatment of patients with psychiatric (co-)morbidity, in order to improve the care of patients with somatopsychic disorders in primary and hospital care settings. Psychiatrists, as well as nonpsychiatric physicians, will have to adopt behavioral medicine treatment strategies for patients with for example, somatization disorders and chronic pain syndromes, and will have to learn treatment strategies other than psychotropic drug prescribing, strategies such as cognitive behavioral treatment for patients with adjustment disorders, anxiety disorders, and the milder depressive disorders (so-called subthreshold disorders), as these disorders make up the bulk of psychiatric comorbidity treated in the primary care sector.

3.2 Guidelines and Quality Assurance

As the awareness for an improved psychological care of medical and surgical patients increased toward the end of the twentieth century, one step has been the development of guidelines in order to define standards of care. In the UK, conjoint working parties of physicians, surgeons and psychiatrists (Royal Colleges of Physicians, and Psychiatrists 1995, Royal Colleges of Surgeons and Physicians 1997) published documents with practical suggestions regarding methods of identifying potentially harmful psychological components of patients' illnesses, and recommendations for the provision of care as well as for referral for psychiatric help when appropriate. As only a minority of patients will need psychiatric care in addition to medical–surgical treatment, these guidelines underline that normally physicians and surgeons should be able to make some assessment of psychological factors. The guidelines propose simple screening mechanisms in order to improve detection of psychological disorders in the general hospital, for example, the *CAGE Questionnaire* for screening for alcohol misuse. Overall, the implementation of guidelines is thought to help in a number of areas, such as in reducing the number of investigations performed for physical symptoms that result from underlying stress, as, for example, in patients with somatization; help in relieving symptoms of stress and improving the quality of life of patients with serious physical illness; and, from an economic perspective, reducing the length of stay in hospital caused by psychiatric comorbidity.

It is assumed that the implementation of guidelines within quality assurance programs will lead eventually to improved patient care. However, measures against which to gauge c-l psychiatric interventions have yet to be established. Given the low referral rate for psychiatric consultation as compared with the high prevalence of medical–psychiatric comorbidity, and the need for specific psychiatric treatment in general hospital inpatients, as a first step to improving care, the C-l Psychiatric Section of the Royal Australian and New Zealand College of Psychiatrists proposes to define the benchmark for psychiatric referrals to be 5 percent of all admissions to medical–surgical wards of a general hospital. If this percentage is not reached, an audit should be performed to establish whether there are identifiable reasons for not providing psychiatric support in an adequate number of patients in medical–surgical departments of a given general hospital.

3.3 Research in C-l Psychiatry

Basic requirement for research in c-l psychiatry is the identification of high-risk patient groups, such as those suffering from a significant amount of psychiatric comorbidity. Failure to identify such high-risk groups, along with the overstated assumption that just one psychiatric consultation might lead to improved patient outcomes may have been the basis of the ambiguous results of general hospital inpatient intervention studies performed in the USA in the 1980s. C-l research in the primary care setting, on the other hand, has demonstrated that restriction to a high-risk group with identifiable psychiatric comorbidity, e.g., high utilizers in primary care suffering from a psychiatric disorder, such as somatoform disorder, may that demonstrate a psychiatric intervention can lead to improved patient outcomes, if the intervention is intense enough, i.e., consisting of an eight-session block of group therapy (Katon and Gonzales 1994).

Problems that need to be solved in order to improve care of patients with medical–psychiatric comorbidity are:

(a) To develop a more precise description of the phenomenology of psychiatric illnesses comorbid with particular physical illnesses, e.g., as in the case of the diagnosis of depression in cancer or stroke patients (Guthrie and Creed 1996).

(b) To study the natural course of psychiatric comorbidity in relation to an underlying or con-

comitant physical disease, e.g., in which patients suffer from a depression not expected to be resolved spontaneously once the physical disease has been treated successfully.

(c) To further study efficacy and effectiveness of psychotherapeutic and psychopharmacological treatment strategies in patients with medical comorbidity. Meta-analyses point out that antidepressants are as effective in depressive patients with medical comorbidity as in those without (Gill and Hatcher 1999).

The effectiveness of different models of care for patients with medical–psychiatric comorbidity with regard to different outcome measures such as clinical improvement, quality of life, or cost effectiveness, will require further investigation, especially in inpatient settings for different patient populations, e.g., acute vs. chronic care patients, with regard to differential effects of more traditional consultation or liaison approaches vs. models of integrated medical–psychiatric care.

3.4 Integrated Medical and Psychiatric Services

A model for integrated medical and psychiatric treatment programs within the general hospital are so-called medical–psychiatric units. Such units received increasing interest in the USA during the 1990s. Medical–psychiatric units are run jointly by physicians, mainly internists, and psychiatrists. They care for high-risk patients, for example, delirious patients who cannot be managed on a medical ward, or suicidal patients in need of acute medical treatment that cannot be provided on a psychiatric ward. It seems possible that such conjoint models of care in the inpatient setting lead to improved patient outcome while saving costs, as compared with traditional models of sequential care with referrals from psychiatric to medical departments and vice versa (Rundell and Wise 1996). They may be the new wave of the future in a changing health care environment that will be looking for more effective ways of treatment beyond the boundaries of traditional departmental structures of general hospitals.

4. Epilogue

Readers interested in widening their knowledge of the topics dealt with in this article are referred to the *Consultation-Liaison Psychiatry Database*, compiled and in part commented upon, by international experts in c-l psychiatry, which contains approximately 2,500 citations of articles, book chapters, and books delineating the state of the art in the field (Strain 1999).

Liberalism

Liberalism is a family of political philosophies, and a set of associated institutions and policies. All liberal philosophies give primacy to the protection of basic liberty. Competing versions of liberalism—such as democratic liberalism and libertarianism—differ in their answers as to what basic liberty is, and what institutions best protect it. Since its origins, liberalism itself has been an object of controversy. At the same

time, liberalism has been committed to defending the set of freedoms—of speech, press, conscience, and association—that support the rights of all parties to carry on such controversies in public.

1. Origins

Although the term 'liberalism' was not used until the early nineteenth century, major elements of liberal political philosophy originate in the seventeenth century. The first systematic defense of a politics that gives priority to individual liberty was John Locke's *Two Treatises of Government* ([1690] 1988). Against Thomas Hobbes's defense of absolute sovereignty (*Leviathan* 1651), Locke argued that individuals have a set of natural rights to life, liberty, and property that they do no alienate to any government, and they therefore have a right to revolt against a government that violates those rights. The American Revolution of 1776 has Lockean liberal roots, as does the political thought of James Madison and other framers of the US Constitution.

Adam Smith offered the first systematic exposition of liberal economic theory (*Wealth of Nations* 1776). Social wealth is generated not by direct state action but by the invisible hand of free competition among producers and consumers. Smith presents a liberal plan of equality, liberty, and justice that links commercial freedom to a constitutional political order protective of civil and political liberties. Although Smith uses 'liberal' in its then everyday sense of open-mindedness of spirit, he links open-mindedness to a political program that grants individuals the greatest freedom from interference compatible with a like freedom for all.

On the Continent, liberal political theory also developed throughout the eighteenth century: The major liberal thinkers of the French Enlightenment criticized the *ancien regime*; Voltaire championed individual freedom of thought and religion (*Lettres philosophiques* 1734); and Montesquieu defended a system of checks and balances and separation of powers as means of protecting individual freedom (*L'Esprit des Lois* 1748). In Germany, Wilhelm von Humboldt defended limited government as a means to facilitate the development of human powers to their highest level in *Ideen zu einem Versuch, die Grenzen der Wirksamkeit des Staats zu bestimmen (Ideas Toward an Investigation to Determine the Proper Limits of the Activity of the State* 1792).

Not until 1812, however, was the term 'liberalism' actually used in politics. The Spanish political party, the *Liberales*, mounted a Lockean defense of constitutional monarchy, parliamentary government, and human rights against absolute monarchy. Ironically, Tory politicians in England called their domestic opponents *'liberales'* rather than 'liberals' in order to suggest that liberal politics were un-English. Before long, however, the term 'liberal' became widely associated throughout the Anglo-Saxon world with a defense of individual liberty and a critique of absolutist government.

2. Development of Conceptions and Controversies

As the influence of liberalism increased throughout the nineteenth and twentieth centuries, different conceptions of liberalism developed, as did controversies between them, and between liberals and their critics. Three major controversies, each discussed below, are the debate between liberalism and libertarianism; conservative, radical, and communitarian critiques of liberalism; and the emergence of political liberalism as an alternative to comprehensive liberalism.

2.1 Democratic Liberalism vs. Libertarianism

The early nineteenth century French philosopher Benjamin Constant contrasted 'the liberty of the moderns'—freedom of speech, religion, and association, and other legal protections of the individual from outside interference—with 'the liberty of the ancients'—the freedom of citizens who collectively exercise popular sovereignty (1819/1988). All forms of liberalism affirm the liberty of the moderns, and therefore give primacy to protecting basic individual liberties against the tyranny of any political authority, no matter how popular. But democratic liberalism puts fewer constraints on popular government than libertarianism.

Two related concerns—about how to protect individual freedom and how to realize the full value of individual freedom—lead many liberal thinkers to ally liberalism closely with democracy. Individuals who are preoccupied with their own private lives may neglect the need to guard their political guardians and they also may be prevented by their government from developing some important part of their own potential. An antidote to these dangers, according to Constant, is political liberty, which will have the effect of enlarging the vision and spirit of citizens, and opening up more public offices and activities to ordinary citizens.

Democratic liberalism condemns the tyranny of the majority but defends representative democracy (John Stuart Mill, *On Liberty 1859* and *Considerations on Representative Government 1861*). Along with *Alexis de Tocqueville* (*Democracy in America 1835*), Mill argues that without effective opportunities to participate in political and civic associations, ordinary people will be easily manipulated by demagogues and public opinion, and individual freedom will become a hollow ideal. Democratic liberalism therefore includes both political and personal freedoms among the most basic individual liberties.

The modern model of liberal democracy differs in two important ways from ancient Athenian democracy. First, most citizens do not directly participate in policy making but are represented by public officials (who are to be held accountable by frequent, free, and fair elections). Second, government is constitutionally required to respect individuals' personal liberties of individuals, not only their political freedoms.

Contemporary conceptions of democratic liberalism support taxation for many public purposes, not only to provide for the common defense and the education of children, but also to maximize the worth of liberty for the least advantaged citizens, as John Rawls argues in *A Theory of Justice* (1971). The power of government is limited for the sake of protecting basic individual liberties, but the limits on government are viewed as compatible with regulating the economy in order to protect the worth of liberty for all individuals. Equality and democracy are regarded as allies of liberty. The overarching aim of liberalism, according to Ronald Dworkin's 'Liberalism' (1978), is to treat free individuals *as equals*, but not equally. Judith Shklar (1998) argues that liberalism requires democracy, because political rights and freedoms are needed to defend freedom. Other liberals defend an increasingly popular conception called deliberative democracy, which defends a politics that respects the basic freedoms and opportunities of all individuals and also encourages publicly accountable deliberation to help resolve political disagreements and promote mutual respect among citizens amidst the disagreements that remain unresolved (Gutmann and Thompson 1996).

Libertarianism, by contrast, downplays both democracy and equality. The classical libertarian Herbert Spencer (1894/1981) defends the unfettered economy on pragmatic grounds—as a way of maximizing social wealth—but also on principled grounds as a reward for individual desert, which he argues is best measured by a free market. Libertarians accept the need for a minimal level of taxation to provide necessary public goods such as a common defense. But taxation for the purposes of redistribution, as contemporary libertarians like Robert Nozick argue (1974), is on a par with forced labor, a clear violation of basic liberty. Libertarians begin with a premise of self-ownership. If individuals own themselves, then they have a right to their natural assets. More controversially, libertarians argue that individuals also have a right to whatever flows from the politically unfettered use of those assets in society.

Democratic liberals and libertarians are united in defending a broad set of civil liberties (freedom of speech, press, association, conscience, and religion), a market economy, and the right to own personal property, but they part company over taxation for social welfare purposes. Whereas democratic liberals subscribe to the American revolutionary slogan 'no taxation without representation', libertarians—who often identify as 'conservatives' in US politics—defend freedom from taxation except when absolutely necessary to support the minimal—'night watchman'—-state. This dispute can be viewed as a family quarrel, and US politics is often characterized as an arena of conflict among competing versions of Lockean liberalism (Hartz 1955).

2.2 *Conservative, Radical, and Communitarian Critiques*

Conservative, radical, and communitarian political perspectives each pose a different challenge to the liberal emphasis on the priority of individual liberty.

The disagreement between Edmund Burke and Thomas Paine ([1992]/[1792] 1995) over the French Revolution reveals the basic tension between conservatism and liberalism. Whereas the American revolutionaries, according to Burke, were fighting to preserve their traditional birthright (the rights of Englishmen), the French revolutionaries were trying to remake their society, a treacherous task, which would 'like a palsy' attack 'the fountain of life itself' (Burke, *The Revolution in France* 1790). Paine avidly supported both revolutions in the name of the kind of liberal philosophy—a universalistic defense of human rights–that is anathema to conservatives like Burke and more recently Michael Oakeshott (1991 *Rationalism in Politics and Other Essays*) who develops a more philosophical version of the conservative critique of liberal rationalism. Liberalism today is defended in theory as in practice on both particularistic and universalistic grounds.

Whereas conservatives argue that liberalism goes too far in defending individual rights, radicals argue that it does not go far enough. According to the radical critique, inspired by the early Marx, liberalism's defense of individual freedom is sorely insufficient to the aim of actually liberating individuals from the oppressive power relationships that are endemic to a capitalistic economy, to which liberalism is committed. Liberal egalitarians (Gutmann 1980) meet radicals on their own ground by arguing that liberalism supports whatever economic system will best secure the worth of liberty for the least advantaged citizens, not just the most advantaged. Other radical critics argue that the coercive and manipulative powers of the state apparatus, modern media, and mass public opinion combine to undermine any possibility of individual liberation. Radical feminists mount a more focused attack on the liberal right to publish pornography, arguing that it furthers the oppression of women.

Drawing upon a conception of humans as historically conditioned beings, communitarians attack liberalism at its foundations for giving priority to individual freedom over the communal values—such as a shared religious faith—that give meaning to

human lives. Liberalism defends the priority of individual rights over the preservation of communal values. It accepts the idea of human beings as historically conditioned and still consistently defends individual liberty as a primary value that politics should protect. The enforcement of individual rights, liberals argue, is necessary to protect people against the contemporary equivalents of witch hunting. Speculation that communal bonds of fraternity can take the place of justice in a modern pluralistic society has not been strong enough to undermine the liberal defense of individual rights (Gutmann in Avineri and de-Shalit 1992).

2.3 Political Liberalism as an Alternative to Comprehensive Liberalism

John Rawl's *Political Liberalism* (1993) marked an important new development in liberal theory. Other conceptions of liberalism—such as the perfectionist and autonomy-based theory of Joseph Raz (1986)—offer comprehensive philosophies of life, which include ideals of personal character, friendship, and association. By contrast, political liberalism is a moral conception concerned only with the basic structure of a society, and presented as a view that is independent of any comprehensive doctrine. Its fundamental terms—such as the idea of individuals as free and equal citizens—are derived from the public political culture of a liberal democracy. Political liberalism recommends its principles as a way of fairly resolving disagreements in a pluralistic society; it does not expect free and equal citizens to agree on one comprehensive conception. Political liberalism instead locates an overlapping consensus in the midst of reasonable pluralism. Like liberalism itself, political liberalism is a family of conceptions, which share the aim of finding fair terms of social cooperation among free and equal members of a democratic society.

Accompanying the development of political liberalism are other conceptions of liberalism, including feminist liberalism and multicultural liberalism. These build on the basic premises of either political or comprehensive liberalism, and explicitly address the concern that women and cultural minorities should not be excluded from enjoying the full benefits of liberal freedoms and opportunities by virtue of their gender, race, ethnicity, or cultural identity. The family of different conceptions of liberalism continues to grow rapidly at the same time as various forms of liberal democracy multiply around the world.

Liberalism and War

Liberalism is the label attached to the philosophies, doctrines, and political movements that are concerned with the relationship between the exercise of political authority and the pursuit of welfare by individuals and groups governed by that authority. No other political and philosophical tradition has sustained as intense and long-standing an effort to eradicate war from modern political life, or at least mitigate its affects on the welfare of societies. Liberal ideas continue to attract thinkers and activists around the world as they struggle to overcome deadly conflicts within societies and the possibility of large-scale war across the globe.

1. The Liberal Tradition

With precedents running back at least to the seventeenth century, liberalism became an established intellectual and political movement from the last

decades of the eighteenth century onward. Figures as famous as Thomas Paine, Immanuel Kant, John Stuart Mill, Richard Cobden, L. T. Hobhouse, Woodrow Wilson, and Thomas Dewey are among the ranks of public intellectuals associated with the liberal tradition.

Liberals have addressed a diverse range of social issues from economic life to education. Common to that diversity is the self-understanding of liberals that their goal is to maximize the well-being of members of society through increased freedom, equity, or security. Political and civil rights, economic and market freedoms, and provisions for the redistribution of wealth have been turned to as means to achieve this well-being. The varying and sometimes contradictory nature of the values—freedom, equity, and security—within the liberal tradition means that liberalism is not reducible to any fundamental principle or doctrine, despite common concerns with political authority and human welfare. Indeed, states and societies that can be counted as liberal have taken quite different forms depending on whether individual economic rights are stressed over the redistribution of wealth or the social security of families.

Liberals have naturally been focused on the political and social life of individual states and societies, since the perfection of civil and political society has been so central to their aspirations. But many liberals, recognizing that domestic life is shaped by forces and processes external to national boundaries such as war, have focused their attention on the nature of international life.

In the international realm, liberal concerns have been concentrated in a number of areas. Most famously, multilateral economic exchange and the relatively free movement of goods and capital across state boundaries (or international 'free markets') have preoccupied liberals. Open economic relations tie states, civil societies, and domestic market economies into complex networks of international economic relations. These relations and networks are taken by liberals to expand the economic freedom of market actors and limit the restrictions to that freedom inherent in state-defined borders. From Adam Smith in the late eighteenth century and the Manchester School of free traders in the nineteenth century, to the architects of Bretton Woods during World War II, liberals have generally assumed that economic openness is essential to well-being within and across national borders.

A second area of liberal concern has been the advancement of liberal forms of government across the globe. From Kant and Woodrow Wilson through Francis Fukuyama (1993), liberals to varying degrees have considered the global spread of representative government, the rule of law, constitutional limits to executive power, and democratic processes as essential to their social vision. Viewing political liberalization as an international process, spreading from nation-state to nation-state, has been compelling for liberals most basically because any discussion of liberalism as a real political and social force in the world has little meaning without the presence of at least some liberal social spaces within it.

Liberals, especially in the twentieth century, have also made the international spread of human rights—political, civil, and economic—a process critical to the promotion of liberalism. Indeed, rights are essential for all areas of liberal concern, from markets to political representation. While the struggle for rights has mostly taken place through political movements operating within individual nation-states, there has been a quite robust international effort to advance a wide range of rights. In the twentieth century human rights were encoded in myriad international declarations at the UN and addressed by many nongovernmental organizations operating on an international basis. Precedents in the nineteenth century include the transnational struggle against the slave trade and protections for minorities and citizens of other countries living abroad through international treaties.

A fourth area of focus in the international realm is national self-determination, which involves the legitimation of claims made in the name collectivities to establish and maintain independent states for self-government. It is the only area of social action in the international realm where there occurred anything like the sort of struggle against authority and power that liberal political and social movements undertook within individual domestic spheres. John Stuart Mill (1991) expressed the liberal belief that without independence it is not possible to fashion 'free institutions.' Liberals in the nineteenth century often supported nationalist movements for independence within Europe at the same time that they overlooked the contradictions posed by the empires their own states and societies pursued outside of Europe and its immediate periphery. Nationalist leaders emerging from the colonial world were, however, able to exploit the principles of self-determination to make claims against these very empires in the mid-twentieth century.

Also, some liberals have believed that human welfare can be advanced by the formation of an international community of states linked for the common purposes of peace, economic progress, or the strengthening of systems of international law. Others have gone further in advocating the construction of a transnational or universal community of humankind within which rights, entitlements, and human security are realized.

2. *War and Society*

A sixth area of concern to liberals has been war. For over 200 years advocates of liberal principles and practices in government, the media, the academy, and

public life have treated most war as inimical to human welfare. At the same time that liberal movements and practices became more widespread across the nineteenth and twentieth centuries the range and extent of destruction associated with war expanded. By the first half of the twentieth century states had devised new strategies to extract massive levels of material resources and human capital from society for war, and to apply them more effectively on the battlefield and ultimately against civilians living in rural and urban settings.

Of course, by almost any account, war is a disruptive force. While the loss of life and resources due to war can be staggering, liberals have had other reasons to be troubled by its destructive effects having to do with their interest in the construction and maintenance of a liberal commonwealth. Their interest in effective civil society, representative government, economic and political freedoms, operational markets, and systems of wealth redistribution has made the stakes of disruption especially high for them. War can lead to the suspension of rights (such as *habeas corpus*); the restraint of activities in the public sphere (such as in media 'black outs'); the rechanneling of economic life (such as in wartime command economies); the concentration of state power (such as in the enactment of martial law); and the restriction of individual access to basic necessities for physical survival (such as in the wartime rationing of food).

In addition, an issue for liberals regarding the effects of war that was prominent prior to World War I is the fear that the occurrence of organized, interstate violence reinforces the dominance of belligerent aristocratic classes over state and society. War and a militant aristocratic culture, in this view, provided an opportunity for the nobility to maintain their dominant positions within the war-making state and to prevent other forms of political and social organization attractive to liberals from becoming more prevalent. It was these very classes, forming an ancien regime of hereditary privilege, that liberals saw themselves struggling against in their pursuit of more diverse forms of political representation and more open economic relations based on robust markets.

While concerns with the impact of war on life inside individual states and societies have dominated the agenda of liberals, they have not ignored the effects of war directly on practices and structures in the international realm deemed relevant to liberalism. In the international realm war could cause disruptions and lead to injustices across a wide range of concerns. Established structures of international commerce and investment can be halted through attacks on trade routes; human rights can be violated across national boundaries through invasion; national aspirations to self-determination and sovereign independence can be undermined through military occupation; bodies of international law can be weakened through blatant disregard; and the international spread of norms of democratic governance can be constrained by subversion and conquest. For liberals concerned with the building of an international or universal community, war is seen as markedly debilitating since states typically take sides in exclusive alliances and wartime pacts that starkly define enemies and friends.

Alternatively, wars can stimulate significant forms of political and social change relevant to liberals. Most directly, liberal causes have been advanced by large-scale, organized violence in the name of liberty, from the American War for Independence onward. Wars can also provide political actors with new conditions and historical contexts within which to operate. For example, out of World War II emerged the Declaration of Human Rights, new international structures for trade and investment, a renewed and more broad-based commitment to democratic governance, a greater legitimacy granted to claims to self-determination by colonized peoples, and new forms of international political community among states in the West. Governments also experimented with new systems of income redistribution through welfare, progressive taxation, and social security. Some liberals like Immanuel Kant (1970) have argued that war can help establish—and strengthen existing—republics. Others have argued that war can be justified in the name of self-determination against tyranny and civil and political rights against oligarchies. But, as recognized by historian Michael Howard (1986), liberals historically have never really come to terms with the fact that war can be a productive force for social change and not just a practice automatically condemned.

3. *Liberal Reforms for Peace*

The long-standing critical attitude of liberalism to war has carried some force in public life in part because thinkers in the liberal tradition have typically combined their condemnations of war with broad-ranging and complicated programs for actually counteracting the conditions and forces that lead to it. These include changes in the political regimes of states; the structure of societies; the nature of the international economy; the character of international life; and the mechanisms available to foster peaceful interactions.

3.1 *Domestic Regime Change*

In 1795, Immanuel Kant made famous in his essay *Perpetual Peace* (1970) the proposition that certain forms of government are more prone to war than others. Specifically, he argued that if a regime could be organized along liberal lines (with a constitution providing for full-fledged representation, a separation of powers, and civil rights) it would be less likely to go to war based on the will of a monarch and more likely

to enter into long-standing peaceful relations with other liberal states. Liberal states, Kant argued, allow for public discussion of the purposes and costs of war and require popular consent for it to be waged.

Although early-twentieth-century leaders like Woodrow Wilson and Franklin D. Roosevelt endorsed versions of the Kantian perspective, it would take 200 years for the proposition 'democracies do not fight one another' to become a central tenet of students of international relations and policymakers in the US government (see Doyle 1997). Convinced of its empirical reality, scholars are still searching for the exact factors that produce the 'democratic peace,' from the acceptance of norms of peaceful conflict resolution in democratic societies to the existence of robust forums for public opinion. Upon its strength, policymakers extol the virtues of promoting and sustaining democracy around the world as a means to help eradicate war. It is generally recognized by scholars, however, that while democratic states are less likely to wage war on one another, they hold out no special pacific tendencies when it comes to war with non-democratic states.

3.2 Transformations in Social Structure

Among the conditions that made the establishment of a liberal regime so crucial for Kant was its power to displace a system of absolutist monarchy that relied on the aristocratic war-making classes described above. For liberals such as Thomas Paine, the noble classes of Europe had not only developed an interest in war as an honorable pursuit that secured their positions within their own countries, it also provided the basis for a Europe-wide transnational aristocratic culture of diplomacy and war. This exclusive culture was seen as being based on secrecy in negotiations and private considerations when it came to decisions about war and peace. Although the revolutions in Europe that occurred from the late eighteenth to the mid-nineteenth centuries had replaced many absolutist with constitutional regimes, aristocrats remained a powerful force in state and society. Thinkers like Joseph Schumpeter (1989) could look back and blame imperialist wars on the continued influence of the aristocracy on the foreign policy of European states.

The answer for most liberals was to advance the political and social fortune of the middle classes within each state and society. Not only did they not carry with them values and codes of war-making, their interests and security were seen as anchored in commercial life and the possession of a wide range of rights for which large-scale conflict was inimical. To the extent that the middle class—or 'bourgeoisie'—could become the predominant political class across Europe there would emerge an entirely new 'peace interest' and culture of public diplomacy.

As the aristocratic influence waned, from the twentieth century on, liberals such as Norman Angell (1972) began to focus more intently on another powerful class: large military industrialists who had a deep commercial interest in the profits of war. And once again, the peace interest of the middle classes was also considered an antidote.

3.3 The Development of International Trade

In much liberal thinking, the rise of commercial classes was to be complemented in the international realm by the emergence of a robust system of international free trade for them to participate in. An overriding concern of liberals in this area has been to counteract mercantilist tendencies in the foreign policies and relations of states. Mercantilism was associated with the pursuit by autocratic states of exclusive economic access to trade routes and special concessions for the extraction of resources—the economic benefits of access for one state would be closed off to other states. Liberals feared that gaining access or enforcing exclusivity constituted grounds for war.

Even as mercantile practices became less prominent in the nineteenth and twentieth centuries as compared with the seventeenth and eighteenth centuries, liberals still worried that protectionist policies could reinforce the sense of rivalry between states. Indeed, colonialism, which had reached new heights in European policy at the end of the nineteenth century, was mostly understood by liberals to be a mercantilist phenomenon that fed competition (annexation brings a set of people and places into the orbit of one state and not another). Liberals generally believed that states were willing to go to war over colonies to protect their interests.

The effectiveness of international trade as an antidote to these practices in the international realm rests on the prospect that, instead of seeking colonies or exclusive access, states would simply promote trade between their citizens and the rest of the world. A vested state interest in securing open access to resources, peoples, and places would develop and concerns with facilitating market competition between individual economic actors would shape policies. The connections between individuals across national boundaries would deepen and widen and rivalry would take form in the productive field of the market rather than the interstate system. This ultimately would reinforce, as John Stuart Mill (Silberner 1946) believed, an interest in peace rather than war (an activity that could be highly disruptive in the international economy).

3.4 The Emergence of New Forms of International Life

According to many liberals, the development of more direct transboundary connections between individuals would make possible the worldwide cosmopolitan

community mentioned above. Commerce, as well as travel and international media, would help create a global body of public opinion, a shared identity as *humanity*, and a common understanding of human rights and justice. This cosmopolitan community of individuals would undermine the belligerent ambitions of governments by making it difficult to mobilize national citizenries for war.

Not all international communities of interest to liberals were grounded in a universal humanity. In the nineteenth century, liberals like the Italian nationalist leader Giuseppe Mazzini and the British Prime Minister William Gladstone argued that Europe constituted a community of nations. If each nation, satisfying its desires for national self-determination, could devote itself to its own national destiny and recognize other nations as part of a common family of nations, then the motives for war would dissipate.

Democracy was a third ground for community besides cosmopolitanism and nationalism. As mentioned above, liberals like Kant and Woodrow Wilson believed that a league of democratic states could form a community capable of preventing war and advancing peaceful means of conflict resolution.

Finally, some liberals have argued that states could form a world federation, bounded by international law and mutual political obligations, within which war would be an unthinkable practice.

3.5 The Establishment of New International Mechanisms

Liberal ambitions regarding international community have gone hand-in-hand with liberal expectations that international law could become a powerful force shaping the action of states within a community of nations. The execution of treaties and pacts and the development of legal theories since the seventeenth century have fueled the hope that normative proscriptions against unilateral decisions to wage non-defensive wars could effectively constrain officials and compel them to pursue peaceful means of conflict resolution and avoid violent intervention in the affairs of foreign countries (which is also contrary to the principle of self-determination).

Other mechanisms pursued by liberals to promote peace besides law include collective security. The basic premise is that states forming a league should agree to avoid war with one another and be willing to punish with sanctions or even collective military action any state that violates international peace and security. This principle was built into both the League of Nations formed after World War I and the UN of today.

Two other relevant mechanisms are arbitration and disarmament. Most liberals have argued that states with disputes should pursue their resolution through the mediation of an institution such as the UN or other third parties such as neutral governments. If arbitration became an accepted part of international relations, then war would become the last rather than the first recourse of states.

Disarmament has been an enduring liberal goal that reached its greatest prominence in the second half of the nineteenth century. Transnational peace movements grew in number on both sides of the Atlantic around the hope that states would abandon their readiness to prepare for and wage war. Many of these associations called for special congresses and treaties, and petitioned governments like Great Britain to take the lead in promoting disarmament.

4. Conclusion

The contrast between the liberal record in the domestic and international spheres with regard to peace and security is sharp. Throughout the nineteenth and twentieth centuries, liberals and their supporters struggled and often succeeded at constructing liberal states and societies in the West, helping to secure individuals and groups against arbitrary violence by states and factions. Liberals, as shown above, also tried to refashion the relations between states along more peaceful lines. However, relative to the domestic sphere they had far less impact. It is true that nineteenth- and twentieth-century thinkers and policymakers associated with the liberal tradition helped to advance the commitments of states to arbitration, disarmament, collective security, and the building of international community. Nonetheless, to this day no institutions exist to tie states and societies in a common security framework that is binding and that limits their ability to wage war.

Liberals certainly changed the discourse of international security. They also helped establish channels of negotiation. However, liberals did not alter the way states organize themselves regarding military power and national security. These practices have remained firmly grounded in the classic model of the war-making state. And while phenomena such as treaties to limit the proliferation of weapons, UN peacekeeping forces, and liberal zones of peace in the West are potential alternatives that currently challenge the classic war-making model, none of these are comparable to the transformation of absolutist into liberal, constitutional states in the West.

There are two important factors to bear in mind when considering the limitations of liberal efforts to promote reforms leading to peace. First, attempts to reform the security sphere were mostly undertaken by a rather narrow range of thinkers, citizens, and statesmen such as Richard Cobden working through relatively small antiwar organizations. If it typically took broad-based, popular political challenges to authority (including the revolutions of 1848) to change domestic spheres, we certainly should not expect to see the reformation of security practices based simply on

the decision of government officials to heed their own conscience or the call to reason by liberal publicists and advocates.

Second, liberals have simply invested most of their intellectual and political capital in the pursuit of more perfect states and societies. Thus, international life has not received the same level of attention. And while liberals have been concerned with interactions between groups and individuals across national boundaries (e.g., trade) and the possibilities of new forms of international community (political union), liberal international political thought has been focused on the relations of states. Indeed, this might be expected since, in the absence of international government, there is no legal or binding political basis to pursue and secure claims important to liberals regarding citizenship, economic rights, or equality, within the international realm.

That there are limits to the liberal approach to war is a claim that has been made by critics of the tradition, who fall broadly into two camps. Realists like Kenneth Waltz (1965) have argued that liberalism offers a misplaced faith in the prospects for and affects of change and reform, both domestic and international. They also are skeptical of the ultimate willingness of states to abandon their own management of their security and capacity to wage war. And they generally fault liberals for failing to recognize the truly enduring presence of war in a world of ambitious and security-minded states.

A second line of critique has come from thinkers associated with the political left who fault liberalism for positions on war that obscure the exclusions and violence liberal states, in practice, underwrite through their foreign policies (see, for example, Robinson 1996). For instance, liberal concerns with building a union of liberal democracies have been condemned for justifying militarized alliances such as NATO that exclude non-liberal states and societies in the developing world and which emphasize differences and security threats rather than commonalities and community across the globe. Likewise, the pursuit of a global liberal economic order has been criticized for leaving the developing world behind in poverty and subjecting unprepared governments to policies that, in the name of privatization, place too much faith in the market and undermine public authority. The shrinking of public authority is often linked to increases in internal conflict within the national boundaries of states no longer capable of ensuring public security. And while liberal principles hold out the hope of a more peaceful world, liberal states have in practice been denounced for helping to perpetuate significant programs of overt and covert violence against individuals and political groups and aiding military build-ups in the developing world, most notably during the Cold War. This violence was sometimes small scale; other times it took on the dimensions of a full-scale civil war (e.g., in Guatemala and Cambodia).

While for some it is easy to separate the pacific values of liberalism from the violent policies of liberal states griped in global conflict, critics, both realist and leftist, remain concerned that the failure to draw out the connections between practice and principle undermines the ultimate impact of the latter.

Liberalism: Historical Aspects

Liberalism is a sociopolitical idea about political order that has contributed substantially, since the late eighteenth century, to the modern age. It aims at creating a civil society, but adjusts its concrete demands to the existing situation of society and the state. This readiness to adjust has made liberalism willing to compromise as well as open to development. The core principles of liberalism endure, but the details of what it understands as civil society have changed in the course of history and have always been debated among liberals. For this reason, the history of liberalism as an idea and as political practice can be adequately understood only as a continuing struggle about interpretation, but as controversial as the definition of liberalism has always been, liberalism has always aimed to make responsible citizenship possible. This is true for all societies, even if the paths liberalism has

taken have differed in Europe, the USA, and other parts of the world. Europe is where liberalism originated and formed its liberal ideas of political order. For this reason, we will concentrate on European liberalism.

Since its beginnings, liberalism has demanded three kinds of citizenship rights: (a) equality before the law, guaranteed by the rule of law; (b) equal opportunities for political participation, made possible by the right to vote and to participate in public life, and (c) the provision of the basic prerequisites for opportunities in life. The demand for equality before the law was made and fulfilled earliest. Then came political equality, though in practice liberals, in contrast to democrats, long favored giving different weights to the votes of members of different classes. Whether and to what extent the state should guarantee social rights has remained controversial among liberals to this day.

1. *Liberalism as an Idea of Political Order*

Liberal thinking centers on the individual, whose freedom of decision is to be defended against state and social constraints. All demands for individual freedom can thus be considered part of the liberal tradition. This would make liberalism as old as human memory, but a liberal doctrine of the state and society first arose in seventeenth century England. Its most influential thinker was John Locke (*Two Treatises of Government*, 1690). The European Enlightenment's attempts to limit Absolutism and to enable 'man's exit from self-caused lack of self-responsibility' (Immanuel Kant) and finally the impetus of the American and French Revolutions (human rights, popular sovereignty, constitutionality) are further important stages of liberal thinking.

As political terms, 'liberalism' and 'liberal' were coined in Spain and did not establish themselves until after 1800. The nineteenth century was then the century of liberalism. No other sociopolitical idea of political order changed the state and society as radically. With the idea of the citizen, liberalism sketched a program for the future that was egalitarian in principle and that was directed against everything that limited individual freedom. At that time, this revolutionary program, which liberals nevertheless wanted to realize evolutionarily in step-by-step reforms, was directed primarily against absolutism and the rule of the nobility, and thus also against class and denominational privileges.

The liberals' central political demand was for a constitutional state. It was to guarantee the continuity of law, secure individual property, and enable the citizen to participate in the state. The liberals saw the absolutist state as their antagonist and wanted to tame it with constitutional law. The individual was to have free access to the public political arena and, as voters, exert influence on the state's decision making process, but the state was not to be stripped of its executive powers, only its functionings to be liberalized. The liberals did not call for a weak 'night watchman' state, but for freedom in and through the state. Liberalism's specific political program varied substantially from country to country and over time. What critics condemned as programmatic weakness or even as a betrayal of principles was precisely the strength of the liberal movement. Thanks to its flexibility, it was able to adjust its idea of political order to very disparate conditions of action. Liberals argued everywhere for the parliamentary form of government, but they also accepted compromises to avoid endangering the stability of state and social order.

Among the large European countries, the liberals' will to establish the parliamentarian system of government was weakest in autocratic Russia and in pre-World War I, Germany. Liberals did not insist upon a particular form of state, but their ideal was parliamentary monarchy; they wanted to preserve the monarchy as a reserve constitution for states of emergency. This sharply distinguished them from the democrats, whose ideal was the republic. The European liberals of the nineteenth century were willing to accept the republican form of state (first in France and Italy), but, since the French Revolution of 1789, most liberals saw the republic as burdened with the odium of social revolution and the annihilation of civil society. The liberals' fear of social revolution put them at a distance from the idea of the republic, which could prevail only through revolution wherever monarchical states existed. In republican North America, this was not an issue. Limiting the power of the state and securing private property were the foci of American property-oriented, individualistic liberalism, which emphasized self-help and self-organization. Franklin D. Roosevelt's New Deal liberalism created the USA's first instruments for state intervention in society and economic policy.

In practice, the liberal idea of political order focusing on a society with egalitarian citizenship was compatible with inequality. The liberals of the nineteenth century wanted immediate implementation only of equality before the law; political equality could wait. They saw freedom of opinion and the right to vote as the most important means of apportioning participatory rights in the state and the community. By the early twentieth century, liberals had accepted democratic equal voting rights, but they never advocated or demanded the establishment of such rights. Rather, the majority of liberals accepted them only when they could no longer be avoided. The core of their idea of civil society was the economically self-sufficient, educated individual.

Liberalism offered an educational program for those who had not yet achieved this social status; the individual himself was to be responsible for its future

fulfillment. This program was directed against a society that apportioned different political rights in accordance with membership in specific groups; but in the century of liberalism, the struggle against the historical and traditional society of privileges did not yet aim at the 'mass democracy' of the twentieth century. When the latter appeared on the horizon in the second half of the nineteenth century, liberalism had to change fundamentally if it was to survive party-political competition for votes. European liberalism was by and large able to cope with this adaptation until the beginning of World War I.

Emancipation to become a citizen with full rights not only developed at different paces for different classes, but also for the two sexes. Only a few nineteenth-century liberals could imagine woman as a citizen; one of these was John Stuart Mill (1859) *On Liberty and Other Essays*, an exceptional liberal figure precisely in the radicality of his emancipatory demand for gender parity. Not until the twentieth century did the majority of average liberals come to accept and recognize woman as having equal political rights. Until then, they used the idea of a naturally given eternal inequality of the sexes to avoid the consequences of their egalitarian model of law. Their constitutional idea of civil society was egalitarian, because it was based on the principle of contractual freedom for all. But they did not want to see this principle applied to the family.

Their refusal to politically equate man and woman turned out to have great consequences for their model of society, because they saw the family as the foundation of the state and civil society. In the long run, the liberals could not suppress the contradiction between their political model of an egalitarian civil society and their attempt to construe the family as fundamentally gender-hierarchical. The egalitarian philosophy of liberalism forged an intellectual weapon against the practice of liberal politics, which tolerated or even affirmed certain forms of political inequality. The golden age of liberalism ended with World War I, although its chances for development seemed more favorable than ever before. After all, the war ended in a victory for the Western democracies (USA, Great Britain, and France), which were regarded as the primary representatives of liberalism, while the monarchies of Central Europe and Russia did not survive the war.

Political liberalism did not sweep the field after the fall of these anti-liberal bulwarks. Instead, the signature of the new epoch was rivalry and finally struggle among the liberal-democratic and the new Bolshevist and fascist ideologies, movements, and states. The National Socialist dictatorship, in whose parlance 'liberalistic' was perverted into a life-endangering, denunciatory pejorative, finally threatened to extinguish forever the central idea of liberalism, the dignity of the individual, first in Germany and then in Europe's conquered states. The disintegration of liberal parties, including in Great Britain, the mother country of liberalism, continued after World War I and even after World War II, but at the same time, the constitutional orders and individual behavioral norms in the Western world have been characterized by fundamental liberal values more than ever before. Their validity is no longer tied to the strength of liberal parties. Liberalism's power to form parties appears to decline when its political ideas prevail and are recognized even by opposing political parties.

The collapse of the Soviet empire seems to confirm this observation. The successor states adopted liberal principles, or what they took to be liberal principles, in their new political and economic orders, but this triumph of liberalism over its communist antagonist has at the same time triggered a new international debate over the central principles of a liberal system of state and society (Ackermann 1992). This debate focuses on the old problem of whether a liberal society can trust solely in the regulative miracle of the market or if it should strive to create a state that, through a 'combination of citizenship rights and chances for welfare' (p. 196), empowers all people 'to take part as citizens in the life of the society' and 'to enjoy the achievements of their time' (Dahrendorf 1987, pp. 196, 219).

2. *Ideas of Social and Economic Order*

Historical liberalism arose in the pre-industrial age. It strove for a civil, rather than bourgeois society, in both its ideas of social and economic order as well as in its model of the state. With the idea of the citizen, European liberalism sketched a vision of the future of a society of citizens without great property-ownership differences that would have contradicted the liberal ideal of a middle-class society with a broad distribution of assets (Schapiro 1958). This socially harmonious guiding idea was directed against the class/feudal order, but did not initially field an industrial view of the world against it. Liberalism comprised a plurality of social ideas that, depending on a country's state of social development, ranged from agrarian models of the future (as in Hungary, Spain, and Italy) to industrial capitalistic models (as in the USA, Great Britain, Belgium, and, in part, France and Germany). The liberals demanded social and economic 'progress,' but not an industrial–capitalistic class society. Only after the mid-nineteenth century did pre-industrial liberal ideas of order pale in favor of industrial capitalistic ones.

This shift, pushed forward by the wave of revolutions of 1848, marked the transition from early liberalism to liberalism in the age of industrialization. Only now, when dynamic industrialization ended the pauperism of the first half of the century and sociopolitical control mechanisms seemed renouncable, did political liberalism fuse with *laissez-faire* economics.

The main current of liberalism now became more bourgeois than ever before, without narrowing to a bourgeois economic liberalism, even in this phase of Manchester Liberalism. Even now, the liberals were not characterized by convinced affirmation of a free, unregulated market. The liberal demand for free trade among states did not rule out a willingness to accept and call for regulation of the market within the state.

Since the last third of the nineteenth century, the trend to eliminate social-welfare aspects of ideas of societal order in favor of *laissez-faire* liberalism was tempered by a renaissance of social-liberal guiding ideas. Like early liberalism, the New Liberalism, an international phenomenon, displayed a marked social responsibility, but it assumed the conditions of an industrial society in which the freedom of the individual would be ensured by a policy of social welfare. Liberals had originally contributed to the political climate that, since the 1880s, gave birth to social security laws, first in Germany and then in rapid succession in other countries. This launched a development that led to the modern type of social welfare state. In the United States, it was not until Roosevelt's New Deal that political theory allowed for the state's substantial involvement, in contrast to the traditional liberalism of interest groups (Lowi 1979).

No less important was community liberalism, which played a key role in the building of infrastructure in the enormously expanding cities, a precondition of urban life. This community welfare policy ranged from improved hygiene through municipal provision of gas and electricity to the new parks, museums, theaters, and mass education facilities. The achievements of community liberalism show how intensely liberals participated in the communal protection of individual life chances when, in the face of social and economic developments, individual provisions were no longer adequate or possible for increasing segments of the population.

But the individual, not the collective, was still the focus of liberal norms and politics. The conviction that the individual must take priority over the collective distinguishes even the decidedly social liberalism of the late nineteenth and twentieth centuries from the other progressive movements, such as socialism. But the dwindling numbers of liberal voters since the early twentieth century, teaches us that the variant offered by the liberal parties as a mediation between collective welfare security and individual freedom to decide no longer had the persuasive power that had characterized the liberal guiding ideas of the nineteenth century.

3. *Liberalism and the Nation*

Beginning in the late eighteenth century, the demands for popular sovereignty and national self-determination became two sides of the same coin. Only states that were recognized as national states could prevail. Liberals took a leading role in making the nation the new supreme principle of legitimacy. Like liberalism, nationalism developed a model opposed to the existing order. Both demands aimed at a society ordered in accordance with egalitarian values, constituted as a state and employing a collective, and thus equally egalitarian concept of sovereignty. This was why nationalism historically arose as, and can still present itself as an ideology of liberation and a movement of emancipation, despite all nationalistic atrocities. Anyone who wanted to ally with nationalism had to accept this basic egalitarian stance. Liberals did so. In the nineteenth century, they became the spokesmen of national movements, formulated their goals, and provided their elites.

This symbiosis of liberalism and nationalism strengthened and shaped both. Liberalism's influence expanded far beyond its narrower primary bourgeois clientele, and nationalism developed a reform program promising more social as well as political democracy. The vision of a national civil society that expands citizenship rights into the social realm and promises to allow all to share in the resources produced by a society were visions of the future common to liberalism and nationalism. These promises of participation for all, regardless of social status, are what made these movements so unrivaled in attractiveness. Liberalism was one of the creators of this vision that, here too, uncoupled itself from liberalism. Socialists and conservatives both adopted it.

The task of mediating between the central liberal principle of the responsible individual and the collective claims of the nation was nowhere more urgent and difficult than in the multinational Habsburg monarchy (Judson 1996). The attempt to de-escalate national conflicts through constitutional guarantees of the right to national cultural individuality failed, but it indicated a path that would be taken with the help of the League of Nations after World War I in Europe's new multinational nation-states. This second attempt failed as well, but fundamental principles based in the guiding liberal idea were formulated: the will of the individual must be central, and no collective has the right to disregard this individual will. Making cultural assimilation the precondition for national minorities to enjoy equal citizenship rights in a society with a different national majority contradicts the central convictions of historical liberalism as it had developed since the late eighteenth century, but liberals have often violated this principle in political practice.

4. *Organization and Milieus*

Even before the emergence of lastingly organized modern parties, liberals tried to penetrate the public

sphere with their ideas and to influence state politics. Liberalism had the most favorable conditions for influence where parliamentary institutions already existed.

Secret organizations with revolutionary intentions, on the other hand, were not part of the liberal arsenal for action, because liberal politics did not aim for revolution, but rather for institutionalized, constitutionally regulated cooperation in state politics. Liberals sought to avoid revolutions or to transform them as rapidly as possible into parliamentarily legitimated reforms and thus to put them in a legal framework.

After parliaments became more significant and male voting rights expanded, political movements that sought a voice in state politics could no longer renounce party organizations. Beginning in the second half of the nineteenth century, the liberals, too, formed parties, though this was more difficult for them than for their competitors on the right and left. The guiding liberal idea of the responsible individual, who would determine the 'common good' in free discussion, continuously acted as a certain obstacle to hierarchically organized decision-making procedures. Among the liberals, the party apparatus generally had less importance than the parliamentary groups and local dignitaries.

The guiding image of civil society that has been associated with liberalism since its beginnings is also reflected in its social profile: its focus is on citizens, not the bourgeoisie. The social origins of liberal spokesmen displayed a broad spectrum, especially in the early phase. Nowhere was it limited to the bourgeoisie. Even in Great Britain, the pioneer of industrialization, from 1859 to 1874, only about 21 percent of the liberal delegates to the House of Commons were entrepreneurs. In Italy and Spain, liberalism found a bulwark among the nobility, and in Hungary the nobility dominated completely. In France, Germany, and Belgium, the bourgeoisie took a more prominent place in leading liberal circles. Everywhere here, liberal opinion-makers were highly respected men from respected families. They stood at a distance from tradition, but did not break with it. This membership in 'good society' was an important precondition for the power of liberal ideas to prevail even in those states that denied liberals access to state offices. A strictly bourgeois liberalism could not have achieved this.

Since the second half of the nineteenth century, the social 'catchment field' of liberal parties narrowed. They became more bourgeois. Two lines of conflict increasingly limited the liberal milieu:

(a) One of the liberal parties' heaviest losses was that the workers, whose number greatly increased during the process of industrialization, turned away from them. This happened earliest in Germany (beginning in the 1860s), while in Great Britain the first workers' party still worked together with the liberals in elections (Lib–Lab coalition), but the British liberals, too, lost their worker votes when the Labor Party rapidly grew after World War I.

(b) The secularity of the state was always a central liberal credo. In political practice, this goal could be tied to religious tolerance, but also to a struggle against Church competencies and claims. Intense conflicts between the state and the Church broke out in many countries on the European continent in the second half of the nineteenth century. This greatly limited the extent of liberal milieus. Catholics loyal to the Church generally turned away from liberal parties, which they saw as representatives of laicism, but the situation was different in Great Britain. Until World War I, the Irish question tied Catholic voters to the liberals, whose strongest support came from nonconformist congregations.

Liberalism: Impact on Social Science

A doctrine with roots in eighteenth century thought, liberalism emerged in the nineteenth century as the prevailing ideology of Western capitalist societies and democracies. Though much transformed by the social and political developments of the twentieth century and seriously challenged by the various movements associated with them, especially fascism and socialism in the first half of the century and feminism, ecologism, and multiculturalism in the second, liberalism has retained its dominant place. It combines philosophical, social, and political elements. Philosophically, liberalism consists of a commitment to the ideals of equality, liberty, individuality, and rationality. However, liberals have combined these concepts in numerous and often opposed configurations, which reflect different social assumptions. Many liberals have believed these values to be inscribed within the very fabric of modern societies, reflecting the innovative technologies, social differentiation, and free movement of labor, goods, and capital characteristic of the commercial and industrial age and its aftermath. Others have thought the links between the two are fortuitous and contingent, and that these and other related social changes, such as the growth of bureaucracy, potentially threaten liberalism. Politically united against traditional and hierarchical societies, liberals have differed, therefore, over whether liberalism requires various kinds of political support, such as the state regulation of markets, or merely the absence of any interference by either the state or others to the spontaneous and autonomous social activities of individuals. Meanwhile, critics of liberalism have either blamed it for all contemporary social ills, or regarded it as a transitory phase to be replaced by superior forms of social organization. Liberalism has featured in social science in correspondingly divergent ways: as the 'natural' value system of modern societies, as a historically and culturally specific phase of social development, as either pernicious or expressive of basic human goods.

1. Liberalism Defined

For analytical purposes it is convenient to break liberalism down into its philosophical, social, and political components, though these form a package that different liberals have interpreted in diverse ways.

1.1 Liberal Philosophy

At a philosophical level, liberals seek the maximal equal liberty possible for all individuals to rationally and freely choose and realize their various projects and preferences without interfering with each other. This position draws together the concepts of equality, liberty, individuality, and rationality in a distinctive way. Liberals value equality in the sense of denying that anyone is the natural subordinate of others. This view does not entail regarding people as the same, merely that everyone has equal moral worth. Instead of seeking equality of outcome like certain socialists, liberals simply desire that all should have an equal opportunity to deploy what talents they do possess on the same basis as everyone else. Their attachment to liberty follows from this interpretation of equality and its implicit endorsement of the moral primacy of the individual. Among moral equals, individuals should be allowed to pursue their own good in their own way to the extent that is compatible with a like liberty for others. Finally, as rationalists, liberals believe that individuals should behave in a coherent and consistent manner and that decisions in the public domain should be open to critical scrutiny and amendment and capable of attaining the reasoned assent of those they affect (see *Freedom/Liberty: Impact on the Social Sciences*).

Though liberals share a moral ethos and broadly agree on the conceptual relationships between liberalism's core values, they offer very different interpretations of them reflecting a wide variety of epistemological and ontological perspectives. Thus, liberals include methodological individualists such as Adam Smith or Herbert Spencer and holists such as Emile Durkheim, materialists such as John Locke and idealists such as T. H. Green or Benedetto Croce, utilitarians such as J. S. Mill and natural rights theorists such as Tom Paine, abstract universalists such as Kant, and historicist relativists such as Herder, and so on. Moreover, their main practical differences stem less from these considerations than from contrasting social visions and political judgements. Though individual thinkers naturally relate these last to their particular metaphysical and methodological views, the connections between them are far from clear cut. Similar theoretical perspectives often generate quite different practical stances, while thinkers of quite diverse theoretical positions may often be in substantial practical agreement.

1.2 Liberal Society

Historically, the most significant social influence on the formation of liberalism was the passage from feudalism to capitalism from the sixteenth to the nineteenth century. This fuelled the liberal attack on ascribed status and its commitment to equality of opportunity. The closed feudal order of inherited rights, with its hierarchical system of aristocratic privileges, was to give way to an open and egalitarian capitalist order, in which an individual's social position and success supposedly mirrored his or her ability and effort—a way of life they felt was best realized in a free market economy.

Some contemporary liberals and many of liberalism's critics regard the ethos resulting from such social origins as essentially materialist, instrumental, and egoistic. Traditionally, however, liberals have been extremely wary of such attitudes and have sought to avoid them. The liberal conception of economic behavior emerged from the experience of the entrepreneurs, traders, shopkeepers, and artisans of early capitalism, and invokes the image of an idealized market order in which rewards are closely linked to effort. This linkage was codified in the labor theory of value and, in the British and North American context at least, drew additional support from the religious beliefs of certain Protestant sects that encouraged industriousness as a mark of salvation. The market also acts as a discovery mechanism, with competition and the profit motive weeding out bad practices and poor products whilst stimulating the search for new processes and commodities, and so promoting the progress of society.

Liberals have disagreed, however, over how far a policy of *laissez-faire* can secure these advantages, and doubts have grown as capitalism has taken on a more corporate form. Most have accepted the need for some regulation to protect the market against itself and maintain its freedom—such as anti-trust and monopolies legislation. Others have sought to distinguish between the economic and social disadvantages that individuals are responsible for and those they are not, supporting quite extensive unemployment insurance and state-supported training schemes, for example, to get the unintentionally out of work back into jobs. Finally, liberals have always acknowledged certain public goods will be badly provided or even neglected by market mechanisms, even if some have believed state provision could employ market elements such as competitive tendering—defense and certain infrastructural goods, such as light-houses, were the classic cases. Clean air, education, and a health service serve as more recent and contentious examples.

1.3 Liberal Politics

The political face of liberalism follows on from the philosophical and social elements outlined above but was additionally influenced by the wars of religion and the rise of modern science in the sixteenth and seventeenth centuries, which fuelled calls for religious toleration and the related belief in rationalism and the moral equality of individuals. Along with the shift from social structures based on status to contractual relations between civic equals, these commitments led to the demand that politics reflect liberal principles. The state, like society as a whole, came to be seen as a voluntary association held together by the mutual consent of its members rather than the ties of deference to social superiors—a conception of political order summed up in the theory of the Social Contract.

The basic components of a liberal political system were established in the wake of the British, American, and French revolutions of 1688, 1776, and 1789, respectively. All three gave rise to new constitutional settlements and bills of rights. Two criteria informed these arrangements. First, laws were to be framed and applied impartially and universally. There were to be no special exemptions for particular groups, such as clerics and nobles, as in the past. Second, the laws were to guarantee to the greatest extent possible the equal right of each individual to pursue their own plan of life. For the majority of liberals, the most basic rights in this respect were traditionally the rights to private property and freedom of belief. These rights were essential to their understanding of the virtues of the market mechanism and of toleration, which they regarded as the embodiments of the new ethos.

At the heart of liberal politics is a distinction between the state and civil society (see *State and Society*). The purpose of the state is to facilitate social interaction rather than to substitute for individual initiative through state control of social institutions. The latter is the mark of dictatorships in liberal eyes. However, social liberals nevertheless believe economic intervention and state provision of certain social goods can have an enabling role, though market liberals contend such steps undermine liberalism. Liberals are also often said to favor a related distinction between the public and private sphere, allowing behavior in the latter they would ban or restrict in the former. However, this distinction has never come out cleanly. To the extent liberals do distinguish between the two it is as a corollary of their views of the state's role in regulating society. The marriage contract, for example, offers a quintessential liberal device of a public character with a clear impact on private behavior. Just as liberals of different hues dispute the degree to which workers are free to sell their labor and the extent to which a valid contract implies certain standards of pay and conditions, so they have also debated whether and in what ways the marriage contract constrains the behavior of couples and grants women, in particular, rights to common property and protection against rape and abuse.

We have already disputed the view of liberalism as promoting possessive individualism in the socioecon-

omic sphere. A related objection contends that liberals advocate subjectivism, skepticism, and relativism in the political sphere, with all views treated as little more than personal opinions. However, the liberal insistence on the individual's right to follow his or her own path does not entail regarding all ways of life as equally valuable. Drawing on the experimental method in modern science and the Protestant defense of freedom of conscience, liberals contend that truth and morality emerge through individuals being allowed to call into question accepted doctrines and try out new and occasionally eccentric or potentially offensive pursuits. Ideas have to be tested for their validity while personal virtue only comes from our taking responsibility for our lives. For the state or any group to paternalistically impose its views on the rest of society risks falling into dogmatic error, demoralizes the population, and produces stagnation. Individuals must be able to make mistakes so that they can learn from them and emerge morally and materially improved.

Nevertheless, liberals have seen no need to tolerate the 'intolerable,' defined as views that are incompatible with treating others as moral equals. Some critics have regarded this position as inconsistent with liberalism's claims to openness. Yet certain limits are clearly implicit in liberalism and would otherwise render it incoherent. Where exactly these boundaries lie and their legitimacy and justifiability are more contentious matters, however. Liberalism has been accused of a gendered, imperialist, and Euro-centric bias, and historically this has often been the case, albeit to differing degrees and with certain important if qualified exceptions, such as J. S. Mill's attack on the *Subjection of Women*. How far gender and multiculturalism remain a blind spot is less clear. Many contemporary liberals maintain that multicultural, gay, and feminist demands for recognition and respect, like other appeals against unjust discrimination, implicitly invoke liberal norms of equality and tolerance. They have simply revealed these principles to have a broader application than certain past liberals had appreciated.

The complexities of the liberal position emerge when we consider their ambivalent view of democracy. Liberals have recognized that democracy offers a means for holding governments to account, obliging policies to be justified and improved through critical debate, and allowing politicians to be peacefully removed when they prove incompetent, biased, or corrupt. However, past liberals sought to limit political citizenship to those with the intellectual attainment and economic resources they believed were required for 'independent' rational decision making—criteria that usually had the effect of ruling out workers and women. Even so, liberals worried about the 'tyranny of the majority' as represented by an irrational and dependent mass, whose votes could be bought by unscrupulous populists willing to pander to their prejudices and interests. As a result, liberals have tended to insist on the need for constitutional safeguards to protect liberal values from being overturned by democratic decisions.

2. *Liberalism and Modern Society*

Social scientists have seen liberalism as either an inherent and defining characteristic of modernity or as threatened by it. Amongst the first camp, moreover, there are those who see it as symptomatic of modernity's ills rather than its advantages, identifying liberalism with a possessive individualism that is not only antisocial but anti sociological as well.

2.1 *Liberalism as the Ethos of Modernity*

The view of liberalism as the ethos of modernity was best expressed by British social scientists such as Adam Smith, Herbert Spencer, J. S. Mill, T. H. Green, and L. T. Hobhouse, and to a lesser extent French thinkers such as Benjamin Constant, Francois Guizot, and Emile Durkheim. For these thinkers, liberalism's philosophical commitment to expanding equal individual liberty was underwritten by a theory of social evolution whereby potential conflicts between different liberties would be harmonized. This latter thesis idealized the market relations between small-scale entrepreneurs characteristic of early capitalism. These were taken as a model of a meritocratic society of self-reliant and responsible citizens, who freely contract with each other for mutual advantage. Liberal politics was conceived as the superstructural products of these social and economic changes. Freedom, reason, morality, and progress came in this way to be identified, with an optimistic account of social development supporting an implicitly ethical naturalist philosophical belief in the compatibility of different forms of self-realization.

Adam Smith's doctrine of the 'invisible hand' of the market and Herbert Spencer's characterization of the 'industrial' form of organization as realizing the 'Law of Equal Freedom' offer classic examples of this position. The first a product of the commercial society of the eighteenth century, the second of the early industrial age of the 1840s, by the late nineteenth century the concentration of capital and the rise of organized labor had made liberals rather less sanguine about the inevitability of their vision. To the dismay of Spencer and other adherents of the earlier 'classical' liberalism, liberals began to envisage a more proactive role for the state in sustaining favorable social conditions. T. H. Green and L. T. Hobhouse, for instance, saw policies such as factory hours regulation and unemployment insurance as mechanisms for promot-

ing freedom of contract and freeing individuals from certain structural constraints. Importantly, though, both saw the state as reducing the mutual interferences between individuals and fostering autonomy. In a similar manner, Durkheim argued that the liberal 'cult of the individual' was inherent to industrial societies and that the modern division of labor fostered an organic solidarity between autonomous agents. However, he had to confront various commercial crises, bankruptcies, and conflicts between capital and labor that suggested a less harmonious picture. He attributed these disturbances to contemporary societies being in a 'transitional phase' in which people had yet to fully assimilate liberal social norms. He too saw a role for the state in fostering these attitudes, with various 'intermediary institutions' serving to inform state policies as to social needs and act as a counter weight to state oppression of the individual (see *Social Question: Impact on Social Thought*).

Critics of liberalism sometimes portray this supposed relationship between liberalism and modernity in negative terms. They associate liberalism with a naturally instrumental and individualist model of human behavior, a disposition they believe is encouraged by the liberal conception of the market and democracy. They also claim it produces a view of social science as following the physical sciences by elaborating general laws of social development on the basis of various constant human passions. Some commentators have even argued that it was only radical and conservative opponents of liberalism who appreciated the distinctiveness of the human sciences by noting, respectively, how human behavior was modified by social structures and by culture, and the capacity of individuals to interpret and evaluate circumstances in different ways. At best, liberalism results in a positivistic bourgeois ideology that ignores the impact on human thought and action of material conditions and productive forces, historically evolving communal traditions and conventions, and the possibility for reflective criticism. Thus liberalism is associated with certain behaviorist versions of political science and economics but not with sociology or anthropology. These arguments result from a highly selective and tendentious reading of the liberal tradition whereby, for example, De Tocqueville becomes a 'conservative,' Durkheim either a 'conservative' or a 'socialist,' and Herbert Spencer, read as an advocate of egoistic possessive individualism, becomes the exemplar of liberal social science. The liberal tradition, however, is much more diverse than this caricature, both methodologically and substantively. The vast majority of liberals distinguished respect for 'individuality' from 'egoism' and even positivist behaviorists, such as J. S. Mill, appreciated that autonomy only flourished given certain material conditions, cultural values, and economic structures and played a part in its turn in how these were fashioned in the future. This awareness of the social and historically contingent character of liberalism is no more evident than in those liberals who saw it as being undermined by modernity.

2.2 *Liberalism as Threatened by Modernity*

The threat posed to liberalism by elements of modernity was especially evident in countries such as Italy and Germany, where a modernizing economy and society went along with fragile and incomplete liberal regimes which ultimately succumbed to fascism. The challenge these developments posed for liberal social science is powerfully illustrated by the 'frustrated' liberalism of the Italian Vilfredo Pareto and the 'disenchanted' liberalism of Weber. Though commonly categorized as sociologists, their work ranges over the whole gamut of the social sciences, covering economics, politics, and, in Pareto's case, social psychology. Pareto was in many respects a sophisticated exponent of the instrumentally rational actor model of liberal individualism and was initially a strong advocate of both *laissez-faire* economics and a libertarian and democratic politics. However, he became convinced that what he called 'logico-experimental' thinking was the exception rather than the rule. Instead, most conduct was 'nonlogical' and arose from certain common psychological dispositions of either a conservative or more inventive kind. Politics simply consisted of the manipulation of these psychic states, a process that had been greatly aided by contemporary mass democracy. The electorate was too large and poorly informed and the decisions needed too numerous and diverse for rational debate to be possible. Democracy simply allowed populist leaders to legitimize their rule via emotive appeals to a popular will that was largely of their own making. He even briefly supported fascism as a possible way of breaking free from this system and establishing a liberal market order from above.

Weber, by contrast, offered a more historically and sociologically nuanced account of similar phenomena. He disputed that economic development *per se* fostered liberalism or that liberal values could be justified *a priori*. Liberalism's apparent basis in natural law had been historically contingent, reflecting the peculiar social and political experiences of early modern Europe outlined above. Not only was this constellation of factors unlikely to reappear, but even within established liberal regimes liberalism was threatened by the spread of economic instrumentalism, bureaucratic rationality, and corporate organization resulting from the further development of capitalism. The chances of liberal democracy being established in societies such as Russia, which had not benefited from the earlier favorable historical experiences, were minimal, therefore. Quite different cultural values were likely to shape the modernizing processes of such

societies, as indeed has occurred throughout Asia where capitalism has by and large taken a nonliberal form. Meanwhile in already existing liberal societies, the autonomous action characteristic of liberalism was possible only for the political leaders and entrepreneurs who controlled and gave direction to the various political and economic administrative structures that govern our lives (see *Modernity*).

Most contemporary liberal thinkers regard Weber as too pessimistic and many believe liberal values can be justified on grounds distinct from their historical and social origins. However, the possible disjunction between late modernity and liberalism, on the one hand, and the search for liberal foundations that appeal to reasons that ought to be accessible to all and so compatible with a variety of different cultures and ideals, on the other, remain the prime challenges a viable liberal theory has to meet.

Libertarianism

Predominantly an American political movement of the twentieth century, libertarianism is a political doctrine whose deepest commitment is to liberty. Libertarians believe that the freedom of the individual is the most important value that should guide political reflection; and that the good society is one in which that freedom is respected. Yet libertarians disagree about what a commitment to individual liberty entails politically; and about the basis of this commitment. To understand libertarianism, then, it is necessary to come to terms with the variety within its tradition; and with its relationship with other political ideas.

Libertarians approach liberty by asking what are the legitimate functions of the state. Broadly, they offer two kinds of answer. The libertarian anarchist answer is that no state is legitimate; for minimal state libertarians, however, the state is legitimate to the extent that its activities are confined to a limited range of functions, including national defense, the protection of individual rights, and the enforcement of contracts. Even within these alternatives, however, further divisions are to be found. Libertarians differ over the proper scope of government, but also over the foundations of individual freedom. Any consideration of libertarianism, then, would have to account not only for the fundamental principles or commitments which give it shape, and for the differences between minimalist and anarchist libertarianisms, but also for the varying doctrines advanced by libertarians from Robert Nozick to Murray Rothbard.

1. *Fundamentals of Libertarianism*

1.1 *Origins*

Libertarianism is a species of liberalism. Liberalism is a tradition of political thought which understands the good society as one in which individuals are free to pursue their own ends rather than one which enforces one particular understanding of what constitutes the good life. Central to liberalism is a commitment to individual liberty. For the liberal, liberty is a good which ought to be honored and protected; and doing so requires recognizing that each and every individual is entitled to a domain within which he or she may act without interference from others. Liberalism, however, describes a broad tradition which includes thinkers as diverse as John Locke in the seventeenth century and John Rawls in the twentieth century.

Libertarianism is that side of liberalism which emphasizes the importance of individual freedom from the state, and which is generally wary of the operation of government. It is skeptical about power, but especially about governmental power. Modern libertarians see themselves in this regard as the heirs of a long tradition in European thought which champions the rights of the individual against the state. While they insist that this tradition stretches back into medieval times, when kings could not create law, or

legislate, but only find or declare law, it is to writers of the seventeenth century that they most commonly turn when looking for the first expressions of libertarian thinking. In particular, it is the ideas of the Levellers—John Lilburne, William Walwyn, and Richard Overton—and later of John Locke, which provide the inspiration for much of libertarianism.

Libertarians take two fundamental ideas from these thinkers. The first is that each individual is entitled to live as he or she chooses provided he or she does not try to force others to live as he or she thinks right. The second is that each individual is entitled to acquire and keep property. If government is necessary, it is to protect these rights by securing individuals against those who would invade or aggress against their property and their persons. But any government that itself violates these rights by coercing them or taking their property without their consent is tyrannical and may rightly be resisted.

Libertarianism has its origins in these ideas, and its heroes are thinkers who have, in different ways, asserted the rights and liberty of the individual against the state. However, libertarianism as an intellectual and political movement did not emerge until after World War I, in America. It arose largely as a response by some intellectuals to the growth of government and the rise of socialism. The most important writers who criticized socialism, central planning, and the growth of government were the Austrian economists Ludwig von Mises and F. A. Hayek who, throughout the 1930s and 1940s, debated the advocates of central planning over the feasibility of socialism. Although based in Europe, their work received a more enthusiastic reception in the USA among intellectuals hostile to the politics and economics of the New Deal. These included H. L. Mencken, Albert Jay Nock, Garet Garret, Rose Wilder Lane, Isabel Paterson, and Henry Hazlitt—journalists, writers, and economists who wrote warning of the dangers to constitutionalism posed by the growth of the state, touting the merits of free-market economics, and defending the virtues of American individualism.

It was in the 1950s that the term 'libertarianism' first came into use to describe this political stance, when Leonard Read, who established the Foundation for Economic Education, began calling himself a libertarian. While the term was rejected by writers like Ayn Rand and her followers, it came into use in the 1960s, and in 1971 the Libertarian Party was founded.

1.2 Principles

Libertarians share two sets of convictions. First, all individuals are entitled to live as they choose, free from interference by other persons or by the state. Second, in the absence of deliberate design by government or the state, order will prevail: granted the freedom to contract and exchange, markets will coordinate the production and distribution of goods better than any other available institutional mechanism. Yet while most libertarians see these two convictions as consistent and mutually supportive, they differ over which is the fundamental basis of libertarian thinking. For Mises the commitment to individual freedom rests on straightforwardly utilitarian considerations: capitalism produces greater human welfare than socialism or the mixed economy. Yet for Murray Rothbard, the rights of the individual are defensible independently of any consequentialist argument.

Both of these convictions are intimately associated with libertarian thinking; however, it is the first which is more important philosophically, since it better identifies what is theoretically distinctive about libertarianism. For libertarians are particularly concerned to defend the freedom of individuals to live without being subject to aggression by others—against their persons or the property they may rightly acquire. An early statement of the first aspect of this claim is was offered by the Leveller Richard Overton, in *An Arrow Against All Tyrants*: 'To every individual in nature is given an individual property by nature, not to be invaded or usurped by any: for everyone as he is himself, so he hath a self-propriety, else could he not be himself, and on this no second may presume to deprive any of, without manifest violation and affront to the very principles of nature …' (Overton 1646, p. 68). This is the thesis of self-ownership. And for libertarians, out of this thesis comes the contention that individual freedom includes the freedom to own private property. The most famous formulation of this claim is John Locke's in his *Second Treatise of Government*: 'Though the earth, and all inferior creatures be common to all men, yet every man has a property in his own person. This nobody has any right to but himself. The labor of his body, and the work of his hands, we may say, are properly his. Whatsoever then he removes out of the state that nature hath provided, and left it in, he hath mixed his labor with, and joined to it something that is his own, and thereby makes it his property.' The centrality to libertarianism of self-ownership, and the corollary right to own property, has led many to conclude that, perversely, the fundamental value for libertarians is not 'liberty' but the right to private property (including, but by no means only, one's property in one's person). All individuals must enjoy liberty; but only that liberty that is consistent with a respect for the property rights of others.

This understanding of individual rights is the basis of the libertarian view of the justification, and proper role, of the state. If individuals own themselves and have a right not to be aggressed against, no government is legitimate save that which enjoys the consent of the people. And the purpose of government is nothing more or less than protecting individuals against those who would violate their rights by

invading their persons or their property. Libertarianism, in this regard, is profoundly antipaternalistic. It is no part of the purpose of government to improve people or society, or even to provide for their welfare. It should not busy itself with human needs or deserts. Its only concern is individual rights.

1.3 The Market

Although its philosophical principles are what make libertarianism distinctive, the emphasis its adherents place on free markets and the virtues of market society is no less important. Libertarians defend capitalism and the market order. For many libertarians, capitalism is simply that form of economic organization which grows out of the freedom of individuals to exchange private property. For others, market society should be defended because it has important virtues of its own.

For thinkers like Hayek and Mises, the defense of the market was crucial to the defense of freedom because they saw the challenge to freedom as coming from modern socialism. Socialism, seemingly being put into practice in the former Soviet Union, and gaining intellectual adherents in the West, criticized the market for being, at once, insensitive to the poor, who fared badly under capitalism, and less efficient than a properly planned economy. Markets were wasteful in production and inequitable in distribution. Socialism's attack on the market made the defense of the market necessary.

In the 1930s, Hayek and Mises devoted their energies to showing the impossibility of socialism, understood as a form of economic organization which eschewed markets. In the absence of the signals sent out by market prices, economic coordination could not happen, and central planners could not acquire the knowledge needed to effect such a coordination, for that knowledge was dispersed throughout society, and often available temporarily and locally. Coordination without markets would produce shortages of some goods and an excess of others: supply and demand would never be in step. Hayek further argued that the deeper danger of socialist central planning was not economic but political. In order to pursue the goal of production without markets, planners would have to resort increasingly to coercion, to curb people's natural proclivities to trade. Central planning required the creation of monopolies; and this would require suppressing those whose activities, intentionally or not, competed with monopoly suppliers. In the long run, Hayek argued, this posed a threat to political freedom, for it would undermine the rule of law by granting to some privileges under the law.

This argument resonated particularly with libertarians in the USA in the 1950s. Here it was deployed less against socialism than against the expanding regulatory state. Government intervention in economic life, libertarians claimed, was neither necessary nor benign. More often than not it upheld privileges—notably those enjoyed by producers and professionals seeking protection from competition which might challenge their monopolies. The most notable proponent of this argument in popular forms was Milton Friedman, notably in his book, *Capitalism and Freedom* (Friedman 1962). However, libertarians, unlike conservatives, also challenged the defensibility of government intervention not only in the economy but also in other areas of society. Friedman and others took issue with the draft, the legal prohibition of drug use, licensing, and various other forms of compulsion by the state.

Another important target of the libertarian challenge was the welfare state. The state was not needed to provide what markets clearly could: health care, disability and unemployment insurance, pensions, among other things. Government, libertarians argued, would, like any monopoly supplier, provide such services at greater cost and lower quality than would be found under competitive conditions. In part they objected to the limiting of individual liberty: compulsory retirement insurance, for example, compelled people to invest old age savings with the state, which provided only one of a range of possible retirement contracts—and not a particularly favorable one at that. The reply that such institutions were needed to ensure that people were protected should they fail to make provision for themselves was rejected as paternalistic.

Nonetheless, libertarians have always disagreed over whether or not it is part of government's role to provide a welfare safety-net. Hayek maintained that government needed to supply some forms of welfare because markets and charity would not be able to meet the demand. Friedman argued for a negative income tax to ensure that no-one dropped below some minimum threshold. Insofar as libertarians have accepted the need for a public policy response to such problems as welfare, however, they have sought to remove the discretionary power of governments, which they think more likely to be captured by particular interests than to become the guardian of the general good.

2. Varieties of Libertarianism

While libertarians share certain general commitments or attitudes, they often differ both in the specific content and in the justification of their philosophical positions. The post-War period has seen the development of numerous attempts to state the case for, and the basis of, libertarianism.

2.1 Nozick's Minimal State Libertarianism

The most important mainstream libertarian is Robert Nozick, whose 1974 book, *Anarchy, State and Utopia*

(Nozick 1974), has been widely discussed and criticized. Beginning wit the presupposition that 'Individuals have rights, and there are things no person or group may do to them (without violating their rights)'; and the conviction that 'So strong and far-reaching are these rights that they raise the question of what, if anything, the state and its officials may do,' Nozick set out to examine, from a libertarian point of view, three of the fundamental questions of political philosophy: can the state be justified?; what principles of justice must govern such a state?; and what would a good society look like if it ran along such principles?

Nozick's first concern is the repudiation of anarchism. He is a minimal state libertarian, and the task of the first part of his book is to show how such a state can, and must necessarily, arise out of a prepolitical state without violating individuals' rights. For Nozick, individuals have rights to their persons and their property; and these rights act as 'side-constraints' on the actions of others, forbidding such others to act in any way that violates rights—even if violating rights would improve the general welfare or, indeed, help reduce the number of rights violations. Rights are absolute; they are also fundamental: rights are good in themselves, and are not derived from some other, more basic, good. For this reason, rights cannot be weighed in the balance with other, competing, goods.

In these circumstances, how could a state ever be justified? Nozick tries to show that, without rights being violated, a minimal state would emerge out of a state of nature in a four-stage process. First, individuals would form mutual protection associations in that condition, so a number of protection agencies would appear. Second, one agency or federation of agencies would come to dominate any given area—through its superior economic efficiency, and without any violation of rights. Third, the dominant agency will rightly be entitled to protect its clients against independent agencies because individuals have the right to protect themselves. Finally, however, the dominant agency will have to extend its protection to those independents by way of compensation for the violation of their (and their clients') rights. Emerging out of all this is a minimal state—one which claims a monopoly on the use of force, while offering protection to all.

What remains doubtful in all this is whether such a state is indeed consistent with libertarian principles, since it must deny persons the right to enforce their rights against others, and require them to pay taxes. And Nozick has duly been criticized for this, particularly by libertarian anarchists. No less controversial, however, is Nozick's insistence that only a minimal state is justifiable: it is no part of the state's right or duty to do more than offer protection. Nozick's theory of distributive justice explains why.

According to Nozick, justice is a matter of how people have come to have the goods they have rather than a matter of the pattern of distribution of people's holdings. Unlike the theory of John Rawls, Nozick's theory is historical rather than structural. There are three principles of justice in holdings: a principle of justice in the acquisition of property; a principle of justice in transfer; and a principle of justice in rectification of past injustice. According to this view, if property is justly acquired, and justly transferred, the resulting distribution of property is, necessarily, just—however small or great the resulting differences of wealth or income among people.

What, however, would make an original appropriation of property just? Can the first person to come across unowned property simply acquire it all? In Nozick's theory, original acquisition is constrained by the 'Lockean proviso': that each is allowed to appropriate as much as he or she desires provided 'enough and as good [is] left in common for others.' The importance of this proviso lies not only in what it forbids by way of future appropriation, however, but also in its implications for all existing holdings. How a person may transfer property will also be governed by the Lockean proviso; and an earlier violation of the proviso may cast doubt on the worth of a particular property right.

Nozick's insistence on the importance of the proviso is consistent with his view of justice as historical rather than structural. His theory is as much an attack on patterned or end-state theories as a defense of his own 'entitlement' theory. End-state theories think of justice in terms of some particular distributive outcome, with which principles of distribution must conform. For Nozick, this is incompatible with a proper understanding of justice and of rights. But he has a further objection: the attempt to secure preferred distributive patterns necessarily requires interference with the voluntary activities of individuals. Liberty upsets patterns, so liberty will have to be compromised if patterns are to be preserved.

Nozick's theory of justice has been vigorously criticized, however, by those who reject his libertarian starting point as well as by others who want to resist his conclusions. The thesis of self-ownership, and Nozick's account of its implications, have been subject to searching examination by G. A. Cohen, in particular.

2.2 *Rand's Objectivism*

While Nozick has dominated academic philosophy, however, no libertarian has reached a wider audience than the Russian-born American writer Ayn Rand. In a series of novels, most famously *The Fountainhead* and *Atlas Shrugged* (Rand 1943, 1957), essays, and newsletter articles, she offered a vigorous defense of capitalism, and articulated a comprehensive philosophy—'Objectivism'—which claimed to set individual rights on a firm epistemological and metaphysical basis.

Capitalism, according to Rand, 'is a social system based on the recognition of individual rights, including property rights, in which all property is privately owned.' On this account, capitalism is understood, or at least defined, not as an economic system but as a social arrangement consistent with the principles of ethics. Capitalist society is one which respects individual rights. The question, however, is: what rights do individuals have, and why do they have these (and not any other) rights? Rand defines the rights an individual has by saying that 'for every individual, a right is the moral sanction of a *positive*—of his freedom to act on his own judgment, for his own goals, by his own *voluntary*, uncoerced choice. As to his neighbors, his rights impose no obligations on them except of a *negative* kind: to abstain from violating his rights.' Rights are thus freedoms to act, but not assurances of anything more than forbearance on the part of others. An important corollary of this, however, according to Rand, is that the individual has a right to acquire property, since human beings need property if they are to survive. The basis of individual rights, she argues, is the right to life. 'The right to life is the source of all rights—and the right to property is their only implementation. Without property rights, no other rights are possible. Since man has to sustain his life by his own effort, the man who has no right to the product of his effort has no means to sustain his life.' But none of this means that an individual is entitled to any particular share of property. All it means is that noone may rightly be prevented from seeking to acquire property noncoercively, and that no one should be prevented from using as he or she wishes the property he or she has rightly acquired.

Rand, in her extensive writings, attempted to defend this stance by showing that it followed from a proper understanding of humans' nature and a grasp of the value of life. This philosophy is called 'objectivism.' Beginning with assumptions about the existence of an 'objective reality,' the centralilty of life as a value, and the importance of reason for humans' survival, she claims to have shown that the only ethically defensible social system is capitalism. Even within libertarianism these arguments have proven controversial. Nozick, for example, finds them unconvincing. But there has been no shortage of philosophers, such as Douglas Den Uyl and Douglas Rasmussen, for whom the construction and defense of a Randian position continues to be an important task.

Although Rand, unlike Nozick, receives little attention from mainstream academic philosophers, the extent of her influence, and the interest of her thought, should not be underestimated. Not only do her books continue to reach a large popular audience, making her one of the best-selling authors of the twentieth century, but she has also exerted a significant influence on academic philosophers, economists, and policymakers (the most famous being Alan Greenspan, Chairman of the Federal Reserve Bank, and co-contributor to Rand's *Capitalism: The Unknown Ideal* (Rand 1967)).

2.3 Murray Rothbard's Libertarian Anarchism

For Ayn Rand, a proper understanding of human rights could yield only a conception of government whose role was limited to the protection of individual rights. Even then, taxation would have to be voluntary; for government, as policeman, could not violate individuals' rights by taking by force what individuals were not prepared to give up. For many libertarians, however, individual rights are in no way compatible with tohe existence of the state. The most important libertarian defender of the anarchist position was Murray Rothbard.

Rothbard has been libertarianism's great polymath: an economist in the Austrian tradition, he was also a historian and social philosopher, as well as a pamphleteer of the highest order. His works ranged from a treatise on economics, *Man, Economy and State*, to a history of *America's Great Depression*, to a philosophical examination of *The Ethics of Liberty* (Rothbard 1970, 1972, 1982).

According to Rothbard, the 'crucial axiom' of the libertarian creed is this: 'no man or group of men have the right to aggress against the person or property of anyone else.' Aggression is defined as 'the initiation of the use or threat of physical violence against the person or property of someone else.' Central to libertarianism, then, is 'the absolute right to private property of every man: first, in his own body, and second, in the previously unused natural resources which he first transforms by his labor.' In Rothbard's view, these two axioms, 'the right of self-ownership and the right to "homestead," establishes the complete set of principles of the libertarian system.'

In common with Nozick and Rand, Rothbard holds that individuals have rights to do as they wish for so long as they do not invade the rights of others. Thus, individuals should be free to use or dispose of their property as they see fit, and live their lives—as well or as badly—as they wish, provided they do not violate anyone's rights. However, Rothbard also maintains that the existence of the state is incompatible with libertarianism, for the state, by definition, must infringe these basic rights. Nozick's 'immaculate conception' of the state, he argues, is unsuccessful both because the logic of its derivation is flawed, and because, even if it could be shown that a state could arise without the violation of rights, this would not serve to legitimize that state (nor, *a fortiori*, any existing state). Nozick, however, has at least offered a philosophical argument attempting to rebut anarchism. Rand, on the other hand, according to Rothbard, does little more than evade the difficulty posed by her own libertarian principles for her claim that that there

is role for government, and for her allegiance to the American state. Rand's patriotic defense of America during the Vietnam War was, for Rothbard, untenable given the fact of military conscription—an unambiguous violation of the libertarian principle of nonaggression and its prohibition of involuntary servitude.

For Rothbard, minimal state libertarianism must either abandon libertarianism's core commitment to nonaggression or lapse into incoherence. None of the extant nonanarchist forms of libertarianism have come to terms with this problem, since none have been able to explain how the most fundamental need of the state—to raise revenue by taxation—could be accounted defensible in libertarian terms. More than any other libertarian, Rothbard has tried to push the principles of libertarianism to their logical conclusion, to show that if individuals have rights, no form of authority which might invade their persons or take their property without their consent is morally legitimate.

2.4 *Hillel Steiner's Left-wing Libertarianism*

In rejecting as flawed the libertarianisms of Nozick and Rand, Rothbard assumes that individuals not only have property in their persons but also can acquire just title to property in the external world. Indeed, for Rothbard, the right to acquire property is not constrained by anything like a Lockean proviso that enough and as good be left over for others. Should all land, for example, be appropriated by those who come to it first, leaving nothing for the johnny-come-latelies, that is simply the way of the world. Thus he rejects the idea, associated in the nineteenth century with Henry George, that the earth itself cannot be owned, even if individuals can own the product of their labor. If the original land is nature- or God-given, he argues, then so are all the people's talents, health, and beauty; if land must be owned only by society, so must everything else. Rothbard therefore rejects any idea that we start by assuming that everyone has an equal claim to land, or to the earth or its resources.

Yet this is itself a highly controversial issue. And some libertarians, notably Hillel Steiner in his *An Essay on Rights* (Steiner 1994), have argued that the correct starting point is an assumption of an equal right of all to the earth and its resources. Persons have, on this account, two original rights: to self-ownership and to an equal share of initially unowned things. Each 'person' is entitled to ownership of himself, for to be owned by others is to be a slave; and so only 'things' may be owned by others. But no one is entitled to appropriate every unowned thing. Indeed, no one is entitled to appropriate more than the Lockean proviso allows. In a world of fully appropriated things, 'each person's original right to an equal portion of initially unowned things amounts to a right to an equal share of their total *value*.' Moreover, and correlatively, any person's possession of a just title to any thing encumbers him or her with a duty to pay every person an equal share of its value. Since there is, Steiner argues, no moral right of inheritance—for only existing, and not past or future persons have rights—the upshot of all this is that a just distribution of things must reflect our original rights, and not the accidents of history or geography. Our just entitlements do not depend upon where, or to whom, we were born. The implication of this libertarian view is that the recognition of libertarian rights is fully consistent with, and indeed requires, a significant measure of property redistribution among persons, and that means all persons, regardless of nationality.

From such libertarian premises, some, like Philippe Van Parjis, who would not describe themselves as libertarians ideologically, go on to argue that justice requires recognizing that everyone is entitled to a form of unconditional basic income. As he points out in *Real Freedom for All*, the core problem for libertarians is to find a non-arbitrary criterion of original appropriation. Homesteading, or an application of the principle of first come, first served, is not, on this view, morally defensible, for it would be a serious error to suggest that anyone could be free living under a regime in which he or she has no property rights, except in his or her person, since all property has already been appropriated and bequeathed. This left-wing libertarianism takes much more seriously the importance of equality as a moral consideratin, just as the other variants of libertarianism reject its significance altogether as a substantive value.

3. *Libertarianism as Ideology*

Politically, libertarianism is often identified as a 'right-wing' ideology but, in fact, its position on the ideological spectrum is problematic. While some libertarians, like Rand, describe themselves as opponents of 'the left' or as right-wing, others, like Rothbard, see themselves as having much more in common with the left as opponents of the state—which they tend to see as the captive or instrument of big business. Moreover, most libertarians try to distinguish (if not dissociate) themselves from conservatives, since they reject the conservative's interest in the regulation of personal morality. To the extent that they align themselves with any other ideological viewpoint, libertarians are inclined to describe themselves as the heirs of classical liberalism. Libertarians as diverse as Hayek, Rothbard, and Steiner have been ready to describe themselves as classical liberals.

In public affairs, however, libertarianism has found itself allied, more often than not, with the conservative side of politics. Over the short history of modern libertarianism, some conservatives have tried to transform it by incorporating its commitment to liberty, but rejecting its hostility to authority and tradition. A notable advocate of such a 'fusionist' view was the American conservative Frank Meyer. To date, however, libertarianism has resisted such attempts. It remains a more radical political philosophy than conservatism can countenance.

Libraries

Although libraries as collections of 'documents' have existed from ancient times, the modern institutional library dates from about the mid-nineteenth century when, in the United States and Europe—the 'West'—a developing print culture accompanied industrialization and the growth of the nation state. An explosion in publishing, not only of books, newspapers, and magazines, but also of administrative and commercial genres—catalogues, manuals, regulations, technical and business reports—prompted the development of libraries to select and organize these print resources. What major Western libraries chose to collect, and how they structured these collections, subsequently became a blueprint for institutional libraries in large and small communities worldwide. In the late twentieth century, an explosion in digital materials had a radical affect on library collecting and organizing practices, while reinforcing their domination by the West.

1. *The 'Modern' Library—a Typology*

Some European countries founded 'national' libraries as early as the seventeenth century, others in the eighteenth and nineteenth centuries, as preservers of their cultural heritage. During the nineteenth century, in North America and parts of Europe, an expanding public sphere included community-supported 'public' libraries. At the same time, colleges and universities multiplied, and 'academic' library collections garnered prestige. Primary and secondary schools also began to support the curriculum through library collections. Public and private organizations established 'special' libraries, as research institutes, religious foundations, and commercial corporations also sought to organize rapidly growing document collections.

1.1 *National Libraries*

A growing national consciousness encouraged the organization of state-funded libraries that acted as both depositories and sources of national bibliography. France's *Bibliothèque Nationale* dates from the fourteenth century, but only in the late nineteenth century did a single published catalogue give unified access to its many collections. In 1841, Antonio Panizzi proposed a set of cataloguing rules for the British Museum Library (now the British Library). In the United States, the Library of Congress (founded in 1800), though not strictly a national library, assumed that role. Librarian Ainsworth Spofford (1864–1897) combined the functions of copyright registration and comprehensive collection of the United States's intellectual product, while under Herbert Putnam

(1899–1939) the Library developed shared cataloging and classification procedures and services that extended its influence—even hegemony—to libraries throughout North America, and from there to other countries worldwide.

1.2 Public Libraries

No single model describes public libraries worldwide. However, many countries have drawn upon British and American experience in establishing public library systems. In nineteenth-century North America and Britain, industrialization spurred the spread of public education. From around 1850, some private libraries began to acquire characteristics typical of public libraries: local tax support, board governance, and accessibility to all members of the community. However, universal literacy was seen by some as a threat, by others as a benefit fostering self-improvement. In the United States and Canada, for example, a faith in 'wholesome' literature for the 'masses' led Progressive Era women's clubs to boost public libraries, as did philanthropist Andrew Carnegie's building program. Public libraries commonly provided free reading materials—and the space in which to read—to children, women, and men of all races and classes, but their collections lacked the diversity of their patrons.

Elsewhere, free public libraries were largely a twentieth-century phenomenon. In China from 1905 the work of American missionary Mary Elizabeth Wood inspired their growth. After 1917, the Russian Revolution spurred the development of public libraries in the USSR so that by 1941 one public library existed for every 2,000 people. In general, late twentieth-century public library services include supporting independent learning and research, maintaining collections of popular adult and children's materials, answering reference questions, providing Internet access, and maintaining space for community activities. However, what—and what not—to collect remains a central issue.

1.3 Academic and School Libraries

As a research model of higher education replaced the classical college, and academic libraries became an essential curricular component, university collections grew dramatically. From mid-nineteenth century on, Harvard's collection expanded from 154,000 volumes to over 12 million, Oxford's Bodleian collection to over 5 million, and the University of Göttingen's to over 3 million. In 1924, S. R. Ranganathan's appointment as librarian at the University of Madras initiated an expansion of Indian academic libraries. By the mid-twentieth century, Moscow State University Library headed an extensive network of academic library collections, and by the mid-1960s, Beijing University's collection held nearly 4 million volumes. Some Western elementary and high schools also developed libraries in the late nineteenth century, many more following suit between the two world wars. After World War II, other countries, including newly-independent Asian, African, and South American states followed suit. Typically, school librarians combine teaching with librarianship to provide materials in various formats and teach students library skills and information literacy.

1.4 Special Libraries

'Special libraries' refers to mission-oriented libraries that range from publicly-funded scientific and technical research libraries to private-sector corporate information centers. Some originated in preindustrial trade, legal, and religious organizations; others—especially those focusing on science, technology, and business—began during the nineteenth century. After World War II, the Cold War expansion of state-funded science and technology fueled a documentation movement that in turn encouraged the growth of corporate and research libraries. The recent rapid increase in digital information resources has prompted another surge in resources devoted to special, especially corporate, libraries.

2. Librarianship

As libraries grew in collection size, librarians' activities diversified. No longer simply guardians of materials repositories, American and British public librarians sought to create methods of locating books in open stacks, and services that targeted new groups of 'users': children, immigrants, rural residents, and the urban poor. Collection management, reference, and cataloging became core components of a new profession: librarianship.

In the late twentieth century, digitization, computer miniaturization, and networking have simultaneously offered solutions and created problems for libraries. Librarians use electronic technology to enhance traditional functions and as new electronic services have proliferated, their reach has expanded far beyond the local institution or community. However, during fiscal stringency, resources assigned to electronic projects detract from those available for print collection, walk-in reference, and youth services. The digital, virtual, or electronic library, sometimes called the library 'without walls' inevitably threatens the traditional library.

2.1 Skills and Techniques

In an expanding print universe, collection management involved selecting materials to build collections and controlling quality by 'weeding' unwanted materials. However, in a mixed print and digital era and with

increasing commodification of information, collection managers face new issues. For example, as commercial publishers entered the scholarly journal publishing market, many serials' prices soared—medical journals by over 90 percent in the 1990s. Another 1990s development—the American 'commercial' university—provides no library services, forcing students to purchase materials or borrow from publicly supported libraries. Materials sharing is, thus, an unequal partnership in which some institutions systematically absorb resources from others. The digital environment is also transforming reference (the personal assistance provided by librarians). Traditional walk-in reference, long augmented by telephone service, is now supplemented, and sometimes replaced, by email and web-based reference, thus reducing services to those without computers.

In the late nineteenth century, librarians developed tools for control of the new but vast array of printed publications. Subject classification and cataloging systems that owed much to contemporary developments in lexicography and the natural sciences helped solve administrative and epistemological problems of book, report, and record description and location. In 1876, the American Melvil Dewey published his *Decimal Classification*, while between 1904 and 1907, Belgians Henri LaFontaine and Paul Otlet produced the *Universal Decimal Classification*. Commercially published periodical indexes also appeared, but it was the mid-twentieth century increase in 'documents' (scientific and technical reports not amenable to traditional classification and cataloging) that prompted a major expansion of professional indexing. The second half of the twentieth century saw attempts to bring scientific, business, and technical 'information' under bibliographic control, including coordinate indexing and the computer analysis of natural language. Combined, issues of intellectual and physical access to documents formed the basis of a new field: information science.

In the 1960s, initiatives to automate information storage and retrieval had far-reaching consequences for libraries worldwide. In 1964, the American corporation Lockheed began making data produced by the National Aeronautics and Space Administration (NASA) commercially available in searchable online databases through DIALOG; similarly, the National Library of Medicine's *Index Medicus* was reborn as MEDLINE in 1971. Online databases multiplied during the 1970s as new vendors created an international market dominated by the United States. Librarians included online searching in their skills repertoire, and struggled to add online database access to an increasingly diverse roster of services.

Librarians were also developing their own electronic databases. American libraries have shared the costs of original cataloging since 1901, when the Library of Congress began to offer ready-cataloged cards for purchase. However, a dramatic increase occurred in the mid-1960s, when the Library of Congress developed the Machine Readable Cataloging (MARC) format for creating, storing, and sharing bibliographic data in what has become an international standardized form. In 1967 a bibliographic utility, the Ohio College Library Center (OCLC), made MARC format available to its members, and in the 1970s, extended its shared cataloging services outside Ohio and to nonacademic libraries. Calling itself the Online Computing Library Center, OCLC later included fee-based public access not only to its catalog of worldwide library holdings but also to journal databases, thus rivaling older commercial database vendors.

As Internet access became widely and internationally available, spreading from universities and other research institutions to businesses and individuals, libraries were quick to make use of it. By setting up networked computers in public areas, they provided direct user access. They made databases of library materials available over the Internet and created gateways to indexes at other Web sites. Libraries also began to digitize documents and graphics materials and make these available over the Web. The Library of Congress began the National Digital Library Program, a cooperative venture with private corporations, to digitize part of its collection, emphasizing special collections of unique items in need of preservation. Conservation and preservation—whether by protection, repair, or copying—have long been core library activities. For much of the twentieth century, conservationists focused on paper deterioration resulting from over-bleaching and the use of acidic alum. One answer was to convert paper documents to microform. But while conversion to digital format can solve libraries' twin problems of space and conservation, it raises new issues, especially the rapid obsolescence of hardware need to 'read' the digital materials.

2.2 Education and Values

For much of the twentieth century, analysis of libraries as cultural and social institutions saw libraries as neutral institutions that could improve people's lives by providing reading materials and educational opportunity. Recently, more critical perspectives have spurred an analysis that highlights the relationship of print and power, and points to ways in which reading is channeled by a social infrastructure shaped, for example, by class and gender relations, as well as ways by which reading itself shaped those relationships.

In North America, librarianship was largely feminized by 1900. The Carnegie-funded Williamson Report (1923) lamented that this caused the profession's low status, and prescribed two-tier staffing: mainly female clerks would perform routine filing and typing, managed by a predominantly male administrative cadre educated in specialized, graduate-level library schools. In 1926, the Carnegie Foundation also helped fund the

University of Chicago's Graduate Library School, stimulating librarians to adopt a research agenda strongly influenced by the empirical, positivist social sciences—'library science.' Library schools awarded doctoral degrees, mostly to men who in turn became library school faculty and large research library administrators, thus reinforcing the gender gap between library managers and clerks.

In the Anglophone West, Victorian values of utilitarian individualism and collective responsibility competed as sources of justification for libraries accessible to the public. Carnegie's systematic support of public libraries in English-speaking countries helped perpetuate a myth of libraries as the foundation of the 'self-made man.' But others, including some North American women's club members, argued for library access to print as essential to an informed citizenry—itself seen as the foundation of republican democracy, resulting in a continuing tension between individualist and collectivist legitimations. Other tensions revolved around collecting 'high' and 'low' cultural items, definitions of 'improving' as opposed to 'pernicious' literature, and its concomitant—'censorship' vs. the 'freedom to read.' Moreover, special libraries constituted a new phenomenon: librarians who defined their mission in private, for-profit terms seen by some public-sector librarians as antithetical to their beliefs, thus fueling a new tension around the opposition of 'public' and 'private.'

In the 1930s, while some librarians supported a value-free library science, others debated what was for many to become a defining professional value: intellectual freedom. Early in the twentieth century, the American Library Association (ALA) regularly blacklisted controversial titles, while World War I librarians banned books by German authors, and books criticizing the war. However, during the 1920s and 1930s, mainstream public opinion turned against intrusive censorship. Exiles from Nazi Germany called for civil liberty; Chinese librarians appealed for American help against Japanese censorship. In 1939, ALA issued the Library Bill of Rights, a policy statement favoring intellectual freedom, that has endured as an expression of a core value in American librarianship. Late twentieth-century political and technological developments have raised new debates about intellectual freedom. In the former Soviet Union, libraries and reading rooms systematically discriminated among readers, making materials defined as anti-Soviet available only in certain restricted locations and under restricted conditions. The end of the Cold War loosened many restrictions, and libraries began to make available the works of previously banned writers. At the same time, electronic transmission has made readily available materials previously controlled through the publishers' and librarians' cultural practices. Availability of sexually explicit material has prompted new calls for censorship in the guise of Internet filtering software. Thus, the late twentieth-century explosion in digital information renews questions among librarians of what to 'collect,' encouraging them to create new means of physical and epistemological access. Traditional professional skills and activities, like providing bibliographic control and user services are in increasing demand, albeit adapted to new technologies, as organizations of all types struggle to meet their changing information needs.

Libraries: Digital, Electronic, and Hybrid

With the integration of electronic resources of all kinds, traditional libraries (see *Libraries*) have had to expand their collection policy and holdings to accommodate items not physically present within the walls of the library building especially those available in electronic form. Similarly, various library functions have had to be extended and new services are evolving, corresponding to different levels of integration of external, electronic resources into existing services, library catalogs, databases, and electronic full text offerings. The expansion of data transfer and search and retrieve (S&R) protocols have changed the means by which libraries are fulfilling their information

mediatory role. Furthermore, use of the information obtained through the library has changed with respect to new regulations and usage conditions, dictated not by the library administration, but by the content providers themselves. In addition, new forms of information resources needed by scholars and students can no longer only be made available via the institutional library: External services and virtual information centers or portals are fulfilling various information demands, though still without adequate quality control and validity checks.

The term 'electronic library' evolved in the 1980s to describe the increasingly automated aspects of library functions, as well as all aspects of creating an online public access library catalog. Individual services, including access to scholarly information stored on CD-ROMS and electronic information resources available through external hosts, such as databases and electronic document delivery, became integrated into the library offerings. Libraries provided these and other services in local area networks (LANS) on the same campus and in wide area networks (WANS), such as library union catalog coalitions and regional library networks.

In the 'electronic library,' resources were often based on digitized copies of the library's own holdings, and digitized surrogates of physical resources (such as photographs of museum and art objects) including items located in other institutions or databases, and these were made available specifically through the user's own library. As technology evolved, electronic resources also include digitized images (both still and moving), sound, and data sets. By the mid-1990s, many libraries had discovered the advantages of a hypertext-based platform for offering the library holdings, access to information resources, and other services, to their internal users via library intranet and to the public via the World Wide Web. This was especially important for libraries, as previously far too often the mixture of formats made total integration of all available electronic information resources impossible.

The combination of networked, distributed electronic resources via the Internet, often completely extraneous to the library resources, as a supplement to or even integrating the two as much as possible led to the designation 'virtual library' for the (often subject-oriented) collections of predominately electronic information resources. Thus, the 'virtual library' is not a library as such, but rather a site in the Internet representing a collection of links or electronic metadata available for individual digital and nondigital items which are usually distributed among an indistinguishable number of web sites produced by heterogeneous institutions. 'Virtual libraries' were usually compiled in a manner and structure which resemble traditional library collections and subject bibliographies. In connection with such subject-oriented collections of active hypertext links to distributed web sites throughout the Internet, the term 'clearinghouse' or 'subject gateway' became quite popular in the last half of the 1990s.

The 'digital library' evolved out of the research focus and technological evolution of these two forms. The digital library represents a more complex integration of digital and nondigital objects in distributed, often digitally noncompatible formats but for which appropriate metadata in a standardized electronic form exist. Metadata are terms used to describe the bibliographic, formal, physical, content, and contextual characteristics of digital and nondigital resources. In addition to achieving standards for metadata, so as to provide precise resource discovery within various digital library collections, digital library architecture of necessity also requires interoperability standards to enable integrated processes of information searching and retrieval in multiple, differently structured collections of digitized objects and digital metadata. Interoperability involves creating data exchange structures which allow a web-based search engine or similar mechanism to gather or 'harvest' metadata from distinctly differently structured data formats and collections into an index structure and reprocess it according to the user's needs. Thus, a digital library makes possible the processing of metadata and other information about collections of diverse digital objects which are in different formats, different internal structures, and different data processing codes. Furthermore, the digital library offers services to process the information resulting from the level of resource discovery and retrieval which range from further search and retrieval precision to document ordering and various other aspects of information processing.

The concept of the 'digital library' evolved out of the potential for digitizing of all forms of media: print, image, sound, complex data sets, and computer simulations of nontime-bound sequences, otherwise not demonstrable events, etc., and retrieving them (or the metadata describing them) in context of multiple, networked information systems. Endres and Fellner (2000) have indicated that the 'digital library' is really a metaphor for the electronic knowledge market and therefore also a metaphor for the provision of knowledge for the society of the future. The digital library often serves as a multidimensional (library) catalog or index to bring together the resource discovery information of every resource which was topically, creatively, or by reason of other connections generatively related. Hence, a search in a digital library could produce not only books and journals articles, but also art works, images, videos, sound files, data sets, complex data simulations, etc. This concept requires, however, search machines which can transcend and work with different data storage formats, different physical mechanisms, and operating codes of various types of computers, and still process diverse kinds of data to produce the desired results.

Hence, a digital library does not only consist of digitized and digitally born information resources, but also of electronic metadata on nondigital objects. Its fundamental components are a robust search engine, an interoperability standard which has taken all heterogeneous collections to be integrated into account, as well as metadata for each information unit in compliance with internationally accepted metadata guidelines. Instrumental in defining and forming the field of digital library research and implementation were a series of digital library research projects beginning with the Defense Advanced Research Projects Agency (DARPA), National Aeronautics and Space Administration (NASA), and National Science Foundation (NSF) jointly sponsored Digital Library Program 1994–98 and a second phase from 1998–2002. In the first phase, six major US universities were awarded grants for research and implementation of six aspects of digital library functions: interoperation mechanism among heterogeneous services (technical architecture and info bus at Stanford University), spatially referenced map information and digital imaging (the Alexandria project at the University of California at Santa Barbara), federating repositories of scientific literature (University of Illinois at Urbana and Champaign), developing the informedia digital video library (Carnegie Mellon University), intelligent agents for information location (University of Michigan-Ann Arbor), and environmental planning and geographic information systems (University of California at Berkeley).

In the second phase of the NSF Digital Library Program, the focus of research was expanded to include test bed development of digital objects, research on scalability of retrieval mechanisms and workflow models, study of use and usability of globally distributed, networked information resources, human–computer interaction, next-generation operational systems, evaluation of digital libraries and the use of digital library technology in the learning environment. In addition, the 'digital libraries life cycle from information creation, access and use, to archiving and preservation' was to be addressed (http://www.dli2.nsf.gov). This second phase was also marked by allied research projects selected under the same program but funded by the Library of Congress, the US National Institute for Health, the National Endowment for the Humanities, and the National Library of Medicine, as their focal points fit more closely to these specialty areas. Not only was a greater subject orientation allowed in the second phase, as opposed to the interdisciplinary approach in phase one, but also the social, behavioral, and economic implications of and effects of new digital libraries in the areas of education, commerce, defense, health services, and recreation were also added as parts of the initiative.

Parallel to these developments in the USA, the UK's higher education boards commissioned a comprehensive study of information provision and electronic information resources in the UK (Follett Report) and various recommendations were realized in the ensuing Electronic Library (eLib) program of the Joint Information Systems Council (JISC) which from 1995–99 supported over 60 research projects in aspects of the digital library structure. During the latter part of this same period, the university system in Australia supported the development of a system of subject-oriented virtual libraries and the Australian government decided officially to supply all government publications and information on an electronic basis with metadata which was closely modeled after the Dublin Core Metadata.

In the USA, Sweden, Finland, Germany, Russia, Japan, Hong Kong, and Australia further digital library research and project implementation (including bilateral international research grants by the US NSF, the European Union and corresponding research funding bodies in other countries), further development of various metadata initiatives, electronic publishing initiatives, efforts towards international standardization, building harvesting robots for standardized metadata and supplementary digital library services such as navigation tools, reference linking and context sensitive linking (SFX), open source codes, the digital object identifier (DOI), other naming methodologies for digital objects (including namespace identification), and a variety of innovative electronic scholarly publishing initiatives (see *Communication: Electronic Networks and Publications*) have been started. Furthermore, the movement towards the digital library and comprehensive navigation and access to electronic resources worldwide has also opened a wide area of research and discussion on the role of the library, the publishers' role and the change of economics in scientific publishing. Economic and business models for electronic publications and content management, preservation of digital objects, archiving of electronic resources, and content management have been additional areas of focus for various workshops, seminars, and large-scale digital library projects worldwide.

In addition, distributed networks enabling shared information on digital objects belonging to national cultural heritage are being implemented by libraries and other institutions, including the Library of Congress in its American Memory Project (http://memory.loc.gov/), California Institute of Technology, and many more with the goal of digitizing unique resources and making them publicly available for research and education. In 1995, the Digital Library Federation (http://www.clir.org/diglib/) was founded to coordinate and guide the implementation and maintenance of the digital library and assure digitization of cultural heritage in the USA. In 2001 there are 25 institutional members and four allied members including consortia and the Association of Research Libraries. The Federation is dedicated to exploring

digital library architectures, systems, and services; investigating standards and best practices; development of digital collections, digital preservation; study of use, users, user support, and user services; monitoring the digital library's changing institutional roles and responsibilities; and coordinating funding strategies for digital library projects.

In 1998, Chris Rusbridge, then head of the eLib Programme, described the next phase in digital library research and characterized this phase as the development of the 'hybrid library' (Rusbridge 1998, Knight ?) Arguing that a pure digital library could not exist because of legacy collections and services, Rusbridge suggests that instead of a 'digital library,' 'hybrid libraries' will provide a 'one-stop shop' for digital and nondigital objects and services. Within the concept of the hybrid library, information resources from various databases, online library catalogs, CD-ROMs, publishers' full text servers, e-print archives and servers, as well as other services join in-house services including nondigitized services, and will all be searchable under the same user interface. Ideally, the user interface will support a robust and precise navigation tool which will function using metasearch mechanisms and harvesting protocols which will enable simultaneous searching in completely differently structured data services. The user can define specific data sets and databases for the search and for different subject areas a set of subject-oriented databases and full text journals online will be suggested. The aspect of customized access to subject-specific resources and personalized information searching mechanisms are being researched and discussed, also in terms of content management and subject portals. The 'hybrid library' thus combines all manner of digital and nondigital information.

The developments surrounding digital, electronic, virtual, and hybrid libraries are symptomatic of impending changes in scholarly publishing, the entire academic realm, and in the sociological structures of education, research, and scholarly activities as a whole. The significance of information management in context of university structures, commercial enterprise, and research endeavors is increasing rapidly. Among the technological and structural changes in library services within the context of the digital, electronic, and hybrid libraries and an information provision structure for educational and research institutions, the professions of librarian and information specialist are being challenged profusely by all the other players in the arena. Researchers publish their own papers in the Net on individual homepages and do information seeking and purchasing directly from their desktops often bypassing library services; publishers index electronic full texts with simple but often sufficient metadata and—through contractual agreements with the author—gaining full rights over distribution, reproduction, and dissemination of the author's intellectual property.

Traditional subscriptions to scientific literature are being made subject to access only through licensing agreements, as opposed to ownership, as was possible with printed versions of the same item. Archiving and permanent accessibility, however, are not guaranteed. Users search using publicly available Internet search engines, believe they have obtained all relevant titles to a given topic, and purchase individual articles directly from the publisher. To survive the massive challenges to the profession, the librarian must become an information specialist, continuously remaining on the cutting edge of information technology, on the various forms of information offered by the content providers, on the cost-effectiveness of physical and electronic document delivery options, and lastly continuously update the users, to train and motivate them to use the full range of adequate information resources. Aspects of free access to information through digital and hybrid libraries, staff competencies in information technology and content management, archiving schemes for consortia sharing of digital information, and evaluation of networked information resources are still areas of the digital, electronic, and hybrid libraries which have not been sufficiently clarified with regard to the responsibility for maintaining access, currency, validity, sustainability and future migration of electronic information sites.

Life Course in History

The history of the life course, of age categories, and of aging is essential to understanding how any society organizes itself over time. The notion of life cycle was first used by social science in the 1930s, but has now been superceded by the more flexible notion of life course. Historians had long been interested in the aging of individuals, but were slower to appreciate the social dimension. Today, however, notions of life course and aging are as essential to historical practice as they are to the social and behavioral sciences.

1. *Foundations of the Field*

Representations of the ages of man had previously attracted the interest of historians of art and religion, but it was not until the 1960s that the life course became a focus of social and cultural history. Beginning with Philippe Ariès' *Centuries of Childhood* (1962), there began a veritable avalanche of studies which have explored the history of every dimension of the Western life course from the Greeks to the present. Today there is a substantial body of literature on the history of childhood, youth, old age, and death, focused mainly on Europe and North America, but also touching on the non-Western world.

Ariès was concerned mainly with representations of aging, but his successors were influenced by the social sciences to direct their attention to behavior. The first generation of new work in the 1960s and 1970s was heavily influenced by historical demography, psychology, biology, and quantitative sociology, seeking to define general patterns of historical development and understand the structures and functions of age groups.

Today, the influence of positivist notions of human development are less evident. In the most recent studies of the life course it is the variability and instability of the life course and age categories that have gained the most attention.

2. *Development of the Field*

The historical study of the life course began with childhood, moved subsequently to youth, old age, and death, and, most recently, has focused attention on mid-life. This sequence is less the effect of research design than historical contingency. The youth movements of the 1960s accounted for the interest in the history of adolescence; the evident importance of older age groups as a consequence of the longevity revolution focused interest on them from the 1970s onwards. Death and dying became important topics in the same period, while the recent work on mid-life reflects the uncertainties experienced by adults in recent decades. What began as a field concerned mainly with the middle-class male life course has now become much more sensitive to gender and ethnic differences, yet another reflection of the ways in which the studies in this area reflect contemporary concerns.

The study of childhood has undergone dramatic changes since it was introduced by Ariès. His notion that there was no concept of the child before the early modern period was immediately challenged by medieval and Renaissance historians who produced linguistic, artistic, and medical evidence of concern with children in their respective periods. The idea that children were subject in pre-modern times to an indifference bordering on neglect has also been modified in recent decades, so that we now have a much more nuanced view of earlier eras of child rearing and childhood, but one that preserves the essence of Ariès' original insight into the malleability of notions of childhood over the centuries. We have come to understand that practices such as abandonment, which may seem cruel to us, made sense in other social and cultural settings.

Ariès' insight into the mutability of age categories also influenced the first generation of studies of youth. It became clear that in pre-modern Europe youth was more a function of social context than biological age. Numerical age was less important than work and marital status in defining the boundary between youth and adulthood. It was not until the later nineteenth century that entry and exit into this age category became standardized, and then mainly for middle-class males who constituted the first group to be called 'adolescents.'

It was not until the twentieth century that everyone was seen as being entitled to both a childhood and an adolescence as these were defined by the emerging medical and psychological sciences. As the understanding of childhood and youth became ever more universal and precise, there developed a notion of a normal life course, leading through adulthood to old age. By following the proper rules of aging, individuals could expect to arrive at what Erik Erikson, the major theorist of the linear life course, deemed a coherent understanding of themselves and life more generally. Failure to move through the prescribed stages of life in a timely manner was often portrayed as a cause of personal and social disorder.

By the 1980s, attention had become focused on old age and death. As more and more people began to live longer, healthier, more active lives, many stereotypes

of older people began to be challenged. Old age could no longer be equated with poor health, debility, and passivity. These changes contributed to new interest in old age in earlier periods, and a more nuanced view of aging and 'retirement' in the past. It turned out that the modern period has no monopoly on notions of good aging or, for that matter, of the good death.

Even adulthood, that part of the life course that had previously been neglected by historians because it seemed so universal and unproblematic, has come in for its share of attention. Awareness of midlife crises, first among men and later among women, prompted a number of recent studies focused on the changing nature of adulthood over time. Studies of fatherhood and motherhood demonstrate just how historically variable this dimension of the life course has also been, and how changing definitions of masculinity and femininity, and of sexual orientation, have affected notions of adulthood over time.

3. *Pre-modern and Modern Life Courses*

Historical work from 1960–2000 has complicated our understanding of the life course and aging in the present as well as in the past. It is now generally agreed that prior to the modern era, age boundaries were more fluid and the life course less rigidly segmented. The identity of pre-modern peoples was determined less by how old they were numerically than by the status or place they occupied in the social order. In a society where heading a household conferred adulthood regardless of age, a propertyless man or woman would remain a 'boy' or 'girl' all his or her life. Schooling was not age graded and there was no set age of retirement.

The nature of the agricultural economy, the absence of centralized institutions, and high levels of mortality and fertility all contributed to this condition. So too did a pre-scientific culture, which had no notion of universal quantifiable laws of nature, but was prepared to accept sudden, nonlinear qualitative change as quite normal.

All this changed in the course of the nineteenth century. For the first time numerical age came to define status for a growing part of the population. In a process that Martin Kohli has called 'chronologization,' age became the criterion for schooling, entry into work, and military service. By the end of the century, it was also associated with entitlements such as retirement and welfare benefits.

Chronologization proceeded fastest among urban populations, affecting middle-class men first, but by the early twentieth century it was shaping the lives of a majority of the European and North American populations. Not only was aging standardized, but it was normalized, producing an acute sense of being too old or too young for certain categories of activities. The life course was organized into a linear sequence consisting of childhood/youth, adulthood, and old age, each with its appropriately gendered roles and expectations. By the mid-twentieth century, norms of successful aging held sway throughout Western society and were being exported to the non-Western world as integral to what it meant to be modern.

In retrospect, we can see that chronologization was the product of an urban industrialized society concerned to maximize productivity through the rationalization of time, including age. The newly developed nation-state was equally interested in maximizing the resources of its citizens by organizing them into age cohorts. These efforts were reinforced by the new biological, medical, and psychological sciences, which took over the responsibility for assigning meaning to age and aging from religion. By the beginning of the twentieth century, each age had its own body of expertise. Childhood was now covered by the newly invented field of pediatrics; adolescent psychology was recognized; and a new discipline of gerontology would soon develop. In our own time, death has become yet another area of expertise, thanatology.

The process of chronologization reached its apogee in the post-World War II period, but by the 1980s some were foreseeing the arrival of the 'age-irrelevant society.' Since 1980 there has been a noticeable dechronologization of the Western life course. Not only has numerical age ceased to be such a powerful determinant of status, but the boundaries between ages have blurred and new age categories such as the 'young-old' or what Peter Laslett called the 'Third Age.'

The timing and sequencing of the life course have become less uniform and normative. The ages of entry into and leaving work and schooling show greater variation. The same is true of marriage and parenting. Given new reproductive technologies, the biological clock is no longer as determinative of women's life course. There is no longer concensus on what constitutes a child, a youth, or an old person. Adulthood, previously that part of the life course that could be taken for granted, has also become problematic.

All this has led to a reconsideration of the linearity of the life course. In the late twentieth century, the institutions that once enforced age norms no longer did so. Schools, employers, and the state all now acknowledge, even encourage, flexibility with respect to age. More concerned with consumption than with production, Western industrial society has encouraged both younger and older age groups to enter into roles in the marketplace previously reserved for adults. Children and the youth have become major consumers, while older persons are encouraged to lead active lives in the consumer society.

The nation-state has also relaxed its age criteria. Its high-tech armies are no longer composed exclusively of young men, but now include not only women but a much wider range of age groups. Today boundaries between age groups blur. The legal distinctions be-

tween childhood and adulthood have become less clear. Legal ages of drinking, driving, and voting have all been revised in recent decades.

While most people still maintain some normative notion of the life course, this gets less reinforcement than it once did from the medical and behavioral sciences. Recent studies have challenged the predictive power of numerical age in everything from learning capacity to physical fitness. It is no longer clear that life follows a uniform, predictable sequence. Gender differences and variation by class and ethnicity have complicated the contemporary picture of aging to the point that generalizations become increasingly suspect.

Today, age is seen as more subjective, more contingent. We seem to be returning to a situation similar to that which existed before the process of chronologization began. But now it is not one's status that determine's one's age, but one's own effort. We are told that how we age is up to us, dependent on how we eat, exercise, and medicate ourselves. Notions of successful aging and the good death were present in earlier periods, but were largely defined by religion. Today, religion competes with the prescriptions of science and medicine. As recent studies show, factors of class, gender, generation, and ethnicity still have a powerful effect on the way we think about age. However subjective age categories have become they do not exist outside history or culture.

4. *Current State of the Field and Future Directions of Research*

Current interest in the history of the life course reflects contemporary uncertainty about aging and the desire to know more about its contingent nature. The history of the life course and aging is no longer so influenced by the behavioral sciences as it once was, while, at the same time, psychologists and sociologists have become more aware of the historicity of their subject. Psychologists now question the notion of a linear life course and the assumption of universal laws of development that underlay it. It is now generally acknowledged that gender, class, race, and cultural background have enormous effect on the life course and life chances.

The relationship between history and the behavioral sciences has been profoundly altered. There is now much greater appreciation of the variability not only of conceptions of age, but of age relations themselves. Aging has ceased to be seen as some invariable law of nature, to be discovered and obeyed. It is no longer a problem to be formulaically solved, but a challenge that confronts every generation and to which there is no one answer, only an ongoing dialogue with ourselves and others about the meaning of age.

No period in history has ever achieved agreement on the question of when life begins and ends, or how the life span should be divided or sequenced. Furthermore, our conceptions of life are not limited to the actual life span. We have the capacity to imagine life before birth and after death, and conceptions like the fetus as 'unborn child' or notions of life after death have very powerful effects on the way we lead our lives.

Over time the perceived number of ages of man has varied enormously. Some cultures have assigned the highest value to the oldest ages; others have valorized childhood or youth over age. The so-called 'prime of life' has been equally variable over time and space. Even within a single society in a given period, people have thought about the life course in very different ways. Religion, which has traditionally been the source of ideas about age and aging, has always been a point of division. Catholics traditionally assigned meaning to particular moments in life, such as the deathbed, while Protestantism insisted that every moment was equally significant in the eyes of God.

Today, intra-religious battles over the meaning of the life course pale in comparison with the struggles between religion and science over the definition of the beginning and ending of life.

Different class groups have also been at odds when thinking about the life course. And there are obvious differences in the ways that different ethnic groups think about age and aging. Gender is also a source of variation. The notion of the linear life course has been closely associated with a certain kind of middle-class masculinity, which places great value on the development of a career. Until recently, few women have had access to careers, their lives having been more contingent on family responsibilities. They have tended to have a more flexible notion of the life course and to be more adaptable than men. In the late twentieth century, when so many people lived beyond all previous societal expectations, this kind of flexibility proved to be a great asset.

It is clear from recent research that the life course is as much the product of culture as of biology. Life is not so much a script we follow, as one we as individuals and as societies write as we go along. In pre-modern times that script was a religious one. In the nineteenth century, the natural and behavioral sciences took over its authorship, producing a grand narrative of the life course sufficiently consistent with the requirements that the dominant economic and political institutions endowed it with until the fourth quarter of the twentieth century.

Today, the traditional naturalistic grand narrative no longer suffices. The global economy demands flexibility; the nation-state ceases to police age boundaries and moves to divest itself of the entitlements (public schooling, mandatory retirement, social security) that were once associated with age. Individuals are encouraged to become more flexible and self-reliant, charged with the responsibility not only for defining but narrating their own life courses. This is reflected in the explosion of personal memoirs and family histories in the last few decades. In the absence

of grand narratives of the life course, everyone seems bent on telling his or her own story.

This new development represents both a freedom and a burden to individuals, and a challenge to experts in the area of life course studies. It requires a new sensitivity to what people are telling us about their lives, new methods that go beyond the old quantitive measures of age to assess subjective experience of aging. It also calls for new theories of aging that take account of the interaction of cultural and biological factors. Historians as well as social scientists now acknowledge that we inhabit not only a physical world but also a symbolic world, and that it is the interplay between the two that determines the history as well as the sociology of the life course and aging.

Historians as well as behavioral scientists have begun to acknowledge that the sources of data they have traditionally relied on to measure aging, mainly physical and behavioral data, tells us only part of what we need to know. They are beginning to explore further the stories that people have told themselves about the aging process and how different subcultures have imagined the life course. For it is through these that we grasp the ways in which people not only think about age but think with age, and how the meanings that are constructed through and around the life course affect the way we live. For we not only live with certain historically defined notions of life course and aging, but live by them. These constitute the source of the meaning as well as the structure of any social system.

Historical studies of the life course and aging are beginning to turn to those humanistic disciplines such as literature and art history traditionally devoted to close analysis of language, narrative, and images. This does not mean that they are discarding the alliances with the behavioral and social sciences that have been so productive to this point, but rather that all the disciplines concerned with the life course and aging have become more aware of the need to examine their epistemological and ontological assumptions.

Life Course: Sociological Aspects

Human lives represent an enduring interest in the social sciences that reflects important social changes over the twentieth century. Most notably, developments after World War II called for new ways of thinking about lives, society, and their relationship. Longitudinal studies of children before the war became studies of adult development in the postwar era. Demographic change also assigned greater priority to the study of adults and aging. The scientific challenge presented by these priorities focused attention on the social pathways of life. This article presents the life course as both concept and theory for studies of lives, human development and aging.

1. Elementary Concepts

In concept, the life course refers to a sequence of age-graded events and social roles that are embedded in social structure and historical change. The life course also defines a field of investigation with a theoretical orientation that guides research in terms of problem identification and formulation, variable selection, rationales of design, and explanatory analysis. Building on advances since the 1960s, life course theory

(Elder 1998) has uniquely forged a conceptual bridge between developmental/aging processes, the social life course, and ongoing changes in society, one based on the premise that age places people in the social structure and in particular birth cohorts.

The life course evolves over an extended period of time, a trajectory of marriage, work, or earnings; and it also takes form within a short time-span, marked by the transition between statuses, such as leaving home, entering a new job, and divorce followed by remarriage. Social transitions are always embedded in trajectories that give them distinctive form and meaning. Life trajectories are constructed by linking states across successive years. Each work trajectory, for example, is marked by a sequence of jobs and transitions between jobs, along with occasional spells of unemployment. A work transition may entail little change or produce a turning point—a redirection of life through changes in situation, meaning, and/or behavior, whether antisocial or conforming. Entry into military service has served as a turning point for men who grew up in poverty and were involved in an adolescent life of crime (Sampson and Laub 1993).

Each of these concepts is applicable to different levels of the life course: (a) institutionalized pathways may be established on the macrolevel by laws and social policies of the state or firm (Mayer and Müller 1986); (b) the life course of the individual is worked out at the microlevel in terms of choices and lines of action; and (c) the developmental or aging trajectory of the individual as defined, for example, in terms of intellectual development. An example of these multiple levels is provided by Spilerman's (1977) analysis of work careers. 'Career line' refers to pathways defined by the aggregated work histories of individuals. They are patterned by industry structures and the labor market. An employee's worklife, one aspect of the life course, varies by the career requirements of the firm and marketplace. At the developmental level, positive and negative changes in worklife have predictable consequences for emotional health. Each level of the life course represents a potential entry point for research. However, contemporary studies are increasingly extended across levels of analysis.

Three concepts have been used interchangeably with the life course—life cycle, life history, and life span. Life cycle generally describes a sequence of life events from birth to death, though it more accurately refers to stages of parenthood over the life course, from the birth of a first child to the departure of children from the home to the childbearing of the next generation. The life cycle is repeated from one generation to the next, but only within the framework of a population. Some people do not have children and consequently are not part of an intergenerational life cycle.

Life history typically refers to a lifetime chronology of events and activities that variably combine data records on social events and sometimes also psychological processes. These records may be obtained from archival materials or from interviews with a respondent. Some life history interviews are prospective and focus on the present and future, while others are retrospective and enable the investigator to obtain information that was not collected in the past. Retrospective life histories (Giele and Elder 1998) record the age (year and month) at which transitions occur in each activity domain, and thus depict an unfolding life course in ways uniquely suited to event history analyses and the assessment of time-varying causal influences.

Life span specifies the temporal scope of inquiry and specialization, as in life span developmental psychology or life span sociology. A life span study extends across a substantial period of life and generally links behavior in two or more life stages. Instead of limiting research to social and developmental processes within a specific life stage, as at middle age, a life span design favors studies of antecedents and consequences that extend beyond a single life stage. Each of these concepts, from life span to life cycle, has an important place in studies of the life course.

2. *The Emergence of Life Course Theory*

Life course ideas coalesced in a theoretical orientation during the 1960s and 1970s. One of the crystallizing forces came from longitudinal studies of children that were extended into adulthood during the 1940s—examples include the Oakland and Berkeley Growth Studies, and the Guidance Study at the University of California, Berkeley. The life-span extension of these studies gave fresh momentum to the study of adult development at a time when few longitudinal studies were underway. Three challenges confronted investigators in the social and behavioral sciences: (a) to replace child-based, growth-oriented accounts of development with concepts that apply to development and aging across the life course; (b) to think about how human lives are socially organized and evolve over time; and (c) to relate lives to an ever-changing society.

The first challenge led to the formulation of life-span concepts of development, especially within the expanding field of life-span developmental psychology (see *Lifespan Development, Theory of*). Distinctive principles include the relative plasticity and agency of the aging organism, the life-long interaction of person and social context, and the multidirectionality of life-span development. Differentiating and cumulating experiences across the life span tend to generate complementary aging dynamics (Dannefer 1987): (a) greater heterogeneity between individuals over time, and (b) enhanced continuity within individuals. Sociological concepts of life-span development include trajectory, transition, and turning point, as well as the

cumulation of advantages and disadvantages over the life course.

Life-span thinking on human development and aging occurred initially with little attention to a well-established 'role theoretical perspective' on human lives, one that dates back at least to Thomas and Znaniecki's (1918–20) *The Polish Peasant in Europe and America* . Role and relationship theories provided a way of thinking about socialization, generational succession, and social networks into the 1960s. The central concept at the time was life cycle; it depicted life organization in terms of social relationships and generational succession through the kinship system. The missing element was temporality. Life cycle models did not specify the timing of role entries or exits or the duration of time-in-role. Also, generational membership failed to locate people with precision in historical time and thus according to social change.

These limitations were addressed by theory and research on age and time. The path-breaking work of Neugarten (1968) documented substantial life variations in social roles by age. Contrary to established views (Eisenstadt 1956), she found that people of the same age varied significantly in the pace and sequencing of life transitions. Ever since this research, the differential timing and order of events has been among the most active topics of life course study, especially in the transition to adulthood (Heinz 1999).

Another age-based contribution to life course theory came from an appreciation of historical variations in people's experiences and lives (Ryder 1965, Riley et al. 1972). Ryder proposed the term 'cohort' as a concept for studying the life course in relation to social change. Cohort refers to the age at which people enter the system; thus, a birth cohort locates people in history according to their birth year. Ryder's life stage principle states that the impact of historical change on the life course reflects the life stage at which the change was experienced (see *Age, Sociology of*).

The three streams of life course theory (social relations/life cycle, age, and life-span concepts of development) came together in a study of children who were born in the early 1920s, grew up in the Great Depression, and then entered service roles in the Second World War (Elder 1974 (orig.), 1998 (new edn.)). The study began with ideas from studies of social relations, such as generation, socialization, and social roles, but soon turned to the analytic meanings of age for ways of linking family and individual experience to historical change, and for identifying age-graded trajectories across the life course. The project tested Ryder's life-stage hypothesis by comparing the effects of drastic income loss in the Great Depression on the life experience of the Oakland cohort members (born 1920–1) with that of a younger Berkeley cohort, born at the upper end of the 1920s. Consistent with the life-stage hypothesis, the younger boys in particular were more adversely affected by family hardship, when compared to the older boys, though such differences faded in the adult years through the impact of military service, family support, and higher education.

By the 1990s, the life course had become a general theoretical framework for the study of lives, human development, and aging (Binstock and George 1996). This development was coupled with the growth of longitudinal studies and the emergence of new methodologies for the collection and analysis of life history data (Giele and Elder 1998, Bryk and Raudenbusch 1992).

3. *Principles of Life Course Theory*

Life course theory is defined by a set of core principles. Most basic is the premise that behavior cannot be fully understood by focusing solely on the specific life stage in question, defined by age or social role. The origins of adolescent and young adult behavior lead back to childhood and the consistency of nurturance and discipline. Likewise, behavioral adaptations at mid-life are not influenced solely by current circumstances, but by developmental trajectories that extend back to childhood and by anticipations of the future. Accordingly, the principle of life-span development states that: human development and aging are lifelong processes.

The early pioneering studies in California became life-long enterprises without an initial life-course vision. More ambitious projects have recently adopted this perspective, such as the national longitudinal studies of birth cohorts in Great Britain (birth dates of 1946, 1958, and 1970). They are scheduled to be followed into the later years of life. Studies across the life course are changing our understanding of poverty (Leisering and Liebfried 1999), work, and achievement, while identifying pathways of resilience and increasing vulnerability.

Preventive measures for health in the later years require knowledge that can only come from programmatic life-course studies of early influences and behavior. However, particular research questions and matters of cost can make compelling arguments for panel studies that are launched with older people, such as the Berlin Aging Study (Baltes and Mayer 1999) of men and women between the ages of 75 and 100. The study includes a retrospective life calendar and draws upon a variety of disciplines in assessing the differences between old age and old old age, and the potential benefit of intervention.

People and their situations change across the life course, raising the probability that influences also differ by stage of life. Empirical evidence documents a SES gradient in emotional depression, but there is reason to expect the mechanisms to vary as people become older. In fact, Miech and Shanahan (2000)

find that education and mastery beliefs in the early adult years offer protection against depressed feelings. By later life, these feelings are mainly a product of low income and poor physical health. With these contrasts in mind, the principle of timing states that: The developmental antecedents and consequences of life transitions, events, and behavior patterns vary according to their timing in a person's life.

Temporal variation across the life course also takes the form of change in the meaning and implications of particular life transitions, such as the loss of a spouse immediately after marriage vs. the more expectable event of death in old age. In theory, the normative concept of social timing specifies an appropriate age for events, such as sexual experience, childbearing, and retirement. Age at retirement has declined in Western societies along with normative expectations concerning the duration of work (Kohli et al. 1991). The timing of lives refers to change and stability in event timetables, to the scheduling of transitions, and to the timing of developmental events, such as puberty.

Social timetables may not correspond with biological change, as illustrated by early maturing girls. They are older in physique than their age and frequently develop associations with older boys that accelerate their onset of sexual experience (Stättin and Magnusson 1990). Neugarten (1968) refers to a social clock by which socially approved age norms are superimposed on the biological organism, as in the relation between sexual norms and the timing of menarche. In these and other ways, the principle of timing is fundamental to the role of 'interdependent lives' in the life course and the principle of linked lives: Lives are lived interdependently and that social-historical influences are expressed through this network of relationships.

The principle of linked lives moves beyond the conventional model of the life cycle by referring to all forms of relationships, not simply those having to do with family and reproduction of the generations. Human lives are typically embedded in and structured by social relationships with kin, friends, and co-workers across the life span. Kahn and Antonucci (1980) refer to these lifetime associates as convoys of social integration, social support, and obligation. Social relationships also represent a vehicle for transmitting and amplifying the effects of stressful change, as in families under the pressures of change. The prevalence of dual career families has centered research on issues of linked lives and timing, including the challenge of synchronizing lives at points of transition, e.g., job offers, retirement.

Issues of timing and linked lives are played out in specific historical contexts, whether adolescence in the prosperous 1920s, depressed 1930s, or war mobilized early 1940s. Especially in societies undergoing rapid change, a different birth year exposes individuals to different historical worlds, with their constraints and options. Historical effects take the form of a cohort effect when social change differentiates the life course of successive cohorts, such as older and younger men before the Second World War. The aforementioned Great Depression study of two birth cohorts (Elder 1974, 1998) illustrates this cohort effect. The principle of lives in time and place asserts that: The life course of individuals is embedded in and shaped by the historical times and places they experience over their lifetime.

History also takes the form of a period effect when the influence of a social change is relatively uniform across successive birth cohorts. Secular trends in the scheduling of marriages and first births across the twentieth century are largely an expression of powerful period effects. A third type of effect occurs through maturation or aging. The heterogeneity of historical experience within birth cohorts calls for inquiry of the change process itself, such as the actual decline of family income. Other examples of historical change in lives include research which highlights a pattern of resilience among urban youth who were 'sent down to the countryside' during the Chinese Cultural Revolution (1966–76) (Zhou and Hou 1999).

Though structured by historical circumstance, the life course is also shaped by the choices people make—a young girl's pregnancy, the decision on whether to carry the child to term, and the issue of who cares for the child and its consequences for the daughter's education and future. During China's Cultural Revolution, the choices of young people were often made by their work unit, but some youth were sent to the countryside and managed to continue their education, postpone marriage, and return to their city of origin. The principle of human agency asserts that: Individuals construct their own life course through the choices and actions they have taken within the constraints and opportunities of history and social circumstances.

Human agency has been a defining theme of biographical studies that extend back to the early Chicago School of Sociology. Within this intellectual tradition, Clausen's *American Lives* (1993) found evidence supporting the hypothesis that competent young people who think about the future with a sense of personal efficacy are more effective in making sound choices and in implementing them. This evolving life course generally reflects a 'loose coupling' between social stages and transitions. Age grades and loose coupling (Elder 1998) can be viewed as opposite sides of the adult life course—its social regulation on the one hand, and the actor's initiative on the other, with its element of disorder.

4. *Challenges and New Directions*

Since the 1970s, the life course has become a lively interdisciplinary field of inquiry, focused around studies of human lives and their social pathways, with

emphasis on the imprint of historical change on trajectories of human development and aging. This time period has witnessed an unparalleled growth of longitudinal samples for life course research along with statistical and methodological innovations for the study of change and multilevel contexts. Life course studies continue to draw upon widely diverse specialties, from developmental science to the sociology of the state. Advances in the field have led to new challenges and directions, as noted below.

First, the task of linking early and later experiences in the life course remains a challenge. Studies have traced the persistent effect of early events and experiences to subsequent outcomes, such as the effect of a teenage birth and military service. But the chain of linking mechanisms is largely uncharted.

Second, studies of the individual life course are beginning to cross levels, but more work is needed to assess the ongoing influence of social structure and change, the impact of cohort life patterns on social structure, and the effect of changing lives on human development and aging.

Third, interlocking trajectories, such as work and family, or work and psychological health, represent a basic distinction of life course theory, but only recently have statistical techniques enabled research to assess this dynamic.

Fourth, biological as well as social events have been linked to life patterns, as in studies of physical maturation. This work and other factors (e.g., sibling samples) are prompting more thought and research on genetic influences.

Fifth, cumulating research on social transitions across the life course suggests that general models of life transitions and their effects are possible at this time.

All of these research challenges and new directions will benefit from a greater investment in comparative study, both within and between societies. More than in the past, the initiation of life course projects is informed by cross-national collaboration and comparative options (see *Age Stratification*).

Life Expectancy and Adult Mortality in Industrialized Countries

This article is concerned with trends, sex differences, and socioeconomic differences in life expectancy since 1950. The focus is on the so-called established market-economy (EME) countries, including Western Europe, North America, Oceania, and Japan (see *Infant and Child Mortality: Central and Eastern Europe*).

1. *Trends in Life Expectancy in Main Groups of Industrialized Countries*

There were some marked differences in life expectancy among groups of the (currently) industrialized countries in the early 1950s. Average life expectancy in the less developed countries (Southern and Eastern Europe, and Japan) was more than four years lower than in the more developed countries in Western Europe, North America, and Oceania (Fig. 1). In the 1950s and 1960s the differences diminished, as life expectancy increased more rapidly in the high mortality countries.

The period from 1945 to 1970 has been called the 'era of antibiotics' (Kannisto et al. 1999). During this period antibiotics proved effective against a wide range of diseases and infections. The increase in life expectancy was therefore fastest in the less developed areas, where infectious diseases were still common and infant and child mortality high (e.g., Southern Europe and Japan).

This convergence of life expectancies proved short-lived, however; the differences between the main groups of countries started to increase during the late 1960s. By 1980 the differences among the regions were far greater than in 1950. By the early 1990s, life expectancy in Japan was more than 12 years higher than in the countries of the former Soviet Union. This was due to the exceptionally rapid increase in life expectancy in Japan and the stagnation and even decline of life expectancy in the (former) Soviet Union. Life expectancy also increased in the market-economy countries other than Japan, but less rapidly so. In the (former) socialist countries of Eastern Europe the increase in life expectancy was slow during the 1970s and 1980s, and these countries lagged far behind the other industrialized countries in the 1990s. This development is discussed in more detail in the article on mortality in Eastern Europe.

Because infant and child mortality was low as early as in the 1970s in the EME countries, decline in adult mortality became a more important and later the dominant cause of the increase in life expectancy in these countries. For example, in England and Wales about one-third of the increase in life expectancy was attributable to the decline in mortality in the age group 0–14 years from 1970 to 1980, but less than one-tenth

Life expectancy at birth (both sexes) in groups of industrialized countries 1991–95

from 1980 to 1990. More than half of the increase in the 1980s was due to the decline in mortality among persons over 65 years of age (Meslé 1996).

In populations with a low life expectancy, infant and child mortality have a strong influence on the level of life expectancy at birth. In the EME countries discussed here, this is no longer the case: death rates in the youngest age groups have dropped to such a low level that they have a minor influence on trends differentials in life expectancy at birth. They are determined almost entirely by mortality in adult ages.

The increase in the importance of adult age groups has been mainly due to the decline of mortality from cardiovascular diseases (coronary heart disease, cerebrovascular diseases, and other diseases of the circulatory system). The decline in cardiovascular disease mortality was slow in the 1950s and 1960s, and in many countries male mortality from these diseases actually increased. The decrease in all-cause mortality in older age groups was modest during this period. Around 1970 mortality among the elderly began to decline in most Western countries as never before in recorded history, and gains in survival were observed even at the highest ages (Kannisto et al. 1999).

An analysis of the decline in adult mortality in the United States led Olshansky and Ault (1986) to conclude that the United States had entered a 'fourth stage in epidemiologic transition.' This new stage is characterized by rapid mortality declines in older people resulting from a postponement of the age at

Table 1
Life expectancy at birth) (both sexes) in 1995 and change from 1966–70 to 1995 in established market economy countries (years)

Country	Life expectancy 1995	Change from 1966–70 to 1995
Japan	79.8	8.7
Sweden	79.1	5.0
Switzerland[1]	78.8	6.6
France	78.7	7.2
Italy	78.4	7.4
Canada	78.3	6.3
Australia[1]	78.2	7.4
Spain	78.1	6.5
Iceland	78.0	4.6
Norway	77.9	4.1
Greece	77.8	6.8
Netherlands	77.7	4.1
Luxembourg	77.4	7.3

which degenerative diseases, particularly cardiovascular diseases, tend to kill. They refer to this new stage as the Age of Delayed Degenerative Diseases (see *Mortality, Epidemiological, and Health Transitions*).

Life expectancy increased in all EME countries from the late 1960s to the 1990s. The increase was greatest in Portugal (see Table 1), which had lagged far behind the other countries in the 1960s. Despite this rapid increase Portugal still had the lowest life expectancy in the EME group in 1995. In general, the increase in life expectancy was below average in countries with a high life expectancy in the 1960s (e.g., Norway, Sweden, and The Netherlands).

Denmark is a special case. Danish life expectancy was relatively high in the 1960s, but since then progress has been clearly slower than in the other EME countries. In 1995, life expectancy in Denmark was second lowest after Portugal in the EME group. Japan is another special case. By the late 1960s life expectancy had reached the average level of advanced industrialized countries, by the mid-1990s Japan had the highest life expectancy in the world at 79.8 years.

Figure 2
Female–male difference in life expectancy at birth, industrialized countries by region 1951–95

Cross-national differences in life expectancy among developed countries are not related to standard of living or the level of gross national product (Wilkinson 1996). For example, rich countries such as the US and Germany have lower life expectancies than Greece and Spain. No systematic analyses have been done of the causes of cross-national differences in life expectancy, but several studies have addressed specific questions. These studies are based on the analysis of differences in mortality by cause of death and in the prevalence of known risk factors for specific causes of death. For example, a partial explanation for the high life expectancy in Japan is the low-fat Japanese diet, which contributes to the very low mortality from heart disease. The low mortality from coronary heart disease in southern Europe has also been explained by reference to dietary factors, more specifically to the so-called Mediterranean diet which includes olive oil, fresh fruits, and relatively little animal fat. The exceptionally slow recent increase in life expectancy in Denmark seems to be related to the high prevalence of smoking- and alcohol-related diseases.

2. *Sex Differentials in Life Expectancy*

Women live longer than men in all industrialized countries, but the difference between female and male

Table 2

[1] The estimate for 1995 is based on earlier period in the following cases: Australia 1994–96; New Zealand 1993–95.

life expectancy varies. At the beginning of the twentieth century the differential in several countries (Bulgaria, Ireland, Italy, and Japan) was small (United Nations Secretariat 1988). The differential was largest (3.9 years) in England and Wales. From the 1930s to the 1970s, increases in the sex differential in life expectancy were a universal feature because women benefited more than men from the decline of mortality.

Figure 2 describes the development of the sex differential in life expectancy for groups of industrialized countries from 1950 to 1995. By the 1950s the average differential in North-Western Europe and North America exceeded five years. The differential was smaller in the less industrialized regions (Eastern and Southern Europe and Japan). In the relatively un-industrialized Soviet Union, however, the difference was clearly largest, almost eight years.

Until the late 1970s the gap between female and male life expectancy grew almost constantly in all regions. This growth was most rapid in the Soviet Union and Eastern Europe. In North-Western Europe, North America, and Oceania the gap started to diminish in the late 1970s and early 1980s, and in Southern Europe a decade later. In Eastern Europe the difference continued to grow rapidly. In the Soviet Union there was a curious temporary decrease from 1976–9 to 1986–9. This was associated with the increase in life expectancy brought about by President Gorbatchev's antialcohol campaign, which had a greater impact on male than female mortality.

Both the sizes of and the trends in the sex difference in life expectancy have varied markedly between countries. For example, France and the United States had approximately the same difference in 1970. In the United States the difference was relatively constant until 1979, and then decreased by more than two years. In France, the sex difference continued to increase into the second half of the 1980s, and diminished only slightly in the early 1990s. In the United Kingdom the decline started earlier than in other countries. In Italy the first signs of decrease did not appear until the 1990s. In 1995 France, Finland, Portugal, and Luxembourg had differentials of more than seven years, whereas the differential was less than five and half years in Sweden, Ireland, Greece, the United Kingdom, Ireland, and Denmark (Table 2).

The lower life expectancy of men in developed countries is due to higher male death rates in all age groups and for most causes of death. An analysis of the contribution of broad groups of causes of death in 26 developed countries in the early 1980s showed that the higher mortality of men from diseases of the

circulatory system, particularly from ischaemic heart disease, made the largest contribution to the differential in life expectancy. Diseases of the circulatory system accounted on average for 40 percent of the total sex differential. Neoplasms (cancer) accounted for 18 percent, more than half of which was due to lung cancer. External causes (accidents, suicide, and violence) accounted for 19 percent. The contributions of these causes of death varied between different countries, however, widely (United Nations Secretariat 1988).

The causes of the higher mortality of men from circulatory diseases, cancer, and other causes of death are only partly known. The size of the sex difference in mortality from each specific cause of death is influenced by a wide variety of environmental and genetic factors, and the contribution of particular factors varies greatly depending on socioeconomic and cultural conditions (Waldron 1986). For example, when maternal mortality was high, that reduced the female–male difference in life expectancy. The decline in maternal mortality has contributed to the increase in the life expectancy gap during this century, but the present very low rate of maternal mortality has hardly any effect on sex differences in life expectancy.

There is evidence to support the hypothesis that female sex hormones reduce women's risk of ischaemic heart disease, in part due to their favorable effects on serum lipids, while men's higher testosterone levels have unfavorable effects on serum lipids. The higher male mortality from ischaemic heart disease is therefore probably due in part to genetic differences between men and women. In countries (e.g., Finland or the United Kingdom) where mortality from ischaemic heart disease is high, these genetic differences contribute more to the overall sex difference in life expectancy than in countries with low mortality from ischaemic heart disease (e.g., Japan or Greece). Waldron (1995) suggests that changes in diet, particularly in the consumption of animal fat, have had greater effects on male than female ischaemic heart disease mortality. It is likely that changes in diet have contributed both to the earlier increase and to the more recent decrease in sex differentials in life expectancy.

A major well-established cause of the increase in the sex differential since the 1930s is that men adopted cigarette smoking much earlier than women. Male cigarette smoking has contributed to the increase in male excess mortality from cardiovascular diseases (particularly ischaemic heart disease), cancer (particularly lung cancer), and diseases of the respiratory system. In her review of 12 studies, most of which were based on samples drawn from the US population from the 1950s to the 1980s, Waldron (1986) estimated that approximately half of the sex difference in adult all-cause mortality was attributable to smoking.

A study on the contribution of smoking to sex differences in life expectancies in four Nordic countries and The Netherlands in 1970–89 (Valkonen and van Poppel 1997) estimated that, on average, more than 40 percent of the average sex difference in these countries in 1970–4 was attributable to more prevalent smoking among men. By 1985–9 the contribution of smoking dropped to approximately 30 percent of the total difference. In all five countries the loss of life expectancy due to cigarette smoking increased among women. In Denmark the loss was 1.6 years in 1985–9, but less than six months in the other countries.

Alcohol use is another important factor contributing to the lower life expectancy of men. There are no cross-national studies, but the contribution of this factor obviously increases in line with rising alcohol-related mortality and growing sex differences in drinking men and women. Mäkelä (1998) estimated that at least one-fifth of the sex difference in life expectancy in Finland in 1987–95 was attributable to the higher male mortality from alcohol-related causes.

Death rates for accidents, suicide, and other violent causes have been found to be higher for males than females in almost all available historical and international data, although the magnitude of the male excess varies. This difference is partly due to the heavier alcohol consumption among men. Social norms and expectations that favor more aggressive and risk-taking behavior among men also play a role. There are also hypotheses that there is a genetic basis for the differences in accident-prone and violent behavior.

There are other factors apart from those discussed above that affect or may affect sex differences in mortality. These include differences in the use of health services, in the prognosis or survival rates for various diseases, economic activity, vulnerability to disruption of social relationships including marriage, etc. However, in the light of the evidence available, these are less significant than behavioral factors.

3. *Socioeconomic Differences in Mortality*

Differences in mortality between subpopulations within countries have been studied by several variables, such as region of residence, rural–urban residence, marital status, and socioeconomic position. These intracountry differences are sometimes as large or larger than cross-country differences, and they are extremely important from the point of view of health and social policy planning. Differences between socioeconomic groups are particularly important because they tend to be greater than other differences between subpopulations.

Figures on mortality by socioeconomic category are not normally presented in regular statistics. The data for England and Wales published by the Registrar General (later the Office of National Statistics) since 1851 in the so-called Decennial Supplements provide the only long-term series of mortality statistics by

occupational and social class (OPCS 1978, Drever and Whitehead 1997). Most of the knowledge about socioeconomic mortality differences is based on specific studies, the results and reliability of which depend on several factors, such as the source and coverage of data, the socioeconomic indicators used, and the way in which mortality and size of mortality differentials are measured.

Despite data problems, study after study in different populations have shown that persons in lower socioeconomic positions die on average at a younger age than those in higher positions. For example, in England and Wales the estimated gap in life expectancy at birth between men in Classes I/II (professional, managerial, and technical occupations) and men in Classes IV/V (partly skilled and skilled workers) was five years in 1987–91; for women the differential was three years (Drever and Whitehead 1997).

Cross-national variations in the extent of socioeconomic differences in mortality by level of education and/or occupational class have been studied in a large-scale project covering 11 Western European countries, the United States, and three former socialist countries in Central and Eastern Europe (Kunst 1997). The main part of the data covered middle-aged men from ca. 1980 to ca. 1990.

In all countries the mortality rate of manual classes was higher than that of nonmanual classes. The relative excess mortality of the manual classes was remarkably similar for most Western European countries and the United States. France and Finland had somewhat greater mortality differences than other Western European countries but smaller than Hungary. The results did not support the view that inequalities in health are smaller in countries where social, economic, and health care policies are to a greater extent influenced by egalitarian principles such as Sweden and Norway (Mackenbach et al. 1997).

It has been observed that male mortality in manual classes is higher than in nonmanual classes for nearly all causes of death. Relative differences are particularly large and systematic in mortality from respiratory diseases and from accidents and violence. The comparative study by Mackenbach and colleagues showed one interesting exception: hardly any class differences were found in France, Switzerland, Italy, and Spain in mortality from ischaemic heart disease. In Portugal mortality rates were higher in the nonmanual than manual classes. On the other hand, socioeconomic gradients in mortality from causes other than ischaemic heart disease were steeper in Southern than in Northern European countries and the United States.

Discussing the reasons for the small differences in mortality from ischaemic heart disease in Southern Europe, Kunst (1997) suggests that this is probably related to the low national levels of ischaemic heart disease. In these countries men seem to be protected against ischaemic heart disease by their frequent consumption of fresh vegetables, fruits, and vegetable oil. Diet may have protected lower socioeconomic groups in particular.

In all countries for which reliable data are available, socioeconomic differences in mortality are smaller among women than men, but there have been no comparative analyses to explore the causes of this phenomenon.

Koskinen and Martelin (1994) found that the smaller socioeconomic differences among women in Finland were mainly due to the different distribution of causes of death among women and men. Causes of death with small (most cancers) or reversed (breast cancer) socioeconomic differentials were more common among women than men. Causes with large differentials (accidents and violence, lung cancer, coronary heart disease), on the other hand, were more common among men.

Data on life expectancy by occupational class for England and Wales as well as for Finland show a clear widening in the gap between manual and nonmanual classes both among men and women since the 1970s (Drever and Whitehead 1997, Valkonen 1999). Results on changes in life expectancy by socioeconomic variables are not available for other countries, but other types of data show that at least relative socioeconomic differences in mortality among men increased in the 1980s in all countries for which some data are available (e.g., the United States, the Nordic countries, and France).

It has been suggested that these trends are a consequence of the general increase in social inequality and income differentials. Although this may be true in some cases, it cannot be generalized to all countries, because mortality differences have increased both in countries where income differentials have increased (e.g., Britain) and in countries where they have decreased (e.g., Finland).

The main common factor contributing to the increase in socioeconomic mortality differentials in several countries is the decline in mortality from cardiovascular diseases, which has been more rapid in the nonmanual and better educated classes than in other population groups. The upper classes have benefited more from the decline in cardiovascular mortality, probably because they have been quicker to adopt recommended health behaviors (concerning diet, smoking, physical activity, etc.), and because they may have had better access to new medical treatments, such as coronary artery bypass grafting and angioplasty.

Causes of socioeconomic differences in mortality have been discussed extensively and many different hypotheses have been offered. Some hypotheses are based on the causal effect of socioeconomic position on mortality. According to these hypotheses differences between classes in material working and living conditions, in health-related behaviors (e.g., smoking, alcohol use, diet) or in the prevalence of psychosocial

stressors cause differences in mortality. Another set of hypotheses is based on assumptions of direct or indirect selection of persons into social classes. According to the direct selection hypothesis, the higher mortality of lower classes is due at least in part to the negative effect of poor health on socioeconomic position. The indirect selection hypothesis assumes that certain characteristics of individuals (e.g., social background, intelligence, or psychosocial traits) affect both their socioeconomic position and their health and mortality.

Life Management, Developmental Psychology of

1. Brief Historical Perspective on the Concept of Life Management

The term life management is not frequently used in the psychological literature. One of the reasons might be that the active role of the individual in managing his or her life has only entered psychological models after the 'cognitive revolution.' In the following section, a brief historical overview of the emergence of the concept of

life management is given, concluding with a tentative definition of the term 'life management.'

1.1 Emergence of the Recognition of the Active Role of the Individual in Shaping One's Life

To introduce the notion of 'life management' into the description and explanation of human development implies the assumption that people actively contribute to their developmental pathways and are not entirely under the control of external stimuli or biological processes. Although hardly controversial nowadays, it took a revolution—the 'cognitive revolution'—to introduce this notion into psychology in the 1960s that was dominated by behaviorism of the Watsonian or Skinnerian type. The importance of self-regulation for describing and predicting human behavior was stimulated by research by Mischel (1968) and Bandura (1969). Their research has convincingly shown that situational, external stimuli are but one factor influencing behavior and that, when attempting to understand human behavior, it is necessary to take sources of behavior regulation into account that lie within the individual (i.e., self-regulatory processes).

Developmental psychology has long been dominated by the view that development is best described either in terms of biologically determined maturation (i.e., unfolding of a biological program or blueprint) or as the result of a specific learning history in the sense of classic and operant conditioning. The latter view is exemplified in Watson's famous statement that if one were to give him a dozen babies he could—by arranging the environmental conditions—produce whatever adults one would wish to see (Watson 1925). Watson also noted that he was overstating the role of the environment but he wanted to juxtapose the introspective approach to psychology focusing on inner states such as feelings and thinking with the behaviorist position. Although the interaction of biological and environmental factors for development has also been stressed early on, for instance by Piaget, the proactive role of the individual in creating his or her development has only been recognized fairly recently (Lerner and Busch-Rossnagel 1981). In this perspective, development is viewed as the co-constructive interplay of biology, culture/society, and the individual (Baltes 1997). On the one hand, individuals proactively shape their environment and place themselves into certain contexts. On the other hand, individuals react to their environment by continuously adapting and reacting to their physical, cultural, and social environment.

One important way in which individuals play an active role in their development is by choosing, committing to, and pursuing a set of (life-)goals such as wanting to become a teacher or deciding to have a child. The kind of goals a person develops and commits to is, again, embedded in sociocultural, biological, and phylogenetic factors. The less behavior is under control of these factors, the more degrees of freedom a person has to choose what personal goals he or she wants to pursue and how. In other words, the less societal or biological influences structure and determine which, when, and how to pursue goals, the more influential are self-regulatory processes for life management.

1.2 An Attempt to Define 'Life Management'

The term 'life management' is only rarely used in the psychological literature. When searching the currently most comprehensive database for publications in psychology (PsychInfo 11/2000) for 'life management,' only 72 publications are listed for the past century, mostly referring to coping with stress in various life-domains such as work, family, or health. In this context, 'life management' is mostly used more or less synonymously with 'coping.' Taking a developmental perspective, however, a focus on coping appears too narrow. I propose to use the term life management in a broader sense to refer to how people actively take part in and shape their developmental trajectories across the lifespan.

2. Central Approaches to Life Management in Developmental Psychology

Currently, there is no unified model of life management in psychology. Instead, there are a number of approaches to life management that can loosely be clustered into three groups: (a) self-regulation models, (b) models focusing on age-related expectations, and (c) models stressing the role of personal goals. Despite their differences, these approaches have in common that they stress motivational, goal-related processes as central processes of life management across the lifespan.

2.1 Self-regulation Theories

In contrast to 'life management,' self-regulation is a popular concept with more than 1,300 entries listed for the past decade in the PsychInfo database (PsychInfo 11/2000). Mostly, self-regulation is used as an explanatory construct intervening between situational/external factors and individual behavior. In these publications, the term self-regulation refers to a variety of different processes located within the individual regulating behavior, such as social comparison, perceived control, emotional control, delay of gratification, or self-efficacy. Despite the heterogeneity of processes that are subsumed under self-regulation, they have one function in common: they are all concerned with internal processes regulating thoughts, feelings, or actions. Very broadly, self-regulation can be defined as 'the extent to which people influence, modify, or control their own behavior' according to

goals or standards (Baumeister and Heatherton 1996, p. 1).

What goals and standards do people adopt? How do people initiate, execute, and end goal-related actions? Feedback-loop models of self-regulation attempt to answer these questions by referring to cybernetic control processes. Carver and Scheier (e.g., 1998) applied cybernetic models to personal goals. Personal goals can be defined as states a person wishes to achieve, avoid, or maintain. In this context, self-regulation comprises the following three aspects. (a) *Setting of goals and standards*: the setting of goals and standards creates a negative discrepancy of the actual and the desired state that the organism tries to overcome by employing goal-relevant means. (b) *Monitoring*: the comparison of the actual and desired state indicates whether the right means are chosen for achieving one's goals/standards or whether other means need to be employed. (c) *Operation* (goal-pursuit): the initiation, maintenance, and ending of actions for attaining one's goals/standards. There is a large empirical basis supporting the importance of each of these processes for describing goal-directed behavior (see Carver and Scheier 1998, for an overview). One of the features that make this model particularly attractive is that it elaborates general processes of self-regulation that are not content specific and that can be applied equally well to goals of varying levels of abstractness, including short-term goals (e.g., wanting to dine at a nice restaurant) and to long-term goals (e.g., wanting to become the owner of a nice restaurant). Taking a developmental approach to life management, however, this model has one severe limitation: it starts when goals or standards are already set, and does not explain the process of goal-setting itself. How do people develop and select the goals that direct their behavior? This issue is central for the concept of developmental tasks and age-related expectations that will be discussed in the following section.

2.2 Age-related Expectations as Guidelines for Managing One's Life Across the Lifespan

The question, what kinds of goals a person selects at a certain age, is tightly linked with theories about normative development. These theories suggest that individual development is embedded in an age-sequential order of developmental tasks. In contrast to the very general feedback-loop model of self-regulation, Erikson (1968) took a highly content-specific approach to life management. According to Erikson's developmental model, there is a sequence of eight developmental stages covering the entire lifespan, each of which is characterized by a specific theme or, in Erikson's terms a 'psycho-social crisis.' According to Erikson, progression to a higher stage can only occur after having successfully solved the previous crises. Examples for such crises are 'identity vs. identity diffusion' in adolescence and 'generativity vs. stagnation' in middle adulthood. In this framework, life management can be viewed as successfully coping with a sequence of salient themes in each life-phase.

Taking a similar approach to life management, Havighurst introduced the concept of 'developmental tasks' referring to 'a task which arises at or about a certain period in the life of the individual, successful achievement of which leads to his happiness and to success with later tasks, while failure leads to unhappiness in the individual, disapproval by society, and difficulty with later tasks' (Havighurst 1972, p. 2). Havighurst proposes a set of about eight developmental tasks for each of the six phases into which he divides the lifespan from 'infancy' to 'later maturity.' Examples of developmental tasks are 'starting a family' for young adulthood, and 'adjustment to retirement' for old age (see *Adulthood: Developmental Tasks and Critical Life Events*).

The notion of a universal and unidirectional hierarchy of psychosocial crises or developmental tasks has been criticized because it neglects variability between cultures, between individuals, and within individuals (i.e., there is no uniform development across domains of functioning). There is high agreement, however, that within most societies there exist age-related expectations that have evolved from and reflect biological, societal, and historical influences. Such age-related expectations provide information about a timetable of being 'on-time' or 'off-time' (Heckhausen 1999, Neugarten 1968), and a frame of reference regarding the kinds of goals that should be pursued at a given age.

Age-related expectations reflect in part age-graded social opportunity structures (i.e., the amount of resources, support, and reinforcement a society provides for pursuing certain goals for people of a specific age). Complementarily, certain goals are more difficult to strive for when deviating from age-related expectations because necessary resources and support might be less accessible or even negatively sanctioned. In other words, age-related expectations contain information about the likelihood of goal attainment for a given point in the lifespan. Motivational psychology has shown that the expectation to succeed is one of the key determinants for selecting a goal. In this sense, age-related expectations function as a guideline for adaptive goal selection because they indicate which goals should best be pursued at which point in the lifespan, and which goals should better be abandoned. Empirical evidence supports the notion that individuals select personal goals that are congruent with the age-related structure of the lifespan.

Taken together, age-related expectations provide a reference standard regarding the kinds of goals that should be pursued at a given point in the lifespan. Moreover, as they reflect age-related opportunity structures, age-related expectations help to guide an

individual towards goals for which resources are available and that, therefore, have a higher likelihood of being achieved than 'off time' goals. In this sense, age-related expectations are important guidelines for life management across the lifespan.

3. *Personal Goals as Building Blocks for Life Management Throughout the Lifespan and into Old Age*

Action-theoretical approaches view goals as central building blocks of life management because goals structure and direct attention, emotions, and behaviors into particular pathways (Emmons 1996). Recently, a number of models have stressed the importance of goal-related processes for developmental regulation and life management. In the author's view, the currently most prominent models are the model of selection, optimization, and compensation (SOC-model), the model of optimization in primary and secondary control (OPS-model), and the model of assimilative and accommodative coping. In this section, how these complementary models—that all have received good empirical support—conceptualize life management is briefly presented.

The SOC-model (Baltes and Baltes 1990, Freund and Baltes 2000) posits that, throughout the lifespan, individuals continually seek to successfully manage their lives through the orchestration of three processes of developmental regulation: selection, optimization, and compensation.

The importance of selection of goals is based on the assumption that, throughout the lifespan, biological, social, and individual opportunities and constraints specify a range of alternative domains of functioning. The number of options, usually exceeding the amount of internal and external resources available to an individual, needs to be reduced by selecting a subset of these domains on which to focus one's resources. Selection (i.e., developing, elaborating, committing to goals) gives direction to development by guiding and focusing resources on certain domains of functioning (specialization). Moreover, goals organize behavior into action sequences and reduce the complexity of a given situation as they guide attention and behavior.

According to the SOC-model, by delineating the range of goals on which to focus one's resources, selection is the first important step for successfully managing one's life. To actually achieve higher levels of functioning in the selected domains (goals), however, optimization needs to take place. Optimization denotes the process of acquiring, refining, coordinating, and applying the means or resources that are necessary to reach the goals envisioned. The importance of optimization is illustrated in the research on expertise. This literature has demonstrated the central role of the deliberate practice of skills, encompassing the acquisition of new skills, the refinement of existing skills, and the integration and automatization of skills for achieving peak-performance. The process of optimization addresses the growth-aspect of development.

The third component of the SOC-model is compensation (see also Dixon and Bäckman 1995). Compensation is aimed at counteracting losses in previously available goal-relevant means and involves substitution of lost means by activating unused means or by acquiring new means. The objective is to maintain functioning in the face of losses of means. A second form of managing losses is to restructure one's goals by focusing resources on the most important goals, adapting goal standards, or substituting no longer achievable goals (loss-based selection). The SOC-model posits that loss-based selection is an important process of life management as it allows one to focus or redirect resources adaptively when other means for the maintenance of functioning substituting the loss (compensation) are not available or would be invested at the expense of more promising goals.

According to the SOC-model, although all of these processes have positive developmental functions, it is their orchestration that contributes mostly to adaptive life management in the face of changing developmental opportunities, demands, constraints, and personal needs.

Building on the SOC-model and focusing on control, Heckhausen and Schulz (see Heckhausen 1999; *Control Behavior: Psychological Perspectives*) propose in their model of optimization in primary and secondary control (OPS-model) two modes of control jointly contributing to life management across the lifespan, primary and secondary control. According to the OPS-model, people have an innate need to control their world and try to maximize their control potential. Primary control encompasses instrumental efforts to modify the environment according to one's goals. Secondary control is employed when primary control strategies directed at the external world are not available or fail. Secondary control focuses on internal aspects such as changing one's goals, engaging in self-protective attributions, or social comparisons. Heckhausen and Schulz distinguish between selective and compensatory forms of primary and secondary control strategies. Selective primary control refers to the investment of means for goal achievement. Compensatory primary control denotes the employment of external resources (e.g., help of others) or the acquisition of alternative means when available internal resources are insufficient. Selective secondary control refers to enhanced selectivity of resource investment into existing goals. Compensatory secondary control denotes cognitive reframing of goals such as devaluation of unobtainable goals. According to the OPS-model, life management is only optimized when the four types of control are orchestrated according to an individual's developmental ecology.

A similar view was developed by Brandtstädter and his colleagues (e.g., Brandtstädter and Renner 1990) in their model of assimilation and accommodation. According to this model, people use two complementary forms of coping to achieve a match between the actual and the desired developmental state, assimilation, and accommodation. Assimilation denotes an actional mode of coping that is characterized by tenaciously pursuing one's goals by modifying the environment according to personal goals. Accommodation refers to a nonintentional, unconscious mode of coping, namely flexible goal adjustment. Accommodation comprises changing, downgrading, or discarding personal goals or lowering one's level of aspirations to match the environment. Following Brandtstädter, people will first use assimilative strategies to close the mismatch between the actual state and personal goals. When assimilative attempts fail, a gradual shift to the accommodative mode occurs, first by investing additional goal-related activities, then by engaging external aids or support systems, and, finally, by adjusting standards or even disengaging from goals.

The three models reported above converge in the importance they place on goals and motivational processes as building blocks of life management. Moreover, these models suggest that key processes of life management across the lifespan lie in the adaptation to developmental ecologies by opportunity-oriented selection, focused investment of resources, and compensation of losses. Age-related changes in the availability and efficiency of resources necessitate the flexible use of goal related strategies. Starting out to be highly positive in childhood through early adulthood, the ratio of gains to losses becomes less favorable with age. Thus, with increasing age, individuals need to allocate more resources into the maintenance of functioning and compensation of losses than into growth (Staudinger et al. 1995). Life management, following these models, encompasses optimizing developmental potential and simultaneously compensating for losses.

4. Outlook

Different lines of research inform us that one important way in which individuals manage their lives is by developing, committing to, and pursuing a set of (life-) goals. What goals a person selects and pursues is embedded in sociocultural, biological, and phylogenetic factors.

An interesting question awaiting empirical investigation is the relative importance of these factors across the lifespan. During childhood, adolescence, and young adulthood, biological constraints and social expectations regarding the kinds of goals to be pursued are relatively strong. In late adulthood and old age, there are fewer normative age-related expectations. This relatively greater social freedom might strengthen the impact of personal goals for life management. At the same time, in old age resources needed for shaping one's environment according to personal goals decline. Therefore, it seems particularly crucial to focus on goals that are both personally very important and for which resources are still available. Future investigations of the interaction of the various factors influencing the selection, pursuit, and maintenance of goals across the lifespan might increase our understanding of how people manage their lives.

Life Table

The life table is perhaps the oldest tool developed for the analysis of survival patterns in human and other populations. Its roots go back at least to the famous book on the English Bills of Mortality that John Graunt published in 1662, a book that is sometimes cited as the beginning of systematic statistical science. Life table techniques are described in detail in most introductory textbooks on the methods of actuarial statistics, biostatistics, demography, and epidemiology (see, e.g., Chiang (1984), Elandt-Johnson and Johnson (1980), Manton and Stallard (1984), Preston et al. (2001). In this article the basic notions of life-table construction are explained with a focus on issues that are sometimes underemphasized in other accounts. More of the underlying mathematical theory can be found in Hoem (1998) and in the textbooks. For the history of the topic, consult Seal (1977), Smith and Keyfitz (1977), and Dupâquier (1996).

1. *A Cohort Life Table*

Classical presentations of life-table techniques typically start with data in a format like that of the first four columns in Table 1. These particular data come from the Eritrean Demographic and Health Survey of 1995 and show the survival up through their fourth birthday of 7,098 girls whose births and deaths were recorded in the survey. This data set is different from normal textbook examples in two ways. First, the data are given for intervals of single-*month* segments instead of the usual single-*year* intervals. Second, the present data are subject to strong heaping in the reported age at death (for the girls that died). In part this is due to a typical inherent inaccuracy of age reporting in societies like the data source at the time of data collection, and in part to the fact that (probably for that very reason) only integer years of age attained was asked except for very young ages at death. By contrast, an individual child's age when observation ended (*age at censoring*) could be computed accurately to the month, for in these data a child's record was censored only because the child's parent was interviewed; the age of a live child could then be calculated from its date of birth. This unconventional data set is used in order to illuminate how a number of practical issues that confront a demographer can be handled in a first analysis of mortality. A more complete investigation would subsequently use intensity-regression methods from event-history analysis (see *Event History Analysis: Applications*), as was done by Woldemicael (1999).

If there had not been any heaping in the reported ages at death, one would calculate $R_x = S_x - \frac{1}{2}(D_x + W_x)$ as an approximate number of person-months of exposure at age x. Here S_x is the number of children who survive to exact age x months, D_x is the number of deaths recorded between exact ages x and $x+1$ months, and W_x is the corresponding number of records that were censored during this interval. The approximation consists in assigning deaths and interviews to in the middle of the month on average. It has become known as the *actuarial method*. The next step would be to compute occurrence/exposure rates D_x/R_x (see *Demographic Techniques: LEXIS Diagram*). The age heaping is abundantly evident in the plot of the 'raw' death rates (converted to 'deaths per 1,000 person-years') in Table 1.

Such age heaping must have been caused by a shift of the real age at death to a reported near-by 'round' *anchor age* like three months, six months, or multiples of 12 months. The deaths in some interval $[x_0 - a, x_0 + b]$ around each anchor age x_0 have largely been assigned to the anchor age instead of to each age in the interval, but the total number of deaths $\sum_{t=-a}^{b} D_{x_0+t}$ in such an interval should be largely correct. Similarly, the total exposures $\sum_{t=-a}^{b} R_{x_0+t}$ in the interval should be about right, even though the individual term in the latter sum may be wide off the mark. Under these circumstances it is more sensible to compute death rates for groups of reported ages and list them in the row for the corresponding anchor age. By this reasoning,

$$m_3 = \sum_{x=2}^{4} D_x / \sum_{x=2}^{4} R_x$$

is entered for age three months,

$$m_6 = \sum_{x=5}^{7} D_x / \sum_{x=5}^{7} R_x$$

is entered for age six months, and so on, as indicated in column 7 of Table 1. For the intervening ages x, rates m_x have been computed by linear interpolation. The corresponding curve of rates is given with the label 'grouped' in Table 1.

The rest of the life-table computations are based on the following simple mathematical theory. Each individual child i has a lifetime T_i with some distribution function $F(t) = P\{T_i \leqslant t\}$ (with $F(0) = 0$), a probability density $f(t) = \mathrm{d}F(t)/\mathrm{d}t$, and a *force of mortality* or *death intensity* $\mu(t) = f(t)/\{1-F(t)\}$. The various lifetimes T_i are independent of each other and they have the same distribution $F(t)$. Simple integration gives $F(x) = 1-\exp\{-\int_0^x \mu(t)\,\mathrm{d}t\}$. The death probability is

$$q_x = P\{T_i \leqslant x+1 \mid T_i > x\} = \{F(x+1)-F(x)\}/F(x)$$

from which is derived

$$q_x = 1-\exp\{-\int_0^1 \mu(x+t)\,\mathrm{d}t\} \tag{1}$$

If one approximates the function $\mu(x+t)$ by the constant m_x for $0 < t < 1$ (the assumption of *piecewise constancy*), then (1) gives $q_x = 1-e^{-m_x}$, which has been used to compute the next-to-last column in Table 1. Finally, a life-table *survival function* is defined as $\ell(x) = \ell(0)\{1-F(x)\}$, with $\ell(0) = 100\,000$. This is the expected number of survivors to exact age x out of an original cohort of $\ell(0)$ initial individuals. Simple manipulation with the definition of q_x gives

$$\ell(x+1) = \ell(x)(1-q_x), \quad \text{for } x = 0, 1, \ldots \tag{2}$$

This is a practical recursive formula by which we have computed the final column in Table 1. From the final entry in the $\ell(x)$ column in Table 1 we see that more than 15 percent of the original cohort of girl babies would die before age 4 (years) according to our data, because $1-0.84859 = 0.15141$.

The mean number of months lived between birth and age n is

$$e^o_{0:\,n} = E\min(T_i, n) = \int_0^n \ell(t)\,\mathrm{d}t/\ell(0) \tag{3}$$

If one partitions the integral here into a sum of n terms $\int_{x-1}^x \ell(t)\,\mathrm{d}t$ for $x = 1, 2, \ldots, n$, use the trapezoidal rule of numerical integration to see that this integral is approximately equal to $\frac{1}{2}\{\ell(x-1)+\ell(x)\}$, and collect terms suitably, we get the numerical approximation

$$e^o_{0:\,n_n} \simeq \left\{ \sum_{x=0}^{n} \ell(x) - \frac{1}{2} - \frac{1}{2}\ell(n) \right\} / \ell(0) \tag{4}$$

The girls in the Eritrean data set lost five months of life on average before they reached their fourth birthday, for according to Eqn. (4) with $n = 48$ months they experienced a mean lifetime of 43 months.

2. Other Life-table Procedures

Life-table construction consists in the estimation of parameters and tabulation of functions like those above from empirical data. The data can be for age at death to individuals, as in the illustrative example, but they can also be observations of duration until recovery from an illness, of intervals between births, of time until breakdown of some piece of machinery, or of any other positive duration variable. In general, a T_i is the duration until occurrence of some event that ends individual survival in a given status. The method of estimation depends on the character of the data. If accurate (ungrouped) individual-level data are available, then the Kaplan–Meier estimator (see *Event History Analysis: Applications*) can be used to estimate ℓ_x for all relevant x, and estimates of the other life-table functions can then be computed subsequently. Alternatively a segment of the Nelson–Aalen estimator can be used to estimate each integral $\int_0^1 \mu(x+t)\,\mathrm{d}t$, Eqn. (1) can then be used to estimate q_x for each integer x, and the rest of the computations follow suit. Sometimes the force of mortality is represented by some function $h(x; \theta)$, where θ is a vector of parameters. For instance, actuaries often use the classical Gompertz–Makeham function $h(x; a, b, c) = a+bc^x$ for the force of mortality in their life tables (see *Demographic Models*; *Demographic Analysis: Probabilistic Approach*).

From any given schedule of death probabilities $q_0, q_1, q_2, \ldots$, the $\ell(x)$ table is easily computed using the recursive Eqn. (2). Much of the effort in life-table construction is, therefore, concentrated on providing a schedule $\{q_x\}$. So far, this account has assumed that the data come from a group of independent individuals who have all been observed in parallel, essentially a cohort that is followed from a significant starting point (namely from birth in our empirical example) and which is diminished over time due to *decrements* (*attrition*) caused by the risk in question and also subject to reduction due to censoring. The empirical example displayed data only for the first four years of life of such a cohort. One would have had to follow the cohort until the end of the cohort's total life to produce a *complete cohort life table*. It is more common to compute a q_x schedule from data collected for the members of a population during a limited time period and to use the mechanics of life-table construction to produce a *period life table* from the q_x values. If real mortality patterns are tied to cohorts, individuals who live at widely differing ages in the observational period do not normally have the same risk structure, and the period life table is taken to reflect the patterns of a

synthetic (fictitious) *cohort* exposed to the risks of the period at their various ages.

Whichever way the life-table survivor column has been produced, Eqn. (4) can always be used to calculate mean numbers of time-units lived under the risk for which the life-table was constructed. If the time unit is a year and n is chosen so large that no one lives more than n years (symbolized by letting $n = \infty$ and $\ell(\infty) = 0$), $e^{o}_{0:\overline{\infty}|}$ is called the *life expectancy* of the life table and is normally denoted e^{o}_{0}. The subscript 0 indicates that the calculation is made for a newborn individual. Similar computations can be made at any age x and one gets expected remaining lifetimes of the form $e^{o}_{x:\overline{n}|} = \int_0^n \ell(x+t)\,\mathrm{d}t/\ell(x)$, with approximation formulas similar to Eqn. (4).

3. *Multiple-decrement tables*

When suitable data are available, the risk of death (or force of mortality) may be partitioned according to mutually exclusive causes of death. Let $\mu_k(t)$ be death intensity or force of mortality for cause k at age t, and let the total force of mortality be $\mu(t) = \sum_k \mu_k(t)$. Then the probability that an individual who is alive at age x will die from cause k before age $x+1$ is

$$q_x^{(k)} = \int_0^1 {}_tp_x \mu_k(x+t)\,\mathrm{d}t \tag{5}$$

where ${}_tp_x$ is the probability of surviving to age $x+t$ for an individual who is alive at age x. For given risk intensities $\{\mu_k(\cdot)\}$, $q_x^{(k)}$ can be computed by numerical integration in Eqn. (5). A corresponding column of $q_x^{(k)}$ values may then be added to the life table for each k, and other cause-specific life table functions may also be computed. Note that $q_x^{(k)}$ is influenced by risk intensities other than $\mu_k(\cdot)$, for

$${}_tp_x = \exp\left\{-\sum_j \int_0^t \mu_j(x+s)\,\mathrm{d}s\right\}$$

where the exponent depends on all $\mu_j(\cdot)$, including those for $j \neq k$.

Several further life-table functions can be defined by formal reduction or elimination of one or more of the risk intensities in formulas like Eqn. (5). In particular, a *single-decrement life table* can be computed for each cause k in order to show what the life table would look like in the hypothetical case where this cause were the only one operating in the study population and where it did so with the risk function estimated from the data. The purpose is to see the '*pure*' effect of the risk in question on a fictitious cohort without interference from other causes. (The decrement probabilities and other features of the single-decrement life table do not depend on any other intensities than the one for which the table is computed.) This does not mean that one should believe that the total risk intensity can actually be reduced to the risk in focus or that this risk operates independently of other causes.

Most single-decrement life-table functions have straightforward interpretations. If, for instance, $\ell_k(x)$ denotes the corresponding survival function, then $\ell_k(x)/\ell_k(0)$ is the probability of surviving to age x in the fictitious table. Suppose, for example, that the study population is a group of unpartnered individuals subject to the competing risks of marital and non-marital union formation as well as to the risk of death. One can then compute a single-decrement life table based on the risk of transition into a nonmarital union alone and find the probability that an individual would end up in such a union by age 50, say, if marriage were no alternative and death did not operate, even though in reality marriages continue to be formed by group members and unpartnered individuals continue to die. In such a table one may get $\ell_k(\infty) > 0$ because the event never occurs to some individuals, even if it operates alone. (We will all die but some individuals never enter a nonmarital partnership even if they live to age 100.)

Life expectancies $e^{o}_{15:\overline{n}|}$ computed in the three-decrement life table would be interpreted as the mean number of years (say) lived in the unpartnered state between ages 15 and $15+n$. In the single-decrement life table for nonmarital-union formation, one possibility is to compute the mean age of entry into a nonmarital union only for those who do enter such a union by age n, that is, the conditional mean

$$\int_0^n \ell_k(x)\,\mathrm{d}x/\{\ell_k(0)-\ell_k(n)\} \tag{6}$$

Conversely one can compute a *cause-deleted life table* by eliminating one or more of the cause intensities in the formulas. To 'remove' cause k, introduce $\mu_{-k}(t) = \mu(t)-\mu_k(t)$ and construct a 'normal' life table by replacing $\mu(t)$ by $\mu_{-k}(t)$ everywhere. This would show what the life table would look like *if* it were possible to eliminate cause k without changing the risk of any other cause. It could be used for example to see how partnering probabilities would appear if the partnering process were undisturbed by mortality. One would then remove the force of mortality from the life-table formulas and operate only with the sum $\mu_{-k}(t)$ of the intensities of marital and nonmarital union formation in the computations. Note that this is again a purely hypothetical construct, in fact it is counterfactual for mortality cannot of course be completely removed.

Life expectancies can of course be calculated for a cause-deleted life table as for any other life table. If $\ell_{-k}(x)$ is the table's survival function and $\ell_{-k}(\infty) = 0$, then a formula for the cause-eliminated life expectancy is $e_0^{(-k)} = \int_0^\infty \ell_{-k}(x)\,\mathrm{d}x/\ell_{-k}(0)$. The classical applications were to cause-of-death removal, and the difference

$e_0^{(-k)} - e_0^o$ was interpreted as the (fictitious) gain in life expectancy produced by removal of cause k. For example, Westergaard (1907) found that according to the English life tables of 1881–90 life expectancy for females would increase by 2.7 years if tuberculosis deaths could be eliminated, by a year if cancer deaths could be removed, and by 1.1 years if deaths due to diarrhea and dysentery could be deleted separately. The effects were not additive, and if all three cause-of-death groups could be removed, the gain would be 5.6 years and not 4.8. The life expectancy for females in the original table was $e_0^o = 47.2$ years.

Lifelong Learning and its Support with New Media: Cultural Concerns

1. Introduction

Learning needs to be examined across the lifespan because traditional notions of a divided lifetime—education followed by work—are no longer tenable (Gardner 1991). Professional activity has become so knowledge-intensive and fluid in content that learning has become an integral and irremovable part of work activities. Learning is a new form of labor, and working often is (and needs to be) a collaborative effort among colleagues and peers. In the emerging information society, an educated person will be someone who is willing and able to consider learning as a lifelong process. More and more knowledge, especially advanced knowledge, is acquired well past the age of formal schooling, and in many situations through educational processes that do not center on traditional schools (Illich 1971). Lifelong learning is more than adult education, which often is restricted to providing people with opportunities to engage in (school-like) learning activities during their adult life. The challenge for lifelong learning is to fundamentally rethink learning, teaching, and education for the information age in an attempt to change mindsets. It involves and engages learners of all ages in acquiring and applying knowledge and skills in the context of authentic, self-directed problems, and it exploits the possibilities offered by new media.

Lifelong learning has emerged as one of the major challenges for the worldwide knowledge society of the future. A variety of recent events supports this claim: (a) 1996 was the 'European Year of Lifelong Learning,' (b) UNESCO (United Nations Educational, Scientific and Cultural Organization) has included 'Lifetime Education' as one of the key issues in its planning, and (c) the G7/G8 group of countries has named 'Lifelong Learning' as a main strategy in the fight against unemployment. Despite this great interest, there are few encompassing efforts to tackle the problem in a coherent way. Lifelong learning is comprehensive; it cannot be investigated in isolation by looking just at one small part of it, such as K-12 education, university education, or worker re-education.

2. Problems in the Information Age

2.1 Lack of Creativity and Innovation

Societies and countries of the future will be successful not 'because their people work harder, but because they work smarter.' Creativity and innovation are considered essential capabilities for working smarter in knowledge societies (Drucker 1994); thus, an important challenge is how these capabilities can be learned and practiced. An implicit assumption is made that self-directed and lifelong learning can influence the creativity and innovation potential of individuals, groups, organizations, and countries (Dohmen 1999).

2.2 Coping with Change

Most people see schooling as a period of their lives that prepares them for work in a profession or for a change of career. This view has not enabled people to

Table 1
Transcending Skinner and Taylor

Skinner–Taylor	Beyond Skinner and Taylor
There is a scientific, best way to learn and to work	Real problems are ill-defined and wicked
Separation of thinking, doing, and learning	Integration of thinking, doing, and learning
Task domains can be completely understood	Understanding is partial, tacit and situated; total coverage is impossible
Objective ways to decompose problems into standardizable actions	Subjective, situated personal interests; need for iterative explorations
All relevant knowledge can be explicitly articulated	Much knowledge is tacit and relies on tacit skills
Teacher–manager as oracle	Teacher–manager as facilitator or coach
Operational environment: mass markets, simple products and processes, slow change, certainty	Customer orientation, complex products and processes, rapid and substantial change, uncertainty and conflicts

cope well with the new realities of our world that (a) most people change careers several times in their lives, even though what they learned in school was designed to prepare them for their first career; and (b) that the pace of change is so fast that technologies and skills to use them become obsolete within 5–10 years.

2.3 School-to-work Transition is Insufficiently Supported

If the world of working and living relies on collaboration, creativity, and framing of problems; deals with uncertainty, change, and distributed cognition; and augments and empowers humans with powerful technological tools, then the world of schools and universities needs to prepare students to function in this world. Industrial-age models of education and work (based on B. F. Skinner and F. W. Taylor; see Table 1) are inadequate to prepare students to compete in the knowledge-based workplace.

2.4 The 'Gift Wrapping' Approach Dominates Educational Reform

Information technologies have been used to mechanize old ways of doing business, rather than fundamentally rethinking the underlying work processes and promoting new ways to create artifacts and knowledge. In learning, these technologies have been used primarily as add-ons ('gift-wrapping') to existing practices (Fischer 1998b) rather than a catalyst for fundamentally rethinking what education should be about in the next century. Conventional frameworks, such as instructionism, fixed curricula, memorization, decontextualized rote learning, etc., are not changed by technology itself. 'Computer literacy' has often been equated with a bag of superficial and transitory knowledge rather than with what really matters about computers: namely, that all people can use them for their own purposes. New technologies and new media (such as the World Wide Web, multimedia design, etc.) are necessary to achieve certain learning objectives and to provide foundations for people to change their mindsets, but they by themselves are not sufficient.

3. Changing Mindsets

Cultures are substantially defined by their media and their tools for thinking, working, learning, and collaborating. A large number of new media are designed to see humans only as consumers. Television is the most obvious medium that promotes this mindset and behavior (Postman 1985). Unfortunately, a consumer mindset does not remain limited to television, but in many cases is a model dominating our culture. In our educational institutions, learners are often treated as consumers, creating a mindset of consumerism for the rest of their lives (Illich 1971). Citizens often feel left out in the decisions by policy makers, denying them opportunities to take an active role. The current mindset about learning, teaching, and education is dominated by a view in which teaching is often fit 'into a mold in which a single, presumably omniscient teacher explicitly tells or shows presumably unknowing learners something they presumably know nothing about' (Bruner 1996). A critical challenge is a reformulation and reconceptualization of this impoverished and misleading conception. Although this model may be more realistic for the early grades in schools, it is obviously inadequate for learning processes as they occur in lifelong learning, where knowledge is distributed among many stakeholders and 'the answer' does not exist or is not known. Learning is more than being taught (Illich 1971). Learning new skills and acquiring new knowledge cannot be restricted to formal educational settings. By integrating working and learning, people learn within the context of their work on real-world problems. Learning does not take place in a separate phase and in a separate place, but is integrated into the work process. The direct usefulness of new knowledge for actual problem situations greatly improves the motivation to learn

Table 2
Comparison of different conceptualizations of school/university and lifelong learning

	School–University	Lifelong learning
Emphasis	'Basic' skills; exposure; access	Education embedded in ongoing work activities; informed participation
Potential drawbacks	Decontextualized, not situated	Relevant concepts are not encountered
Problems	Given	Constructed
New topics	Defined by curricula	Arise incidentally from work situations
Structure	Pedagogic or 'logical' structure	Work activity
Roles	Expert–novice model	Asymmetry of knowledge; reciprocal learning
Teachers–coaches	Expound subject matter	Engage in work practice
Mode	Instructionism (knowledge absorption)	Constructionism (knowledge construction)

new materials because the time and effort invested in learning are immediately worthwhile for the task at hand—not merely for some putative long-term gain.

Many conventional frameworks are grounded in the behaviorist learning theory of Skinner and the models of industrial work of Taylor. Table 1 contrasts these approaches with new goals and new objectives for the information age.

The conceptual framework outline in Table 1 provides the foundation to differentiate between school and lifelong learning, as illustrated by Table 2. Schools often create mindsets about learning, teaching, and collaboration that would require a 'big switch' at some point in people's lives: seeing themselves as active contributors rather than as passive consumers. To create different mindsets, we need to change our formal educational institutions to environments in which knowledge is (collaboratively) created, externalized and shared (Arias et al. 2000; http://www.cs.colorado.edu/~gerhard/papers/tochi99.pdf.). Skills and processes that support learning as a lifetime habit must be developed, and efforts must be undertaken for learners to develop a positive attitude, enjoyment, and motivation toward learning—because no one will engage in processes and attitudes during their whole life for goals and objectives that they do not like.

4. *Emphasizing New Forms of Learning from a Lifelong Learning Perspective*

Lifelong learning refers to a society in which learning possibilities exist for those who want to learn. Table 3 summarizes four innovative forms of lifelong learning, and addresses their contributions toward the creation of mindsets and the media requirements generated by them.

5. *The Impact of Lifelong Learning Themes on Mindsets*

Impacting mindsets is a socio–technical design problem (Fischer 1999). Research and practice should be conducted as an instrument of change to alter and improve the way people learn and think. Creating innovative media and technologies supporting a 'new' mindset requires the following co-evolution: we must rethink and reinvent learning, working, collaboration, and education in the context of new media, and simultaneously we must invent and create new media in the context of learning, working, collaboration, and education.

5.1 *From Consumers to Active Contributors*

To create designer mindsets, one of the major roles for new media and new technologies is not to deliver predigested information to individuals, but to provide the opportunity and resources for social debate, discussion, and collaborative knowledge construction. In many human activities, learning cannot be restricted to finding knowledge that is 'out there.' If nobody knows the answer, we have to create new knowledge. The knowledge to understand, frame, and solve many problems does not exist, but is constructed and evolved during the process of solving these problems (Schön 1983). From this perspective, *access* to existing information and knowledge (often seen as the major advance of new media) is a limiting concept. Many social and technological innovations are limited to provide primarily better access, leading to 'consumer' cultures (Fischer 1998a). Other research focuses on and creates support for lifelong learning activities grounded in informed participation (Arias et al. 2000; http://www.cs.colorado.edu/~gerhard/papers/tochi99.pdf.). This goal creates the challenge to develop open, evolvable systems, allowing end-users themselves to extend their tools and information spaces, and thereby become independent (if they desire) of professionals.

5.2 *New Media in Support of Lifelong Learning*

The most promising way to provide opportunities for an active contributor mindset is to allow learners and workers to engage in design activities by creating environments supporting them in making external

Table 3
Overview of new forms of learning contributing to lifelong learning

Form	Complementing form	Contribution towards mindset creation	Major challenges	Media requirements
Self-directed learning	Prescribed learning	Authentic problems	Problem framing	Understanding evolving tasks
Learning on demand	Learning in advance	Coverage is impossible; obsolescence is guaranteed	Identifying the breakdown leading to the demand; integration of working and learning	Critics; supporting reflection-in-action
Informal learning	Formal learning	Learning by being in the world	Larger, purposive activities provide learning opportunities	End-user modifiability
Organizational learning	Individual learning	The individual human mind is limited	Shared understanding	Externalizations understandable by all stakeholders

artifacts that they can reflect upon and share with others. Over the last 10 years, design environments have been created which support the different forms of learning described in Table 3. These environments are not only used to instruct and assist novice designers, but they are able to support designers as lifelong learners. A specific example of a domain-oriented design environment is the *Envisionment and Discovery Collaboratory* (Arias et al. 2000; http://www.cs.colorado.edu/~gerhard/papers/tochi99.pdf.). This system (for details see: http://www.cs.colorado.edu/~13d/systems/EDC/) not only provides access to existing information, but allows all participants to engage in self-directed learning by supporting informed participation and collaborative knowledge construction. It combines physical and computational simulations to allow organizational learning by supporting group decision-making, mutual learning processes, and the creation of shared understanding. The incremental design and construction of an externalized world provides numerous opportunities for all involved stakeholders for self-directed learning and learning on demand.

The 'open source' movement (O'Reilly 1999) that is currently emerging as a new paradigm for software development represents an exciting perspective for a society of lifelong learners. 'Open source' approaches regard software and other cognitive artifacts not as a commodity to be consumed, but one that is collaboratively designed and constructed—providing a model for the knowledge society of the future.

6. *Evaluation*

Self-directed learning, learning on demand, informal learning, and organizational learning are fundamentally different from the traditional classroom learning dominated by curricula and tests. Evaluation of these forms of learning is an important, unresolved research topic in itself; there are no off-the-shelf assessment techniques available for these new forms of learning. These new approaches require alternatives to standard tests and the experimental methods of psychology, which measure how people perform on predetermined tasks undertaken by subjects in a laboratory or in an instructionist classroom. Approaches from anthropology, sociology and ethnography that study people 'in the wild,' as they go about their everyday activities in offices, homes, schools, laboratories, or wherever they live their lives are needed to evaluate these forms of learning. It is all too easy to collect data and statistics about those things that are easiest to identify and count or measure but have little or no connection with the objectives in which we are really interested. We have to develop evaluation techniques based on performance-based examinations or execution of large-scale projects and portfolios (Gardner 1991). It is obvious that a change

of mindsets cannot be evaluated by a test; it requires assessment of motivation, interest level, and participation in communities of learners combined with techniques for long-term longitudinal assessment.

7. Conclusions

Peter Drucker argued that 'There is nothing so useless as doing efficiently that which should not be done at all.' Adding new media and new technologies to existing practices will not change the mindsets that learners will acquire in our formal educational institutions. These mindsets are the major stumbling blocks preventing people from engaging in lifelong learning. Moving beyond the 'gift-wrapping approach' requires that we explore fundamentally new possibilities and limitations of computational media on how we think, create, work, learn, and collaborate. New tools will not just help people do cognitive jobs more easily but in the same way they used to, but they will also lead to fundamental alterations in the way problems are solved. A lifelong learning perspective requires that we change mindsets. This will include, for example, that teachers understand their roles not only as truth-tellers and oracles, but as coaches, facilitators, and mentors; and that knowledge is not presented as a commodity to be acquired or delivered, but as a human struggle to understand and as a source to deal with personally meaningful problems. The future of how we live, think, create, work, learn, and collaborate is not out there to be 'discovered'—it has to be invented and designed. Mindsets grounded in seeing learning as an important part of human lives will be an integral part of the future.

Lifespan Development: Evolutionary Perspectives

From an evolutionary perspective, reproductive success can be understood as the driving force for specific developmental pathways which represent coherent answers to contextual demands. The sequence and structure of developmental stages across the lifespan constitute reproductive styles that promise best inclusive fitness within the respective context. Although the prolongation of the lifespan in humans compared with all other species is certainly a result of selective forces, senescence seems not to be shaped by natural selection, but rather a by-product of earlier neutral or beneficial gene expression.

1. Evolutionary Assumptions

Evolutionary theorizing considers striving for optimal reproductive success as the ultimate goal also of human development. This assumption not only specifies that the proximate regulation of physical and biological systems, but also social behavior and the complex psychology of human beings, follow a reproductive logic. Reproductive success is expressed in terms of inclusive fitness which comprises the individual's own procreation (Darwinian fitness) and the procreation of relatives with whom the individual shares genes (indirect fitness), thus establishing the

principle of kin selection (Hamilton 1964). Therefore, the evolutionary perspective focuses on the gene as the unit of analysis. However '… it is not the naked gene, that is exposed to selective forces directly' (Mayr 1994, p. 206), but rather the 'realized animal, that lives or dies, breeds or helps the relatives' (Daly and Wilson 1983, p. 32). Although individuals are considered as 'vehicles' of their genes (Dawkins 1976), the importance of the phenotypical individual for determining reproductive success has recently been (re)emphasized (Laland et al. 2000). This view has implications for the metatheoretical perspective on the nature of humans. It can be assumed that genetic 'egoism' is correlated with respective psychological characteristics, thus leading to the consequence that humans are not regarded as altruistic and cooperative *per se*, but rather as a result of—possibly implicit and non-intentional—selfish cost–benefit calculations.

However, it is not the adult individual who represents the product of evolution; rather, the whole lifespan with the different developmental phases is shaped by selective forces with the eventual exception of senescence, which itself seems not to be a product of selection. Aging is a concomitant of sexually reproducing individuals because the generational change increases the speed of evolution. The inevitability of death due to environmental stressors during human history has resulted in a decrease of individuals with increasing age, so that the power of natural selection decreased also (Medawar 1952).

Life-history theory (Alexander 1990) regards the developmental course of the individual lifespan as the result of a trade-off between investment into one's own growth and development (somatic effort) and investment into reproduction, comprising the functional systems of mating and parenting (reproductive effort; Chisholm 1996). Somatic efforts accumulate reproductive potential whereas reproductive efforts decrease the residual reproductive value. Evolution has thus shaped humans into being reproductive strategists who constantly have to make 'decisions' about the best allocation of investment (Voland 1998). The heuristics of reproduction are contingent upon environmental demands, which comprise material and ecological forces as well as social complexity (see Dunbar 1996). Especially the evolution of intelligence as a necessary prerequisite for exploring environmental resources and regulating the social behavior of expanding groups favored learning as a second asset of adaptation. Yet learning is not random, but follows (genetically imposed) biases and constraints ('central tendencies,' MacDonald 1997; 'epigenetic rules,' Lumsden and Wilson 1981) to acquiring specific environmental information during specific phases of development allowing easy learning at these points in time (Boyd and Richerson 1985).

Psychological development across the lifespan can simultaneously be interpreted as a structured sequence of developmental tasks in order to improve social and cognitive skills as well as the formation of a reproductive style. Evolutionary socialization models have described the ontogeny of individuals' reproductive styles as a meaningful passage through the developmental tasks of childhood and adolescence. In particular, the resource situation and the family climate during early childhood are considered to be predictive of attachment formation. The quality of attachment in turn influences psychological adjustment during late childhood. Psychological development also influences neurophysiological, maturational processes, leading to the somatic consequence of defining the beginning of puberty. The beginning of puberty channels the reproductive style, especially with regard to the age at which first giving birth, the spacing, and number of children with the respective implications for parental investment (Belsky et al. 1991, Keller 1996). Empirical studies from different parts of the world have supported the view of different developmental trajectories as specified by these models. The new perspective of evolutionary theorizing is thus the assumption that neurophysiological and psychological regulations of behavioral development (proximate causes) are influenced by adaptive, i.e., phylogenetically shaped, mechanisms which serve the ultimate function of optimizing reproductive success. The postreproductive phase is therefore not subject to the same degree of selection pressure as the prereproductive and reproductive life phases (Baltes 1997, Geary and Bjorklund 2000). Accordingly, old age is not a distinct phase in stage conceptualizations of the life-history approach (Bogin 1997).

In the following, the functional significance of the different developmental phases for reproductive success will be analyzed. The developmental phases of infancy, childhood, adolescence, adulthood, and old age will be briefly characterized with respect to their possible evolutionary roots. Old age is included in this analysis, since the assumption of structural continuity implies that earlier experiences shape later ones, so that the quality of old age could be regarded as a consequence of the earlier reproductive life (Keller 1991).

2. *Developmental Phases Across the Lifespan*

2.1 *Infancy*

The extreme helplessness ('altriciality') of the human newborn can be considered as part of a reproductive strategy to becoming a better adult ('better adult hypothesis,' Alexander 1990), since it allows the baby to invest all available resources in growth and development. This view is in contrast with the common interpretation of infants' helplessness as a consequence of a physiological preterm birth, due to hominid brain growth. Early development is shaped by the invest-

ment that parents allocate to each child individually, depending on their own and the child's reproductive values (e.g., age of parent, social support, sex, and birth position of child). Early experiences form the basis of the psychological adaptation to the respective physical and social environment in prompting phenotypic development. Accordingly, infants adopt internal representations of social relationships (see *Attachment Theory: Psychological* and *Adult Psychological Development: Attachment*) and a primary conception of the self, focusing on the expectations of reciprocity as the balance of give and take that can be expected in future social relationships.

2.2 Childhood

At about 2 years of age, a developmental transition with a new focus on the extension of the physical and social range of children's activities can be observed in many cultural contexts. This marks the beginning of children's apprenticeship which involves the adoption of promising strategies for acquiring resources in their particular environment. Mediated through the culturally primed beliefs and values ('ethnotheories') of their social environment, children acquire and construct their environmental and social competence through participatory learning as well as by adopting and creating developmental niches ('niche picking') which include the implicit and explicit reflection of sex differences as concomitants of adult reproductive life.

2.3 Adolescence

Adolescence constitutes the transition from childhood to adulthood. The beginning of adolescence is universally defined by entry into puberty. The duration of adolescence, however, differs substantially across cultures, varying from transitional rituals during a few weeks to a stage which last several years, depending mainly on economic constraints and educational provisions (see Schlegel and Barry 1991). The attainment of sexual maturity is a biological marker variable with a hereditary component and it is contingent upon ecological factors, such as nutritional status and physical condition, as well as previous socialization experiences, especially the security and stability of the early home environment. At the same time, this marker variable is believed to be predictive of future reproductive decisions (e.g., age at first sexual intercourse and age at first childbirth, duration of interbirth intervals). Although similar developmental trajectories for males and females have been empirically identified, sex-specific reproductive strategies with their respective costs make it likely that environmental factors influence female fecundity more strongly than male. Therefore, and owing to the greater accessibility of menarche as an empirical datum, female developmental trajectories are overrepresented in the literature. Psychosocial stress in the family of origin, especially marital conflict and father absence, has been documented as decreasing the age of menarche in different contextual systems. Particularly the divorce of parents during a child's first five years of life could reliably be related to early menarche (Chasiotis et al. 1998). The perception of this environmental scenario may support the development of a more quantitative oriented reproductive style with lesser parental investment whereas marital stability could be considered as part of a qualitative style with higher maternal and paternal investment. Thus, low ecological stress (i.e., good nutritional status and a balanced physical condition) as well as high psychosocial stress (e.g. divorce of parents before the age of five years) can result in earlier maturation, whereas high ecological stress and/or low psychosocial stress can lead to later maturation. The main reproductive function of the variability of sexual maturity is to reduce the costs of premature reproduction. If an individual 'waits' for sexual maturity, the resources can be allocated to growth which will increase the reproductive value at maturity. On the other hand, the delay might decrease the probability of surviving until the reproductive age (Charnov 1989).

The onset of reproduction varies with the duration of adolescence across cultural contexts. Especially in traditional rural societies, reproduction begins soon after sexual maturity and seems to be more quantitatively oriented, whereas reproduction in urban educated societies is delayed until the end of an educational moratorium and seems to be more qualitatively oriented.

2.4 Adulthood

In evolutionary terms, adulthood is the phase of reproduction with the challenge to resolve various allocation conflicts. First, the conflict between current and future reproduction (i.e., investment in growth or reproduction) has to be addressed, culminating in the decision of when to start reproduction, and the related issue of nepotistic effort, i.e., investing in one's own offspring or temporarily (or even permanently) adopting the role of a 'helper in the nest' (Voland 1998). The second allocation conflict concerns the question of investment in quality or quantity of offspring, which determines the number and spacing of children. Since these decisions not only have to be made generally as an expression of reproductive style, but also individually for each offspring separately, parent–child conflict is an inevitable consequence (Trivers 1974). Survival and psychological adaptation are facilitated when not only maternal, but also paternal investment is spent on the infant. It is assumed that partner

bonding and family cohesion evolved as psychological mechanisms to facilitate the development of 'better adults.' This view seems to confirm the relationship between father's absence and (increased) infant mortality in traditional societies, e.g., among the Ache Indians in South America (Hill and Hurtado 1996).

However, the determinants of reproductive success differ for males and females. Females *per se* make a higher investment owing to intrauterine pregnancy and nursing, supporting a qualitative parenting style with higher investment in fewer offspring. They have to decide whether they want to continue to look for a better mate or start reproducing. The prototypical male strategy, on the other hand, should be more quantitative, that is, to invest less in more offspring, due mainly to the fact that it is difficult for a male to know precisely whether he is the father of an infant ('paternity insecurity'). Moreover, males show greater variability in their reproductive rates, from having no children to having many children. Men have to decide between the 'cad versus dad' strategies, i.e., maximizing fertilization or parental investment (Voland 1998). The trade-off that individuals have to accept therefore entails the balance of mating and parenting efforts. Studies on partner selection have documented universal preferences for the two sexes: females prefer partners with characteristics indicative of economic success, whereas males prefer females with characteristics that indicate reproductive capacity (youth, health). In addition, there is preference by both males and females for mates who are similar to themselves in a variety of characteristics ('assortive mating'). Parental investment constitutes the intergenerational link through which the offspring experiences the socialization style that the parent has developed as a result of their own past as well as current experiences. In the case of human beings, not only time and energy as parameters of investment decisions have to be taken into consideration, but also psychological care systems which prepare the psychology of the phenotypic adult (Keller 2000).

2.5 *Old Age*

Old age covers the postgenerative phase of the lifespan. Yet it has been proven meaningful to differentiate a third young–old age span from about 60 to 75 years where the vital capacity has improved to compensate for about five years due to cultural evolution, from a fourth age span from around 80 to 100 years (cf., Baltes 1997) which has emerged due to increasing life expectancy, but where senescence has predominantly detrimental effects. These might originate as by-products from possibly two processes: (a) selective neutrality of the genome by no effect at early life and deleterious effect at later life and (b) antagonistic pleiotropic gene action that supports reproductive success during the reproductive life stages (Martin et al. 1996). One detrimental factor that has been identified across species may be metabolic oxidative damage operating in macromolecules. On the other hand, it has been argued that the extension of the lifespan serves individual fitness by supporting the development of the child's and grandchild's generation. Although this 'grandmother' hypothesis (Peccei 1995) is controversial, researchers nevertheless report that being a grandparent increases life satisfaction in old age. The physical deterioration especially of the old–old age requires extra societal cultural resources which at the same time become more difficult to be exploited effectively. Accordingly, the regulation and compensation of losses become a major mechanism for ontogenetic processes (Baltes 1991). Relating interindividual differences in regulatory competencies to the earlier reproductive life histories might be a challenge for lifespan psychology.

3. *Outlook*

Although essential questions such as the interplay of genetic and social influences on phenotypic development remain open, the evolutionary view on the human lifespan offers a stimulating perspective on many controversial issues of psychological development, e.g., the nature of sex differences or the normative character of secure attachment relationships. During their ontogenetic development, individuals, based on universal genetic programs (e.g., for language acquisition, partner preferences, parenting styles), acquire the contextually relevant ecological and social and cultural information (e.g., mortality rate of their population, economic constraints, cultural values) both intentionally and intuitively to promote their psychological development so that it is adaptive for the reproductive style that promises best inclusive fitness in the given situation. Old age challenges the cultural nature of humans in a very special way, since trade-offs are no longer associated with epigenetic rules or central tendencies. Humans therefore have to use the accumulated knowledge of the previous life stages in order to redefine and redirect the allocation of resources and balance universally evolved behavioral heuristics, ontogenetically acquired styles, and situational regulations, making each life history unique. The question of assumed ultimate causes, 'how do these behavioral regulations or these motivational systems contribute to reproductive success,' might allow us to reframe empirical findings and adapt research designs accordingly.

Lifespan Development, Theory of

1. Lifespan Development, Psychological Aspects

In psychology, the study of human development from infancy until old age has been conducted under the auspices of lifespan psychology (see also *Life Course: Sociological Aspects*). In this article, first, a brief historical sketch of the development of lifespan psychology as a field is discussed; second, central constructs and theoretical tenets are presented and illustrated by empirical results; third, methodological issues related to the study of lifespan development are examined; and finally concluding commentary and future perspectives are offered.

2. Historical Background

Johann Nicolaus Tetens (1777) is considered the founder of the field of developmental psychology in Germany. From this beginning, in Germany development was studied as a lifelong phenomenon. In the USA and in other European countries, such as England, developmental psychology emerged around the turn of the nineteenth century with a strong emphasis on child development. In recent decades, however, a lifespan approach has become more prominent in North America as well, for several reasons. Interdisciplinary synergism is one reason: especially in sociology, which is related to scholars such as Bernice Neugarten or Glen Elder, life course sociology took hold as a powerful intellectual force. A second factor was the emergence of gerontology as a field of study including the search for lifelong precursors of aging. And finally, a third reason may have been the coming of age of several longitudinal studies of child development that had started in the 1920s and 1930s (Baltes et al. 1998).

The first West Virginia Conference on lifespan development—which turned into a series of conf-

erences as well as a book series titled *Life-span Development and Behavior* (Baltes and Brim, first eds.)—probably marks the emergence of lifespan psychology as a modern psychological theory and field of study (Goulet and Baltes 1970, Thomae 1959). The establishment of lifespan psychology is illustrated by the 1980 *Annual Review of Psychology* article. In the late 1990s, the continued importance of lifespan psychology is illustrated by contributions to the new *Handbook of Child Development* and another *Annual Review of Psychology* article.

3. *Lifespan Psychology: Definitions, Metatheoretical Perspectives, and Theoretical Claims*

Lifespan developmental psychology or lifespan psychology deals with the study of individual development (ontogenesis) as it extends across the entire life course. Influenced by evolutionary perspectives, neofunctionalism, and contextualism, lifespan psychology defines development as selective age-related change in adaptive capacity (Baltes 1997). In particular, this adaptive capacity involves the acquisition, maintenance, transformation, and attrition in psychological functions and structures. The focus on selection and selective adaptation highlights that development neither is a uniform nor integrated phenomenon across different domains of functioning and across time. This implies that development is conceived as a developing system comprising a multidimensional and multifunctional dynamic. Owing to selective adaptation, different parts of the developing system develop at different rates, in different directions, for different purposes, and may show continuities as well as discontinuities. A further consequence of this definition is that at any point in the lifespan, development is considered as being constituted by gains and losses. With increasing age, the proportion of gains to losses changes in favor of losses. Criteria of what constitutes a gain and what a loss can be of a subjective and objective nature. Losses, in the sense of selection and of crises, are even considered crucial motors of development (Montada et al. 1992, Riegel 1976).

Considering one domain of psychological functioning as an example may help to illustrate this terminological maze. Take for instance, the lifespan development of intellectual functioning. Two main components (multidimensionality) with very different developmental trajectories (multidirectionality) have been distinguished. The two components are the mechanics and the pragmatics of the mind or fluid and crystallized intelligence (e.g., Baltes et al. 1998). The mechanics refer to cognition as an expression of the neurophysiological architecture of the mind as it evolved during biological evolution. The cognitive mechanics are assessed by tasks of reaction speed or inferencing. In contrast, the pragmatics of cognition are associated with the bodies of knowledge available from and mediated through culture. The cognitive pragmatics are operationalized using tests of verbal ability or knowledge. While losses emerge in the mechanics of the mind quite early in development (after 25 years of age), the pragmatics are characterized first by gains and later by stability until quite late in adulthood. The mechanics and pragmatics of the mind also illustrate the notion of the developing system, as they do not operate in isolation but complement each other to support proactive, selective adaptation.

Besides multidimensionality and multidirectionality, the concepts of multifunctionality, equifinality, and multicausality are crucial when taking a dynamic-system view on lifespan development. Multifunctionality relates to the fact that one and the same developmental change can serve multiple purposes. Research on the concept of dependency provides impressive examples for how in old age, dependency not only implies the loss of autonomy but also the gain of social contact (Baltes 1996). Equifinality in turn refers to the notion that multiple roads can lead to the same developmental outcome. The example of intellectual development illustrates that one and the same behavioral outcome, such as a given cognitive performance, can be attained by using aspects of the mechanics of the mind if one is not used to that cognitive task or it can be accomplished by accessing one's experience with the task that is by referring to pragmatic aspects of the mind.

Multidimensionality and multidirectionality of development highlight the fact that within one individual there is variability in functioning across different domains. Lifespan psychology, however, is also interested in the intraindividual variability of functioning within one domain across time. This is an aspect of behavior that other subdisciplines of psychology often have devaluated as error variance. Lifespan psychology takes intraindividual variability seriously and considers it as an indicator of the plasticity of development. The notion of plasticity implies that any given developmental outcome is but one of numerous possible outcomes. The search for the conditions, range and limits as well as age-related changes in plasticity is fundamental to the study of lifespan development (Lerner 1984).

Over the years, systematic work on the concept of plasticity necessitated further differentiation. One involved the distinction between baseline reserve capacity and developmental reserve capacity (e.g., Kliegl et al. 1989). Baseline reserve capacity refers to the current level of plasticity available to individuals. For instance, how many words from a list of 20 can a person remember. Developmental reserve capacity specifies what is possible in principle given optimizing interventions. That is, how many words can a person remember after learning a mnemonic technique and practicing this technique for extended periods of time. Such training studies have found that there are impressive intellectual training gains well into old

age. Training studies comparing young and old participants, however, have also demonstrated that the training efficiency or developmental reserve capacity is much reduced in old age (Lindenberger and Baltes 1995).

Developmental reserves decline with age. But it is not only the amount of reserves that changes but also the functions that they serve. With increasing age, reserves are less used for growth and more and more for maintenance, recovery and eventually also for the management of loss (Staudinger et al. 1995).

The concepts of plasticity and reserve capacity also highlight the contextual interdependencies of development. Ontogenetic and historical contextualism is another key element of lifespan psychology (Riegel 1976). Contextualism stands in contrast to mechanist or organismic models of development. Lifespan contextualism is related to ecological–contextualist perspectives as well as action-theoretical positions that emphasize the importance of both individual and social–contextual factors in the regulation of development (Smith and Baltes 1999). According to lifespan contextualism, individuals exist in contexts that create and limit opportunities of individual pathways. But individuals also select and create their own contexts.

Contexts evolve according to at least three different logics (Baltes et al. 1980). One is the normative age-graded logic, the second is the history-graded logic, and finally third there is an idiosyncratic or non-normative logic. The age-graded logic refers to those biological and environmental aspects that, because of their dominant age correlation, shape individuals in relatively normative ways. Examples are developmental tasks such as starting school or retirement, or the age-based processes of physical maturation (puberty, menopause). The history-graded logic concerns those variations in ontogenetic development that are due to historical circumstances. Take for instance, the historical evolution of the educational system or the effect of war on ontogenetic development. Finally, the non-normative logic reflects individual–idiosyncratic events of a biological or environmental nature, such as winning the lottery or losing a leg in an accident. All three logics also interact in their shaping of ontogenetic development. In order to understand or predict development, age-graded, history-graded, and person-specific factors have to be taken into account. However, besides contributing to similarities in development, these logics, as Dannefer has argued, also contribute to systematic interindividual variations owing to, for instance, social class.

4. *Outlines of an Architecture of Human Development*

Lifespan contextualism with its three logics leads to the discussion of the two main influences shaping human development: biology and culture. It is in the theoretical conceptualization and study of these two driving developmental forces that lifespan psychology has made the most progress in recent years by formulating the overall biological and cultural architecture of lifespan development (Baltes 1997). This architecture also illustrates the interdisciplinary nature of lifespan development, and how lifespan psychology profits from advances in biology or cultural anthropology. Figure 1 illustrates the three pillars of this architecture. The specific form (level, shape) is not crucial, what is critical is the overall direction and the reciprocal relation between the three functions.

Figure 1
Schematic representation of the basic assumptions about the average dynamics between biology and culture across the life span (after Baltes 1997)

The first element of the tripartite argument derives from an evolutionary perspective. The older the organism, Finch has argued, the less the genome benefited from the genetic advantages associated with evolutionary selection. This assertion is in line with the idea that evolutionary selection has been tied to the process of reproductive fitness and its location in the first half of the life course. This general statement holds true even if indirect positive effects are carried into old age, for instance, though grand-parenting, coupling and exaptation. This age-associated diminution of evolutionary selection benefits was further affected by the fact that in earlier times few people reached old age. Thus, most people died before negative genetic attributes were activated or possible negative biological consequences of earlier developmental events became manifest. The negative consequences of the relative neglect during evolution of the second half of life is amplified by other aspects of biological aging. For instance, biological aging involves wear and tear as well as the accumulation of errors in genetic replication and repair.

The middle panel of Figure 1 summarizes the overall role of culture in lifespan development. Culture, in this context, refers to all psychological, social, material, and symbolic (knowledge-based) resources that humans have produced over the millennia. Among these cultural resources are literacy, cognitive skills, motivational dispositions, physical structures, the world of economics, as well as medical and physical technology. The age-related increase in the need for

culture is defined by two aspects. First, the farther we expect human ontogenesis to extend into old age, the more necessary it will be for particular cultural resources to emerge to make this possible. Take, for instance, the increase in life expectancy or educational status during the twentieth century. The genetic make-up did not change during this time. It is primarily through the medium of more advanced levels of culture that people are able to develop throughout longer spans of life. The second part of the argument relates to the age-related biological weakening of the body and the related need for cultural support (material, social, economic, psychological) to generate and maintain high levels of functioning.

The third pillar of the architecture of lifespan development is the decrease in efficacy of cultural resources, that is how much effect a cultural resource has. Despite the acquisition of a variety of bodies of knowledge, the efficiency of cultural factors is reduced, even though large interindividual differences exist in onset and rate of these losses in efficiency. Consider cognitive training interventions as an example of a cultural resource. Research has demonstrated that the older the adult the more time and practice it takes, for instance, to attain the same learning gains. Moreover, in some domains of cognitive functioning and at high levels of performance, older adults may not be able to reach the same level of functioning as younger adults even after extensive periods of training (Baltes et al. 1998). In other words, the efficacy of the cognitive intervention is reduced.

5. *Methodological Issues Related to Lifespan Psychology*

The search for methods adequate for the study of developmental processes across the lifespan has been a continuing part of the agenda of lifespan researchers (e.g., Lindenberger and Baltes 1995, Magnusson 1998, Nesselroade 1991). One example of methodological innovation is a strategy to examine the scope and limits of plasticity. It is a perennial question of cognitive-aging researchers, for instance, whether aging losses in cognitive performance reflect age-related experiential deficits rather than biological decline. The testing-the-limits paradigm has been developed to answer this question (Kliegl et al. 1989). The testing-the-limits paradigm compresses time by providing for high-density developmental experiences, and by doing so to identify asymptotes of performance potential. These asymptotes, obtained under putatively optimal conditions of support, are expected to estimate the upper range of developmental reserve capacity. Again, this paradigm has been most widely used in research on cognitive development and its plasticity. For instance, in the area of memory functioning, a testing-the-limit approach has been applied. Given young and old participants undergo the same intensive training procedure in a memory technique originally not known to any participant, it was found that after long periods of training and practice, older adults were not able to reach the levels of performance of young adults. These age differences have been much more pronounced than those identified in standard training studies.

Another example is the development of methods that allow the measurement of development including its interindividual differences and contextual variations. Traditionally, the main designs used in developmental psychology were cross-sectional and longitudinal methods. Both methods are characterized by serious flaws, however, when it comes to understanding development. Cross-sectional designs, in which different age groups are compared at one historical point in time, confound chronological age and generational membership. In addition, in a cross-sectional design it is impossible to track individual change trajectories. Longitudinal designs, on the other hand, while providing insight into individual change trajectories, do so only with regard to one single cohort. The challenge to track individual and historical change within one design resulted in the formulation of so-called sequential methods (for history see Baltes et al. 1998). The sequential methods combine sequences of cross-sectional studies (cross-sectional sequence) with successions of longitudinal studies (longitudinal sequence). When both sequences are applied at once exhaustive information about interindividual differences in developmental trajectories, about retest effects, as well as historical change is obtained. As Schaie has demonstrated (1996), cohort effects can be positive or negative, and can concern different age periods to different degrees.

6. *Conclusion and Future Developments*

Since its formation as a theoretical orientation for the study of human development between infancy and old age, lifespan psychology has advanced our knowledge about human development. A couple of examples may illustrate this point. For instance, we owe it to lifespan psychology that it is now known in which way and to which degree cohort effects can mask age differences (Schaie 1996), or that we have learnt about the reserves of human development, be it in terms of cognitive functioning, self and personality, or social functioning (Staudinger et al. 1995). With its orientation towards understanding developmental plasticity, lifespan psychology has opened new vistas on possibilities of intervention, and has eventually succeeded in making intraindividual variability of functioning a construct of interest to many researchers outside of the field of development (Nesselroade 1991). Finally, it has been lifespan psychology characterized by an orientation towards understanding human development as a dynamic system with functional consequences that has

started to further our understanding of the interplay between different areas of psychological functioning, such as cognition, emotion, and motivation, as well as our insight into ecologically relevant and complex constructs such as wisdom and art of life (e.g., Baltes et al. 1998, Labouvie-Vief 1994, Staudinger 1999).

Needless to say, a number of issues remain to be explored. Lifespan psychologists, for instance, have only started to integrate the study of functional aspects of human development with the investigation of microgenetic processes. Projects along these lines have been to ask which are the regulatory processes that allow the aging person to maintain comparatively high levels of well-being and fulfilling lives (e.g., Baltes and Baltes 1990, Brandtstädter and Greve 1994, Heckhausen and Schulz 1995, Staudinger et al. 1995). Within the field of cognitive aging more and more research is oriented towards understanding the microanalytic processes that may underlie the age-related decline in the cognitive mechanics.

Another issue that needs further theoretical and empirical work is the study of the ecology of human development. There is too little systematic work on classifying environments in their effects on human development. And finally the dynamic systems approach borrowed from physics has not yet been explored to its fullest when it comes to understanding human development.

Lifespan psychology does not prescribe the goals of development. Rather, it has taken on the mission to accumulate and disseminate knowledge about which processes and characteristics contribute under which circumstances to the optimization of development. Eventually, it will be this kind of knowledge that every individual may use to compose his or her life in a fulfilling manner.

Lifespan Theories of Cognitive Development

Most lifespan theories of cognitive development (LTCD) provide an integrative framework for the description, explanation, and optimization of cognitive development across different functional domains and age periods. Arguably the first LTCD dates back to Johann Nicolaus Tetens (1736–1807), a philosopher and psychologist of the Enlightenment

era. Tetens (1777) noted that well-trained skills are less likely to decline with advancing adult age than the basic abilities underlying their acquisition, and this observation and conceptual distinctions related to it have remained at the heart of LTCD.

1. Central Assumptions of LTCD

Most LTCD are based on two central assumptions (Baltes et al. 1998):

(a) Cognitive development reflects the operation of two intertwined components, one biological and the other cultural. The specific definition and terminology regarding the two components varies across different LTCD (see Sect. 3). In general, the biological component is construed as an expression of the neurophysiological architecture of the mind as it evolved during biological evolution and unfolds during ontogeny. In contrast, the cultural component refers to bodies of knowledge available from and mediated through culture.

(b) During ontogeny, potential related to the biological component is *invested into* various cultural domains, thereby leading to the acquisition of culturally transmitted bodies of knowledge. A good example is the acquisition of reading and writing skills. Hence, at any point in time during development, two types of cognitive capacities can be distinguished: (i) the capacity to invest (i.e., to acquire new knowledge of various sorts) and (ii) the capacity to think and act on the basis of acquired knowledge.

2. Theoretical Background: the Lifespan Dynamics Between Biology and Culture

Cognitive development participates in the general lifespan dynamics between biology and culture (see also *Lifespan Development*, *Theory of*). According to Baltes (1997), these dynamics can be characterized by three interrelated lifespan trends: (a) a decrease in evolutionary selection benefits; (b) a concomitant increase in the need for culture; and (c) a decrease in the efficacy of culture in reaching adaptive outcomes.

2.1 Decrease in Evolutionary Selection Benefits

This proposition speaks to the biological component of cognition, and derives from an evolutionary perspective on the nature of the genome and its age-correlated changes in expression and biological potential. During evolution, the older the organism, the less the genome benefited from the genetic advantages associated with evolutionary selection. After maturity, and with age, the expressions and mechanisms of the genome lose in functional quality. This holds true even though some indirect positive evolutionary selection benefits may be carried into old age (e.g., through grandparenting). The age-associated diminution of evolutionary selection benefits and its implied association with an age-related loss of biological potential is further accentuated by the fact that fewer people reached old age in earlier times.

2.2 Increase in Need for Culture

The second proposition summarizes the overall perspective on lifespan development associated with culture and culture-based processes. Among these cultural resources are physical structures, the world of economics as well as that of medical and physical technology, but also cognitive skills such as formal logic, literacy, and written documents. The argument for an age-related increase in the 'need' for culture has two parts. First, for human ontogeny to have reached increasingly high levels of functioning across historical time, whether in physical or psychological domains, there had to be a conjoint evolutionary increase in the richness and dissemination of the resources and 'opportunities' of culture. The second argument for the proposition relates to the biological weakening associated with age. That is, the older we are, the more we need culture-based resources to generate and maintain high levels of functioning. For instance, in old age, it generally takes more time and practice to attain the same amount of learning gains than in early adulthood (see next).

2.3 Decrease in the Efficiency of Culture

The efficiency of cultural factors and resources in producing desired outcomes decreases with age, especially during the second half of life. There are three major causes for this age-related reduction in cultural efficiency. The first is age-related loss in biological potential. The second is related to the shape of *learning curves*, which express the process of knowledge acquisition in specified domains. Such curves generally start out steep and then reach an asymptote. Given that older individuals, on average, are more likely to find themselves in later phases of learning than younger individuals (i.e., closer to the asymptote), increasing amounts of effort and technology are needed to produce further gains. The third cause refers to negative consequences of earlier learning on later learning (i.e., *negative transfer*).

2.4 Consequences for LTCD

In combination, the two core assumptions of LTCD and the general lifespan dynamics between biology and culture predict the presence of multidirectionality in cognitive lifespan development: the biological component of cognition is expected to decline after maturity, reflecting the decrease in evolutionary selec-

Figure 1
Lifespan theories of cognitive development posit two-component models of cognition. The top section defines the categories, the bottom section illustrates postulated lifespan trajectories (after Baltes et al. 1998; cf., Hebb 1949, Cattell 1971). In advanced old age, the trajectories show less and less differentiation (Lindenberger and Baltes 1997)

tion pressures with age. In contrast, the cultural component of cognition is expected to increase with age as long as knowledge maintenance and knowledge acquisition outweigh age-based losses in biological potential (see Fig. 1).

Moreover, any given cognitive performance can be portrayed as the combined outcome of biological and cultural systems of influence (Lindenberger and Baltes 1997). Age differences in skilled chess performance (Charness and Bosman 1990) illustrate this point. The mean age at which a world championship is first won is about 46 years for correspondence chess but about 30 years for tournament chess. In correspondence chess, players are permitted three days to deliberate a

move; in tournament chess, deliberation averages three minutes per move. Conceivably, the difference in peak age reflects differences in the relative importance of task-relevant mechanisms with a strong biological component, such as speed of perception and working memory, and mechanisms with a strong cultural component, such as procedural and declarative knowledge about chess.

3. *Variation in Terminology and Scope Among LTCD*

3.1 *Two-component LTCD*

Two-component LTCD vary in terminology and scope (Baltes et al. 1998). As mentioned, Tetens (1777) was the first to propose an LTCD. His distinction between biology-based *absolute capacities* and culture-based *relative capacities* anticipated central ideas and findings regarding lifespan cognitive development, such as the investment relation and the divergence in age gradients between the two components.

Within the psychometric research tradition, the most influential LTCD is the theory of *fluid* and *crystallized intelligence* (*Gf–Gc theory*) introduced by Raymond B. Cattell (see *Cattell, Raymond Bernard (1905–98)*) and modified by John Horn (Cattell 1971, Horn 1989). Fluid intelligence represents the biological component; it is called fluid because it can be invested into various cultural domains. In contrast, crystallized intelligence represents the cultural component; it is called crystallized because it has solidified into knowledge. Gf–Gc theory summarizes a vast amount of empirical evidence obtained through *standardized testing* and *factor analysis*.

More recently, Paul Baltes (1987) also proposed a model with two components, the biology-based *mechanics* and the culture-based *pragmatics* of cognition. In comparison with the Gf–Gc distinction, the two-component model introduced by Baltes is broader in scope. For instance, in addition to the emphasis on individual differences and measurement precision inherited from Gf–Gc theory, the model seeks to integrate findings from cognitive psychology, evolutionary psychology, cultural psychology, cognitive neurosciences, and developmental biology (Baltes et al. 1998). Hebb's (1949) distinction between intelligence A (intellectual power) and intelligence B (intellectual products) resembles the mechanics–pragmatic distinction. Additional LTCD are mentioned in Baltes et al. (1998).

3.2 *Structuralist (NeoPiagetian) LTCD*

Two-component LTCD are functionalist in character. For instance, they emphasize the local nature of developmental adaptations during knowledge acquisition, selective specialization, and transfer. In contrast, *structuralist* LTCD posit that lifespan intellectual development follows a stage-like movement towards higher (more mature) forms of reasoning and thought (Labouvie-Vief 1982, Blanchard-Fields 1989). Building upon the theory of cognitive development formulated by Jean Piget, structuralist LTCD search for the emergence of one or more 'post-formal' or 'dialectical' stages of cognitive development after the advent of formal operations, the highest stage in Piaget's theory (see *Piaget, Jean (1896–1980)*). The conceptual description of these post-formal stages often connects personality development (e.g., generativity in the *Eriksonian* sense) with logical considerations (e.g., awareness and acceptance of contradiction). As a consequence of this particular linkage, the emergence of post-formal stages is expected to be accompanied by increments in reflexivity and general awareness for the human condition.

Generally, two-component, functionalist LTCD seem more amenable to operational definition and empirical investigation than structuralist LTCD (Baltes et al. 1998). For instance, from a functionalist perspective, the search for higher forms of reasoning can be redirected into a search for bodies of acquired knowledge with a high degree of generality and meaning.

The following sections focus on two-component LTCD. First, the mechanics–pragmatics distinction is elaborated in some detail. Select findings and hypotheses will be summarized thereafter.

4. *Two-component Models of Cognition: the Mechanics–Pragmatics Distinction*

4.1 *The Mechanics of Cognition*

In the mechanics of cognition, the predominant age-graded ontogenetic pattern is one of maturation, stability, and aging-induced decline. Age-based changes in this component early and late in ontogeny are assumed to be strongly influenced by genetic and other brain status-related factors, albeit in fundamentally different ways. Early in ontogeny (i.e., during embryogenesis, infancy, and early childhood), age-based changes in the mechanics primarily reflect the unfolding and active construction of more or less domain-specific and predisposed processing capabilities (Wellman and Gelman 1992). In contrast, negative changes in the mechanics of cognition late in life result from brain-related consequences of less effective phylogenetic selection pressures operating during this period.

The cognitive mechanics, then, reflect fundamental organizational properties of the central nervous system. In terms of psychological operations, these

properties are indexed by the speed, accuracy, and coordination of elementary processing operations as assessed in tasks measuring the quality of information input, sensory and motor memory, discrimination, categorization, and selective attention, as well as reasoning ability in highly overlearned or novel domains.

4.2 The Pragmatics of Cognition

In contrast to the mechanics, the pragmatics of the mind reveal the power of human agency and culture. Developmental changes in this component reflect the acquisition of culturally transmitted bodies of *declarative* and *procedural knowledge* that are made available to individuals in the course of *socialization*. Some of these socialization events are normative but specific to certain cultures (e.g., formal schooling), others are more universal (e.g., mentoring), and still others are idiosyncratic or person-specific (e.g., specialized ecological and professional knowledge). In all cases, the corresponding bodies of knowledge are represented both internally (e.g., *semantic networks*) and externally (e.g., books). Pragmatic knowledge systems are acquired during ontogeny but may build on evolutionarily prestructured, domain-specific knowledge (Siegler and Crowley 1994).

Compared with the mechanics, the pragmatics of cognition direct the attention of lifespan researchers towards the increasing significance of acquired knowledge in cognitive behavior (Ericsson and Lehmann 1996). Typical examples include reading and writing skills, educational qualifications, professional *expertise*, and varieties of everyday problem-solving, but also knowledge about the self and the meaning and conduct of life (Staudinger and Pasupathi 2000) (see *Wisdom, Psychology of*).

4.3 The Relation Between Mechanics and Pragmatics

A common misunderstanding about two-component LTCD is that biological and cultural components are assumed to operate separately. As illustrated by the intersecting circles in Fig. 1, LTCD recognize that cognitive behavior reflects the joint operation of biological and cultural systems of influence, and posits that biological (mechanic) and cultural (pragmatic) development interact in complex and changing ways throughout life. During infancy and early childhood, the unfolding of the mechanics is dependent upon the acquisition of pragmatic knowledge. For instance, the ability of newborns to prefer the language spoken by their mothers during pregnancy over other languages has a strong biological component, but this component needs cultural specification (e.g., one specific language is preferred over another). Later in life, the acquisition and maintenance of pragmatic knowledge increasingly serve the function to buffer (circumvent) the negative consequences of mechanic decline. Moreover, at least in some cases, pragmatic knowledge is acquired as a compensatory reaction to losses in the mechanics (Freund et al. 1999). In agreement with Sect. 2, the buffering and compensatory functions of pragmatic knowledge increase in importance but decrease in efficiency with advancing age.

Another misunderstanding about the two-component model concerns its relation to the issue of *domain generality* versus *domain specificity*; that is, to the question whether a given set of cognitive mechanisms applies to a large or a small number of task domains. Here, the mechanics are often identified with *domain generality* in cognitive development, and the pragmatics with *domain specificity*. At first sight, this seems reasonable because acquired bodies of knowledge tend to be specialized (e.g., knowledge about chess), whereas mechanisms associated with basic learning capabilities tend to generalize across domains (e.g., the *law of reinforcement*). However, at closer inspection, the mapping is not so clear. First, certain components of the mechanics are dedicated to, or at least particularly important for, specific domains (e.g., infants' preference for human faces). Second, some bodies of acquired knowledge, such as *knowledge about the fundamental pragmatics of life* (with *wisdom* being its highest expression; see *Wisdom, Psychology of*), are general in the sense that their range of applicability is very broad. Therefore, the distinction between domain generality and domain specificity is correlated but not identical with the mechanics–pragmatics distinction.

5. Select Findings and Hypotheses Associated with LTCD

LTCD attempt to integrate and generate research findings and hypotheses across different content domains and age periods. A few central examples may suffice for illustration; more can be found in Baltes et al. (1998).

5.1 Divergence of Mechanic and Pragmatic Age Gradients

The most longstanding evidence in support of the mechanics–pragmatics distinctions is the difference between maintained and vulnerable intellectual abilities observed in lifespan studies of psychometric intelligence (Jones and Conrad 1933). Abilities that critically involve the mechanics, such as reasoning, memory, spatial orientation, and perceptual speed, generally show a pattern of monotonic and roughly linear decline during adulthood, with some further acceleration of decline in very old age. In contrast,

predominantly pragmatic abilities, such as verbal knowledge and certain facets of numerical ability, remain stable or increase up to the sixth or seventh decade of life. They only start to evince some decline in very old age, when the mechanics fall below a certain threshold in most individuals.

5.2 Differentiation–Reintegration Hypothesis of Interindividual Differences in Intellectual Functioning Across the Lifespan

As a general rule, the degree of covariation across different intellectual abilities, often represented as the prominence of a general factor (*g*) of intellectual functioning, appears to decrease from childhood to middle adulthood, and to increase again in very old age (Baltes and Lindenberger 1997, Lindenberger and Baltes 1997). This empirical regularity is well captured by assuming curvilinear age-based changes in the importance of domain-general mechanic constraints on cognitive performance, as formulated by the *differentiation–reintegration hypothesis* of intellectual lifespan development (for its origins, see Baltes et al. 1998; also *Intelligence: Central Conceptions and Psychometric Models*).

5.3 Malleability and Plasticity

A central theme in *lifespan psychology* concerns the malleability, and especially optimization, of psychological functioning and behavior throughout all phases of life. The effects of cohort, historical period, and environmental change on age changes and age differences in cognitive performance are one indication of malleability (Schaie 1996). Experimental *testing-the-limits* procedures offer another, more direct way to explore age differences in upper limits of performance potential (Baltes and Kliegl 1992). In adulthood, cognitive plasticity continues to be present in cognitively healthy older adults, albeit to a lesser degree than in young adults. In fact, when pushed to the upper limits of performance in tasks which critically involve the mechanics, the performance distributions of young and old adults are close to non-overlapping (Baltes and Kliegl 1992). For the most part, cognitive plasticity reflects the acquisition of novel cognitive tools (e.g., the investment of existing mechanic potential), rather than an amelioration of the mechanic component itself.

5.4 Search for Basic Determinants of Mechanic Development

Attempts have been made to identify domain-general mechanisms acting as pacemakers for lifespan changes in the mechanics of cognition. Among the most prominent constructs are *information processing rate*, *working memory capacity*, and the ability to suppress irrelevant information (*inhibition*). Supportive evidence has been gathered for each of the three constructs at both ends of the lifespan, especially with respect to information processing rate (Salthouse 1996). At the same time, all three constructs suffer from a lack of direct evidence at the physiological level and from difficulties in making differential predictions. A closer link to cognitive neurosciences and formal modeling approaches is expected to foster progress in this area of research (Li and Lindenberger 1999).

5.5 Relative (e.g., Rank Order) Stability and Level Stability in Intellectual Functioning Across the Lifespan

Generally, relative stabilities computed after identical lapses of time show a strong increase in magnitude from middle childhood to adolescence into middle adulthood and early old age (Hertzog and Schaie 1986), followed by a probable decrease in old and very old age. According to LTCD, these age-based changes in relative stability need to be interpreted in conjunction with age-based changes in level (Molenaar et al. 1991). The specific prediction is that interindividual differences change more rapidly early in development because the intellectual repertoire is smaller but growing faster than at later points in ontogeny, thereby giving room for larger amounts of new variance per unit time (both environmental and genetic). Similarly, the preponderance of age-based losses in very old age may not only lead to decrements in level but also to a reshuffling of individual differences. Both predictions specify relations between changes in covariance and changes in mean level over time, and call for the use of complex statistical modeling techniques. In this respect, they point to the more general phenomenon of a close connection between conceptual and methodological advances in the context of LTCD.

6. Conclusion

Compared with the large number and great diversity of cognitive-developmental theories about specific age periods (e.g., infancy), content domains (e.g., faces), and processes (e.g., recognition), LTCD form a small and relatively homogeneous set. One characteristic feature of this set is to articulate disparate bodies of knowledge about cognitive development with general propositions about the overall architecture of human ontogeny. The resulting bird's eye view on cognitive lifespan development stresses the variability and modifiability of human development at the inter- and intraindividual level, but it also stresses its invariant, age-dependent properties. The future role played by LTCD will depend on their utility for scholars working on more specific aspects of cognitive development, and on their ability to link the field of cognitive lifespan development to neighboring fields and disciplines.

Likelihood in Statistics

A statistical model for phenomena in the sciences or social sciences is a mathematical construct which associates a *probability* with each of the possible outcomes. If the data are discrete, such as the numbers of people falling into various classes, the model will be a discrete probability distribution, but if the data consist of measurements or other numbers that may take any values in a continuum, the model will be a continuous probability distribution. When two different models, or perhaps two variants of the same model differing only in the value of some adjustable parameter(s), are to be compared as explanations for the same observed outcome, the probability of obtaining this particular outcome can be calculated for each and is then known as the *likelihood* for the model or parameter value(s) given the data. This article enlarges on the definition of likelihood, discusses its properties and uses, and relates it to other approaches to statistical inference.

1. Probability and Likelihood Distinguished

Probabilities and likelihood are easily (and frequently) confused, and it is for this reason that in 1921 R.A. Fisher introduced the new word: 'What we can

find from a sample is the likelihood of any particular value of [the parameter], if we define the likelihood as a quantity proportional to the probability that, from a population having that particular value, the [observed sample] should be obtained. So defined, probability and likelihood are quantities of an entirely different nature' (see *Fisher, Ronald A (1890–1962)*).

The first difference to be noted is that the variable quantity in a likelihood statement is the hypothesis (a word which conveniently covers both the case of a model and of particular parameter values in a single model), the outcome being that actually observed, in contrast to a probability statement, which refers to a variety of outcomes, the hypothesis being assumed and fixed. Thus a manufacturer of dice may reasonably assert that the outcomes 1, 2, 3, 4, 5, 6 of a throw each have 'probability' 1/6 on the hypothesis that his dice are well-balanced, whilst an inspector of casinos charged with testing a particular die will wish to compute the 'likelihood' for various hypotheses about these probabilities on the basis of data from actual tosses.

The second difference arises directly from the first. If all the outcomes of a statistical model are considered their total probability will be 1, since one of them must occur and they are mutually exclusive; but since in general hypotheses are not exhaustive—one can usually think of another one—it is not to be expected that the sum of likelihoods has any particular meaning, and indeed there is no addition law for likelihoods corresponding to the addition law for probabilities. It follows that only 'relative' likelihoods are informative, which is the reason for Fisher's use of the word 'proportional' in his original definition.

2. *The Likelihood Function*

The most important application of likelihood is in parametric statistical models. Consider the simplest binomial example, such as that of the distribution of the number of boys r in families of size n (an example which has played an important role in the development of statistical theory since the early eighteenth century). The probability of getting exactly r boys will be given by the binomial distribution indexed by a parameter p, the probability of a male birth. Denote this probability of r boys by $\mathrm{P}(r|p)$, n being assumed fixed and of no statistical interest. Then we write

$$\mathrm{L}(p \parallel r) \propto \mathrm{P}(r|p)$$

for the likelihood of p given the particular value r, the double vertical line $\parallel$ being used to indicate that the likelihood of p is not conditional on r in the technical probability sense. In this binomial example $\mathrm{L}(p\|r)$ is a continuous function of the parameter p and is known as the 'likelihood function.' When only two hypotheses are compared, such as two particular values of p in the present example, the ratio of their likelihoods is known as the 'likelihood ratio.'

The value of p which maximizes $\mathrm{L}(p\|r)$ for an observed r is known as the 'maximum-likelihood estimate' of p and is denoted by p^; expressed in general form as a function of r it is known as the 'maximum-likelihood estimator.' Since the pioneering work of Fisher in the 1920s it has been known that maximum-likelihood estimators possess certain desirable properties under repeated sampling (consistency and asymptotic efficiency, and in an important class of models sufficiency and full efficiency). For this reason they have come to occupy a central position in repeated-sampling (or 'frequentist') theories of statistical inference (see *Estimation: Point and Interval*). However, partly as a reaction to the unsatisfactory features which repeated-sampling theories display when used as theories of evidence, coupled with a reluctance to embrace the full-blown Bayesian theory of statistical inference, likelihood is increasingly seen as a fundamental concept enabling hypotheses and parameter values to be compared directly.

3. *The Likelihood Principle*

The basic notion, championed by Fisher as early as 1912 whilst still an undergraduate at Cambridge but now known to have been occasionally suggested by other writers even earlier, is that the likelihood ratio for two hypotheses or parameter values is to be interpreted as the degree to which the data support the one hypothesis against the other. Thus a likelihood ratio of 1 corresponds to indifference between the hypotheses on the basis of the evidence in the data, whilst the maximum-likelihood value of a parameter is regarded as the 'best-supported value', other values being ranked by their lesser likelihood accordingly. This was formalized as the *Law of Likelihood* by Ian Hacking (1965). Fisher's final advocacy of the direct use of likelihood will be found in his last book *Statistical Methods and Scientific Inference* (1956).

Such an approach, unsupported by any appeal to repeated-sampling criteria, is ultimately dependent on the primitive notion that the best hypothesis or parameter-value on the evidence of the data is the one which would explain what has in fact been observed with the highest probability. The strong intuitive appeal of this can be captured by recognizing that it is the value which would lead, on repeated sampling, to a precise repeat of the data with the least expected delay. In this sense it offers the best statistical explanation of the data.

In addition to specifying that relative likelihoods measure degrees of support, the likelihood approach requires us to accept that the likelihood function or ratio contains all the information we can extract from

the data about the hypotheses in question on the assumption of the specified statistical model—the so-called 'Likelihood Principle.' It is important to include the qualification requiring the specification of the model, first because the adoption of a different model might prove necessary later and second because in some cases the structure of the model enables inferences to be made in terms of 'fiducial probability' which, though dependent on the likelihood, are stronger, possessing repeated-sampling properties which enable confidence intervals to be constructed (see *Fiducial and Structural Statistical Inference*).

Though it would be odd to accept the 'Law of Likelihood' and not the 'Likelihood Principle', Bayesians necessarily accept the Principle but not the Law, for although the likelihood is an intrinsic component of Bayes's Theorem, Bayesians deny that a likelihood function or ratio has any meaning in isolation (see *Bayesian Statistics*). For those who accept both the Law and the Principle it is convenient to express the two together as:

> *The Likelihood Axiom*: Within the framework of a statistical model, all the information which the data provide concerning the relative merits of two hypotheses is contained in the likelihood ratio of those hypotheses on the data, and the likelihood ratio is to be interpreted as the degree to which the data support the one hypothesis against the other (Edwards 1972).

The likelihood approach has many advantages apart from its intuitive appeal. It is straightforward to apply because the likelihood function is usually simple to obtain analytically or easy to compute and display. It leads directly to the important theoretical concept of 'sufficiency' according to which the function of the data that is the argument of the likelihood function itself carries the information. This reduction of the data is often a simple 'statistic' such as the sample mean (see *Statistical Sufficiency*). Moreover, the approach illuminates many of the controversies surrounding repeated-sampling theories of inference, especially those concerned with ancillarity and conditioning. Birnbaum (1962) argued that it was possible to derive the 'Likelihood Principle' from the concepts of sufficiency and conditionality, but to most people the Principle itself seems the more primitive concept and the fact that it leads to notions of sufficiency and conditioning seems an added reason for accepting it.

Likelihoods are multiplicative over independent data sets referring to the same hypotheses or parameters, facilitating the combination of information. For this reason 'log-likelihood' is often preferred because information is then combined by addition. In the field of genetics, where likelihood theory is widely applied, the log-likelihood with the logarithms taken to the base 10 is known as a LOD, but for general use natural logarithms to the base e are to be preferred, in which case log-likelihood is sometimes called 'support.' Most importantly, the likelihood approach is compatible with Bayesian statistical inference in the sense that the posterior Bayes distribution for a parameter is, by Bayes's Theorem, found by multiplying the prior distribution by the likelihood function. Thus when, in accordance with Bayesian principles, a parameter can itself be given a probability distribution (and this assumption is the Achilles' heel of Bayesian inference) all the information the data contain about the parameter is transmitted via the likelihood function in accordance with the 'Likelihood Principle.' It is indeed difficult to see why the medium through which such information is conveyed should depend on the purely external question of whether the parameter may be considered to have a probability distribution, and this is another powerful argument in favor of the Principle itself.

4. *Parameter Estimation*

In the case of a single parameter the likelihood function or the log-likelihood function may easily be drawn, and, if it is unimodal, limits may be assigned to the parameter, analogous to the confidence limits of repeated-sampling theory. Calling the log-likelihood the 'support', m-unit support limits are the two-parameter values astride the maximum at which the support is m units less than at the maximum. For the simplest case of estimating the mean of a normal distribution of known variance the 2-unit support limits correspond closely to the 95 percent confidence limits which are at ± 1.96 standard errors. In this normal case the support function is quadratic and may therefore be characterized completely by the maximum-likelihood estimate and the curvature at the maximum (the reciprocal of the radius of curvature) which is defined as the 'observed information.' Comparable definitions apply in multiparameter cases, leading to the concept of an m-unit support region and an observed information matrix. In cases in which the support function is not even approximately quadratic the above approach may still be applied if a suitable transformation of the parameter space can be found.

The representation of a support function for more than two parameters naturally encounters the usual difficulties associated with the visualization of high-dimensioned spaces, and a variety of methods have been suggested to circumvent the problem. It will often be the case that information is sought about some subset of the parameters, the others being considered to be nuisance parameters of no particular interest. In fortunate cases it may be possible to restructure the model so that the nuisance parameters are eliminated, and in all cases in which the support function is quadratic (or approximately so) the dimensions corresponding to the nuisance parameters can simply be ignored. Several other approaches are in use to eliminate nuisance parameters. Marginal likelihoods rely on finding some function of the data which does

not depend on them; notable examples involve the normal distribution, where a marginal likelihood for the variance can be found from the distribution of the sample variance which is independent of the mean, and a marginal likelihood for the mean can similarly be found using the t-distribution. Profile likelihoods, also called maximum relative likelihood, are found by replacing the nuisance parameters by their maximum-likelihood estimates at each value of the parameters of interest. It is easy to visualize from the case of two parameters why this is called a profile likelihood.

Naturally, a solution can always be found by strengthening the model through adopting particular values for the nuisance parameters, just as a Bayesian solution using integrated likelihoods can always be found by adopting a prior distribution for them and integrating them out, but such assumptions do not command wide assent. When a marginal likelihood solution has been found it may correspond to a Bayesian integrated likelihood for some choice of prior, and such priors are called neutral priors, to distinguish them from so-called uninformative priors for which no comparable justification exists. However, in the last analysis there is no logical reason why nuisance parameters should be other than a nuisance, and procedures for mitigating the nuisance must be regarded as expedients.

5. *Relation to Significance Testing*

All the common repeated-sampling tests of significance have their analogues in likelihood theory, and in the case of the normal model it may seem that only the terminology has changed. At first sight an exception seems to be the χ^2 goodness-of-fit test, where no alternative hypothesis is implied. However, this is deceptive, and a careful analysis shows that there is an implied alternative hypothesis that allows the variances of the underlying normal model to depart from their multinomial values. In this way the paradox of small values of χ^2 being interpreted as meaning that the model is 'too good' is exposed, for in reality they mean that the model is not good enough and that one with a more appropriate variance structure will have a higher likelihood. Likelihood ratio tests are based on the distribution under repeated-sampling of the likelihood ratio and are therefore not part of likelihood theory.

When likelihood arguments are applied to models with continuous sample spaces it may be necessary to take into account the approximation involved in representing data, which are necessarily discrete, by a continuous model. Neglect of this can lead to the existence of singularities in the likelihood function or other artifacts that a more careful analysis will obviate.

It is often argued that in comparing two models by means of a likelihood ratio, allowance should be made for any difference in the number of parameters by establishing a 'rate of exchange' between an additional parameter and the increase in log-likelihood expected. The attractive phrase 'Occam's bonus' has been suggested for such an allowance (Edwards 1969). However, the proposal seems only to have a place in a repeated-sampling view of statistical inference, where a bonus such as that suggested by Akaike's information criterion is sometimes canvassed.

The major application of likelihood theory so far has been in human genetics, where log-likelihood functions are regularly drawn for recombination fractions (linkage values) (see Ott 1991), but even there a reluctance to abandon significance-testing altogether has led to a mixed approach. Other examples, especially from medical fields, will be found in the books cited below.

6. *History and Further Reading*

Although historically the development of a likelihood approach to statistical inference was almost entirely due to R.A. Fisher, it is interesting to recall that the Neyman–Pearson approach to hypothesis testing derives ultimately from a remark of 'Student's' (W. S. Gosset) in a letter to E. S. Pearson in 1926 that 'if there is any alternative hypothesis which will explain the occurrence of the sample with a more reasonable probability … you will be very much more inclined to consider that the original hypothesis is not true', a direct likelihood statement (quoted in McMullen and Pearson 1939). Indeed, it has been remarked that 'Just as support [log-likelihood] is Bayesian inference without the priors, so it turns out to be Neyman–Pearson inference without the ′errors′′ (Edwards 1972).

The literature on likelihood is gradually growing as an increasing number of statisticians become concerned at the inappropriate use of significance levels, confidence intervals and other repeated-sampling criteria to represent evidence. The movement is most advanced in biostatistics as may be seen from books such as Clayton and Hills (1993) and Royall (1997), but general texts such as Lindsey (1995) and Sprott (2000) exist as well. Amongst older books Cox and Hinkley (1974) contains much that is relevant to likelihood, whilst Edwards (1972, 1992) was the first book to advocate a purely likelihood approach, and is rich in relevant quotations from Fisher's writings. The history of likelihood is treated by Edwards (1974; reprinted in Edwards 1992).

Limbic System

1. Introduction

In this article current ideas about the anatomical structures and functions of the limbic system will be described. The information will be limited to the limbic system as found in most mammals with greatest emphasis placed on structures prominent in the human brain. From the start it should be noted that there is less than universal agreement both about the structures that should be included in the limbic system and also about the roles played by them in mental functions and behavior. Some of the reasons for the differences of opinion among scientists arise from the many different approaches used to investigate the limbic system in both clinical and research settings. The simplest description of the limbic system is a set of highly interconnected anatomic areas lying below the cortical surface but above the most central regions of the forebrain, namely the thalamus, the hypothalamus, and areas of the ventral forebrain called the basal ganglia. Suggestions for other approaches to understanding the limbic system will be presented.

2. History of the Term, Limbic System

2.1 Early History

In the middle and later parts of the 1800s anatomists became interested in a region of tissue that surrounds the most medial parts of the brain, i.e., the thalamus, hypothalamus (together, the diencephalon), and the basal ganglia (caudate, putamen, nucleus accumbens, and associated regions). This medial band of tissue lies underneath the neocortical mantle and largely is separated from it by various sulci (fissures or indentations). In 1878 the French scientist Paul Broca described this deep band of tissue as a separate 'lobe' of the brain containing phylogenetically older cellular structures as well as the tracts that interconnected its various regions. Because it lies below the overlying neocortex it is hidden from external viewing. Broca argued that this hidden lobe was a common denominator of all mammalian brains and gave it the name 'the great limbic lobe.' The word limbic, which means border or fringe, was used because it is a fringe region around the deeper, more medial brain regions. Over time, many cortical regions, nuclear groups, and tracts have come to be considered components of the limbic lobe. Figure 1 shows a simplified diagram of the limbic lobe in the otter as drawn by Broca in 1878. The white area in this drawing represents the limbic lobe. From this illustration the great size of the limbic lobe is apparent, as is its strong connection with the large olfactory tracts in this animal. While in most mammals the limbic system is connected with the olfactory apparatus, the strength of the connections varies from species to species. Nevertheless the limbic lobe was originally thought to be that part of the brain associated with the sense of smell. As a result, it

Figure 1
A modified version of Broca's drawing of the limbic system of the otter. In this sketch the brain is shown as if it had been cut along the longitudinal axis near the midline. The white area extending from the olfactory bulbs and surrounding the most medial parts of the brain represents the 'limbic lobe'

became known as the 'smell brain' or the rhinencephalon. Since the human has a relatively small olfactory system and smell was considered to be of little importance to people, it was relatively neglected by anatomists for many years.

2.2 More Recent History

It was in the late 1930s that some scientists began to think of the limbic system as being involved with emotional experiences, learning, and memory. Comparative anatomists were finding that the limbic system and its basic connections with other brain regions were quite similar in all vertebrates. This was most obvious in mammals. The great American anatomist C. Judson Herrick demonstrated similarities in the connections of limbic structures with other brain regions from the salamander through mammals (see Herrick 1956). In the salamander the most medial portions of the brain contain areas that are the primitive versions of at least three of the major cell groupings of the limbic system in all species, namely the septal area, the hippocampus, and the amygdala. Moreover, he was able to demonstrate that all of these areas had strong connections to the hypothalamus and the medial forebrain bundle. Each of these structures is discussed in detail in other sections of this encyclopedia.

2.3 The Medial Forebrain Bundle

In the salamander Herrick (1948) demonstrated a medial forebrain bundle that runs through the body of the hypothalamus. This bundle is found in all mammals and probably all vertebrates. It contains fibers running in both directions from the olfactory apparatus to brain stem nuclear groups, interchanging fibers with many nuclei of the hypothalamus along the way. These connections remain extensive throughout all mammalian brains. The medial forebrain bundle contains a number of powerful pathways connecting one end of the forebrain to the hindbrain. These pathways allow the forebrain and limbic system to modulate both somatic and visceral activity and provide routes whereby the internal organs and bodily actions can influence the activity of higher brain functions. Through the medial forebrain bundle and through other neural routes information from every sensory system reaches the limbic system.

2.4 The Papez Circuit

Research into the functions of the limbic system was greatly stimulated by a paper by Papez (1937). In it he argued that a particular set of limbic structures comprised the neural mechanism for the expression of the emotions. The pathways involved were extensive but the final projection leading to the subjective experience of emotion led from the hypothalamus to the anterior nucleus of the thalamus and then to the cingulate cortex. MacLean further championed the involvement of the limbic system with emotional behavior in a series of articles in the 1940s and 1950s (e.g., MacLean 1949, 1958). Both Papez and MacLean emphasized the importance of understanding the roles played by the cortical components of the limbic system.

3. Cortical Limbic Regions

In neuroanatomy the term cortex simply refers to tissue with neurons arranged in a layered pattern. In the human the neocortex is a thin sheet of layered neural tissue on the surface of the cerebral hemispheres. In animals with a large number of fissures about two-thirds of the total neocortex is buried within the walls of fissures. In the main, the cells of the neocortex are organized into six fairly recognizable layers. A considerable amount of cortical tissue in the forebrain is not neocortical but rather of a simpler design and with different patterns of cellular organization. Much of this non-neocortical tissue surrounds the limbic system, as seen by the white area in Fig. 1. The cingulate cortex (derived from the Latin word for belt or girdle) is one example of this more primitive cortex. It seems reasonable to consider the primitive cortical areas surrounding almost all of the limbic system structures as 'transitional cortex' in the sense that it comes between limbic structures and this tissue acts, in many if not all cases, as routes of entry and exit of neuronal information for the limbic structures. Other transitional cortices often mentioned are the entorhinal cortex, the periamygdaloid cortex, the pyriform cortex, and the subgenual cortex, to name but a few.

4. Nuclear Groups and Major Structures

The major nuclear structures usually considered as cornerstones of the limbic system are the septal area, the amygdala (see *Amygdala (Amygdaloid Complex)*), the hypothalamus (see *Hypothalamus*), the anterior nuclear group of the thalamus, and the hippocampus (see *Hippocampus and Related Structures*). The last region is actually a primitive forebrain cortical mass (archicortex). These nuclei and some of the neural pathways between them are shown in Fig. 2. They represent what many people think of as the limbic system. But, based on both the degree of anatomical

Figure 2
A schematic representation of many of the most commonly cited cell groups and fiber tracts of the limit system as found in the brains of primates. The hippocampus, amygdala, and frontal lobe region are identified as such. The fornix (connecting the hippocampus, septal areas, and the mammillary bodies, M,) is also labeled clearly. The stria terminalis also is designated. This is a major pathway interconnecting portions of the amygdala with the hypothalamus and other forebrain regions. M.F.B.: medial forebrain bundle. D. B.: diagonal band of Broca. In this drawing the diagonal band is shown as a fiber tract. However, most scientists consider it to be a nerve cell rich area continuous with the medial septal area. Sep: septal area. Olf. Bulb: olfactory bulb. Modified from MacLean 1949

interconnections and functional considerations, many other nuclear groups have to be included to represent a reasonably complete limbic system in terms of knowledge at the start of the twenty-first century. For example, the nucleus accumbens and the ventral and medial portions of the caudate nucleus share strong neural interconnections with several major limbic regions. Functionally, they have attributes associated with limbic activities. One such attribute is their participation in the generation of feelings of pleasure.

4.1 *Fiber Tracts*

The major tracts of the limbic system include the fornix (hypothalamus–septal area–hippocampus), the stria terminalis (amygdala–hypothalamus), the mammillothalamic tract (mammillary bodies of the hypothalamus to the anterior nuclei of the thalamus), and the cingulum bundle (running through the cingulate cortex from one end to the other). Although this last tract is sometimes thought to be a private association pathway for the limbic lobe, actually it carries fibers of neocortical origin forward and backward through the brain.

Of course, as described above, these nuclei, cortical areas, and tracts represent but a rough approximation of the true complexity of the regions and pathways. All of these limbic categories are far more complex than have been described above. The interested reader is referred to Paxinos (1995) for the anatomic details of the rat brain and to Crosby et al. (1962) for the human.

5. *Ever-increasing Complexity*

5.1 *The Consequences of Increased Knowledge*

In general, the complexity of the limbic system arises from the ever-increasing subdivisions of the larger limbic units and pathways. As new methods of identifying subdivisions of larger regions became available through advances in anatomical, physiological, and behavioral methods, finer differentiations of limbic structures were necessary. For example, as many as 22 distinct nuclear divisions within the main body of the amygdala have been proposed. But anatomical differentiation does not imply functional specificity or homogeneity within the subdivisions of anatomical areas. Even the most important, or at least best known, tracts within the limbic lobe have multiple components. For example, the large group of fibers connecting the septal area and the hippocampus has at least three separate components, that is, a large bundle just below the corpus callosum, a fiber bundle that travels for long distances in the *corpus callosum*, and a fiber bundle traveling over the top of the corpus callosum (the *fornix longus*).

5.2 *Contacts with Areas Beyond Traditional Limbic Regions*

As more and more has been learned about the connections of the various structures of the limbic system, it has become impossible to think of any nuclear group as an isolated entity. For example, the amygdala has strong connections with the prefrontal cortical areas, both the lateral and orbital regions (see *Prefrontal Cortex*), and with various neocortical and transitional cortical and neocortical regions of the temporal lobe (see *Temporal Lobe*). No unit of the limbic system operates on its own but rather in close collaboration with these other regions of the forebrain mantle. Every component of the limbic system has multiple associations with areas and nuclei below the

forebrain regions, including dopamine-containing cell groups of the ventral tegmentum and the substantia nigra. The fibers from these nuclei pass through the medial forebrain bundle to the hypothalamus and the anterior extremes of the forebrain, as well as the nucleus accumbens.

5.3 Extensions of Limbic Structures

Several years ago, the concept of an 'extended amygdala' was proposed (Alheid et al. 1995). The reason for the creation of this concept was that many areas, pathways, and nuclei associated with these pathways seem closely tied to specific functions of certain regions of the amygdala. They seemed to be regions that were true extensions of systems originating in the body of the amygdala, forming a unified system. Some of these associated regions were not located close to the amygdala itself. The same sort of approach could be used with the hippocampus. Some distant regions of the brain can produce similar effects to those obtained from stimulation or lesions of the hippocampus. They mimic one or more of the functions of the hippocampus. Such areas are strongly connected with the hippocampus through known neuronal pathways despite distant locations. One example would be the hindbrain sites involved in food intake and blood sugar regulation (Ritter et al. 2000). Thus, there is a basis for the concept of an 'extended hippocampus.' The process of creating 'extended' limbic areas, or for that matter 'extended' visual or auditory systems, would soon make every part of the brain an extension of many, perhaps all, of what are thought to be the major functional groupings of the brain. The use of 'extended' systems in the brain may not turn out to be a useful approach. It should not be forgotten that at all times many parts of the brain are working together to accomplish specific goals.

6. A Different Approach

The problem faced by scientists studying the limbic system is that while most have a general idea of the history and the traditional functions associated with a 'visceral' and emotion-related set of neural structures, there are no firm boundaries between limbic and nonlimbic forebrain regions. Evidence can be cited to implicate every area of the brain, including the neocortical mantle, in visceral, autonomic, and emotional behavior and experience. Given this situation, it is appropriate to reject an all-or-none, black or white, approach to the limbic system. It is time to recognize that every area of the brain may have involvement with 'limbic functions' at certain times or in certain situations.

This can be accomplished by adopting a Fuzzy Logic approach (Klir and Folger 1988) to the limbic system in which every area of the brain has some degree of limbic involvement (see Isaacson 1993). The question then becomes not whether an area is or is not a part of the system but to what degree the area is associated with limbic functions. The amount of this association may, of course, change under different circumstances. The cortical regions as well as the nuclei and pathways found in Figs. 1 and 2 would certainly have high degrees of 'limbic-ness' but this would not exclude their participation in other types of brain functions since they would also have varying degrees of associations with other brain systems. At the same time it would not exclude other brain areas from participating in limbic functions to some degree and at certain times. This approach would also fit with the fundamental principle of the human brain, namely that under all but the most unusual conditions, the brain's systems operate together as a harmonious whole.

Liminality

The concept of 'liminality,' as developed and introduced into anthropological discourse by Victor Turner in the 1960s and 1970s, derives from the work of Arnold van Gennep, a French ethnologist and folklorist. In his protostructural analysis of transition rituals, *Les rites de passage*, published in 1909, but not translated into English until 1960, van Gennep (1960) argued that 'regeneration' was the law of life, and that it was accomplished through rites of passage which have three major phases: 'separation, transition or margin (limen), and incorporation.' This article examines Turner's elaboration and application of 'liminality' in ritual and symbolic studies, its primary dimensions of 'communitas' and 'reflexivity,' the distinction between 'liminal' and 'liminoid,' and the popularity and significance of these concepts throughout the human sciences.

1. *'Liminality' and African Ritual*

Like other anthropologists associated with the Rhodes-Livingstone Institute in the 1950s, Turner read and found relevant to his fieldwork Henry Junod's use of van Gennep's interpretative apparatus for understanding Thonga ritual in *The Life of a South African Tribe* (Junod 1927). During their layover in Cape Town, before returning to Manchester, England, Turner's wife and academic partner, Edie, attended Monica Wilson's seminar on van Gennep and *rites de passage*.

Turner's first published use of van Gennep's theory came in 1960 in a conference paper on Ndembu circumcision ritual (Turner 1962). This was one of four essays analyzing rites of passage published by mentor Max Gluckman in *Essays on the Ritual of Social Relations*. Gluckman's own essay 'Les rites de passage,' lays out van Gennep's theory regarding transitions, and his three-part model of such rituals. Like van Gennep, Turner was especially interested in the threshold or 'liminal' phase with its dance of old and new and promise of regeneration, and with the classificatory ambiguity embodied in, for example, being no longer a boy but not yet a man.

In 1964, Turner reformulated and developed van Gennep's concept and introduced the term 'liminality' in 'Betwixt and Between: The Liminal Period in rites de passage,' a paper presented at the American Ethnological Society meetings, and published that same year in the AES Proceedings. This model of 'processual analysis' was reprinted as the key Chapter 4 in *The Forest of Symbols: Aspects of Ndembu Ritual* (Turner 1967), and 'liminality,' as not only a phase or space in a rite of passage, but as the condition or state of being 'betwixt and between,' soon became commonplace in ritual studies. 'Liminality' also began to extend its reach throughout academic disciplines, referring to places, persons, and processes far afield from tribal ritual.

2. *The Ritual Process*

The Ritual Process: Structure and Anti-structure (Turner 1969) was based on the Lewis Henry Morgan Lectures that Turner delivered at the University of Rochester in 1966. As he wrote in 1977 in the foreword to the paperback edition of this book, 'it was in the course of these lectures that I crossed the threshold between the study of ritual in an African tribal context and the analysis of processual symbols in cross-cultural and transtemporal terms.' In the 'incursive nomadism' of his own work, Turner was to use 'liminal' to describe everything from millenarian movements and pilgrimage processes in industrial society, to cross-cultural play phenomena, to cultural performances and the written genres of literate cultures, and finally to experimental postmodern theater and to the functioning of the human brain. Cultures and societies, he argued, were processes not systems, and all sociocultural processes were, of necessity, characterized by a dialog between structure and antistructure, which was used synonymously both with 'liminal' or 'liminality' and with 'communitas.'

3. *'Liminal' to 'Liminoid'*

By the early 1970s, the adjective 'liminal' had been coupled with so many diverse phenomena, and Turner had been so criticized by his anthropological colleagues, that he felt compelled to introduce the term 'liminoid' to refer to the secular leisure genres and optional play forms of complex industrial society, reserving 'liminal' for sacred, prescribed, ritualized transitions between states in small-scale, stable societies (Turner 1974b). In answer to criticism that he had overgeneralized and overextended the concept of 'liminality,' he now insisted that 'liminoid' genres are similar to but not identical with the ritually 'liminal.' The distinction never really caught on—in part because people found the word 'gratingly neologistic'; in part because Turner himself had already coupled 'liminal' with many phenomena other than tribal ritual; but in largest part because the characteristics, if not the consequences, of the situation being described, whether a Ndembu circumcision ritual, a carnival in

Rio, a Pueblo clown performance, or a Dostoevski novel, are much the same.

Turner discovered, as he wrote in 1974, that the concept of liminality, of social antistructure was 'the theoretical operator' necessary to processualism, to a view of society as dynamic and dramatic (Turner 1974a); to getting beyond what he regarded as 'the dualistic rigor mortis of the system of binary oppositions' (1974b), and to a 'comparative symbology' method. And, like the interstitial ritual situation that 'liminality' described, the concept offered him 'the possibility of standing aside and formulating alternatives' and 'the freedom to meditate and speculate' (1974a).

4. *Liminality and Communitas*

In *The Ritual Process*, Turner (1969) also argued that the phenomenon of 'communitas' epitomized antistructure and that this relation of full, unmediated communication was one of the fundamental aspects of 'liminality.' These transient, undifferentiated states of relatedness are 'seedbed[s] of cultural creativity,' both the source of structures and at the same time their critique (Turner 1974b). As he repeatedly argued (1969), 'no society can function without a dialectic between structure and "communitas."' In response to criticisms that his formulations and applications of this concept were, like 'liminality,' too general and universal, Turner (1974a) was to distinguish among 'spontaneous,' 'ideological,' and 'normative' 'communitas.'

5. *Liminality and Reflexivity*

Like 'communitas,' the idea of 'reflexivity' is implicit in his earliest formulations of liminality. In 'Betwixt and Between' (1967) Turner suggests that 'liminality may be partly described as a state of reflection.' Drawing upon William James's 'law of dissociation,' he argues that Ndembu figures such as the man-lion monsters who appear to neophytes 'break the cake of custom and enfranchise speculation.' Subsequently, he was to argue that major 'liminal' and 'liminoid' situations are 'occasions on which a society takes cognizance of itself,' of 'plural reflexivity' (1974a), and that 'social drama is the major form of plural reflexivity in human social action' (in MacAloon 1984).

Turner's genius was to recognize not only that conflict and ambiguity provoke thought, but further that only when there is a breach in social relations, a discontinuity in customary process, a gap or aporia in discourse, or the deliberate paradox and disordering of liminal symbols, do we truly reflect upon the order of things. The betwixt and betweenness that he described as 'liminality' is a paradoxical and universal human experience. Like all paradoxes—whether in life, literature, or religion, and whether rhetorical, logical, or epistemological—the paradoxes of the 'liminal' situation embody and engender 'reflexivity.'

Turner also had a genius for generating variations on a theme, and for organizing colleagues around these topics. Between 1977 and 1984, he engendered and participated in two interdisciplinary symposia and one Wenner-Gren international conference focused on 'reflexivity.' All were published as books or special issues of journals: Babcock (1980), Ruby (1982), and MacAloon (1984). In the last years of his life, Turner became increasingly interested in a 'multiplicity of desacralized performative genres' that 'have assumed the task of plural reflexivity' (Turner 1985), in 'the ways in which both "liminal" and "liminoid" phenomena constitute metalanguages (including nonverbal ones), devised for talking about the various languages of everyday' (Turner 1992).

6. *A Critical Commonplace*

As a consequence of the formulations that Turner made in lectures and publications between 1962 and 1982, 'liminality' has become virtually a household word, not only in anthropology and the social sciences generally, but in literary and religious studies as well. Like 'irony' in the New Literary Criticism of several decades ago, 'androgyny' in early feminist theory, or 'deconstruction' in post-structuralist theory, Turner's formulation of 'liminality' gave 1970s scholars across the disciplines a model of and a word for talking about central incertitudes—the ambiguity, paradox, and disorder as well as the order of the human condition.

With the more recent interdisciplinary developments of cultural studies, postcolonial theory, resistance studies, and queer theory, and the increasingly positive valuation of the interstitial, the hybrid, the *mestizaje* in the last two decades of the twentieth century, 'liminality' has become even more popular and visible. In addition to the critical terms already mentioned, 'liminality' is also the paradigm for the recognition and valuing of borderlands and borderland epistemology, contact zones, heteropias, undecidability, instability, indeterminacy, disorder, gynesis, impurity, dialogism, heteroglossia, the carnivalesque, the pharmakon, transgender, and third sexes and genders, etc. Largely because of Turner's championing of the *via negativa*, such ambiguous states and spaces are now regarded as fundamental, necessary, and desirable rather than problematic.

Few concepts in the social sciences produce their own journal. In 2000, *LIMEN: A Journal for the Theory and Practice of Liminal Phenomena* was founded in the politically liminal space of Croatia. 'Liminal' is no longer a marked adjective. In scholarly publications, it is commonly used without quotation marks

and without references. 'Liminality' is a crossover term not only among disciplines, but between academic and popular discourse. Novels, movies, actors, musicians all talk about 'that space in between,' for which 'liminal' has become the adjective of choice.

Linear Algebra for Neural Networks

Linear algebra is particularly well suited to analyze the class of neural networks called associators. These quantitative models learn to associate input and output patterns adaptively with the use of learning algorithms. When the set of input patterns is different from the set of output patterns, the models are called heteroassociators. When input patterns and output patterns are the same, the models are called autoassociators. Associators consist of layers of elementary units called neurons. Information flows from the first layer (the input layer), to the last one (the output layer). Some architectures may include intermediate layers (the hidden layers). Typically neurons from a given layer are connected to the neurons of another layer. Linear algebra operations describe the transformations of the information as it flows from one layer to another one.

1. Prerequisite Notions and Notations

Vectors are represented by lower case boldface letters (e.g., $\boldsymbol{x}$), matrices by upper case boldface letters (e.g., $\boldsymbol{X}$). The following elementary notions are supposed to be known (see Abdi et al. 1999, for a neural network approach): the transpose operation, (e.g., $\boldsymbol{x}^{\mathrm{T}}$), the norm of a vector (e.g., $\|\boldsymbol{x}\|$), the scalar product (e.g., $\boldsymbol{x}^{\mathrm{T}}\boldsymbol{w}$) and the product of two matrices (e.g., $\boldsymbol{AB}$). We will use also the elementwise or Hadamar product (e.g., $\boldsymbol{A} \circledast \boldsymbol{B}$).

2. Projection

2.1 Cosine Between Two Vectors

The *cosine* of vectors $\boldsymbol{x}$ and $\boldsymbol{y}$ is the cosine of the angle made by the origin of the space and the points defined by the coordinates of the vectors. Thus,

$$\cos(\boldsymbol{x}, \boldsymbol{y}) = \frac{\boldsymbol{x}^{\mathrm{T}}\boldsymbol{y}}{\|\boldsymbol{x}\| \; \|\boldsymbol{y}\|}. \tag{1}$$

The cosine reflects the *similarity* between vectors. When two vectors are proportional to each other (i.e., when they have the same direction), their cosine is equal to 1; when they are orthogonal to each other, their cosine is equal to 0.

2.2 Distance Between Vectors

Among the large family of *distances* between vectors, the most popular by far is the *Euclidean* distances. It is closely related to the cosine between vectors and is defined as

$$\begin{aligned} \mathrm{d}^2(\boldsymbol{x}, \boldsymbol{y}) &= (\boldsymbol{x}-\boldsymbol{y})^{\mathrm{T}}(\boldsymbol{x}-\boldsymbol{y}) = \boldsymbol{x}^{\mathrm{T}}\boldsymbol{x}+\boldsymbol{y}^{\mathrm{T}}\boldsymbol{y}-2\boldsymbol{x}^{\mathrm{T}}\boldsymbol{y} \\ &= \|\boldsymbol{x}\| + \|\boldsymbol{y}\| \\ &\quad -2[\cos(\boldsymbol{x}, \boldsymbol{y}) \times \|\boldsymbol{x}\| \times \|\boldsymbol{y}\|] \\ &= \sum (x_i - y_i)^2. \end{aligned} \tag{2}$$

2.3 Projection of One Vector onto Another Vector

The (orthogonal) projection of vector $\boldsymbol{x}$ on vector $\boldsymbol{w}$ is defined as

$$\mathrm{proj}_{\boldsymbol{w}}\boldsymbol{x} = \frac{\boldsymbol{x}^{\mathrm{T}}\boldsymbol{w}}{\boldsymbol{w}^{\mathrm{T}}\boldsymbol{w}}\boldsymbol{w} = \cos(\boldsymbol{x}, \boldsymbol{w}) \times \frac{\| \boldsymbol{x} \|}{\| \boldsymbol{w} \|}\boldsymbol{w}. \tag{3}$$

The norm of $\mathrm{proj}_{\boldsymbol{w}}\boldsymbol{x}$ is its distance to the origin of the space. It is equal to

$$\| \mathrm{proj}_{\boldsymbol{w}}\boldsymbol{x} \| = \frac{|\boldsymbol{x}^{\mathrm{T}}\boldsymbol{w}|}{\| \boldsymbol{w} \|} = |\cos(\boldsymbol{x}, \boldsymbol{y})| \times \| \boldsymbol{x} \| . \tag{4}$$

2.4 Illustration: Hebbian and Widrow–Hoff Learning Rules

A neural network consists of cells connected to other cells via modifiable weighted *connections* called *synapses*. Consider a network made of I input cells and only one output cell. The information is transmitted via the synapses, from a set of external input cells to the output cell which gives a response corresponding to its state of activation. If the input pattern and the set of synaptic weights are given by I-dimensional vectors denoted $\boldsymbol{x}$, and $\boldsymbol{w}$, the activation of the output cell is obtained as

$$a = \boldsymbol{x}^{\mathrm{T}}\boldsymbol{w}. \tag{5}$$

So the activation is proportional to the norm of the projection of the input vector onto the weight vector. The *response* or *output* of the cell is denoted o. For a linear cell, it is proportional to the activation (for convenience, assume that the proportionality constant is equal to 1). *Linear heteroassociators* and *autoassociators* are made of linear cells. In general, the output of a cell is a function (often, but not necessarily, continuous), called the *transfer function*, of its activation

$$o = f(a). \tag{6}$$

For example, in *backpropagation networks*, the (nonlinear) transfer function is usually the logistic function

$$o = f(a) = \mathrm{logist}\, \boldsymbol{w}^{\mathrm{T}}\boldsymbol{x} = \frac{1}{1+\exp\{-a\}}. \tag{7}$$

Often, a neural network is designed to associate, to a given input, a specific response called the target, denoted t. *Learning* is equivalent to defining a rule that specifies how to add a small quantity to each synaptic weight at each learning iteration. Learning makes the output of the network closer to the target.

Learning rules come in two main flavors: *supervised* (e.g., Widrow–Hoff) which take into account the error or distance between the response of the neuron and the target and *unsupervised* (e.g., Hebbian) which do not require such 'feedback.' The Hebbian learning rule modifies the weight vector at iteration $n+1$ as

$$\boldsymbol{w}_{[n+1]} = \boldsymbol{w}_{[n]} + \eta t \boldsymbol{x} \tag{8}$$

where η is a small positive constant called the learning constant. So, a Hebbian learning iteration moves the weight vector in the direction of the input vector by an amount proportional to the target.

The Widrow–Hoff learning rule uses the error and the derivative of the transfer function (f') to compute the correction as

$$\boldsymbol{w}_{[n+1]} = \boldsymbol{w}_{[n]} + \eta f'(a)(t-o)\boldsymbol{x}. \tag{9}$$

So, a Widrow–Hoff learning iteration moves the weight vector in the direction of the input vector by an amount proportional to the error.

For networks with several cells (say J) in the output layer, the pattern of activation, output, and target become J-dimensional vectors (denoted $\boldsymbol{a}$, $\boldsymbol{o}$, and $\boldsymbol{t}$, respectively), and the synaptic weights are stored in an $I \times J$ matrix $\boldsymbol{W}$. The learning equations become

$$\boldsymbol{W}_{[n+1]} = \boldsymbol{W}_{[n]} + \eta \boldsymbol{x}\boldsymbol{t}^{\mathrm{T}} \text{ (Hebbian) and}$$

$$\boldsymbol{W}_{[n+1]} = \boldsymbol{W}_{[n]} + \eta(f'(\boldsymbol{a}) \circledast \boldsymbol{x})(\boldsymbol{t}-\boldsymbol{o})^{\mathrm{T}}$$

$$\text{(Widrow–Hoff)} \tag{10}$$

(the derivative of the transfer function is applied elementwise).

In general, several (say K) input/target associations are to be learned. Then the set of input patterns is stored in an $I \times K$ matrix denoted $\boldsymbol{X}$, the activation and target patterns respectively are stored in $J \times K$ matrices denoted $\boldsymbol{A}$ and $\boldsymbol{T}$ respectively. The activation and learning iterations can be computed for all the patterns at once (this is called *batch* mode). The output matrix is computed as

$$\boldsymbol{O} = f(\boldsymbol{A}) = f(\boldsymbol{W}\boldsymbol{X}^{\mathrm{T}}) \tag{11}$$

(f is applied elementwise). The learning equations become

$$\boldsymbol{W}_{[n+1]} = \boldsymbol{W}_{[n]} + \eta \boldsymbol{X}\boldsymbol{T}^{\mathrm{T}} \text{ (Hebb) and} \tag{12}$$

$$\boldsymbol{W}_{[n+1]} = \boldsymbol{W}_{[n]} + \eta(f'(\boldsymbol{A}) \circledast \boldsymbol{X})(\boldsymbol{T}-\boldsymbol{O})^{\mathrm{T}}$$

$$\text{(Widrow–Hoff).} \tag{13}$$

3. Eigenvalues, Eigenvectors, and the Singular Value Decomposition

Eigenvectors of a given square matrix, $\boldsymbol{W}$ (resulting from its *eigendecomposition*) are vectors invariant under multiplication by $\boldsymbol{W}$. The eigencomposition is best defined for a subclass of matrices called *positive semi-definite* matrices. A matrix $\boldsymbol{X}$ is positive semi-definite if there exists another matrix $\boldsymbol{Y}$ such that $\boldsymbol{X} = \boldsymbol{Y}\boldsymbol{Y}^{\mathrm{T}}$. This is the case for most matrices used in neural networks and so we will consider only this case here.

Formally, a (nonzero) vector $\boldsymbol{u}$ is an eigenvector of a square matrix $\boldsymbol{W}$ if

$$\lambda \boldsymbol{u} = \boldsymbol{W}\boldsymbol{u}. \tag{14}$$

The scalar λ is the *eigenvalue* associated with $\boldsymbol{u}$. So, $\boldsymbol{u}$ is an eigenvector of $\boldsymbol{W}$ if its direction is invariant under multiplication by $\boldsymbol{W}$ (only its length is changed if $\lambda \neq 1$). There are, in general, several eigenvectors for a given matrix (at most as many as the dimension of $\boldsymbol{W}$). They are in general ordered by decreasing order of their eigenvalue. So, the first eigenvector, $\boldsymbol{u}_1$ has the largest eigenvalue λ_1. The number of eigenvectors with a non-zero eigenvalue is the rank of the matrix.

The eigenvalues of positive semi-definite matrices are always positive or zero (a matrix with strictly positive eigenvalues, is *positive definite*). Also, any two eigenvectors with different eigenvalues are orthogonal, i.e.,

$$u_l^{\mathrm{T}} u_{l'} = 0 \quad \forall l \neq l'. \tag{15}$$

In addition, the set of eigenvectors of a matrix constitutes an orthogonal basis for its rows and columns. This is expressed by defining two matrices: the eigenvector matrix, $\boldsymbol{U}$, and the diagonal matrix of the eigenvalues: $\boldsymbol{\Lambda}$. The eigendecomposition of $\boldsymbol{W}$ (with rank L) is

$$\boldsymbol{W} = \boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{U}^{\mathrm{T}} = \sum_{l}^{L} \lambda_l u_l u_l^{\mathrm{T}},$$
$$\text{or equivalently: } \boldsymbol{\Lambda} = \boldsymbol{U}^{\mathrm{T}}\boldsymbol{W}\boldsymbol{U}. \tag{16}$$

The *singular value decomposition* (SVD) generalizes the eigendecomposition to rectangular matrices. If $\boldsymbol{X}$ is an $I \times K$ matrix, its SVD is defined as

$$\boldsymbol{X} = \boldsymbol{U}\boldsymbol{\Delta}\boldsymbol{V}^{\mathrm{T}} \quad \text{with} \quad \boldsymbol{U}^{\mathrm{T}}\boldsymbol{U} = \boldsymbol{V}^{\mathrm{T}}\boldsymbol{V} = \boldsymbol{I}$$
$$\text{and } \boldsymbol{\Delta} \text{ being a diagonal matrix.} \tag{17}$$

($\boldsymbol{I}$ being the identity matrix). The diagonal elements of $\boldsymbol{\Delta}$ are real positive numbers called the singular values of $\boldsymbol{X}$. The matrices $\boldsymbol{U}$ and $\boldsymbol{V}$ are the left and right matrices of singular vectors (which are also eigenvectors, see later). The SVD is closely related to the eigendecomposition because $\boldsymbol{U}$, $\boldsymbol{V}$, and $\boldsymbol{\Delta}$ can be obtained from the eigendecomposition of matrices $\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X}$ and $\boldsymbol{X}\boldsymbol{X}^{\mathrm{T}}$ as

$$\boldsymbol{X}\boldsymbol{X}^{\mathrm{T}} = \boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{U}^{\mathrm{T}}, \quad \boldsymbol{X}^{\mathrm{T}}\boldsymbol{X} = \boldsymbol{V}\boldsymbol{\Lambda}\boldsymbol{V}^{\mathrm{T}}, \quad \text{and } \boldsymbol{\Delta} = \boldsymbol{\Lambda}^{\frac{1}{2}} \tag{18}$$

(note that $\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X}$ and $\boldsymbol{X}\boldsymbol{X}^{\mathrm{T}}$ have the same eigenvalues).

The eigen- and singular value decompositions are used in most fields of applied mathematics including statistics, image processing, mechanics, and dynamical systems. For neural networks, they are essential for studying the dynamics of linear autoassociators and heteroassociator.

3.1 Iterative Processes

A linear heteroassociator using the Widrow–Hoff rule, learning modifies only the eigenvalues of the weight matrix. Specifically, if the patterns to be learned are stored in an $I \times K$ matrix $\boldsymbol{X}$, with singular value decomposition as $\boldsymbol{X} = \boldsymbol{U}\boldsymbol{\Delta}\boldsymbol{V}^{\mathrm{T}}$, then the learning equation (see Eqn. 12) becomes [because for a linear heteroassociators, $\boldsymbol{O} = \boldsymbol{A}$, and $f'(\boldsymbol{A}) = \boldsymbol{I}$]

$$\begin{aligned}\boldsymbol{W}_{[n+1]} &= \boldsymbol{W}_{[n]} + \eta \boldsymbol{X}(\boldsymbol{T} - \boldsymbol{A})^{\mathrm{T}} \\ &= \boldsymbol{U}\{\boldsymbol{\Delta}^{-1}[\boldsymbol{I} - (\boldsymbol{I} - \eta\boldsymbol{\Delta}^2)^{n+1}]\}\boldsymbol{V}^{\mathrm{T}}\boldsymbol{I}^{\mathrm{T}}\end{aligned} \tag{19}$$

(see Abdi 1994, p. 54).

The Hebbian weight matrix corresponds to the first iteration of the algorithm, i.e.,

$$\begin{aligned}\boldsymbol{W}_{[1]} &= \boldsymbol{U}\{\boldsymbol{\Delta}^{-1}[\boldsymbol{I} - (\boldsymbol{I} - \eta\boldsymbol{\Delta}^2)^1]\}\boldsymbol{V}^{\mathrm{T}}\boldsymbol{T}^{\mathrm{T}} \\ &= \boldsymbol{U}\{\eta\boldsymbol{\Delta}\}\boldsymbol{V}^{\mathrm{T}}\boldsymbol{T}^{\mathrm{T}} = \eta\boldsymbol{X}\boldsymbol{T}^{\mathrm{T}}.\end{aligned} \tag{20}$$

Equation 19 characterizes the value of η that allow the iterative process to converge. Denoting by $\delta_{\max}$ the largest singular value of $\boldsymbol{X}$, if η is such that

$$0 < \eta < 2\delta_{\max}^{-2} \tag{21}$$

then it can be shown that (see Abdi 1994)

$$\lim_{n \to \infty} (\boldsymbol{I} - \eta\boldsymbol{\Delta}^2)^n = 0, \quad \text{and}$$
$$\lim_{n \to \infty} \boldsymbol{W}_{[n]} = \boldsymbol{U}\boldsymbol{\Delta}^{-1}\boldsymbol{V}^{\mathrm{T}}\boldsymbol{T}^{\mathrm{T}} = \boldsymbol{X}^{+}\boldsymbol{T}. \tag{22}$$

The matrix $\boldsymbol{X}^{+} = \boldsymbol{U}\boldsymbol{\Delta}^{-1}\boldsymbol{V}^{\mathrm{T}}$ is the *pseudo-inverse* of $\boldsymbol{X}$. It gives a least-square optimal solution for the association between the input and the target. Thus, the linear heteroassociator is equivalent to *linear multiple regression*. If η is outside the interval defined by Eqn. 21, then both the singular values and the elements of the weight matrix will grow at each iteration. In practice, because neural networks are stimulated by digital computers. The weight matrix will eventually reach the limits of the precision of the machine.

When the target vectors are the same as the input vectors (i.e., when each input is associated to itself), the linear heteroassociator becomes a linear autoassociator. The previous approach shows that, now, the Hebbian weight matrix is the cross-product matrix

$$\boldsymbol{W}_{[1]} = \boldsymbol{X}\boldsymbol{X}^{\mathrm{T}} = \boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{U}^{\mathrm{T}}. \tag{23}$$

With Widrow–Hoff learning, when convergence is reached, all nonzero eigenvalues of the weight matrix are equal to 1. The weight matrix is then said to be *spherical*; it is equal to

$$\boldsymbol{W}_{[\infty]} = \boldsymbol{U}\boldsymbol{U}^{\mathrm{T}}. \tag{24}$$

Because the statistical technique of *principal component analysis* (PCA) computes the eigendecomposition of a cross-product matrix similar to $\boldsymbol{W}$, the linear autoassociator is considered as the neural network equivalent of PCA.

4. Optimization, Derivative and Matrices

Neural networks are often used to optimize a function of the synaptic weights. The *differentiation* of a function is the major concept for exploring optimization problems and, for neural networks, it involves differentiating vectors or matrix functions. In this context, we need to consider the transfer function as being a function of the weight vector. This is expressed by rewriting Eqn. 6 as

$$o = f(\boldsymbol{w}). \tag{25}$$

The derivative of $f(\boldsymbol{w})$ with respect to the $I \times 1$ vector $\boldsymbol{w}$ is denoted by $\nabla_{f(\boldsymbol{w})}$. It is also called the gradient of f, i.e.,

$$\nabla_{f(\boldsymbol{w})} = \frac{\partial f}{\partial \boldsymbol{w}} = \left[\frac{\partial f}{\partial w_1}, \ldots, \frac{\partial f}{\partial w_i}, \ldots, \frac{\partial f}{\partial w_I} \right]^{\mathrm{T}}. \tag{26}$$

For example, the derivative of the output of a linear neuron is

$$\begin{aligned} \frac{\partial f}{\partial \boldsymbol{w}} &= \left[\frac{\partial \boldsymbol{w}^{\mathrm{T}}\boldsymbol{x}}{\partial w_1}, \ldots, \frac{\partial \boldsymbol{w}^{\mathrm{T}}\boldsymbol{x}}{\partial w_i}, \ldots, \frac{\partial \boldsymbol{w}^{\mathrm{T}}\boldsymbol{x}}{\partial w_I} \right]^{\mathrm{T}} \\ &= [x_1, \ldots, x_i, \ldots, x_I]^{\mathrm{T}} = \boldsymbol{x}. \end{aligned} \tag{27}$$

When a function is twice differentiable, the second order derivatives are stored in a matrix called the *Hessian* matrix of the function. It is often denoted by $\boldsymbol{H}$ or ∇_f^2 and is formally defined as

$$\boldsymbol{H} = \nabla_f^2 = \begin{bmatrix} \frac{\partial^2 f}{\partial w_1^2} & \frac{\partial^2 f}{\partial w_1 w_2} & \cdots & \frac{\partial^2 f}{\partial w_1 w_I} \\ \frac{\partial^2 f}{\partial w_2 w_1} & \frac{\partial^2 f}{\partial w_2^2} & \cdots & \frac{\partial^2 f}{\partial w_2 w_I} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial^2 f}{\partial w_I w_1} & \frac{\partial^2 f}{\partial w_I w_2} & \cdots & \frac{\partial^2 f}{\partial w_I^2} \end{bmatrix}. \tag{28}$$

4.1 Conditions for Minimum

A standard problem is to show that a given learning rule finds an optimum solution in the sense that a function of the weight vector (or matrix) called the *error function* reaches its minimum value when learning has converged. Often, the error function is defined as the sum of the squared error over all patterns.

When the gradient of the error function can be evaluated, a necessary condition for optimality (i.e., either minimum or maximum) is to find a weight vector $\tilde{\boldsymbol{w}}$ such that

$$\nabla_{f(\tilde{\boldsymbol{w}})} = 0. \tag{29}$$

This condition is also sufficient provided $\boldsymbol{H}$ is positive definite (see Haykin 1999).

4.2 Taylor Expansion

The Taylor expansion is the standard technique used to obtain a linear or a quadratic approximation of a function of one variable. Recall that the Taylor expansion of a continuous function $f(x)$ is

$$\begin{aligned} f(x) &= f(a) + (x-a)\frac{f'(a)}{1!} + (x-a)^2\frac{f''(a)}{2!} \\ &\quad + \ldots (x-a)^n \frac{f^{[n]}(a)}{n!} + \ldots \\ &= f(a) + (x-a)\frac{f'(a)}{1!} + (x-a)^2\frac{f''(a)}{2!} + \mathscr{R}_2. \end{aligned} \tag{30}$$

(Where $\mathscr{R}_2$ represents all the terms of higher order than 2, and a is a 'convenient' value at which to evaluate f).

This technique can be expected to matrix and vector functions. It involves the notion of gradient and Hessian. Now a vector function $f(\boldsymbol{x})$ is expressed as:

$$f(\boldsymbol{x}) = f(\boldsymbol{a}) + f(\boldsymbol{x}-\boldsymbol{a})^{\mathrm{T}}\nabla_{f(\boldsymbol{a})} + f(\boldsymbol{x}-\boldsymbol{a})^{\mathrm{T}}\nabla^2_{f(\boldsymbol{a})}f(\boldsymbol{x}-\boldsymbol{a}) + \mathscr{R}_2. \tag{31}$$

4.3 Iterative Minimization

A learning rule can be shown to converge to an optimum if it diminishes the value of the error function at each iteration. When the *gradient* of the error function can be evaluated, the gradient technique (or *steepest descent*) adjusts the weight vector by moving it in the direction opposite to the gradient of the error function. Formally, the correction for the $(n+1)$-th iteration is

$$\boldsymbol{w}_{[n+1]} = \boldsymbol{w}_{[n]} + \boldsymbol{\Delta} = \boldsymbol{w}_{[n]} - \eta\nabla_{f(\boldsymbol{w})} \tag{32}$$

(where $\nabla_{f(\boldsymbol{w})}$ is computed for $\boldsymbol{w}_{[n]}$).

As an example, let us show that for a linear heteroassociator, the Widrow–Hoff learning rule minimizes iteratively the squared error between target and output. The error function is

$$\begin{aligned} e^2 &= (t-o)^2 = t^2 + o^2 - 2to \\ &= t^2 + \boldsymbol{x}^{\mathrm{T}}\boldsymbol{w}\boldsymbol{w}^{\mathrm{T}}\boldsymbol{x} - 2t\boldsymbol{w}^{\mathrm{T}}\boldsymbol{x}. \end{aligned} \tag{33}$$

The gradient of the error function is

$$\frac{\partial e}{\partial \boldsymbol{w}} = 2(\boldsymbol{w}^{\mathrm{T}}\boldsymbol{x})\boldsymbol{x} - 2t\boldsymbol{x} = -2(t - \boldsymbol{w}^{\mathrm{T}}\boldsymbol{x})\boldsymbol{x}. \tag{34}$$

The weight vector is corrected by moving it in the opposite direction of the gradient. This is obtained by adding a small vector denoted $\boldsymbol{\Delta}_{\boldsymbol{w}}$ opposite to the gradient. This gives the following correction for iteration $n+1$:

$$\begin{aligned} \boldsymbol{w}_{[n+1]} &= \boldsymbol{w}_{[n]} + \boldsymbol{\Delta}_{\boldsymbol{w}} = \boldsymbol{w}_{[n]} - \eta\frac{\partial e}{\partial \boldsymbol{w}} \\ &= \boldsymbol{w}_{[n]} + \eta(t - \boldsymbol{w}^{\mathrm{T}}\boldsymbol{x})\boldsymbol{x} \\ &= \boldsymbol{w}_{[n]} + \eta(t-o)\boldsymbol{x}. \end{aligned} \tag{35}$$

This gives the rule defined by Eqn. 9.

The gradient method works because the gradient of $\boldsymbol{w}_{[n]}$ is a first order Taylor approximation of the gradient of the optimal weight vector $\tilde{\boldsymbol{w}}$. It is a favorite technique in neural networks because the popular error backpropagation is a gradient technique.

Newton's method is a second order Taylor approximation, it uses the inverse of the Hessian of $\boldsymbol{w}$ (supposing it exists). It gives a better numerical approximation but necessitates more computation. Here the correction for iteration $n+1$ is

$$\boldsymbol{w}_{[n+1]} = \boldsymbol{w}_{[n]} + \boldsymbol{\Delta} = \boldsymbol{w}_{[n]} - (\boldsymbol{H}^{-1})(\nabla_{f(w)}) \tag{36}$$

(where $\nabla_{f(\boldsymbol{w})}$ is computed for $\boldsymbol{w}_{[n]}$).

Linear and Nonlinear Programming

Linear and nonlinear programming refers, broadly speaking, to the area of applied mathematics dealing with the following problem: find numerical values for a given set of variables so that they are *feasible* (i.e., they satisfy certain *constraints*, typically given by equalities or inequalities) and also a certain criterion, called *objective function*, which depends on such variables, is optimized, that is it attains its minimum value among all the combination of feasible variables. As an example, we describe in Section 3 the *diet problem*, consisting of finding a combination of ingredients which satisfy nutritional requirements at minimum cost. Unlike classical problems of applied mathematics, most of which originate in physics, linear and nonlinear programming problems generally lack solutions given by closed formulae, and must be solved through numerical procedures, called *algorithms*, performed on computers.

Different features of the problem data (e.g., linearity or nonlinearity of the objective function and the constraints) call for different methods in order to achieve efficient solution of the problem. The design of such algorithms, and the analysis of their performance,

are the backbone of the theoretical side of the area. On the practical side, the ability of these methods to solve very large problems (i.e., with a large number of variables) has allowed for the modeling of highly realistic and detailed real life situations, so that nowadays these methods are routinely applied to the day-to-day execution of complex tasks in a wide range of activities, like oil refineries, power stations, airlines and many others.

1. Linear Programming: History and Relevance

Linear Programming (LP) was one of the first achievements of Operations Research, which can be described as an interphase between mathematics, engineering, and economics, or as the formulation and implementation of mathematical models of complex systems. When the American army was confronted with the logistics involved in the World War II effort, it became clear that traditional allocation procedures were insufficient. On the other hand, computers, the first of which were being developed at the same time, offered the promise of actual solutions of many previously intractable problems. The US Air Force, which needed to deliver in time up to 20,000 different items to bases all around the world, created an Operations Research office, staffed with several bright and young mathematicians, many of whom continued their research on the same topic after the war in the Rand Corporation. One of them was G. Dantzig, who chose the LP problem, as formulated in Section 2, as an object deserving careful study. This choice was particularly succesful. Several special cases, such as transportation problems, or minimum cost flow problems, which correspond to LP problems where the matrix A of Section 2 has a particular structure (e.g., each a_{ij} is either 0 or 1) had been or were being studied at the time, and efficient methods for their solution were being introduced. For the transportation problem, the work in 1939 by the Russian mathematician L. V. Kantorovich (1960) clearly anticipated Dantzig's LP theory, but it became known in the West much later. The methods for these special instances were, however, rather different from each other and hardly generalizable, while, on the other hand, the LP format comprehended all of them, and seemed in fact rather universal, in the sense that most problems in economics could be cast in this setting, at the cost of approximating nonlinear functions by linear ones (see Section 4). At the same time, the LP problem was not too general, in the sense that it was possible to devise an efficient method for the numerical solution of all its instances, provided their data were not too large, using the then available computational equipment. This procedure, called the SIMPLEX method (see Section 3), was introduced by Dantzig in 1947 (Dantzig 1949), and it had an enormous impact in several research fields, among them economics.

At that time, the mathematization of economics was at a rather initial stage, and most mathematical results offered only new qualitative insights, rather than effective procedures for finding numerical solutions of economic problems, because of the complicated nature of the modeling tools, nonlinear in general. LP and SIMPLEX allowed actual computation of solutions for any problem where an economic agent (a firm, for instance) has to choose the most efficient among many possible courses of action, provided that all the relevant variables could be connected through linear relations, such as the input-output matrices proposed in the 1930s by V. Leontieff, which enter the LP formulation as the matrix A of Eqn. (5) below. This situation gave rise to a new area of economic research, called activity analysis (Koopmans 1951, Gale 1960) which involved many of the most distinguished economists at the time, such as T. Koopmans, K. Arrow, D. Gale, and others. The influence of LP en economics was reinforced by the introduction of the *duality theory* of LP. Shortly after Dantzig obtained his first results on LP, he showed them to one of the leading mathematicians of the time, von Neumann, who was then developing another new branch of applied mathematics, namely game theory (Von Neumann and Morgenstern 1944). Observing immediately that a certain class of games fitted the LP format, Von Neumann suggested the extension to LP of a game theoretic result, giving birth to LP duality, which, given an LP problem (e.g., Eqns. (2)–(3) below), associates with it another problem, called *dual*, which shares exactly the same data c, b, and A, but arranged in a different way. Duality plays a very significant role in economic models, where the variables of the dual problem, called shadow prices, have an interesting economic interpretation. The Dantzig–Wolfe decomposition method (Dantzig and Wolfe 1960), which was a SIMPLEX-based method for solving certain special instances of LP problems, but which could also be seen as a model of a central planning procedure combined with autonomous decision by lower level agents, reinforced this impact of LP on economics, which produced perhaps, as a negative side effect, exaggerated attempts to force the modeling of nonlinear economic phenomena as linear ones.

The impact of LP on mathematics was also significant, and contributed to reinforcing the status of the new computational mathematics viz-a-viz the classical branches (e.g., analysis, geometry, algebra). Its success resulted from its ability to offer SIMPLEX as an efficient computational procedure and the LP duality theory as a theoretical counterpart. It should be mentioned that the mathematical tools required by the LP theory are rather elementary, and the theory could easily have been developed more than a century before it appeared. In fact, for the cases in which no inequalities are present (e.g., Eqns. (4)–(5) without Eqn. (6), but with a nonlinear f instead of cx) the theory for the resulting equality constrained mini-

mization problem had been started by Lagrange at the beginning of the nineteenth century, and thousand of papers had been written on it, while only a handful of them had been devoted to the subject of linear inequalities, like Eqn. (3) or Eqn. (6), before 1945 (Dantzig 1963). A very likely reason for this oversight lies in the fact that the motivation for the study of minimization problems had been, for centuries, mainly research in physics, studying systems which move along deterministic trajectories, which are usually expressed by equalities. Inequalities, on the other hand, are typical of economic situations where agents are constantly confronting options for possible action rather than following fixed trajectories determined by initial conditions. The low level of formalization of economics up to the 1940s, combined with the impossibility of developing at that time numerical methods, in the absence of computers, kept the field of linear inequalities outside mainstream mathematics for a century and a half.

2. *Linear Programming: Definition and Example*

The LP problem is formulated as follows. The data consists of

(a) a string c and n real numbers: $c_1, \ldots, c_n$ (an n-vector c);

(b) a string b of m real numbers: $b_1, \ldots, b_m$ (an m-vector b), and

(c) a rectangular array A of mn real numbers (an $m \times n$-*matrix* A):

$$\begin{array}{l} a_{11}, a_{12}, \ldots, a_{1n} \\ a_{21}, a_{22}, \ldots, a_{2n} \\ \ldots\ldots\ldots\ldots\ldots\ldots \\ a_{m1}, a_{m2}, \ldots, a_{mn}. \end{array}$$

The unknowns to be determined form an n-vector $x = (x_1, \ldots, x_n)$. The *objective function* f is defined as

$$f(x) = c_1x_1 + c_2x_2 + \cdots + c_nx_n.$$

The *feasible region* F consists of all the n-vectors $x = (x_1, \ldots, x_n)$ such that

$$\begin{array}{l} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n \leqslant b_1 \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n \leqslant b_2 \\ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \\ a_{m1}x_1 + a_{m2}x_2 + \cdots + a_{mn}x_n \leqslant b_m. \end{array} \tag{1}$$

The problem consists of finding an n-vector $x^* = (x_1^*, \ldots, x_n^*)$, belonging to F, which minimizes $f(x)$ in F, meaning that the m inequalities, Eqn. (1), are satisfied with x_i^* instead of x_i $(1 \leqslant i \leqslant n)$, and that $c_1x_1^* + c_2x_2^* + \ldots c_nx_n^* \leqslant c_1x_1 + c_2x_2 + \ldots c_nx_n$ for all n-vector $x = (x_i, \ldots, x_n)$ which also satisfies the m inequalities in Eqn. (1). In short mathematical notation, this is written as

$$\min cx \tag{2}$$

$$\text{s.t. } Ax \leqslant b. \tag{3}$$

An LP problem presented as Eqns. (2)–(3) is said to be in *canonical* form. There are other forms which are *equivalent* to it, in the sense that a solution of the canonical form allows one to obtain in an immediate way a solution of the equivalent form and conversely. One such form consists of inverting all the inequalities in (1) ('$\geqslant$' instead of '$\leqslant$'). The most important equivalent form is the *standard* one, where the unknowns are required to be nonnegative $(x_1 \geqslant 0, \ldots x_n \geqslant 0)$ and the inequalities in Eqn. (1) are changed into equalities, which is denoted in short notation as

$$\min cx \tag{4}$$

$$\text{s.t. } Ax = b \tag{5}$$

$$x \geqslant 0. \tag{6}$$

We present next as an example a particular instance of the so called *diet problem*, which is a case of the LP in canonical form with reversed inequalities. The manager of a poultry ranch has three alternative chicken food products with prices c_1, c_2, and c_3 per pound. Let a_{11}, a_{12}, and a_{13} be the protein content of a pound of products 1, 2, and 3 respectively, and a_{21}, a_{22}, and a_{23} the corresponding mineral contents per pound. If b_1 and b_2 are the minimal amounts of protein and minerals required for every chicken in the ranch, then the inequalities

$$\begin{array}{l} a_{11}x_1 + a_{12}x_2 + a_{13}x_3 \geqslant b_1 \\ a_{21}x_1 + a_{22}x_2 + a_{23}x_3 \geqslant b_2 \end{array}$$

mean that an amount of x_1 pounds of product 1, x_2 pounds of product 2, and x_3 pounds of product 3 satisfy such minimal nutritional requirements, and a solution $x^* = (x_1^*, x_2^*, x_3^*)$ of the diet problem

$$\min cx$$

$$\text{s.t. } Ax \geqslant b_1$$

indicates the amounts of each product which satisfy the nutritional requirements at the lowest possible cost.

3. Linear Programming: SIMPLEX and other Computational Methods

The first significant result in LP theory concerns the feasible region F, which, for a problem in standard form, consists of those n-vectors x which satisfy Eqns. (5)–(6). When $n = 3$, such set is a polyhedron in the usual sense. For larger values of n, it is still what mathematicians call an n-dimensional polyhedron, and the result says that if the LP problem has solutions, then at least one *vertex* of the polyhedron F is a solution. Also, assuming that $m < n$ and that nothing in Eqn. (5) is superfluous, vertices of F are precisely the n-vectors obtained as follows: choose $n-m$ components of the vector x and give them the value 0. Look at Eqn. (5) as a system of m equations but now in m unknowns, namely the components of x which have not been set to 0, or, in other words, form an $m \times m$-matrix B with the m colums of the matrix A correspoding to the nonzeroed variables, and look at the system $Bx = b$. If such a system has a solution $\tilde{x}$ with nonnegative components, the resulting vector x (formed by the components of $\tilde{x}$ plus the zeroes in the remaining components) is a vertex of F. These facts provide immediately the following 'brute force' procedure for solving LP problems: consider consecutively each one of the possible choices of m out of the n original colums of A. Check whether each choice gives raise to a vertex $\bar{x}$, and if it does, evaluate the objective function at $\bar{x}$, that is, compute $f(\bar{x}) = \sum_{j=1}^{n} c_j \bar{x}_j$. Compare all the values so obtained and pick up the vertex x^* with the lowest value for $f(x^*)$. The drawback is that the number of choices of m objects out of n grows very fast with m and n. For instance, if we take an LP problem with n unknowns and the following $2n$ inequalities

$$x_i \leqslant u_i \quad (1 \leqslant i \leqslant n) \tag{7}$$

$$-x_i \leqslant -l_i \quad (1 \leqslant i \leqslant n) \tag{8}$$

meaning just that each variable x_i must be between a lower bound l_i and an upper one u_i, the resulting polyhedron F has 2^n vertices, resulting from all the possible choices of $x_i = l_i$ or $x_i = u_i$ for each of the n variables. Now, 2^n grows very fast: for $n = 100$, checking all the vertices exceeds the capabilities of any existing computer. The SIMPLEX methods, instead of checking all the vertices, proceeds as follows. It constructs one vertex, say $\bar{x}$, and checks whether it is or not a solution (which is a rather 'easy' task). If it is not, it does not proceed to just any other vertex, but to one which is *adjacent* to $\bar{x}$, which mathematically means that it shares with $\bar{x}$ all but one of its $n-m$ zero components. There are at most n adjacent vertices (corresponding to all possible choices of the nonshared column) and at least one, say $\hat{x}$, has an objective value $f(\hat{x}) < f(\bar{x})$. Then $\hat{x}$ is taken as the new candidate, and, if it is not a solution, then the process is repeated with vertices adjacent to $\hat{x}$, and so on, until a solution is found, which is guaranteed to happen. How long does this procedure take? More than 50 years of practice show that, almost always, the number of visited vertices is not too high; generally less that $m \log n$, which is negligible as compared to, for example 2^n (rigorous versions of this statement on the average performance of SIMPLEX can be found in Borgwardt 1987 and Smale 1983). However, Klee and Minty (1972) found a highly artificial example, with a carefully chosen objective function f, and a feasible set F obtained as a slight variation of the one given by Eqns. (7)–(8), for which SIMPLEX goes through all the 2^n vertices before finding the solution, which is just the last one.

Despite Klee and Minty's example, SIMPLEX was absolutely superior to any other known procedure for solving LP problems, in terms of computational performance. Thus, the following theoretical issue was posed: does it exist a method for LP which is *never* too slow, for instance such that the number of arithmetic operations required to solve any particular LP problem does not exceed a fixed power of the size of the problem (understood as some measure of the size of c, b, and A)? SIMPLEX is not up to this requirement, because it needs more than 2^n operations to solve Klee and Minty's example, and 2^n exceeds any fixed power of n, which can be taken as a measure of the size of this specific LP problem. Methods with such property were called *polynomial*. The fact that no polynomial method for LP had been found in the first 30 years after the introduction of SIMPLEX, made most mathematicians think that no such method could ever be devised, and therefore it was a surprise when Kachyan presented such a procedure in 1979 (Kachyan 1979). Unfortunately, Kachyan's method, called the *elipsoidal* one, turned out to be far worse than SIMPLEX in almost all problems (though, of course, much better in the very rare cases in which SIMPLEX takes almost forever, like in Klee and Minty's example). Thus, the elipsoidal method aroused only theoretical interest, and did not replace SIMPLEX in any 'real life' application. Nevertheless, existence of a polynomial method (albeit inefficient in the average) encouraged research attempting to find a procedure which would be both polynomial and efficient in practice (i.e., 'good' both in the average cases and in the worst ones). Such a method was discovered by Karmarkar in 1984 (Karmarkar 1984), and extensive progress has been achieved in this class of methods for LP (called *interior point* ones) since the mid-1980s (Roos et al. 1997). They differ from SIMPLEX in the fact that, instead of considering only vertices, which lie in the boundary of the feasible polyhedron F, all the intermediate vectors, which are tested as candidates for solutions, are taken in the interior of this polyhedron. Thus, these methods fully neglect the combinatorial nature of LP problems (i.e., the facts that for an LP problem with solutions there exists a vertex which is a solution, and that the number of vertices is finite). Interior point methods are

quite efficient, but none of the many of those which have been proposed turned out to be universally superior to all others (nor to SIMPLEX, for that matter). Currently, the situation in LP, regarding computational methods, is similar to most other applied mathematics areas: instead of a method universally superior to all others, as was the case for LP between 1947 and 1984, a variety of methods are available, some of which are clearly superior, in terms of computational performance, for some specific cases of LP problems, but inferior to at least another one for other types of LP problems.

4. Nonlinear Programming: Theory and Relevance

As soon as LP was born, it was clear to its inventors and practitioners that linearity of the data severely limited the ability to model most real life systems, and therefore, already in the late 1940s, attention was given to the nonlinear programming problem (NLP), which generalizes LP through the admission of rather arbitrary functions, instead of linear ones, both in the objective and in the constraints, so that its mathematical formulation can be given as

$$\min f(x_1, \ldots, x_n) \tag{9}$$

$$\text{s.t. } g_1(x_1, \ldots, x_n) \leqslant 0, \ldots, g_m(x_1, \ldots, x_n) \leqslant 0. \tag{10}$$

Here, both f and the g_i's ($1 \leqslant i \leqslant m$) are functions which assign to each n-vector $x = (x_1, \ldots, x_n)$ a real number denoted as $f(x_1, \ldots, x_n)$ and $g_i(x_1, \ldots, x_n)$ respectively. This assignment is generally nonlinear, in the sense that it might involve, for example powers of the variables, $x_1, \ldots, x_n$ larger than 1.

The first theoretical difference with LP arises from the fact that generally it is impossible to devise procedures able to produce, after a finite number of arithmetic operations, an exact solution of the problem. Thus, the general feature of an NLP method is that it generates a sequence of n-vectors (to be denoted as $x^0, \ldots, x^k, \ldots$), starting from a given n-vector x^0. In general, none of the x^k's will be a solution, but for large enough k, each component of the vector x^k should be very close to the corresponding component of a solution of the problem. An exception to this situation is the special case of quadratic programming (Boot 1964), in which all the g_i's are linear (i.e., as in Eqn. (1)) and the objective function f is quadratic, that is

$$f(x_1, \ldots, x_n) = \sum_{j=1}^{n} \sum_{k=1}^{n} d_{jk} x_j x_k + \sum_{j=1}^{n} c_j x_j \tag{11}$$

where the real numbers d_{jk} form an $n \times n$-matrix D. For this case there exist several extensions of the SIMPLEX method for LP, which produce exact solutions, but with the following limitation: each one of these methods works for a certain class of matrices D; in fact, no known method is able to provide exact solutions for an arbitrary quadratic programming problem.

Another very important theoretical issue refers to necessary and/or sufficient conditions on an n-vector x^* to be a solution of Eqns. (9)–(10). In the case of equality constraints, that is, when all the inequalities in Eqn. (10) are replaced by equalities—such a condition was known in the early nineteenth century—if we denote as $\nabla f(x)$ the n-vector whose j-th component is the derivative of f with respect to its j-th variable at the n-vector x, and we use the same definition for $\nabla g_i(x)$ ($1 \leqslant i \leqslant m$), then the so called *Lagrangian* condition states that

$$\nabla f(x) = u_1 \nabla g_1(x) + \cdots + u_m \nabla g_m(x) \tag{12}$$

where the real numbers $u_1, \ldots, u_m$ are called Lagrangian multipliers. In fact, if x solves Eqns. (9)–(10), then Lagrange multipliers do exist. Conversely, existence of Lagrange multipliers for a given n-vector x^*, together with an additional condition involving second order derivatives of f and the g_i's at x^*, guarantee that x^* is a *local solution* of the problem, meaning that $f(x^*) \leqslant f(x)$ for all x satisfying Eqn. (10) and close enough to x^* (i.e., such that all the differences $x_i^* - x_i$ are small enough). The extension of the Lagrangian condition to the case of inequality constraints was the first theoretical achievement of NLP. The resulting conditions, called Karush–Kuhn–Tucker ones, were published by Kuhn and Tucker (1951), and had been anticipated in Karush's MSc dissertation. They state that the Lagrange multipliers, besides satisfying the Lagrangian condition, Eqn. (12), must be nonnegative, and also that $u_i = 0$ if $g_i(x) < 0$. Also, an additional condition, called *constraint qualification*, must be imposed on the feasible region, that is, on the set of n-vectors which satisfy Eqn. (10). The 150 years between the establishment of the conditions for the equality and the inequality constrained cases is again just a consequence of classical mathematicians' lack of interest in inequalities, as discussed above. A third important theoretical issue was the extension to NLP of the duality theory of LP. This was achieved only in the *convex* case (Rockafellar 1970) that is, when both f and all the g_i's are convex. We recall that a function h is convex when

$$h(\alpha x + (1-\alpha)y) \leqslant \alpha h(x) + (1-\alpha) h(y)$$

for all n-vectors x and y and all real number α between 0 and 1.

Though NLP is used extensively in many real-life applications, it is much less widespread than LP. This is due to the facts that NLP lacks an universal method, like SIMPLEX for LP, so that the procedure to be used must be chosen according to the nature of the specific problem, and that NLP methods in general do not work as black boxes, fed with the problem data and handing over the solution, but rather must be fine

tuned, choosing appropriate parameters, properly interpreting the output of the method, etc. Thus, an expert in Operations Research, unavailable in most moderate sized institutions, is required for successful implementation and solution of NLP problems. On the other hand, the impact of NLP on mathematics itself has been much deeper than the one of LP. Important results in several classical areas, like convex analysis and variational analysis, have been drastically improved as a consequence of the development of NLP theory (see Rockafellar 1970, Rockafellar and Wets 1998).

5. Nonlinear Programming: Methods

The simplest case to be considered is the *unconstrained* one, where the conditions in Eqn. (10) are absent, and the problem consists just of minimizing the function f. Most methods for this case generate sequences of n-vectors $x^0, \ldots, x^k, \ldots$ which approximate a local solution of the problem. The simplest ones, which were known in the nineteenth century, though they only became significant with the advent of computers, are *Cauchy's* methods, or *steepest descent*, and *Newton*'s method. Newton's method generally requires less iterations than Cauchy's for attaining a certain precision (i.e., a sufficiently good approximation x^k will be achieved with a lower value of k) but each of its steps is more time consuming (see Mangasarian 1969). More modern methods for unconstrained minimization include quasi-Newton ones, which combine the best features of Cauchy's and Newton's methods (Dennis and Moré 1977), and trust region methods (Dennis and Schnabel 1983).

In the *constrained* case, the constraints $g_i(x) \leqslant 0$ $(1 \leqslant i \leqslant m)$ are present, and most methods reduce the original problem Eqns. (9)–(10) to a sequence of simpler problems, each one of which has to be solved by another appropriate procedure. Most methods can be seen as belonging to one of the three following families:

(a) Feasible methods: each step consists of two stages. In the first one the constraints are ignored and an unconstrained method is used to reduce the objective f; in the second one only the constraints in Eqn. (10) are taken into account (see Avriel 1976).

(b) Sequential quadratic programming: in these methods, at each step the problem is approximated by a quadratic programming problem, which can then be solved with one of the exact methods mentioned in section 5 (see Gomes et al. 1999).

(c) Penalty methods: In this case, the original problem Eqns. (9)–(10) is replaced by a sequence of unconstrained problems, each one of which is then solved with some method for unconstrained optimization. Within this family of methods, special attention has been given to the so called augmented Lagrangian methods (see Bertsekas 1982), devised to find at the same time approximate solutions to the problem and approximate Lagrange multipliers, as defined by (12).

Efficient implementations of any of the methods above usually require knowledge of the first and second derivatives of f and the g_i's. Also, excepting in the convex case, the generated n-vector approximate in general just local solutions, as discussed in Section 5. Recent research in NLP has attempted to overcome these two limitations. Nonsmooth optimization is devoted to devising methods which work for problems whose data functions do not have derivatives (Clarke 1983), while global optimization addresses the issue of finding *global* solutions, that is, n-vectors x^* satisfying Eqn. (10) and such that $f(x^*) \leqslant f(x)$ for all other n-vector x which also satisfies Eqn. (10), and not only for n-vectors close to x^* (Horst and Tuy 1993).

Linear Hypothesis

1. Introduction

The term 'linear hypothesis' is often used interchangeably with the term 'linear model.' Statistical methods using linear models are widely used in the behavioral and social sciences, e.g., regression analysis, analysis of variance, analysis of covariance, multivariate analysis, time series analysis, and spatial data analysis. Linear models provide a flexible tool for data analysis and useful approximations for more complex models.

A common object of linear modeling is to find the most precise linear model that explains the data, to use that model to predict future observations, and to interpret that model in the context of the data collection. Traditionally, analysis of variance models have been used to analyze data from designed experiments while regression analysis has been used to analyze data from observational studies but the techniques of both analysis methods apply to both kinds of data. See also *Experimental Design: Overview* and *Observational Studies: Overview*.

2. Definition

The linear hypothesis is that the mean (average) of a random observation can be written as a linear combination of some observed predictor variables. For example, Coleman et al. (1996) provides observations on various schools. The dependent variable y consists of the average verbal test score for sixth-grade students. The report also presents predictor variables. A composite measure of socioeconomic status x_1 is based on father's and mother's education, family size and intactness, home items, and percent of fathers who are white collar. Staff salaries per pupil is x_2. The average score on a verbal test given to the school's teachers is x_3. Denoting different schools using the subscript i and the mean of y_i by m_i, a linear hypothesis states that for some unknown numbers (parameters) β_0, β_1, β_2, and β_3,

$$m_i = \beta_0 + \beta_1 x_{i1} + \beta_1 x_{i2} + \beta_3 x_{i3}$$

Mosteller and Tukey (1977, pp. 326, 566) and Mosteller et al. (1983, pp. 408–20) give excerpts and analysis of the data.

In other applications, the predictors only identify whether an observation is in some group. For example, in 1978 observations y_{ij} were collected on the age at which people in Albuquerque committed suicide, see Koopmans (1987, p. 409). Here i is used to identify the person's group membership (Hispanic, Native American, non-Hispanic Caucasian), and j identifies individuals within a group. The three categories are taken to be mutually exclusive for the present discussion (although the US government now allows for individuals to identify themselves with multiple races in various surveys and the decennial census). We can define group identifier predictor variables. Let δ_{1i} take the value 1 if an individual belongs to group 1 (Hispanic) and 0 otherwise, with similar predictors to identify other groups, say δ_{2i} and δ_{3i} for Native Americans and non-Hispanic Caucasians. Note that the predictor variables do not depend on the value of j identifying individuals within a group. Denoting the mean of y_{ij} by m_{ij}, a linear hypothesis states that for some unknown parameters μ, α_1, α_2, α_3,

$$m_{ij} = \mu + \alpha_1 \delta_{1i} + \alpha_2 \delta_{2i} + \alpha_3 \delta_{3i}$$

Since two of the δs are always zero, this model is often written more succinctly as

$$m_{ij} = \mu + \alpha_i$$

A linear hypothesis is usually combined with other assumptions about the observations y. Most commonly, the assumptions are that the observations are independent, have the same (unknown) variance σ^2, and have normal (Gaussian) distributions. For the two examples, these assumptions are written

$$y_i \text{ indep. } N(m_i, \sigma^2) \quad \text{and} \quad y_{ij} \text{ indep. } N(m_{ij}, \sigma^2)$$

where, for example, $N(m_i, \sigma^2)$ indicates a normal distribution with mean m_i and variance σ^2. Incorporating these additional assumptions, the linear

hypothesis becomes a full-fledged linear model, traditionally written

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3} + \varepsilon_i,\ \varepsilon_i \text{ indep. } N(0, \sigma^2) \tag{1}$$

and

$$y_{ij} = \mu + \alpha_i + \varepsilon_{ij},\ \varepsilon_{ij} \text{ indep. } N(0, \sigma^2) \tag{2}$$

where the εs are unobservable random errors.

Both theoretical and computational work with linear hypotheses and linear models is facilitated by the use of matrices. If $i = 1, 2, 3, 4$, the model (1) can be written as the equality of two 4×1 matrices

$$\begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix} = \begin{bmatrix} \beta_0 + \beta_1 x_{11} + \beta_2 x_{12} + \beta_3 x_{13} + \varepsilon_1 \\ \beta_0 + \beta_1 x_{21} + \beta_2 x_{22} + \beta_3 x_{33} + \varepsilon_2 \\ \beta_0 + \beta_1 x_{31} + \beta_2 x_{32} + \beta_3 x_{33} + \varepsilon_3 \\ \beta_0 + \beta_1 x_{41} + \beta_2 x_{42} + \beta_3 x_{43} + \varepsilon_4 \end{bmatrix}$$

Using properties of matrix algebra, this can be rewritten as

$$\begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix} = \begin{bmatrix} 1 & x_{11} & x_{12} & x_{13} \\ 1 & x_{21} & x_{22} & x_{23} \\ 1 & x_{31} & x_{32} & x_{33} \\ 1 & x_{41} & x_{42} & x_{43} \end{bmatrix} \begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \beta_3 \end{bmatrix} + \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \varepsilon_4 \end{bmatrix}$$

Similarly, model (6) for $i = 1, 2, 3$, $j = 1, 2$ can be written using δ as

$$\begin{bmatrix} y_{11} \\ y_{12} \\ y_{21} \\ y_{22} \\ y_{31} \\ y_{32} \end{bmatrix} = \begin{bmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \mu \\ \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{bmatrix} + \begin{bmatrix} \varepsilon_{11} \\ \varepsilon_{12} \\ \varepsilon_{21} \\ \varepsilon_{22} \\ \varepsilon_{31} \\ \varepsilon_{32} \end{bmatrix}$$

In general, a linear model is traditionally written using matrices as

$$Y = X\beta + e \tag{3}$$

where Y is a $n \times 1$ matrix containing the observable random variables y, X is a $n \times p$ matrix containing observed predictors, β is a $p \times 1$ matrix containing unobservable parameters, and e is a $n \times 1$ matrix containing unobservable random errors. To have a full-fledged model, assumptions must be made about the distribution of e. One standard assumption is that the mean value of each element of e is 0. Denote the $n \times 1$ matrix of mean (expected) values as $\mathrm{E}(e)$. This assumption is written

$$\mathrm{E}(e) = 0$$

The corresponding linear hypothesis involves the mean values of the entries of Y, i.e., $\mathrm{E}(Y)$. The linear hypothesis is that

$$\mathrm{E}(Y) = X\beta$$

for some matrix β. Another standard assumption about e is that the covariance matrix, the $n \times n$ matrix of variances and covariances between the ε_is or equivalently between the y_is is

$$\mathrm{Cov}(e) = \mathrm{Cov}(Y) = \sigma^2 I$$

where I indicates the $n \times n$ identity matrix that has 1s on the diagonal and 0 elsewhere.

An alternative way to write model (3) in terms of each y_i using some matrices is

$$y_i = x_i'\beta + \varepsilon_i$$

$i = 1, \ldots, n$ where β is as before and x_i' is the ith row of the X matrix.

See also *Analysis of Variance and Generalized Linear Models* and *Linear Hypothesis: Regression (Basics)*.

3. *Estimation*

The unknown parameters of the linear model are the elements of β, the βs, and the variance of an observation, σ^2; they must be estimated from the data. The β_js are generally estimated using least squares estimation. For given data Y, the least squares estimates are the values of β_j that minimize

$$\sum_{i=1}^{n} (y_i - x_i'\beta)^2 \quad \text{or equivalently} \quad (Y - X\beta)'(Y - X\beta)$$

where the prime on $(Y - X\beta)'$ indicates the matrix transpose of $(Y - X\beta)$. (The transpose of a matrix turns the columns of the original matrix into the rows of a new matrix.)

Under the standard assumptions, least squares estimates have optimal statistical properties. If the ε_is are independent $N(0, \sigma^2)$, then the least squares estimates provide maximum likelihood estimates (MLEs) and minimum variance unbiased estimates (MVUEs). A MVUE is an estimate that has less variability than any other unbiased estimate. If we drop the assumption of normality but retain independence (actually 0 covariances) and equal variances, least squares

estimates are best linear unbiased estimates (BLUEs). A BLUE is an estimate based on a linear combination of the observations that has less variability than any other unbiased estimate based on a linear combination of the observations.

In matrix terms, the least squares estimates, say, $\hat{\beta}$, are obtained as solutions to the normal equations

$$X'X\beta = X'Y$$

Typically, in regression problems, the unique solution is

$$\hat{\beta} = (X'X)^{-1}X'Y$$

In general, if $X'X$ is singular, so that $(X'X)^{-1}$ does not exist, an infinite number of solutions exist, giving an infinite number of least squares estimates. Any one of these estimates is just as valid as any other, but fortunately, for all practical purposes, the estimates are unique. This means that whenever a linear parameter $\lambda'\beta$ is identifiable in the model (estimable), the least squares estimate of the parameter is uniquely defined. See also *Statistical Identification and Estimability* and *Analysis of Variance and Generalized Linear Models*.

The other unknown parameter to be estimated is σ^2, the variance of an observation. To estimate the variance, first rearrange the model into

$$\varepsilon_i = y_i - x_i'\beta \quad \text{or} \quad e = Y - X\beta$$

Then estimate β to get the residuals

$$\hat{\varepsilon}_i = y_i - x_i'\hat{\beta} \quad \text{or} \quad \hat{e} = Y - X\hat{\beta}$$

The sum of the squared residuals is called the sum of squares error,

$$SSE = \sum_{i=1}^{n} \hat{\varepsilon}_i^2 = (Y - X\hat{\beta})'(Y - X\hat{\beta})$$

The degrees of freedom error (dfE) is n minus the rank of the matrix X, i.e.,

$$df\text{E} = n - r(X)$$

The rank of X is the number of free parameters that can be fitted to the model by least squares. The variance σ^2 is estimated by the mean squared error,

$$MSE = \frac{SS\text{E}}{df\text{E}}$$

See also *Estimation: Point and Interval*.

4. Testing

The basic idea of testing is to create some model for the process of generating the data, and evaluate whether the observed data are consistent with that model. For example, such a model might be

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3} + \varepsilon_i, \quad \varepsilon_i \text{ indep. } N(0, \sigma^2)$$

One can think of this model has having four parts: (a) ε_i are independent, (b) ε_i have $\text{E}(\varepsilon_i) = 0$, i.e.,

$$\text{E}(y_i) = m_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3}$$

(c) ε_i have common variance σ^2, (d) ε_i are normally distributed. Data that are inconsistent with the model may occur whenever any of these four parts is inappropriate.

In the context of testing the linear hypothesis, it is assumed that these four specifications are correct and a further refinement of the model is then imposed by placing an additional restriction on

$$\text{E}(y_i) = m_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3}$$

The test is usually thought of as a test of this additional restriction, generally called the null hypothesis. For example, the additonal restriction could be the null hypothesis H_0: $\beta_1 = \beta_3 = 0$. In the sixth grade verbal test example, this hypothesis indicates that the variables x_1, socioeconomic status, and x_3, teachers mean verbal test score, have no ability to help predict sixth graders' mean verbal test scores. The test of whether the data are consistent with a model that incorporates $\beta_1 = \beta_3 = 0$ is based on assuming that the null hypothesis and items (a) through (d) are all correct. If assumptions (a) through (d) are correct, then data that are inconsistent with the model suggest that either $\beta_1 \neq 0$ or $\beta_3 \neq 0$ or both, i.e., that the null hypothesis is not true. However, in reality, data that are inconsistent with the model can result if any of the assumptions are violated, i.e., any of the four itemized assumptions or the null hypothesis. Because of this, if one is interested in testing only the null hypothesis, it is crucial to do everything possible to validate the assumptions embodied in items (a) through (d). See also *Hypothesis Testing in Statistics* and *Significance, Tests of*.

There are two ways to think about testing a linear hypothesis. One is to think in terms of testing models and the other is to think in terms of testing parameters.

4.1 Models

In testing models one assumes the validity of a (full) model and tests to see if some smaller (reduced) model

is consistent with the data. For example, with the verbal test score data a full model might be

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3} + \varepsilon_i, \quad \varepsilon_i \text{ indep. } N(0, \sigma^2)$$

incorporating all three predictors. The reduced model may incorporate the idea that the socioeconomic and mean teacher verbal score variables x_{i1} and x_{i3} are not important, yielding

$$y_i = \beta_0 + \beta_2 x_{i2} + \varepsilon_i, \quad \varepsilon_i \text{ indep. } N(0, \sigma^2)$$

In this context, the null hypothesis is that the reduced model provides an adequate explanation for the data. In any particular test, the full model need not incorporate all of the variables that have been measured. It need only be a model that is plausibly correct.

Both the full model and the reduced model have sums of squares error, degrees of freedom error, and mean squared errors associated with them. The reduced model is rejected as being inconsistent with the data if the following F statistic is too large,

$$F = \frac{SSE(\text{Red}) - SSE(\text{Full})}{dfE(\text{Red}) - dfE(\text{Full})} / MSE(\text{Full})$$

If the reduced model is true, then both the full model and the reduced model are true, so both MSE(Red) and MSE(Full) are estimates of σ^2. It can then be shown that $(SSE(\text{Red}) - SSE(\text{Full}))/(dfE(\text{Red}) - dfE(\text{Full}))$ is also an estimate of σ^2, so both the numerator and the denominator of F are estimates of σ^2, and the ratio should be about 1. Of course, there is sampling variability associated with the F statistic. The theoretical F distribution describes the usual distribution of values one will encounter when making such calculations. It depends on two parameters: $dfE(\text{Red}) - dfE(\text{Full})$ degrees of freedom for the numerator and dfE(Full) degrees of freedom for the denominator.

On the other hand, if the reduced model is an inadequate explanation of the data, it can be shown that $(SSE(\text{Red}) - SSE(\text{Full}))/(dfE(\text{Red}) - dfE(\text{Full}))$ estimates σ^2 plus a positive number, so that if the reduced model is bad, the F statistic should be larger than 1. If the observed value of the F statistic is so much larger than 1 as to be inconsistent with the theoretical F distribution, one can reasonably conclude that the reduced model is an inadequate explanation of the data, i.e., one rejects the null hypothesis.

4.2 Parameters

The other way to perform tests in the linear hypothesis is to specify a null hypothesis in terms of the parameters. For example, if we assume the verbal test score model

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3} + \varepsilon_i, \quad \varepsilon_i \text{ indep. } N(0, \sigma^2)$$

we might be interested in testing the null hypothesis H_0: $\beta_1 = \beta_3 = 0$ in which socioeconomic status and teachers mean verbal test score have no ability to predict. One way to test this hypothesis is to identify the reduced model associated with it, i.e.,

$$y_i = \beta_0 + 0x_{i1} + \beta_2 x_{i2} + 0x_{i3} + \varepsilon_i, \quad \varepsilon_i \text{ indep. } N(0, \sigma^2)$$

or

$$y_i = \beta_0 + \beta_2 x_{i2} + \varepsilon_i, \quad \varepsilon_i \text{ indep. } N(0, \sigma^2)$$

For a more complicated example, suppose two previous studies had suggested the hypothesis H_0: $\beta_1 + \beta_3 = 5$ and $\beta_2 = 0$. We can rewrite the hypothesis as H_0: $\beta_1 = 5 - \beta_3$ and $\beta_2 = 0$, and create a reduced model by substitution,

$$y_i = \beta_0 + (5 - \beta_3)x_{i1} + 0x_{i2} + \beta_3 x_{i3} + \varepsilon_i, \quad \varepsilon_i, \text{ indep. } N(0, \sigma^2)$$

Rearranging terms gives a reduced model

$$y_i - 5x_{i1} = \beta_0 + \beta_3(x_{i3} - x_{i1}) + \varepsilon_i, \quad \varepsilon_i \text{ indep. } N(0, \sigma^2)$$

This is just a new linear model with a new dependent variable $y_i - 5x_{i1}$ and one predictor variable $(x_{i3} - x_{i1})$. One can compute SSE(Red) and dfE(Red) in the usual way for this new model, and simply substitute these quantities into the usual formula for the F statistic to get the test.

If the data are consistent with the reduced model, we have a more precise model than the one we started with. While testing provides no assurance that the reduced model is correct, the data are at least consistent with it. This more precise model can be investigated for the validity of its predictions and its usefulness in explaining the data collection process.

In addition, (estimable) parametric hypotheses can be tested directly using matrices, without identifying the reduced model. For example, the hypothesis H_0: $\beta_1 + \beta_3 = 5$ and $\beta_2 = 0$ can be written in matrix form by creating a matrix Λ' that, when multiplied by β, isolates $\beta_1 + \beta_3$ and β_2. The hypothesis is

$$\Lambda'\beta \equiv \begin{bmatrix} 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \beta_4 \end{bmatrix}$$

$$= \begin{bmatrix} \beta_1 + \beta_3 \\ \beta_2 \end{bmatrix} = \begin{bmatrix} 5 \\ 0 \end{bmatrix} \equiv d$$

In matrix terms the F statistic for a null hypothesis $H_0 : \Lambda'\beta = d$ is

$$F = \frac{(\Lambda'\hat{\beta} - d)'[\Lambda'(X'X)^{-}\Lambda]^{-}(\Lambda'\hat{\beta} - d)}{r(\Lambda)MSE} \tag{4}$$

where $\hat{\beta}$ is a least squares estimate of β, $r(\Lambda)$ is the rank of the matrix Λ, and A^{-} is a generalized inverse of the matrix A. If A^{-} exists, it is the unique generalized inverse. The reduced model test and this direct test give the same F statistic and use the same degrees of freedom.

Confidence regions can be constructed using the F distribution. For the example, we can construct a simultaneous confidence region for $\beta_1 + \beta_3$ and β_2 as follows. Let $F(0.95, r(\Lambda), n - r(X))$ be the number so that with probability 0.95

$$\frac{(\Lambda'\hat{\beta} - \Lambda'\beta)'[\Lambda'(X'X)^{-}\Lambda]^{-}(\Lambda'\hat{\beta} - \Lambda'\beta)}{r(\Lambda)MSE} \leqslant F(0.95, r(\Lambda), n - r(X))$$

Here, $MSE(X'X)^{-}$ is an estimate of the covariance matrix of $\hat{\beta}$ and $MSE[\Lambda'(X'X)^{-}\Lambda]$ is an estimate of the covariance matrix of $\Lambda'\hat{\beta}$. After substituting the observed values of $\Lambda'\hat{\beta}$ and MSE into the inequality, the only thing that is unknown in this inequality is the value of $\Lambda'\beta$. A confidence region for $\Lambda'\beta$ consists of all the values that can be substituted for $\Lambda'\beta$ while maintaining the truth of the inequality. A precise definition of the 95 percent confidence region is as the collection of all values d in (4) that would not be rejected by an $\alpha = 0.05$ level F test. If Λ' has only one row, the confidence region simplifies to a confidence interval. See also *Estimation: Point and Interval.*

5. *Bayesian Estimation*

An alternative to least squares estimation is Bayesian estimation. In Bayesian estimation the parameters of the linear model are considered to be random and probability distributions reflecting the investigator's prior knowledge about the parameters are specified. Using Bayes theorem, the prior probability distributions are updated into posterior distributions that reflect the information embodied in the data. All statistical inferences are then based on the posterior distributions. Sometimes, a noninformative (improper) prior is used in which case, interval estimates arrived at using Bayesian methods are numerically equal to the interval estimates obtained from classical methods, only the interpretations of the intervals change. Alternatively, real prior information is often specified by taking the prior distribution of β given σ^2 to be a multivariate normal distribution and the prior distribution of σ^2 to be an inverse gamma distribution. This leads to modified least squares estimates that are shrunk towards the mean of the prior distribution β with corresponding changes to interval estimation. See also *Bayesian Statistics*; *Distributions, Statistical: Special and Continuous*; *Elicitation of Probabilities and Probability Distributions.*

6. *Model Checking*

Valid testing of a null hypothesis requires that all of the four itemized assumptions embodied in the model be true. Confidence intervals and regions are collections of parameter values that cannot be rejected by tests, so they also require the validity of the basic assumptions in the model as do Bayesian and non-Bayesian estimation. Model checking is considered an integral part of all statistical inference. A variety of methods have been developed for model checking. Most are based on plotting the residuals, see *Linear Hypothesis: Regression (Graphics)*. These methods include checking the normality assumption by plotting the ordered (standardized (Studentized)) residuals against (some approximation to) the expected order statistics of a standard normal distribution. Such a plot should be approximately linear if the data are normal.

The (standardized (Studentized)) residuals are also plotted against their corresponding predicted variables or any other variable (that does not depend on y) for which a measurement is available for each observation. In these plots, any identifiable systematic structure is an indication of problems with the assumptions.

Heteroscedasticity refers to having observations with different variances. In some models, formal tests for equal variances are available, e.g., Bartlett's test and the model-based tests discussed in Carroll and Ruppert (1988).

Lack of fit refers to the problem of having specified an incorrect linear mean structure, i.e., an incorrect linear hypothesis. Formal tests for lack of fit are often based on identifying clusters of observations that have similar predictor variables, i.e., similar rows of the X matrix, see Christensen (1996a, Sect. 6.6). Miller et al. (1998) have provided optimal methods for grouping observations into near replicate clusters.

The independence assumption is perhaps the hardest to evaluate. If the observations are taken at equally spaced time intervals, standard time series methods are often applied to the residuals. More generally, Christensen and Bedrick (1997) proposed creating rational subgroups (clusters) of the observations in which one suspects the observations may be more similar within clusters than between clusters. The methods of near replicate lack of fit tests can then be applied to test the independence assumption.

7. Weighted Models and Covariance Estimation

The standard assumption in linear models is that the observations all have the same variance and that the observations are all independent. If either or both of those assumptions is invalidated, different methods of estimation and testing are required. The usual linear model has

$$Y = X\beta + e, \quad \mathrm{E}(e) = 0, \quad \mathrm{Cov}(e) = \sigma^2 I$$

Writing a model

$$Y = X\beta + e, \quad \mathrm{E}(e) = 0, \quad \mathrm{Cov}(e) = \sigma^2 V$$

where $\sigma^2 V$ is the variance–covariance matrix of the observations (and also of the unobservable errors), V can incorporate unequal variances for observations as well as correlations between observations. Assume that V has an inverse matrix V^{-1}.

Rather than using least squares estimates of β, we use weighted least squares estimates that minimize

$$(Y - X\beta)' V^{-1} (Y - X\beta)$$

for given Y and X. The estimates can be obtained by solving the normal equations

$$X' V^{-1} X\beta = X' V^{-1} Y$$

Typically, in regression problems, the unique solution is

$$\hat{\beta} = (X' V^{-1} X)^{-1} X' V^{-1} Y$$

These estimates are also BLUEs. Moreover, under the assumption that the observations have a multivariate normal distribution, the weighted least squares estimates are MLEs and MVUEs. The variance σ^2 is estimated by $MSE = SSE/dfE$ as before, except now

$$SSE = (Y - X\hat{\beta})' V^{-1} (Y - X\hat{\beta})$$

Testing a full model and a reduced model, works as before, with the F statistic still being

$$F = \frac{SSE(\mathrm{Red}) - SSE(\mathrm{Full})}{dfE(\mathrm{Red}) - dfE(\mathrm{Full})} / MSE(\mathrm{Full})$$

Note that incorporating the more general matrix V has no effect on the process of identifying reduced models—which only depend on the mean structure and not on the variance–covariance structure of the data.

All of these methods presume that V is known. In practice, V is often unknown and must be estimated from the data. This greatly complicates the entire process of data analysis. Typically, when V is estimated, weighted least squares estimates are not BLUEs or MVUEs, nor does the F statistic have an F distribution under the null hypothesis that the reduced model is true. Nonetheless, the ideas behind weighted regression are fundamental to many applications of the linear hypothesis.

A common application of weighted regression is when the observations are independent but have different variances. If the relative sizes of the variances are known, then V is known. Often the variance of each observation is modeled as a function of some predictor variables, see Carroll and Ruppert (1988).

Split plot models involve groups of observations that all have the same correlation. For example, in an experiment that involves different ways of scheduling classes in schools and different ways of assigning homework to students, the behavior of the schools might be considered independent of each other, but a group of five students taken from the same school should have similarities with each other, while being independent of students from other schools. This correlation structure must be incorporated into V. If the same number of students are measured from each school, i.e., if the groups of observations having the same correlation are all of the same size, many linear models still allow one to use least squares estimates and their associated F tests.

Mixed models involve the use of random effects, Partition X and β into two parts, so as to write

$$Y = X_1\beta_1 + X_2\beta_2 + e$$

Instead of considering β_1 and β_2 as fixed unknown parameters, treat β_2 as random. Assume that $\mathrm{E}(\beta_2) = 0$ and $\mathrm{Cov}(\beta_2) = \sigma^2 D$ with, say, e and β_2 independent. Consolidate all of the random parts into $\xi = X_2\beta_2 + e$ and write a linear model

$$Y = X_1\beta_1 + \xi, \quad \mathrm{E}(x) = 0, \quad \mathrm{Cov}(\xi) = \sigma^2 (X_2 D X_2' + I)$$

where $V = X_2 D X_2' + I$. Typically, D has to be estimated. To estimate β_1, simply use the estimate of D to get an estimate of V which is then treated as the true V.

Mixed models get much more complicated. X_2 is often partitioned into submatrices $Z_1, \ldots, Z_r$ and β_2 is correspondingly partitioned into γ_k, so as to write

$$Y = X_1\beta_1 + \sum_{k=1}^{r} Z_k \gamma_k + e$$

where $\mathrm{E}(\gamma_k) = 0$, $\mathrm{Cov}(\gamma_k) = \sigma_k^2 I$, and the γ_k are independent. The σ_k^2 are unknown parameters, and various methods such as residual (restricted) maximum likelihood (REML) and minimum norm

quadratic unbiased estimation (MINQUE) are used to estimate them. See also *Hierarchical Models: Random and Fixed Effects*; *Longitudinal Data*.

Another application of weighted estimation is in the analysis of spatial data. With spatial data, observations that are taken close together spatially are usually more correlated than observations taken far apart. V reflects the spatial correlations of the observations and X may reflect the locations of the observations. Models for V are developed based on the distances between observations. A common application in geographic information systems is map making, in which predictions are made for a very fine grid of locations. An individual best linear unbiased predictor for an observation on the grid, say, y_0 corresponding to location x_0' is

$$\hat{y}_0 = x_0'\hat{\beta} + V_{oY}V^{-1}(Y - X\hat{\beta})$$

where V_{0Y} is a matrix of covariances between y_0 and the original observations in Y. In practice, both V and V_{0Y} must be estimated from the data. See also *Spatial Statistical Methods*.

Multivariate linear models involve creating linear models for several variables at once. For example, y_{i1} might measure verbal ability and y_{i2} mathematical ability. Obviously, for any individual i, y_{i1} and y_{i2} may be correlated. The multivariate linear model fits

$$y_{i1} = x_i'\beta_1 + \varepsilon_{i1} \quad \text{and} \quad y_{i2} = x_i'\beta_2 + \varepsilon_{i2}$$

simultaneously. See also *Multivariate Analysis: Overview*.

Time series data involve observations $y_1, y_2, y_3, \ldots$, taken at regular time intervals. The correlation between two observations depends on the amount of time between them. One simple linear model for explaining the behavior of such data is a first order autoregression model.

$$y_i = \beta_0 + \beta_1 y_{i-1} + \varepsilon_i$$

in which the observation at time $i-1$ is used to predict the observation at time i. See also *Time Series: General* and *Time Series: ARIMA Methods*

Generalized linear models involve transforming the mean before making the linear hypothesis. For example, if observations y_i have means m_i one might make the hypothesis that

$$\log(m_i) = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3}$$

This hypothesis together with assumptions about the distribution of y_i form a generalized linear model. In particular, since the linear hypothesis is based on the log transformation, this would be called a log-linear model. Parameter estimates are typically found by performing a series of weighted least squares analyses. Generalized linear models allow for the analysis of a variety of nonnormally distributed data. See also *Analysis of Variance and Generalized Linear Models*; *Multivariate Analysis: Discrete Variables (Loglinear Models)*; *Multivariate Analysis: Discrete Variables (Logistic Regression)*

8. Conclusion

Models based on the linear hypothesis, and their generalizations provide tools for analyzing a wide variety of data. Linear hypotheses allow one to address numerous interesting questions about the mean structure of the data. Moreover, the models can adjust for very general forms of dependence among the data. Linear models and their generalizations continue to be the most important and widely used models for the statistical analysis of data.

Linear Hypothesis: Fallacies and Interpretive Problems (Simpson's Paradox)

The study of relationships between two quantities has been important since earliest times: from the connection between weather and the hunted animals, down to cigarettes causing lung cancer. In the laboratory sciences it is possible to determine the relationship by controlling the conditions, changing one quantity and observing the effect of the change on the other. In the social and behavioral sciences this determination is not possible for three, related, reasons. First, conditions can rarely be controlled. Second, it is often not possible to set a quantity at an assigned value. Third, the relationship may not be exact but possess a random element, as with the heights of parents and their children. As a result, it is not easy to determine the nature of any possible relationship between quantities. Often an apparent connection has been found, on further study, to be spurious. We begin by looking at one of the more bizarre possibilities, usually known as Simpson's paradox (Simpson, 1951), but known to earlier writers. A more recent reference is Lindley and Novick (1981). Chapter 6 of Pearl (2000) contains a fine discussion in terms of causation. It is explained using some illustrative, medical data.

Patients were given either a treatment T, or a placebo T', to alleviate a condition. After a fixed time, it was observed whether they had recovered, R, or not, R'. Table 1 gives the data in the form of a 2×2 contingency table: thus 16 patients recovered, even with the placebo. The table also provides the marginal totals and the two recovery rates. The treatment appears to have been effective in increasing the recovery rate over the placebo by 10 percent. (As an aside, the numbers here are small, 80 patients in all; but the phenomenon could persist with 8,000. It is not the effect of small samples that is at issue.) There is an apparent relationship between treatment and recovery, but it has a random element and outside conditions have not been controlled.

One of these conditions is the patient's sex. Table 2, in the same form, gives the data for the men who participated in the study. Again the treatment has an effect but in the opposite direction, reducing the recovery rate by 10 percent. Common sense might suggest that a treatment which was overall beneficial, but harmful to men, would be highly beneficial for women. The data for them can be found by subtracting the cell entries in Table 2 for men from those for all patients in Table 1. Thus no new information is needed. The results are given in Table 3. Common sense misleads: the recovery rate for women also drops by 10 percent as a result of the treatment, just as with the men. This is a treatment which is bad for men, bad for women, but good for all of us. This is the paradox. It is here in an extreme form of complete reversal when an additional factor is included. It often arises in the form where there is some change in relationship when extra information is included. How can this happen?

It is easy to see what has gone wrong in the medical example. The condition is more serious for the women, with lower recovery rates than the men. Yet the treatment has been mainly given to the men—30 of them, against only 10 women. Perhaps the doctor was suspicious of the treatment and felt it was too

Table 1

	R	R′		Rate
T	20	20	40	50%
T′	16	24	40	40%
	36	44	80	

Table 2

Males	R	R′		Rate
T	18	12	30	60%
T′	7	3	10	70%
	25	15	40	

Table 3

Females	R	R′		Rate
T	2	8	10	20%
T′	9	21	30	30%
	11	29	40	

dangerous to give to the susceptible women. The consequence is that overall the treatment appears beneficial because it has been mainly given to the men, who were much more likely to recover in any case than were the women. Once this is appreciated, it is clear, from the data for the two sexes separately, that the treatment is harmful. Or is it clear? Here are two considerations that raise doubts:

(a) First, suppose that another quantity in addition to sex is included: for example, whether the patient came from a rural or urban environment. There would then be four contingency tables; one for rural males, one for urban females, and so on. We do not give the data, but it could happen that for each of these four tables there was a 10 percent improvement in the recovery rate, as with the overall data in Table 1. For this to happen, the allocation of patients would need to depend heavily on sex and environment, but it could happen. Furthermore, it could happen for some factor that was unrecognized by the scientists responsible for the experiment. The lesson is that, without some care in the consideration of quantities beyond the two that are the prime object of study, it is easy to be misled about the relationship between them.

(b) Second, suppose the numbers in the three tables remain unaltered but they apply to an agricultural, rather than medical, example. The treatment and placebo are replaced by two varieties of maize; recovery is now high yield as against low; and being male becomes growing tall as opposed to short. Thus the phenomenon of males having a higher recovery rate than females, corresponds to tall plants giving a greater proportion of high-yielders. Finally, the recovery rate is replaced by the proportion of plants with a high yield. In the medical example, it was suggested that the treatment was harmful. This translates, in the agriculture case, to T' giving the better yield. Is that really right? Surely T gave the better yield (Table 1) and grew taller (Tables 2 and 3). The suggestion is that the conclusions, from the same data, are quite different in the two contexts. The reason is that, whereas the medical treatment has no influence on sex, which maize variety is grown does influence the heights of the plants. The causal patterns in the two cases are not the same.

There is another way of appreciating the distinction between the agricultural and medical examples that avoids the difficult concept of causation. Suppose, on the evidence of the tables, and no other, you had another patient with the condition: would you give them the treatment? The answer is No, because the chance of recovery for treated males is less than for males having the placebo, and similarly for females, so that sex (which is outside your control) is irrelevant, and not influenced by the treatment applied. But when it comes to which variety of maize to plant, the replacement for sex, growing height, is influenced by the variety chosen. Hence the chances referred to above are irrelevant; only the chances of high yield for each variety are relevant and the growing height does not matter since it is determined by the choice of variety. Thus T is the better maize.

Notice that in all these examples, one of the quantities, T, could be set at a chosen value. Often this is not possible and the scientist merely passively observes whether T or T' obtains. In this case, transferring from the data to a new patient, in the manner of the last paragraph, becomes even more difficult. There can be a substantial difference between observing that an event occurs and arranging that it occurs. A person who is naturally a nonsmoker can behave quite differently from one who has been pressured into giving up smoking.

In order fully to appreciate what is going on, it is necessary, as always, to argue abstractly; to escape from the contexts of medicine or agriculture and to examine what principles are involved. This requires some mathematics and here the specific tool of probability. We write $p(A/B)$ for the probability that event A occurs, when it is known, or supposed, that event B has occurred. AB denotes the event which occurs if, and only if, both A and B occur. Then a reasonable interpretation of Table 1 is that $p(R/T) = 0.5$, $p(R/T') = 0.4$ and that T is preferred to T'. From now on think of R, T, and M (for male) as any three events and R', T', M' as their negations. The medical and agricultural examples provide illustrations. A third, social example with racist overtones is provided by the case, T is white (T' black), R is intelligent, and M upper, social class. All data are hypothetical.

Tables 2 and 3 refer, in this abstract form, to probabilities like $p(R/TM)$, differing from those in Table 1 by the inclusion of the conditioning event M or M'. These are related to the probabilities of Table 1 by the standard results

$$p(R/T) = p(R/TM)p(M/T) + p(R/TM')p(M'/T) \quad (1)$$

and

$$p(R/T') = p(R/T'M)p(M/T') + p(R/T'M')p(M'/T') \quad (2)$$

These introduce two extra probabilities, $p(M/T)$, and $p(M/T')$. Table 1 compared the probabilities on the left-hand sides of the two equations. Tables 2 and 3 compared the probabilities vertically above one another on the right. Those on the left were larger in the upper equation; those on the right were smaller

there. The reason for the paradox is that, on the right-hand sides of the two equations, the weights attached to those probabilities in order to combine them to produce those on the left, namely $p(M/T)$ in the upper, and $p(M/T')$ in the lower, are different. The difference was noted earlier with the treated patients being predominately male.

The paradox can be avoided if the weights are the same; namely $p(M/T) = p(M/T')$, for then any differences on the right will be reflected on the left. The general conclusion is that in studying a relationship involving T, any extraneous factor, M, should, if possible, arise with the same probability whether T is true or not. M and T should be independent. Statisticians say M is confounded with T if the probabilities are not equal. The sound recipe is to avoid confounding. Much effort has been put into designing experiments with little or no confounding.

We referred above to the difference between the medical and agricultural examples, in that the former resulted in a preference for T', the latter for T. The reason is that in the medical case, the scientist has control over $p(M/T)$ and, in particular, can avoid confounding by having the same proportion of males amongst treated patients as among those receiving the placebo. With the two varieties of maize, the proportion growing tall, M, is outside the scientist's control, so $p(R/T)$ is what matters. The reader may like to consider the politically-sensitive example mentioned above where the same data refer to the relative intelligences of black and white people.

The discussion so far has referred to events occurring or not. An event can be thought of as a quantity which takes only two values, 1 when it occurs, 0 when it does not. The probability that it occurs is then the expectation of the quantity. Looked at from this viewpoint, probability is a special case of expectation. The ideas above, including Simpson's paradox, extend to general quantities, X, Y, and Z, replacing T, R, and M, whenever the expectations are linear, as they necessarily must be when only two numbers, 1 and 0, are involved. Suppose then that the expectation of X, given Y and Z, is linearly dependent on their values,

$$E(X/Y,Z) = \alpha + \beta Y + \gamma Z \tag{3}$$

If, still retaining the dependence on Y, expectations are taken over Z, the result is

$$E(X/Y) = \alpha + \beta Y + \gamma E(Z/Y)$$

If $E(Z/Y)$ is also linear, equal to $\lambda + \mu Y$, then

$$E(X/Y) = \alpha' + \beta' Y \tag{4}$$

where

$$\alpha' = \alpha + \gamma\lambda \text{ and } \beta' = \beta + \gamma\mu$$

The contrast between Eqns. (4) and (3) is similar to that between Tables 1 and 2. For example, it could happen that β was positive but β' negative. If so, Eqn. (3) suggests that an increase in Y would be expected to produce an increase in X. Equation (4) similarly suggests a decrease in X.

More careful analysis modifies these statements. Changing γ in Eqn. (3) provides a measure of the effect on X, whilst Z is constant. No such restraint on Z is present in Eqn. (4). This is similar to Simpson's paradox, where Tables 2 and 3 held Z, now M or M' constant, whereas Table 1 did not. It explains the difference between the agricultural and medical examples. Z, height, cannot be held constant; whereas Z, sex can.

It is common for Eqn. (3) to be included in a statement like

$$X = \alpha + \beta Y + \gamma Z + \varepsilon$$

where ε is a random error with zero mean. Similarly Eqn. (4) becomes

$$X = \alpha' + \beta' Y + \varepsilon'$$

Statements in this form, unlike Eqns. (3) and (4), disguise the fact that the real distinction between them lies in the conditions under which X is being studied. Just as with Eqns. (1) and (2), the important subtleties arise because of the conditions. Thus ε' hides the fact that the variation of Z is included within it; ε does not. It is typically advantageous, when thinking about an expectation, or probability, to recognize the conditions that are assumed to hold, as well as the quantity being expected. In particular, probability depends on two arguments, not one; the uncertain event whose probability is being evaluated, and the events that are supposed to have occurred, the conditions. Distinction is sometimes made between probability and conditional probability. In reality, all probabilities are conditional. Care is needed in working with conditional expectations.

The main conclusion is that it is difficult to establish whether or not there exists a connection between two quantities and, if there does, to determine its precise form. The difficulty principally arises from the presence of other quantities that may disturb any apparent relationship. If controlled experimentation is possible, then consideration of interactions and the avoidance of confounding can be helpful in producing sound conclusions. With observational studies, in contrast, great care is necessary in avoiding inferences that the data do not fully support. An important reason why the social and behavioral sciences are less advanced than the physical ones is that controlled experimentation is more often possible in the latter than in the former.

These considerations do not deny the possibility of establishing relationships in society; merely that more

care is required. Emphasis needs to be placed on other quantities and the influence they might have on the relationship. These should be measured and the data incorporated into the analysis. On the other hand, there will be factors, like height in the agricultural example, which, although influential, can be left out of the analysis. All the time it is necessary to bring to the fore the conditions under which the basic relationship obtains. In consideration of that between X and Y, it is essential to take into account Z.

Linear Hypothesis: Regression (Basics)

Regression analysis is the study of how a response variable depends on one or more predictors, for example how crop yield changes as inputs such as amount of irrigation or type of seed are varied, or how student performance changes as factors such as class size and expenditure per pupil are varied. In this article, we present the basics of the *linear regression model*, in which (a) the dependence of the response on the predictors is through the mean and (b) the mean of the response given the predictors is a linear function of the predictors. This is probably the most important and frequently encountered regression model.

1. Introduction

Regression analysis is the study of *dependence*: how does a response variable change as the values of one or more predictor variables are changed? In the general case, we have a response variable y, a set of predictor variables x, and we seek to understand the *conditional distributions* given by $F(y|x)$ as the predictors x are varied. Although the study of dependence probably began even earlier, two principal ideas lead to modern regression analysis (Stigler 1986). At the beginning of the nineteenth century, Legendre in France and Gauss

Figure 1
Scatterplot for the regression of *RCC* on *LBM*

in Germany studied the mean of a response as the predictors are varied using parametric models with only a few parameters. They suggested estimating the parameters by minimizing the sum of squared errors, which is the foundation for the least squares methods commonly used today. Toward the end of the nineteenth century in England, Galton, and later Pearson and Yule, provided many of the modern notions of correlation that provide a language for understanding dependence.

An example of a regression problem with one predictor is given graphically in Fig. 1, where the response variable $y = RCC$ is the red cell count and $x = LBM$ is the lean body mass in kilograms for 202 elite athletes that trained at the Australian Institute of Sport in the early 1990s (from Cook and Weisberg 1999). This scatterplot serves two general purposes in a regression context. First, it can help the viewer find separated or otherwise unusual points. In Fig. 1, one of the athletes had an unusually high value of *RCC*, about 7, with a relatively modest value of *LBM*. Such separated points are often of interest in their own right, and in any case they may have substantial effects on any computed summaries. The second use for this graph is to visualize how the conditional distribution $F(RCC|LBM)$ changes as the value of *LBM* is varied. Conditioning on *LBM* means looking at narrow vertical slices in the plot. The points within a slice represent approximately a sample from the distribution of *RCC* given that *LBM* is 'fixed' at the midpoint of the interval. We can visually integrate the contents of many slices to summarize changes in conditional distributions as we move from left to right. In Fig. 1, for example, we can see that the *mean function*, $E(RCC|LBM)$ that joins the mean in each slice appears to increase as we move from left to right, and furthermore that the increase appears to be

approximately the same for all values of *LBM*. In addition, we have enough points to say something about the conditional variability by examining the *variance function* $\mathrm{Var}(RCC \mid LBM)$. The variability appears to be approximately the same across the plot, or apparently $\mathrm{Var}(RCC \mid LBM = 50) \approx \mathrm{Var}(RCC \mid LBM = 80)$, or any other value.

2. Simple Linear Regression

The simple linear regression model makes assumptions concerning both the mean function $\mathrm{E}(y \mid x)$ and the variance function. In particular, we assume that for some transformation $u = u(x)$, we can write

$$\mathrm{E}(y \mid u) = \beta_0 + \beta_1 u \tag{1}$$

This equation requires some careful explanation. First, following Cook and Weisberg (1999), we allow the predictor x to be replaced by any monotonic transformation of it, such as the logarithmic, or inverse transformation. Doing so considerably expands the range of problems that can be handled using simple regression. Given this transformation, Eqn. (1) says that the expected increase in y for a unit increase in u is always equal to β_1 units, regardless of the initial value of u. Thus in a graph of y vs. u, the mean function specified by Eqn. (1) is a straight line with intercept β_0 and slope β_1.

The mean function of Eqn. (1) concerns average behavior, but says nothing about the variation. Suppose we have observed data $(x_i, y_i), i = 1, \ldots, n$, observed on n units, and suppose further that we have computed $u_i = u(x_i)$ for the known transformation u. Of course the points (u_i, y_i) will not fall exactly on the line (they certainly do not do so in Fig. 1). The unobservable differences

$$\varepsilon_i = y_i - \mathrm{E}(y_i \mid u_i)$$

are called *errors*. By construction, if the model is correct the errors are random variables with mean zero and variance given by a positive constant σ^2. This amounts to assuming that the variance function $\mathrm{Var}(y \mid x)$ is constant. We assume that the ε_i are independent random variables. They are often assumed to be normally distributed, but the normality assumption is required only for inference, not for estimation.

The model given by Eqn. (1) and the assumptions concerning variability just described greatly simplify the regression problem by reducing the mean function to only two parameters, and the variance function to only one parameter. When this model is appropriate, it gives a very elegant summary to a regression problem.

2.1 Fitting

The most common method of estimating the unknown parameters in Eqn. (1) based on data uses ordinary least squares. Find the values $\hat{\beta}_0$ and $\hat{\beta}_1$ of (β_0, β_1) that minimize the residual sum of squares function $RSS(\beta_0, \beta_1)$, given by

$$RSS(\beta_0, \beta_1) = \sum_{i=1}^{n} (y_i - \mathrm{fit}_i)^2 \tag{2}$$

where $\mathrm{fit}_i = \beta_0 + \beta_1 u_i$. Finding the estimates is an elementary calculus problem, and in general the estimates are unique and are given by a formula. The estimate of σ^2 is just $\hat{\sigma}^2 = RSS/(n-2)$, where *RSS* is the value of the residual sum of squares function evaluated at the estimates, and $n-2$ is the degrees of freedom, which is equal to the number of observations n minus the number of parameters estimated in the mean function, which is 2 for simple linear regression in Eqn. (1).

Table 1 gives typical computer output for fitting the simple linear regression model to the athletes data. The column marked Estimate gives the estimated coefficients, so the intercept is estimated to be about 3.47. The estimated slope of 0.019 suggests that we

Table 1
Simple linear regression of *RCC* on *LBM*

	Coefficient estimates		
Label	Estimate	Std. error	*t*-value
Constant	3.46616	0.136820	25.334
LBM	0.0193060	0.00206768	9.337
R squared:		0.303574	
Sigma hat:		0.383145	
Number of cases:		202	
Degrees of freedom:		200	

expect *RCC* to increase on the average by about 0.019 units for each 1 kg increase in *LBM*. The column marked Std. error gives the estimated standard errors of these values, which are computed as $\hat{\sigma}$ times a constant that depends on the values of the u_i but not on the response. The t-values are the ratio of the estimate to its standard error. These are appropriate test statistics for the hypotheses that each of the coefficients in turn is equal to zero. Assuming normal errors, these values can be compared with the t_{n-2} distribution to get significance levels. In the athletes data, tests concerning the intercept are of little interest. The test that the slope is equal to zero vs. the general alternative has value $t = 9.34$ and a corresponding tiny significance level, suggesting clearly that *RCC* increases with *LBM*.

A common summary statistic for the fit of a regression is the quantity R^2, which is defined to be the *fraction of the variability in the response explained by the model*, so

$$R^2 = \frac{SYY - RSS}{SYY} \tag{3}$$

where $SYY = \mathrm{E}(y_i - \bar{y})^2$ is the total variability in the response ignoring the predictors. If $R^2 = 1$, then $RSS = 0$ and the mean function matches the data perfectly. If $R^2 = 0$, then $SYY = RSS$, and knowledge of the predictors tells us nothing about the response. For the athletes data, $R^2 = 0.30$, so about 30 percent of the variability in *RCC* is explained by *LBM*. R^2 is a most appropriate measure when the corresponding scatterplot appears to be an elliptical swarm of points which in turn suggests bivariate normality of both the response and the predictor. This is a very strong assumption that appears to be appropriate for this example.

2.2 Diagnostics

The residuals are defined to be the differences between the observed values y_i and the fitted values $\hat{y}_i = \hat{\beta}_0 + \hat{\beta}_1 u_i$, so $e_i = y_i - \hat{y}_i$. Unlike the errors ε_i, the residuals e_i are observable, and so they can be used in graphs and other procedures as a check on the assumptions of the fitted model. Imagine drawing a scatterplot of the residuals vs. u. If the model is correct, then we should expect that the conditional distribution of $e \mid u$ should be the same as we move from left to right: the mean function should be constant and the variance function should be constant. If the model is not correct, then either of these two characteristics may not hold. The residual plot for the athletes data is shown in Fig. 2. As one would have expected, the model for the mean function matches the data fairly well, as both the mean and variance functions appear to be constant. The other interesting feature is the poor fit for one athlete with very high *RCC*. Deleting this case and refitting can tell us about the impact of this point on the fitted equation; doing so results in only minor changes in the estimated coefficients or in $\hat{\sigma}$. Other separated points can cause very large changes in estimates, and such points are called influential.

Figure 2
Residual plot from simple regression of *RCC* on *LBM*

3. Multiple Regression

Many regression problems require consideration of more than one predictor, and it is required to understand how the response y depends simultaneously on the predictors $x_1, x_2, \ldots, x_p$. For example, the dependence of *RCC* on *LBM* discussed so far ignores the fact that these data consist of both male and female athletes, and one might reasonably assume that gender differences are important. This will require either fitting separate models for the two populations of males and females, or more generally including gender effects in the mean function. Other problems might require additional predictors; in the athletes data, for example, including height, weight, or some blood chemistry variables might be appropriate.

We begin with p predictors $x_1, \ldots, x_p$, and from these we will build a set of k *terms* $u_0, u_1, \ldots, u_{k-1}$, to get the multiple linear regression mean function

$$\mathrm{E}(y \mid u_1, \ldots, u_{k-1}) = \beta_0 u_0 + \beta_1 u_1 + \cdots + \beta_{k-1} u_{k-1} \tag{4}$$

Including terms, which are functions of the predictors, makes this model very general. For example, a model with one predictor x might include the terms $u_0 = 1$ for the intercept, $u_1 = x$, $u_2 = x^2$ and $u_3 = x^3$, so polynomial models are included in the multiple linear regression class. In addition, the u terms can include interactions (e.g., $u = x_1 x_2$), transformations (e.g., $u = \log(x_1)$), and other functions of the predictors. Quantitative variables like gender can be included in a model by defining *factors*, which are sets of indicator

variables (often having the values 0 or 1) that correspond to the levels of the factor. For example, the variable *Treatment* with three levels can be included in a model with two indicator variables, the first with the value 1 for units that received treatment T1 and 0 otherwise; the second with the value 1 for units getting treatment T2, and 0 otherwise; T3 is indicated if both indicators are equal to 0. Since gender has only two levels, only one indicator variable is required.

Suppose that *Gender* has the value 1 for females and 0 for males. Figure 3 shows a fit of the mean function

$$\mathrm{E}(RCC \mid LBM, Gender) = \beta_0 + \beta_1 Gender + \beta_2 LBM + \beta_3 LBM \times Gender \quad (5)$$

to the athletes data. This is a multiple regression model with two predictors, *LBM* and Gender, and four terms, an intercept, an interaction, and terms for *LBM* and *Gender*. For males, *Gender* = 0 and (5) becomes

$$\mathrm{E}(RCC \mid LBM, Gender = 0) = \beta_0 + \beta_2 LBM$$

Figure 3
Regression of *RCC* on *LBM* controlling for gender. Points for females are marked with a X and have a fitted line given by the dashed line. Points for males are marked with a 0 and the fitted line is the solid line

while for females, *Gender* = 1 and

$$\mathrm{E}(RCC \mid LBM, Gender = 1) = (\beta_0 + \beta_1) + (\beta_2 + \beta_3) LBM$$

We recognize that this model fits straight lines separately for each gender with intercept and slope β_0 and β_2 for males, and $\beta_0 + \beta_1$ and $\beta_2 + \beta_3$, for females. We see from the fitted least squares lines shown in Fig. 3 that within gender the regression have different intercepts (males appear to have higher *RCC* than females), but the two groups appear to have approximately equal slopes, and those two slopes may well be zero. Thus, by conditioning on group, the relationship between *RCC* and *LBM* disappears. Table 2 summarizes the ordinary least squares fit based on model (5). The fitting method is a direct generalization of the method for simple regression given at (2), except that fit_i is now defined using (5). We now see that the estimates for *LBM* and *LBM* × *Gender* are very small both in absolute value, and small relative to their standard errors. All this suggests that, given gender, *RCC* and *LBM* are independent.

This example illustrates that choice of predictors in a regression problem can be very important. The initial analysis, ignoring gender, suggested that *RCC* increased with increasing *LBM*. This spurious dependence appears to be due to gender differences: women have lower values of *LBM* than men, on the average, and they also appear to have lower values of *RCC* than do men (at least for elite athletes). The initial analysis reflected gender differences, not a meaningful relationship between the response and the predictor.

4. *Interpreting Parameters*

Weisberg (1985) reported the results of a regression to study per capita fuel consumption for the United States as a function of four predictors: *Tax* rate, in cents per gallon, *Dlic*, the fraction of adults with drivers licenses; *Inc*, the per capita income in thous-

Table 2
Multiple linear regression of *RCC* on *LBM* and *Gender*

	Coefficient estimates		
Label	Estimate	Std. error	*t*-value
Constant	4.85114	0.255403	18.994
Gender	−0.666013	0.372175	−1.790
LBM	0.00234984	0.00339170	0.693
LBM × *Gender*	0.00164645	0.00595363	0.277
R squared:		0.466583	
Sigma hat:		0.337009	
Number of cases:		202	
Degrees of freedom:		198	

ands of dollars, and *Road*, the number of miles of roadway in the state. The fitted linear regression model was:

$$Fuel = 377 + 35Tax + 13Dlic - 66Inc - 2.4Road$$

Assuming that this mean function is appropriate for these data (a question that should always be considered in trying to understand a regression problem), how are the parameter estimates to be interpreted? For example, the coefficient of -66 for *Inc* suggests that for every \$1,000 increase in per capita income, fuel consumption will decrease by about 66 gallons per person, assuming that all other predictors could be held fixed at their current values. Similarly, the value of $+35$ for *Tax* suggests that for every penny increase in fuel tax, consumption goes *up*, contrary to the common sense result that increasing cost through taxes should decrease consumption, assuming all other factors are held fixed. How can this happen?

These data are observational: tax rates are determined by state legislatures in response to many other factors, possibly including the per capita fuel consumption. Thus the observed positive relationship may be due to high consumption causing an increase in taxes, rather than the other way around. There is no way to sort out an issue like this one without actually experimentally changing variables and observing what happens; this is surely not possible in setting tax rates.

As another example, Weisberg (1985) reported on the regression summary of the dependence of accident rate per million vehicle miles on speed limit *Slim*, number of access points *Acpt* and length *Len* of a segment for 39 segments of major Minnesota highways. The fitted model was

$$Rate = 9.32 - 0.77Len - 0.10Slim + 0.10Acpt$$

We get the sensible result that increasing the number of access points in a segment, while keeping the other two variables fixed, will increase the accident rate by 0.1. The other two coefficients are less obvious. The negative sign for *Slim* suggests that increasing speed limits will lower accident rates (these data predate the original reduction of the maximum speed limit to 55 mph), but once again we cannot tell if higher speeds cause fewer accidents, or if dangerous segments of road encourage the highway department to lower the speed limit; both would give rise to the negative coefficient.

The coefficient for *Len* is also curious; why should accident rate be related to the length of the segment, since the rate is already adjusted for the miles driven? If most accidents occur at isolated dangerous spots that are relatively rare, then increasing the length of a segment by a small amount is unlikely to include another dangerous spot. The longer segment will then have about the same number of accidents, but a lower value for accidents per million vehicle miles. Consequently, the negative association between the rate and the length, adjusted for the other variables, is an artifact of the way the data are collected. It has no intrinsic interest on its own, but it must be included in all regression models to remove the effect of this artifact.

5. Conclusion

Regression methodology generally seeks to understand the dependence of a response variable on a set of predictors as the predictors are varied. This very general methodology finds application in almost every branch of human inquiry. The approach to regression briefly outlined here is expanded at a relatively low mathematical level in Cook and Weisberg (1999). Fox (1997) provides another entry to the literature on regression, at about the same level. Draper and Smith (1998) requires a modestly higher level of mathematical sophistication.

Almost any of the popular statistical computing package will include programs for fitting the type of models discussed in this article. The larger programs like SAS offer several seemingly different procedures with names like 'proc reg' and 'proc glm' that in reality are just fitting the regression models described here. Newer approaches to regression require extensive use of graphics, and several programs are specifically designed for graphics, for example, the free program Arc that is described in Cook and Weisberg (1999).

Linear Hypothesis: Regression (Graphics)

Regression analysis is the study of how a response variable depends on one or more predictors. For example, as a part of an ecological study of New Zealand mussels, we might wish to study the dependence of muscle mass Y (g), the edible portion of a mussel, on the size of the shell as represented by the

shell height X_1, shell length X_2, and shell width X_3 (mm). We later use a data set from this study containing observation on 82 mussels.

Graphical displays can be quite useful in regression analysis because they can be used to visualize dependence, to discover unexpected relationships, to guide the choice of a model, and to check and refine plausible models. In this article, we present the basic ideas and methods of regression graphics.

1. Introduction

The overarching goal of a regression analysis is to understand how the conditional distribution of the response variable Y given a vector of p predictors $\mathbf{X} = (X_j, j = 1, \ldots, p)$ depends on the value assumed by $\mathbf{X}$. While attention is often restricted to the mean function $\mathrm{E}(Y|\mathbf{X})$ and perhaps the variance function $\mathrm{Var}(Y|\mathbf{X})$, in full generality it is the conditional distribution of $Y|\mathbf{X}$ that is of interest. The population of New Zealand mussels can be viewed as consisting of several subpopulations, one for each distinct shell size as represented by the value of $\mathbf{X}$. In the regression we wish to study how the distribution of muscle mass changes as we move between subpopulations.

Linear regression is a restrictive but common form of analysis in which $\mathrm{E}(Y|\mathbf{X})$ is expressed as a linear function of the predictors and the data are used to estimate the unknown coefficients of the predictors (see *Linear Hypothesis: Regression (Basics)*). For example, we might begin an analysis of the mussel regression by fitting the linear regression model

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \sigma\varepsilon \qquad (1)$$

where ε is an unobservable random error with mean 0 and variance 1, the βs are unknown regression coefficients, and σ is the unknown standard deviation. In this particular model, the distribution of $Y|\mathbf{X}$ depends on $\mathbf{X}$ only through the mean function

$$\mathrm{E}(Y|\mathbf{X}) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 \qquad (2)$$

which is linear in $\mathbf{X}$. The variance function is constant $\mathrm{Var}(Y|\mathbf{X}) = \sigma^2$ under the model.

The choice of a model can be problematic, and is often the most difficult part of a regression analysis. Beyond the general notion that linear models may serve as useful approximations, there is little prior information to support model (1) for the mussel regression and data-based modifications may well be required. Graphics can be useful in the choice of a first model. If the mussel regression had only one predictor X_1, a two-dimensional scatter plot of Y vs. X_1 could be used to visualize how the conditional distribution $Y|\mathbf{X}_1$ changes with the value X_1. Similarly, if the regression had only two predictors, say X_1 and X_2, we could use

Figure 1
Scatterplot matrix for the mussel regression.

a computer-generated three-dimensional plot of Y vs. (X_1, X_2) to visualize the conditional distributions. But the mussel regression has three predictors, requiring a four-dimensional plot to view the data in full. Four-dimensional plots can not be viewed in their entirety in our three-dimensional world, so we must find indirect low-dimensional methods of viewing regression data when there are more than two predictors.

For instance, a scatterplot matrix of the mussel data is shown in Fig. 1. The diagonal cells in the scatterplot matrix serve to name the axes for the individual plots and show the observed range for each variable. The top row contains plots of the response vs. each of the predictors, and the predictors are plotted in the lower left 3×3 array. This scatterplot matrix contains much information: we see that each of the mean functions for the marginal regressions in the top row is curved and that the variance functions are increasing. There are fairly strong linear relationships between the predictors, indicating that collinearity may be an issue. This type of information from low-dimensional plots can be useful but unfortunately may have little to do with the regression of Y on $\mathbf{X}$. The fact that the marginal mean functions $\mathrm{E}(Y|X_j)$, $j = 1, 2, 3$, are curved does not necessarily imply that the full mean function $\mathrm{E}(Y|\mathbf{X})$ is a nonlinear function of $\mathbf{X}$. Similarly, we cannot safely conclude that the variance function $\mathrm{Var}(Y|\mathbf{X})$ is not constant.

Plots of convenience such as the scatterplot matrix of Fig. 1 may not portray the regression accurately and can misdirect the analysis. Low-dimensional plots must be constructed and interpreted carefully if we are to avoid such possibilities. In regression graphics we pursue low-dimensional *sufficient summary plots* which contain all the information on Y that is available from

Figure 2
Summary plot for the mussel regression.

X, and which avoid the distortion that can result from simple convenient displays of the data.

Figure 2 shows a summary plot of muscle mass Y vs. the linear combination of the predictors

$$\mathbf{b}^T\mathbf{X} = 0.50X_1 + 0.08X_2 + 0.86X_3 \tag{3}$$

Methods of regression graphics discussed later in this article enable us to infer that this plot is *sufficient* and thus contains all the information on muscle mass Y that is available from the three predictors in **X**, namely shell height, length, and width. Because the plot is inferred to be sufficient and because no model was used in its construction, we can use it to guide the remaining analysis including the choice of a first model. We conclude from the plot that the mean function is curved and that the variance function is very likely not constant. Both conclusions contradict model (1).

2. *Sufficient Summary Plots*

Dimension reduction is a leitmotif of statistics. For instance, starting with a sample $z_1, \ldots, z_n$ from a univariate normal population with mean, μ and variance 1, we know that the sample mean $\bar{z}$ is sufficient for μ (see *Statistical Sufficiency*). This means that we can replace the original n-dimensional sample with the one-dimensional mean $\bar{z}$ without loss of information on μ.

In the same spirit, dimension reduction without loss of information is a dominant theme of regression graphics. The goal of a regression study is to infer about the conditional distribution of the response Y given the $p \times 1$ vector of predictors **X**. A central goal of regression graphics is to reduce the dimension of **X** without loss of information on the conditional distribution of $Y|\mathbf{X}$ and without requiring a model. We call this sufficient dimension reduction, borrowing terminology from classical statistics. Sufficient dimension reduction leads naturally to sufficient summary plots which contain all of the information on the regression that is available from the sample.

In regression graphics we search for the smallest number $d \leqslant p$ of linear combinations of the predictors, say $\mathbf{b}_1^T\mathbf{X}, \ldots, \mathbf{b}_d^T\mathbf{X}$, that contain all the information about Y that is available from **X**. To formalize this idea, we re-express it in the form of a conditional independence statement

$$Y \perp\!\!\!\perp \mathbf{X} | \mathbf{B}^T\mathbf{X} \tag{4}$$

Here columns of the $p \times d$ matrix **B** are the vectors $\mathbf{b}_1, \ldots, \mathbf{b}_d$ so that $\mathbf{B}^T\mathbf{X}$ is the $d \times 1$ vector of linear combinations $\mathbf{b}_1^T\mathbf{X}, \ldots, \mathbf{b}_d^T\mathbf{X}$. The notation '$\perp\!\!\!\perp$' means independence. The statement is, thus, that Y is independent of **X** given any values for the d linear combinations $\mathbf{B}^T\mathbf{X} = (\mathbf{b}_1^T\mathbf{X}, \ldots, \mathbf{b}_d^T\mathbf{X})^T$. The value of d is called the structural dimension of the regression of Y on **X**, and we refer to a regression as having kD structure for $k = 0, 1, \ldots, p$. We can always find a value of d and a corresponding matrix **B** so that Egn(4) is true. For example, (4) is always true when $d = p$ and $\mathbf{B} = \mathbf{I}$.

If a regression has 0D structure, then $Y \perp\!\!\!\perp \mathbf{X}$, and the predictors contain no information about the response. In such cases, a simple histogram or other graphical representation of the marginal distribution of Y is a sufficient summary plot. If $d = 1$ then all the information about Y that is available from **X** is contained in a single linear combination $\mathbf{b}_1^T\mathbf{X}$, and a plot of Y vs. $\mathbf{b}_1^T\mathbf{X}$ is a sufficient summary plot for the regression. Under 2D structure all the information about Y that is available from **X** is contained in two linear combinations $(\mathbf{b}_1^T\mathbf{X}, \mathbf{b}_2^T\mathbf{X})$, and a three-dimensional plot of Y vs. $(\mathbf{b}_1^T\mathbf{X}, \mathbf{b}_2^T\mathbf{X})$ is a sufficient summary plot for the regression.

Each of the following regression models is an example of a regression with 1D structure.

$$Y = b_0 + \mathbf{b}^T\mathbf{X} + \sigma\varepsilon \tag{5}$$

$$Y^{(\lambda)} = b_0 + \mathbf{b}^T\mathbf{X} + \sigma\varepsilon \tag{6}$$

$$Y = f(\mathbf{b}^T\mathbf{X}) + \sigma\varepsilon \tag{7}$$

$$Y = f(\mathbf{b}^T\mathbf{X}) + \sigma(\mathbf{b}^T\mathbf{X})\varepsilon \tag{8}$$

Model (5) is the linear regression model. In model (6) we have a linear regression model after some response transformation represented by the unknown parameter λ. The mean function in model (7) is $\mathrm{E}(Y|\mathbf{X}) = f(\mathbf{b}^T\mathbf{X})$, where f may be unknown or known, but it depends on only one linear combination of the predictors and thus the regression still has 1D structure. Similarly, in model (8) both the mean and standard deviation functions may depend on $\mathbf{b}^T\mathbf{X}$. Generalized linear models with corresponding link functions also have 1D structure. The class of re-

gression models with 1D structure is quite large and covers many models used in practice. A regression model with 2D structure can be considerably more complex that a regression with 1D structure. The model

$$Y = f(\mathbf{b}_1^T\mathbf{X}, \mathbf{b}_2^T\mathbf{X}) + \sigma(\mathbf{b}_1^T\mathbf{X}, \mathbf{b}_2^T\mathbf{X})\varepsilon$$

is one example of a regression with 2D structure.

The structural dimension d of a regression and the corresponding linear combinations $\mathbf{B}^T\mathbf{X}$ will generally be unknown. In the next section we discuss methods for estimating these quantities, leading to estimated sufficient summary plots.

3. *Estimating Sufficient Summary Plots*

There are several methods for estimating sufficient summary plots or properties thereof. While there are no restrictive constraints placed on the foundations of regression graphics as represented by Eqn. (4), some constraints are necessary for estimation. The most notable is that there should be no strong nonlinear relations among the predictors. This requirement constrains the marginal distribution of $\mathbf{X}$ and not the conditional distribution of $Y|\mathbf{X}$ as is usual when modeling in practice. It is part of the cost of insuring that certain low-dimensional plots contain useful information on the regression. There are several methods for insuring that this requirement holds in practice, including the possibility of using power transformations of the predictors to remove extreme nonlinearities.

Returning to the scatterplot matrix in Fig. 1, we see that the mean functions in the predictor plots are all strongly linear, and thus we can proceed to infer about properties a sufficient summary plot. A first inference is available from the *inverse response plots* of X_j vs. Y in the last column of the scatterplot matrix. Since all of these plots have the same shape we infer that $d = 1$ and thus that there is a two-dimensional sufficient summary plot. The justification for this conclusion is based on the vector of inverse mean functions $\mathrm{E}(\mathbf{X}|Y)$. If all inverse mean functions are linear related so that for some function $m(Y)$ of the response $\mathrm{E}(X_j|Y) = \mathrm{E}(X_j) + \alpha_j m(Y)$, $j = 1, \ldots, p$, then 1D structure is indicated. Next, if $d = 1$ as we have just inferred then there is a $p \times 1$ vector $\mathbf{b}$ such that (a) $Y \perp\!\!\!\perp \mathbf{X}|\mathbf{b}^T\mathbf{X}$ and (b) a plot of Y vs. $\mathbf{b}^T\mathbf{X}$ is a sufficient summary of the regression.

The next issue in our discussion of the mussel data is how to estimate $\mathbf{b}$. If there are no strong nonlinear relations among the predictors then $\mathbf{b}$ can be estimated as the coefficient vector of $\mathbf{X}$ from the ordinary least squares regression of Y on $\mathbf{X}$. And the estimated sufficient summary plot can be taken as a plot of Y vs. the fitted value $\hat{Y}$ from this same regression. This is how the summary plot of Fig. 2 was produced. No model is being assumed in this use of ordinary least squares. Indeed, we saw previously that the multiple linear regression model (1) is not sustained by the data. Nevertheless, the estimated coefficient vector $(\hat{\beta}_1, \hat{\beta}_2, \hat{\beta}_3)^T$ still provides a consistent estimate of $\mathbf{b}$. Estimation methods other than least squares can be used as well, provided the objective function is convex.

There are several more comprehensive methods for inferring about sufficient summary plots. All are based on transforming the original vector $\mathbf{X}$ of p predictors to p estimated linear combinations

$$\mathbf{X} = \begin{pmatrix} X_1 \\ X_2 \\ \vdots \\ X_p \end{pmatrix} \rightarrow \mathbf{Z} = \begin{pmatrix} \hat{\mathbf{b}}_1^T X \\ \hat{\mathbf{b}}_2^T X \\ \vdots \\ \hat{\mathbf{b}}_p^T X \end{pmatrix}$$

The p estimated linear combinations $\hat{\mathbf{b}}_j^T\mathbf{X}$ are ordered on the likelihood that they will be needed in a sufficient summary plot. If it is inferred that $d = 0$ then none of the linear combinations is needed. If it is inferred that $d = 1$ then only the first is needed and a plot of Y vs. $\hat{\mathbf{b}}_1^T\mathbf{X}$ is the estimated summary plot. Similarly, if the structural dimension is inferred to be $d = 2$ then only the first two estimated linear combinations are needed and a three-dimensional plot of Y vs. $(\hat{\mathbf{b}}_1^T\mathbf{X}, \hat{\mathbf{b}}_2^T\mathbf{X})$ is the estimated summary plot.

There are three primary numerical methods for producing the vector $\mathbf{Z}$ of linearly transformed predictors, each with its own advantages and disadvantages

(a) Sliced Inverse Regression (SIR)
(b) Sliced Average Variance Estimation (SAVE)
(c) Principal Hessian Directions (pHd)

SIR and SAVE use the column of inverse response plots in a scatterplot matrix of the predictors and the response, as discussed previously in connection the mussel data. They measure the shape of the inverse response plots by first replacing the response Y with a discrete version $\tilde{Y}$ constructed by partitioning the range of Y into K *slices*. SIR then gauges the shapes of the inverse mean functions $\mathrm{E}(\mathbf{X}|\tilde{Y})$, while SAVE gauges the shapes of the inverse functions $\mathrm{E}(\mathbf{X}|\tilde{Y})$ and the inverse variance functions $\mathrm{Var}(\mathbf{X}|\tilde{Y})$ simultaneously. The number of slices is a tuning parameter in both approaches. pHd is based on third moments between the response and the predictors, and does not have a tuning parameter. Each method comes with an inference procedure for the structural dimension d of the regression. In particular, beginning with $\mathbf{Z}$ predictors, graphical regression is a method for visually estimating the structural dimension of a regression and the corresponding summary plot.

SIR is good at estimating sufficient summary plots with linear trends, but it does not generally work well for finding plots with curvature and little linear trend. pHd works best for finding quadratic trends. SAVE is

Figure 3
Estimated sufficient summary plot from SAVE for the bank note data.

Figure 4
Scatterplot of residuals versus fitted values from the ordinary least squares fit of model (1).

the most comprehensive, but may miss information when it is concentrated in linear trends where SIR works well.

We use a data set on 200 Swiss bank notes for illustration. The response is binary with $Y = 1$ indicating a counterfeit note and $Y = 0$ indicating a genuine note. The methods of regression graphics discussed previously apply equally to regressions with continuous and binary responses. There are six predictors, each giving a different aspect of the size of a note: X_1 = length of bottom edge, X_2 = diagonal length, X_3 = left edge length, X_4 = length at center, X_5 = right edge length, and X_6 = top edge length.

Application of SAVE to the bank note data indicated 2D structure. Shown in Fig. 3 is a binary response plot of the first two linear combinations $(\hat{\mathbf{b}}_1^T\mathbf{X}, \hat{\mathbf{b}}_2^T\mathbf{X})$. We infer that this plot contains all the information about a note's authenticity that is available from the six predictors. The summary plot shows an outlying genuine note, good separation between the genuine and counterfeit notes, and a bimodal distribution within the counterfeit notes. The outlying genuine note could be a mislabeled counterfeit note, and the bimodal distribution within the counterfeit notes might reflect two different production processes.

4. *Special Purpose Graphics*

In addition to sufficient summary plots, there are a variety of special purpose graphics that can be used to address specific issues. These visualization methods mostly center on assessing or improving a target model.

Perhaps the most common graphical methods of model assessment are based on searching for dependence between residuals from the fitted model and the predictors. The various methods for estimating sufficient summary plots can be used to detect such dependence by simply using residuals in place of the response. In this setting the model is sustained when no information is found to contradict 0D structure.

A plot of residuals vs. fitted values from the ordinary least squares fit of model (1) is shown in Fig. 4. The horizontal line intersecting zero on the vertical axis was added as a visual reference. If the model was correct, this plot should leave the impression that the residuals are independent of the fitted values. Because the residuals and fitted values in the plot are clearly dependent, we have information to contradict 0D structure and the model is called into question.

CERES plots, including the class of partial residual plots can be used to study the need for predictor transformations in a multiple regression model such as model (1). Similar graphical methods are available for studying the need for response transformations. Net-effect plots can be used to study the contribution of a selected predictor to the regression. Versions are available for both model-based and model-free regression studies. Marginal model plots can be used to assess model adequacy.

5. *Further Reading*

The approach to regression graphics based on sufficient summary plots and many special purpose graphics were discussed at a relatively low mathematical level by Cook and Weisberg (1999). A more advanced treatment that requires knowledge of linear models and linear algebra was given by Cook (1998a). Sliced inverse regression and the method of principal Hessian directions were proposed by Li (1991, 1992). Sliced average variance estimation was proposed by Cook and Weisberg (1991). Extensions of these

methods were studied by Cook (1998b), Ferré (1998), Filliben and Li (1997), Hsing and Carroll (1992), Schott (1994), Velilla (1998), and Zhu and Fang (1996). Graphical regression was proposed by Cook (1998a). The mussel data were taken from Camden (1989). The bank note data were taken from Flury and Riedwyl (1988); the analysis follows Cook and Lee (1999) who studied regressions with a binary response.

Linear Hypothesis: Regression (Quantile)

Quantile regression is a statistical technique intended to estimate, and conduct inference about, conditional quantile functions. Just as classical linear regression methods based on minimizing sums of squared residuals enable one to estimate models for conditional mean functions, quantile regression methods offer a mechanism for estimating models for the conditional median function, and the full range of other conditional quantile functions. By supplementing the estimation of conditional mean functions with techniques for estimating an entire family of conditional quantile functions, quantile regression is capable of providing a more complete statistical analysis of the stochastic relationships among random variables.

Quantile regression has been used in a broad range of application settings. Reference growth curves for childrens' height and weight have a long history in pediatric medicine; quantile regression methods may be used to estimate upper and lower quantile reference curves as a function of age, sex, and other covariates without imposing stringent parametric assumptions on the relationships among these curves. Quantile regression methods have been widely used in economics to study determinents of wages, discrimination effects, and trends in income inequality. Several studies have modeled the performance of public school students on standardized exams as a function of socioeconomic characteristics like their parents' income and educational attainment, and policy variables like class size, school expenditures, and teacher qualifications. It seems rather implausible that such covariate effects should all act so as to shift the entire distribution of test results by a fixed amount. It is of obvious interest to know whether policy interventions alter performance of the strongest students in the same way that weaker students are affected. Such questions are naturally investigated within the quantile regression framework.

In ecology, theory often suggests how observable covariates affect limiting sustainable population sizes, and quantile regression has been used to directly estimate models for upper quantiles of the conditional distribution rather than inferring such relationships from models based on conditional central tendency. In survival analysis, and event history analysis more generally, there is also often a desire to focus attention on particular segments of the conditional distribution, for example survival prospects of the oldest-old, without the imposition of global distributional assumptions.

1. Quantiles, Ranks, and Optimization

We say that a student scores at the τth quantile of a standardized exam if he performs 'better' than the proportion τ, and 'worse' than the proportion $(1-\tau)$, of the reference group of students. Thus, half of the students perform better than the median student, and half perform worse. Similarly, the quartiles divide the population into four segments with equal proportions of the population in each segment. The quintiles divide the population into five equal segments; the deciles into

Figure 1
Quantile regression ρ function

10 equal parts. The quantile, or percentile, refers to the general case.

More formally, any real valued random variable, Y, may be characterized by its distribution function:

$$F(y) = \text{Prob}(Y \leqslant y)$$

while for any $0 < \tau < 1$:

$$Q(\tau) = \inf\{y : F(y) \geqslant \tau\}$$

is called the τth quantile of Y. The median, $Q(1/2)$, plays the central role. Like the distribution function, the quantile function provides a complete characterization of the random variable, Y.

The quantiles may be formulated as the solution to a simple optimization problem. For any $0 < \tau < 1$, define the piecewise linear 'check function,' $\rho_\tau(u) = u(\tau - I(u < 0))$ illustrated in Fig. 1.

Minimizing the expectation of $\rho_\tau(Y - \xi)$ with respect to ξ yields solutions, $\hat{\xi}(\tau)$, the smallest of which is $Q(\tau)$.

The sample analogue of $Q(\tau)$, based on a random sample, $\{y_1, \ldots, y_n\}$, of Y's, is called the τth sample quantile, and may be found by solving,

$$\min_{\xi \in \mathrm{R}} \sum_{i=1}^{n} \rho_\tau(y_i - \xi)$$

While it is more common to define the sample quantiles in terms of the order statistics, $y_{(1)} \leqslant y_{(2)} \leqslant \ldots \leqslant y_{(n)}$, constituting a sorted rearrangement of the original sample, their formulation as a minimization problem has the advantage that it yields a natural generalization of the quantiles to the regression context.

Just as the idea of estimating the unconditional mean, viewed as the minimizer,

$$\hat{\mu} = \text{argmin}_{\mu \in \mathbb{R}} \sum (y_i - \mu)^2$$

can be extended to estimation of the linear conditional mean function $E(Y|X = x) = x'\beta$ by solving;

$$\hat{\beta} = \text{argmin}_{\beta \in \mathbb{R}^p} \sum (y_i - x_i'\beta)^2$$

the linear conditional quantile function, $Q_Y(\tau \mid X = x) = x_i'\beta(\tau)$, can be estimated by solving;

$$\hat{\beta}(\tau) = \text{argmin}_{\beta \in \mathbb{R}^p} \sum \rho_\tau(y_i - x'\beta)$$

The median case, $\tau = 1/2$, which is equivalent to minimizing the sum of 'absolute' values of the residuals has a long history. In the mid-eighteenth century Boscovich proposed estimating a bivariate linear model for the ellipticity of the earth by minimizing the sum of absolute values of residuals subject to the condition that the mean residual took the value zero. Subsequent work by Laplace characterized Boscovich's estimate of the slope parameter as a weighted median and derived its asymptotic distribution. F. Y. Edgeworth seems to have been the first to suggest a general formulation of median regression involving a multivariate vector of explanatory variables, a technique he called the 'plural median.' The extension to quantiles other than the median was introduced in Koenker and Bassett (1978).

2. *An Example*

To illustrate the approach, we may consider an analysis of a simple first order autoregressive model for maximum daily temperature in Melbourne, Australia. The data are taken from Hyndman et al. 1996. In Fig. 2 we provide a scatter plot of 10 years of daily temperature data: today's maximum daily temperature is plotted against yesterday's maximum. Our first observation from the plot is that there is a strong tendency for data to cluster along the (dashed) 45 degree line implying that with high probability today's maximum is near yesterday's maximum. But closer examination of the plot reveals that this impression is based primarily on the left side of the plot where the central tendency of the scatter follows the 45 degree line very closely. On the right side, however, corresponding to summer conditions, the pattern is more complicated. There, it appears that either there is another hot day, falling again along the 45 degree line, or there is a dramatic cooling off. But a mild cooling off appears to be more rare. In the language of conditional densities, if today is hot, tomorrow's temperature appears to be bimodal with one mode roughly centered at today's maximum, and the other mode centered at about 20 degrees Celsius.

Several estimated quantile regression curves have been superimposed on the scatterplot. Each curve is specified as a linear B-spline. Under winter conditions these curves are bunched around the 45 degree line, however, in the summer it appears that the upper quantile curves are bunched around the 45 degree line and around 20 degrees. In the intermediate temperatures the spacing of the quantile curves is somewhat greater indicating lower probability of this temperature range. This impression is strengthened by

Figure 2
Melbourne maximum daily temperature: the plot illustrates 10 years of daily maximum temperature data (in degrees Celsius) for Melbourne, Australia as an AR(1) scatterplot. The data is scattered around the (dashed) 45 degree line suggesting that today is roughly similar to yesterday. Superimposed on the scatterplot are estimated conditional quantile functions for the quantiles $\tau \in \{.05, .10, \ldots, .95\}$. Note that when yesterday's temperature is high the spacing between adjacent quantile curves is narrower around the 45 degree line and at about 20 degrees Celsius than it is in the intermediate region. This suggests bimodality of the conditional density in the summer

considering a sequence of density plots based on the quantile regression estimates. Given a family of reasonably densely-spaced estimated conditional quantile functions, it is straightforward to estimate the conditional density of the response at various values of the conditioning covariate. In Fig. 3 we illustrate this approach with several density estimates based on the Melbourne data. Conditioning on a low previous day temperature we see a nice unimodal conditional density for the following day's maximum temperature, but as the previous day's temperature increases we see a tendency for the lower tail to lengthen and eventually we see a clearly bimodal density. In this example, the classical regression assumption that the covariates only affect location of the response distribution, but not its scale or shape, is violated.

3. *Interpretation of Quantile Regression*

Least squares estimation of mean regression models asks the question, 'How does the conditional mean of Y depend on the covariates X?' Quantile regression asks this question at each quantile of the conditional distribution enabling one to obtain a more complete description of how the conditional distribution of Y given $X = x$ depends on x. Rather than assuming that covariates only shift the location or scale of the conditional distribution, quantile regression methods enable one to explore potential effects on the shape of the distribution as well. Thus, for example, the effect of a job-training program on the length of the participants' current unemployment spell might be to lengthen the shortest spells while dramatically reducing the probability of very long spells. The mean treatment effect in such circumstances might be small, but the treatment effect on the shape of the distribution of unemployment durations could, nevertheless, be quite significant.

3.1 *Quantile Treatment Effects*

The simplest formulation of quantile regression is the two-sample treatment-control model. In place of the classical Fisherian experimental design model in which the treatment induces a simple location shift of the response distribution, Lehmann (1974) proposed the following general model of treatment response:

> Suppose the treatment adds the amount $\Delta(x)$ when the response of the untreated subject would be x. Then the distribution G of the treatment responses is that of the random variable $X + \Delta(X)$ where X is distributed according to F.

Special cases obviously include the location shift model, $\Delta(X) = \Delta_0$, and the scale shift model, $\Delta(X) = \Delta_0 X$, but the general case is natural within the quantile regression paradigm.

Doksum (1974) shows that if $\Delta(x)$ is defined as the horizontal distance between F and G at x, so

$$F(x) = G(x + \Delta(x))$$

then $\Delta(x)$ is uniquely defined and can be expressed as

$$\Delta(x) = G^{-1}(F(x)) - x$$

Changing variables so $\tau = F(x)$ one may define the quantile treatment effect,

$$\delta(\tau) = \Delta(F^{-1}(\tau)) = G^{-1}(\tau) - F^{-1}(\tau).$$

In the two sample setting this quantity is naturally estimable by

$$\hat{\delta}(\tau) = \hat{G}_n^{-1}(\tau) - \hat{F}_m^{-1}(\tau)$$

where G_n and F_m denote the empirical distribution functions of the treatment and control observations, based on n and m observations, respectively.

Formulating the quantile regression model for the binary treatment problem as,

$$Q_{Y_i}(\tau \mid D_i) = \alpha(\tau) + \delta(\tau) D_i$$

Figure 3
Conditional density estimates of today's maximum temperature for several values of yesterday's maximum temperature based on the Melbourne data. These density estimates are based on a kernel smoothing of the conditional quantile estimates as illustrated in the previous figure using 99 distinct quantiles. Note that temperature is bimodal when yesterday was hot

where D_i denotes the treatment indicator, with $D_i = 1$ indicating treatment, $D_i = 0$, control, then the quantile treatment effect can be estimated by solving,

$$(\hat{\alpha}(\tau), \hat{\delta}(\tau))' = \operatorname{argmin} \sum_{i=1}^{n} \rho_\tau(y_i - \alpha - \delta D_i)$$

the solution $(\hat{\alpha}(\tau), \hat{\delta}(\tau))'$ yields $\hat{\alpha}(\tau) = \hat{F}_n^{-1}(\tau)$, corresponding to the control sample, and

$$\hat{\delta}(\tau) = \hat{G}_n^{-1}(\tau) - \hat{F}_m^{-1}(\tau)$$

Doksum suggests that one may interpret control subjects in terms of a latent characteristic: for example in survival analysis applications, a control subject may be called frail if he is prone to die at an early age, and robust if he is prone to die at an advanced age. This latent characteristic is thus implicitly indexed by τ, the quantile of the survival distribution at which the subject would appear if untreated. And the treatment, under the Lehmann model, is assumed to alter the subjects control response, $\alpha(\tau)$, making it $\alpha(\tau) + \delta(\tau)$ under the treatment. If the latent characteristic, say, the propensity for longevity, were observable *ex ante*, then one could view the treatment effect $\delta(\tau)$ as an explicit interaction with this observable variable. In the absence of such an observable variable, however, the quantile treatment effect may be regarded as a natural measure of the treatment response.

It may be noted that the quantile treatment effect is intimately tied to the two-sample QQ-plot, which has a long history as a graphical diagnostic device. The function $\hat{\Delta}(x) = G_n^{-1}(F_m(x)) - x$ is exactly what is plotted in the traditional two sample QQ-plot. If F and G are identical then the function $G_n^{-1}(F_m(x))$ will lie along the 45 degree line; if they only differ by a location scale shift, then $G_n^{-1}(F_m(x))$ will lie along another line with intercept and slope determined by the location and scale shift, respectively. Quantile regression may be seen as a means of extending the two-sample QQ plot and related methods to general regression settings with continuous covariates.

When the treatment variable takes more than two values, the Lehmann–Doksum quantile treatment effect only requires minor reinterpretation. If the treatment variable is continuous as, for example, in dose-response studies, then it is natural to consider the assumption that its effect is linear, and write,

$$Q_{Y_i}(\tau \mid x_i) = \alpha(\tau) + \beta(\tau) x_i$$

We assume thereby that the treatment effect, $\beta(\tau)$, of changing x from x_0 to $x_0 + 1$ is the same as the

treatment effect of an alteration of x from x_1 to x_1+1. Note that this notion of the quantile treatment effect measures, for each τ, the change in the response required to stay on the τth conditional quantile function.

3.2 Transformation Equivariance of Quantile Regression

An important property of the quantile regression model is that, for any monotone function, $h(\cdot)$;

$$Q_{h(T)}(\tau \mid x) = h(Q_T(\tau \mid x)).$$

This follows immediately from observing that;

$$\text{Prob}(T < t \mid x) = \text{Prob}(h(T) < h(t) \mid x).$$

This equivariance to monotone transformations of the conditional quantile function is a crucial feature, allowing one to decouple the potentially conflicting objectives of transformations of the response variable. This equivariance property is in direct contrast to the inherent conflicts in estimating transformation models for conditional mean relationships. Since, in general, $E(h(T) \mid x) \neq h(E(T \mid x))$, the transformation alters in a fundamental way what is being estimated in ordinary least squares regression.

A particularly important application of this equivariance result, and one that has proven extremely influential in the econometric application of quantile regression, involves censoring of the observed response variable. The simplest model of censoring may be formulated as follows. Let y_i^* denote a latent (unobservable) response assumed to be generated from the linear model;

$$y_i^* = x_i'\beta + u_i \quad i = 1, \ldots, n$$

with $\{u_i\}$ iid from distribution function F. Due to censoring, the y_i^*'s are not observed directly, but instead one observes;

$$y_i = \max\{0, y_i^*\}$$

Powell (1986) noted that the equivariance of the quantiles to monotone transformations implied that in this model the conditional quantile functions of the response only depended on the censoring point, but were independent of F. Formally, the τth conditional quantile function of the observed response, y_i, in this model may be expressed as:

$$Q_i(\tau \mid x_i) = \max\{0, x_i'\beta + F_u^{-1}(\tau)\}$$

The parameters of the conditional quantile functions may now be estimated by solving;

$$\min_b \sum_{i=1}^{n} \rho_\tau(y_i - \max\{0, x_i'b\})$$

where it is assumed that the design vectors x_i, contain an intercept to absorb the additive effect of $F_u^{-1}(\tau)$. This model is computationally somewhat more demanding than conventional linear quantile regression because it is nonlinear in parameters.

3.3 Robustness

Robustness to distributional assumptions is an important consideration throughout statistics, so it is important to emphasize that quantile regression inherits robustness properties of the ordinary sample quantiles. The estimates and the associated inference apparatus have an inherent distribution-free character since quantile estimation is influenced only by the local behavior of the conditional distribution of the response near the specified quantile. Given a solution $\hat{\beta}(\tau)$, based on observations, $\{y, X\}$, as long as one doesn't alter the sign of the residuals, any of the y observations may be arbitrarily altered without altering the initial solution. Only the signs of the residuals matter in determining the quantile regression estimates, and thus outlying responses influence the fit in so far as they are either above or below the fitted hyperplane, but how far above or below is irrelevant.

While quantile regression estimates are inherently robust to contamination of the response observations, they can be quite sensitive to contamination of the design observations, $\{x_i\}$. Several proposals have been made to ameliorate this effect.

4. Computational Aspects of Quantile Regression

Although it was recognized by a number of early authors, including Gauss, that solutions to the median regression problem were characterized by an exact fit through p sample observations when p linear parameters are estimated, no effective algorithm arose until the development of linear programming in the 1940s. It was then quickly recognized that the median regression problem could be formulated as a linear program, and the simplex method employed to solve it. The algorithm of Barrodale and Roberts (1974) provided the first efficient implementation specifically designed for median regression and is still widely used in statistical software. It can be concisely described as follows. At each step, we have a trial set of p 'basic observations' whose exact fit may constitute a solution. We compute the directional derivative of the objective function in each of the $2p$ directions that correspond to removing one of the current basic observations, and taking either a positive or negative step. If none of these directional derivatives are negative the solution has been found, otherwise one chooses the most negative, the direction of steepest descent, and goes in that direction until the objective function ceases to decrease. This one dimensional search can be formulated as a problem of finding the

solution to a scalar weighted quantile problem. Having chosen the step length, we have in effect determined a new observation to enter the basic set, a simplex pivot occurs to update the current solution, and the iteration continues.

This modified simplex strategy is highly effective on problems with a modest number of observations, achieving speeds comparable to the corresponding least squares solutions. But for larger problems with, say $n > 100{,}000$ observations, the simplex approach eventually becomes considerably slower than least squares. For large problems recent development of interior point methods for linear programming problems are highly effective. Portnoy and Koenker (1997) describe an approach that combines some statistical preprocessing with interior point methods and achieves comparable performance to least squares solutions even in very large problems.

An important feature of the linear programming formulation of quantile regression is that the entire range of solutions for $\tau \in (0, 1)$ can be efficiently computed by parametric programming. At any solution $\hat{\beta}(\tau_0)$ there is an interval of τ's over which this solution remains optimal, it is straightforward to compute the endpoints of this interval, and thus one can solve iteratively for the entire sample path $\hat{\beta}(\tau)$ by making one simplex pivot at each of the endpoints of these intervals.

5. Statistical Inference for Quantile Regression

The asymptotic behavior of the quantile regression process $\{\hat{\beta}(\tau): \tau \in (0, 1)\}$ closely parallels the theory of ordinary sample quantiles in the one sample problem. Koenker and Bassett (1978) show that in the classical linear model;

$$y_i = x_i\beta + u_i$$

with u_i iid from dfF, with density $f(u) > 0$ on its support $\{u \mid 0 < F(u) < 1\}$, the joint distribution of $\sqrt{n}(\hat{\beta}_n(\tau_i) - \beta(\tau_i))_{i=1}^m$ is asymptotically normal with mean 0 and covariance matrix $\Omega \otimes D^{-1}$. Here $\beta(\tau) = \beta + F_u^{-1}(\tau)e_1$, $e_1 = (1, 0, \ldots, 0)'$, $x_{1i} \equiv 1$, $n^{-1}\sum x_i x_i' \to D$, a positive definite matrix, and

$$\Omega = (\omega_{ij} = (\min\{\tau_i, \tau_j\} - \tau_i\tau_j)/(f(F^{-1}(\tau_i)f(F^{-1}(\tau_j)))$$

When the response is conditionally independent over i, but not identically distributed, the asymptotic covariance matrix of $\xi(\tau) = \sqrt{n}(\hat{\beta}(\tau) - \beta(\tau))$ is somewhat more complicated. Let

$$\xi_i(\tau) = x_i\beta(\tau)$$

denote the conditional quantile function of y given x_i, and $f_i(\cdot)$ the corresponding conditional density, and define;

$$J_n(\tau_1, \tau_2) = (\min\{\tau_1, \tau_2\} - \tau_1\tau_2)n^{-1}\sum_{i=1}^{n} x_i x_i'$$

and

$$H_n(\tau) = n^{-1}\sum x_i x_i' f_i(\xi_i(\tau))$$

Under mild regularity conditions on the $\{f_i\}$'s and $\{x_i\}$'s, we have joint asymptotic normality for vectors $(\xi(\tau_i), \ldots, \xi(\tau_m))$ with mean zero and covariance matrix

$$V_n = (H_n(\tau_i)^{-1}J_n(\tau_i, \tau_j)H_n(\tau_j)^{-1})_{i=1}^m$$

An important link to the classical theory of rank tests was made by Gutenbrunner and Jurečková (1992), who showed that the rankscore functions of Hájek and Šidák (1967) could be viewed as a special case of a more general formulation for the linear quantile regression model. The formal dual of the quantile regression linear programming problem may be expressed as;

$$\max\{y'a \mid X'a = (1-t)X'1,\ a \in [0, 1]^n\}$$

The dual solution $\hat{a}(\tau)$ reduces to the Hájek and Šidák rankscores process when the design matrix, X, takes the simple form of an n vector of ones. The regression rankscore process $\hat{a}(\tau)$ behaves asymptotically much like the classical univariate rankscore process, and thus offers a way to extend many rank based inference procedures to the more general regression context.

6. Extensions and Future Developments

There is considerable scope for further development of quantile regression methods. Applications to survival analysis and time-series modeling seem particularly attractive, where censoring and recursive estimation pose interesting challenges, respectively. For the classical latent variable form of the binary response model where;

$$y_i = I(x_i'\beta + u_i \geqslant 0)$$

and the median of u_i conditional on x_i is assumed to be zero for all $i = 1, \ldots, n$, Manski (1985) proposed an estimator solving,

$$\max_{\|b\|=1} \sum (y_i - 1/2)I(x_i'b \geqslant 0)$$

This 'maximum score' estimator can be viewed as a median version of the general linear quantile regression estimator for binary response;

$$\min_{\|b\|=1} \sum \rho_\tau(y_i - I(x_i'b \geqslant 0))$$

In this formulation it is possible to estimate a family of quantile regression models and explore, semi-parametrically, a full range of linear conditional quantile functions for the latent variable form of the binary response model.

Koenker and Machado (1999) introduce inference methods closely related to classical goodness of fit

statistics based on the full quantile regression process. There have been several proposals dealing with generalizations of quantile regression to nonparametric response functions involving both local polynomial methods and splines. Extension of quantile regression methods to multivariate response models is a particularly important challenge.

7. Conclusion

Classical least squares regression may be viewed as a natural way of extending the idea of estimating an unconditional mean parameter to the problem of estimating conditional mean 'functions,' the crucial step is the formulation of an optimization problem that encompasses both problems. Likewise, quantile regression offers an extension of univariate quantile estimation to estimation of conditional quantile functions via an optimization of a piecewise linear objective function in the residuals. Median regression minimizes the sum of absolute residuals, an idea introduced by Boscovich in the eighteenth century.

The asymptotic theory of quantile regression closely parallels the theory of the univariate sample quantiles; computation of quantile regression estimators may be formulated as a linear programming problem and efficiently solved by simplex or barrier methods. A close link to rank based inference has been forged from the theory of the dual regression quantile process, or regression rankscore process.

Recent nontechnical introductions to quantile regression are provided by Buchinsky (1998) and Koenker and Hallock (2001). Most of the major statistical computing languages now include some capabilities for quantile regression estimation and inference. Quantile regression packages are available for R and Splus from the R archives at http://lib.stat.cmu.edu/R/CRAN and Statlib at http://lib.stat.cmu.edu/S, respectively. Stata's central core provides quantile regression estimation and inference functions. SAS offers some, rather limited, facilities for quantile regression.

Linguistic Anthropology

'Linguistic anthropology' is an interdisciplinary field dedicated to the study of language as a cultural resource and speaking as a cultural practice. It assumes that the human language faculty is a cognitive and a social achievement that provides the intellectual tools for thinking and acting in the world. Its study must be done by detailed documentation of what speakers say as they engage in daily social activities. This documentation relies on participant observation and other methods, including audiovisual recording, annotated transcription, and interviews with participants.

As an interdisciplinary field, linguistic anthropology has often drawn from and participated in the development of other theoretical paradigms. Some of its own history is reflected in the oscillation often found among a number of terms that are not always synonyms: linguistic anthropology, anthropological linguistics, ethnolinguistics, and sociolinguistics. Its main areas of interest have changed over the years, from an almost exclusive interest in the documentation of the grammars of aboriginal languages to the analysis of the uses of talk in everyday interaction and throughout the life span (Duranti 1997, Foley 1997). This article provides a brief historical account of linguistic anthropology, and highlights important past and present issues, theories, and methods.

1. Linguistic Anthropology within the Boasian Tradition

In the holistic tradition established by Franz Boas (1858–1942) in the USA at the beginning of the twentieth century, anthropology was conceived as

comprising four subfields: archaeology, physical (now 'biological') anthropology, linguistics (now 'linguistic anthropology'), and ethnology (now 'sociocultural anthropology'). This vision of anthropology differs from the one found in the European tradition, where linguistics and social anthropology remained rigidly separate disciplines for most of the twentieth century, despite the emphasis on the use of native languages in fieldwork among UK anthropologists, and the theoretical and methodological influence of Bronislaw Malinowski (1884–1942), who wrote about the importance of linguistic research for an anthropological understanding of human societies. In the 1950s, the adoption of the term 'ethnolinguistics' (reflecting the European preference for 'ethnology' over '(cultural) anthropology') for those studies that merged linguistic and anthropological interests signaled the intellectual recognition, at least in some European academic circles, of the importance of an 'ethnological side' of linguistic studies (Cardona 1976), but the institutional recognition of such a discipline within European anthropology has been slow to come. European scholars with research interests similar to those of North American linguistic anthropologists are thus more likely to be found in departments of linguistics, foreign languages and literatures, folklore, communication, sociology, or psychology.

To understand the special role given to the study of languages in the Boasian tradition, we must go back to the time when anthropology became a profession in the USA, in the period between the last decades of the nineteenth and the first decades of the twentieth century. In that time, the study of American Indian languages emerged as an essential part of anthropological research. John Wesley Powell (1834–1902), the founder of the Bureau of Ethnology, later renamed Bureau of American Ethnology (BAE), supported, through grants from the US government, linguistic fieldwork, in the belief that by collecting vocabularies and texts from American Indian languages, it would be possible to reconstruct their genetic relations and thus help in the classification of American Indian tribes. Boas himself had become fascinated by the grammatical structures of Chinook and other languages of the American northwest coast early on in his fieldwork, and seized the opportunity to work for the BAE and edit the *Handbook of American Indian Languages* (1911).

Although Boas, a diffusionist, was quite skeptical of the possibility of using languages for reconstructing genetic relations between tribes—and was against any correlation between language and race—he tried to transmit to his students a passion for the details of linguistic description and the conviction that languages were an important tool for (a) fieldwork, and (b) the study of culture, especially because the categories and rules of language are largely unconscious and thus not subject to secondary rationalizations. Furthermore, Boas was committed to what later became known as 'salvage anthropology,' that is the documentation of languages and cultural traditions that seemed on the verge of disappearing. This enterprise—a struggle against time due to the great damage already done, by the end of the nineteenth century, to the indigenous cultures of the Americas by European colonizers—produced valuable information on Native American traditions, but it had its methodological and theoretical drawbacks, the most flagrant of which was the inability to see or accept the effects of cultural contact and colonization.

Through his writing and teaching, Boas brought scientific rigor to linguistic description and helped demolish a number of unfounded stereotypes about the languages that were then called 'primitive.' In an 1889 article entitled 'On alternating sounds,' Boas argued that the commonly held view that speakers of American Indian languages were less accurate in their pronunciation than speakers of Indo-European languages was false and probably due to the lack of linguistic sophistication of those who had first tried to describe indigenous languages. Consistent with his cultural relativism, Boas believed that each language should be studied on its own terms rather than according to some preset categories based on the study of other, genetically unrelated languages (e.g., Latin). In his 'Introduction' to the *Handbook* (1911), Boas provided an overview of the grammatical categories and linguistic units necessary for the analysis of American Indian languages and argued against overgeneralizations that would obscure differences across languages. He identified the sentence (as opposed to the word) as the unit for the expression of ideas, and listed a number of grammatical categories that are likely to be found in all languages, while pointing out that the material content of words (the meaning of lexical items) is language-specific and that languages classify reality differently. One language might express the semantic connections among words pertaining to the same semantic field by modifying one basic stem, whereas another language might have words that are etymologically completely unrelated. As examples of the latter type, Boas (1911) mentioned the different words that are used in English for concepts centered around the idea of 'water'—'lake,' 'river,' 'brook,' 'rain,' 'dew,' 'wave,' 'foam'—and four different words for concepts based on 'snow' in Eskimo. These examples were later taken out of context and the number of words for 'snow' in Eskimo (languages) grew larger and larger over the next decades in both academic and popular publications.

It was Edward Sapir (1884–1939) who, more than any other of Boas's students, further developed Boas's interest in grammatical systems and their potential implications for the study of culture, and trained a new generation of experts of American Indian languages (e.g., Mary Haas, Morris Swadesh, Benjamin Lee Whorf, Carl Voegelin). Unlike Boas, however, Sapir was not a four-field anthropologist. He wrote and

lectured on culture and personality, but had no interest in archaeology or physical anthropology, which he saw as being more appropriately housed in museums than in anthropology departments. Furthermore, whereas Boas was skeptical of genetic reconstruction and tended to favor acculturation as a cause of similarities between languages, Sapir was a strong believer in the power of the comparative method, which he used to reconstruct Proto-Athabascan and posit the Na-Déné linguistic group (comprising Athabascan, Tlingit, and Haida).

While he was at Yale, Sapir encouraged his students to go into linguistics rather than anthropology, and it is no accident that they ended up calling themselves 'anthropological linguists.' They thought of themselves primarily as linguists, as demonstrated by their dedication to the study of the grammatical structures of American Indian languages (and other previously undocumented languages). Their emphasis on fieldwork and their preference for historical and descriptive linguistics kept them separate from the new linguistics of the 1960s, Chomsky's generative grammar. To anthropological linguists such as Mary Haas the advent of this new paradigm was a threat because (a) it seemed more committed to linguistic theory than to languages, and in fact devalued grammatical description *per se*; (b) it was (especially at the beginning) almost exclusively based on English—Chomsky argued that one could posit universals of language by working on one language; and (c) it predicated the need for linguists to work on their own intuitions instead of working with native speakers or inferring grammatical rules on the basis of a corpus of elicited texts (Haas 1987). This last point was particularly problematic for those students of Native American languages who often had only one or two old speakers to work with and could not find younger speakers to train in linguistic theory and methods.

1.1 Linguistic Relativity in the History of Linguistic Anthropology

Linguistic relativity is a general term used to refer to various hypotheses or positions about the relationship between language and culture (see *Sapir–Whorf Hypothesis*). Although Sapir and Whorf differed in their discussion of the relationship between language and culture, and never produced a joint formulation of what is meant by linguistic relativity, there is no question that the themes and issues often identified as linguistic relativity are the continuation of the Boasian paradigm. First, Sapir and Whorf followed Boas's intellectual curiosity for the indigenous languages of North America as a way of channeling a more general fascination for alternative ways of being in the world and the desire to make sense of those ways. Second, to the extent to which it started from an emphasis on human diversity, linguistic relativity was related to cultural relativism, if not a corollary of it. It was accompanied by a concern for the proper representation of grammatical systems that could not be described using the categories of European languages. Third, the same antiracist attitude that characterized Boas's views on human diversity seemed to motivate the lack of value judgment associated with linguistic diversity.

For Sapir, linguistic relativity was a way of articulating what he saw as the struggle between the individual and society (Mandelbaum 1949). In order to communicate their unique experiences, individuals need to rely on a public code over which they have little control. Linguistic rules are usually unconscious, and it is difficult for individual speakers to enter the logic of the linguistic system and alter it to their liking. In this perspective, linguistic relativity becomes a way of exploring the power that words have over individuals and groups. It is thus a precursor to more recent topics in linguistic anthropology, such as language ideologies (see Sect. 4.3).

Sapir never developed the conceptual framework or methodology for testing the implications of these intuitions about the language faculty. This task was left to another important figure in the history of linguistic anthropology, Benjamin Lee Whorf (1897–1941), a chemical engineer who worked as an insurance inspector, taught himself linguistics, and after 1931 entered into contact with Sapir and his students at Yale. Although Whorf started out sharing several of the basic positions held by Boas and Sapir on the nature of linguistic classification, he developed his own conceptual framework, which included the distinction between *overt* and *covert* grammatical categories, and an important analytical tool for understanding what kinds of categorical distinctions speakers are sensitive to—this issue was later further developed in the work on metapragmatics (Whorf 1956). Contrary to popular belief, Whorf was not so much concerned with the number of words for the same referent (e.g., 'snow') in different languages, but with the implications that different grammatical systems and lexicons have for the way in which speakers make inferences about the world. He believed that ways of thinking may develop by analogy with 'fashions of speaking,' a concept that was later revived by Hymes's notion of 'ways of speaking.'

Whorf's work was harshly criticized in the 1960s and 1970s, especially after the publication of Berlin and Kay's (1969) study of color terminology, in which they claimed that lexical labels for basic color terms are not arbitrary but follow universal principles. But more recent studies have given support to some of Whorf's ideas (Lucy 1992), and even the universality of basic color terminology and its innate perceptual saliency have been questioned (e.g., Levinson 2000). Sapir and Whorf's ideas about the unconscious aspects of linguistic codes continued to play an important part in the history of linguistic anthropology, and re-

appeared in the 1980s in the context of a number of research projects, including the study of language ideology (Kroskrity 2000).

2. Linguistic Anthropology in the 1960s

In the same years in which Chomsky's generative grammar was becoming popular in the USA, two other important programs were also launched: the ethnography of communication and urban sociolinguistics (see *Sociolinguistics*).

Through his own qualitatively oriented work and his collaboration with Charles Ferguson on multilingualism in South Asia, John Gumperz criticized the notion of 'language' as used by linguists, and introduced the notions of variety, repertoire, and linguistic community or speech community. In the same years, Dell Hymes launched a call for a comparative study of communicative events to capture the ways in which speaking is a cultural activity and should be studied as such. His collaboration with Gumperz produced a new paradigm in linguistic anthropology, one in which researchers were expected to study both knowledge and use of languages through ethnographic methods (Gumperz and Hymes 1964). The object of inquiry was no longer the grammars of indigenous languages, but communicative events and contextual variation within and across speech communities. Although Hymes stressed the need to see linguistics as part of anthropology, and insisted on the name 'linguistic anthropology' over 'anthropological linguistics,' he also helped defined a domain of inquiry that was in many ways independent of both linguistics and the other subdisciplines within anthropology. Whether intended or not, this effort resulted in a type of linguistic anthropology that was much less preoccupied with grammatical description and linguistic reconstruction than the one practiced by the previous generations, and more focused on the performance of language and consequently its aesthetic and political dimensions. This emphasis on the actual use of language allowed for great progress in the understanding of the cultural organization of speaking, but left scholars in other fields worrying about linguistic issues that were still central to anthropology, such as language evolution. While Chomsky was leading an antibehavioristic 'cognitive revolution,' Gumperz and Hymes were trying to develop a paradigm in which language behavior could be fully explored as social activity. In this perspective, the notion of communicative competence was central (see *Communicative Competence: Linguistic Aspects*).

2.1 From Communicative Competence to Performance

The documentation of variation and the observation of the social life of speech had taught fieldworkers that Chomsky's notion of ideal speaker-hearer was problematic for many reasons, including the fact that not all members of a speech community have access to the same verbal resources or the same opportunities to use them. In his writings, Hymes shifted the focus from Universal Grammar to linguistic diversity. This change had methodological implications. From eliciting grammatical patterns and speech genres (e.g., myths, traditional stories, proverbs, riddles) from native speakers, linguistic anthropologists shifted their attention to the actual use of language in social interaction. Gumperz and Hymes's students went to the field with the goal of studying how language was being used in different events (e.g., ceremonies, village councils, classrooms) and different places (e.g., at a street corner, market, dinner table). Linguistic performance—the use of language (or its significant absence)—became the starting point of any investigation (Bauman and Sherzer 1974).

Hymes and others reconceptualized performance as a realm of social action, which emerges out of the interaction with other speakers and as such is not reducible to the use of the linguistic knowledge controlled by one individual. The focus on performance allowed fieldworkers to recognize the creative dimensions of any act of speaking, the role of individuals and groups in the reproduction and transformation of linguistic codes and the institutions they support, the responsibility associated with any display of one's verbal skills, and the interactive construction of messages and meanings.

3. Context

In an ethnographic approach, language is seen as permeable to social situations and social roles while at the same time helping to define those situations and roles. This means that linguistic anthropologists need analytical tools and units of analysis to define the context of speech. With this goal in mind, in the late 1960s Hymes expanded Jakobson's model of the speech event, and proposed the 'SPEAKING Model,' with each letter of the word 'speaking' standing for a cluster of dimensions of speech events that ethnographers of communication should explore: Situation, Participants, Ends, Act Sequences, Key, Instrumentalities, Norms, and Genre (Hymes 1967 reprinted in Hymes 1974). This list was meant to provide an etic grid for comparative purposes, and although it was rarely used in its entirety or formally adopted by researchers, it helped many to identify dimensions of verbal communication that had been left out of previous investigations. In the meantime, Gumperz refined his analysis of multilingualism and language contact, and became interested in the analysis of face-to-face interaction. He expanded the concept of linguistic repertoire to include the range of resources that speaker-hearers use to make inferences about the ongoing context. This line of inquiry resulted in the

notion of contextualization cues, linguistic features through which 'speakers signal and listeners interpret what the activity is, how semantic content is to be understood and how each sentence relates to what precedes or follows' (Gumperz 1982, p. 131). Typical examples of contextualization cues are intonational patterns, paralinguistic features (e.g., tempo, pausing), choice of code (e.g., English vs. Spanish), use of key words, and formulaic expressions. They can be studied in order to make sense of both successful and unsuccessful communication—'crosstalk' was the name with which miscommunication between people with different cultural backgrounds came to be known (thanks especially to a BBC program centered around Gumperz's research on South Asian speakers of English in the UK).

In the late 1970s and early 1980s, the notion of context was also being revisited by a number of other researchers within linguistic anthropology. Michael Silverstein (1976) proposed a model of indexicality that could be adapted to the sociocultural study of language in and as context. He identified linguistic signs along a continuum from highly presupposing (i.e., they can be interpreted only on the basis of an existential connection with some independently established aspect of context) to highly creative (i.e., constitutive of their own context). Deictic terms like 'this' in 'this room is cold' are presupposing because it is assumed that the room must exist for the utterance to be interpretable, whereas second-person pronouns (e.g., 'you' in English, *tu* in Spanish) are creative, given that they establish the identity of the addressee/recipient while simultaneously creating the role of addressee/recipient in the ongoing speech event. Languages that have socially differentiated second-person pronouns (e.g., the classic T/V type of distinction of many European languages, French *tu/vous*, Spanish *tu/Usted*, German *du/Sie*, and Italian *tu/Voi* or *tu/Lei*) are more extreme examples of systems in which words are used to activate or establish the relevant social coordinates of equality/inequality, solidarity/power. The study of indexicality has become a major focus of interest in contemporary linguistic anthropology, and has been accompanied by a renewed interest in the role of the human body in the establishment of the referential grounding of most communicative acts (Hanks 1990).

A more recent effort toward the definition of context is Elinor Ochs's (1996) model for the construction of social identities, which is based on a number of situational dimensions established through language use: social acts, activities (a sequence of two or more acts), and affective and epistemic stances.

The 1990s saw a rethinking of the concept of context in part due to: (a) a renewed awareness of the role of theory and methodology in defining the difference between the message and its context (Duranti and Goodwin 1992); (b) the influence of a number of theorists from other disciplines (e.g., Pierre Bourdieu, Anthony Giddens, Mikhail Bakhtin, Michel Foucault, Clifford Geertz, Paul Ricoeur); (c) the use of the concept of ideology in trying to understand how speakers conceptualize what constitutes appropriate and interpretable language; and (d) the introduction and wider adoption of new recording technologies (e.g., video, digitized images), and their implications for the definition of what constitutes an empirically adequate representation of speaking or, more broadly, communication.

4. *New Trends*

The last two decades have seen the development of several new projects involving the interface between language and other cultural resources. Three of the most important ones are language socialization, multilingualism, and the study of the linguistic dimensions of power and control.

4.1 *Language Socialization*

Although the acquisition of communicative competence was always meant to be an important part of the program in the ethnography of communication, the field of language socialization did not fully develop until the mid-1980s, when Elinor Ochs and Bambi B. Schieffelin (1984) defined it as (a) the process of getting socialized *through* language and (b) the process of getting socialized *to* language, and offered some specific directions for research. By applying an anthropological reading to prior work on language acquisition, they reframed it as embedded in culturally specific expectations about the role of children and adults in Western societies and, particularly, in white middle-class families. Using their discovery that neither one of the two speech communities they had studied (i.e., in Papua New Guinea and in Samoa) have a register corresponding to what is known as 'baby talk' or 'motherese,' Ochs and Schieffelin not only demonstrated that simplification in talking to infants, contrary to what was suggested by some linguists and psycholinguists, is not universal, but also, and more importantly, that simplification in talking to infants correlates with other forms of accommodation to children, and local conceptualizations of children and their place in society.

Although related to child language acquisition studies, language socialization studies examine the cultural implications of what is being done with, to, around, and through talk to children, with the theoretical assumption that learning is a two-way street, and that both experts and novices may come out of routine social encounters with new ways of thinking, acting, and feeling.

Language socialization is conceptualized as a never-ending process because speakers never stop learning

new ways of using language, for example in school, at work, in church, at play. Among the various forms of 'secondary socialization,' literacy has occupied an important role in linguistic anthropology. The work of Shirley Brice Heath (1983) has been very influential in showing the benefits of an ethnographic study of literacy practices in the home, where children are exposed to literacy in ways that may or may not be precursors of the type of activities they will encounter in school.

4.2 *Multilingualism: New Perspectives on Contact and Change*

In the 1980s the writings of Mikhael Bakhtin (and one of his alter egos, Valentin Voloshinov) were particularly influential for their conceptualization of meaning as a joint activity, the attention given to coexisting styles and voices within the same 'text,' and the identification of both centripetal (toward unity and standardization) and centrifugal forces (away from unity and standardization) in language use. The notion of a unitary language then becomes both empirically and ideologically suspect because it hides from us the inequality inherent in any linguistic system, as well as the potential and actual aesthetic effects of the juxtaposition of multiple voices and coexisting language varieties. Bakhtin's work inspired a number of linguistic anthropologists including Jane and Kenneth Hill (1986), who introduced the notion of syncretic language to describe the mixing of grammars that takes place in contemporary Mexicano (Nahuatl) (see *Code Switching: Linguistic*). Even when speakers are no longer considered bilingual, some aspects of their 'lost' language and its cultural contexts are maintained, sometimes in occasional code switches and in a variety of other hybrid constructions. It is the task of the researcher to find out what survives of the old code and under what conditions it reappears in spoken or written discourse. Communities differ in the extent to which they recognize the presence of alternative ways of speaking. Ideological positions based on linguistic purism, enforcement of national identity, and control over ethnic boundaries play an important role in the types of language varieties that are supported or oppressed (Schieffelin et al. 1998).

4.3 *Power and Control*

The study of speaking as a cultural practice cannot be made without encountering the issue of how language can be used to control the action of others. A number of contributions within linguistic anthropology have dealt with this issue.

Building on Goffman's notion of 'face work' and Grice's conversational maxims, Penelope Brown and Stephen Levinson (1987, first published in 1978) presented a theory of politeness as a set of strategies based on rational principles used to mitigate 'face threatening acts.' (see *Politeness and Language*). In this theory, language plays a crucial role in mediating differences in power between speakers.

Other approaches have stressed the lack of control that speakers have over their linguistic resources. For example, the analysis of traditional oratory by Maurice Bloch defined it as a coercing system within which speakers could only reproduce the existing power relations. Earlier work on language and gender also uncovered some of the implications in linguistic codes and linguistic routines that are responsible for defining female speakers not only as different, but as weak, unassertive, or submissive (see *Language and Gender*). More recent work has questioned some of these findings, at least as generalized statements about women, and stressed the importance of careful analysis of face-to-face encounters. Marjorie H. Goodwin (1990) found the girls in her study as assertive and confrontational as boys. But she also discovered that there were some differences in the interactional strategies used by boys and girls. Among girls, offenses were constructed out of reported deeds, and especially reported speech, by absent parties (in the so-called 'he-said-she-said' sequences).

As researchers improve their understanding of the subtle functioning of different language varieties (e.g., codes, dialects, registers, genres, styles) in the definition of social identities (e.g., gender, race, ethnicity), they unveil the active roles that speakers play in adapting existing linguistic resources to their interactional goals, and their ability simultaneously to index multiple social worlds and their associated identities (Hall and Bucholtz 1995, Zentella 1997).

The power of new technologies in the definition of persons and their rights was a central theme of Michel Foucault's historical analysis of the development of asylums and other institutions that dealt with health in France. In a similar vein, but using detailed analysis of face-to-face encounters in which participants communicate through talk, gestures, and the use of material artifacts, Charles Goodwin (1994) identified a series of interpretive procedures (e.g., 'coding,' 'highlighting') which use particular types of inscription techniques to constitute what he calls 'professional vision.'

5. *Methods*

In the last few decades of the twentieth century, there was considerable improvement in the tools used in documenting language use. Whereas descriptions of verbal activities such as greetings, proverbs, insults, and speechmaking used to be based on participant observation or on work with native speakers, today researchers are expected to have recordings of exchanges in which the phenomena they describe are occurring spontaneously. As the technology for visual documentation improves and becomes more access-

ible, we are able to notice phenomena (e.g., synchronization between talk and gestures) which used to be missed in past analysis of verbal communication. At the same time, audiovisual documentation has also increased the level of intrusion into people's lives. This means that researchers must be ever more aware of the social and ethical dimensions of fieldwork. The relationship between researchers and their subjects is as delicate and as important as any other human relationship and as such requires care, mutual respect, and honesty. If the goal of our study is a better understanding of the role played by language in the human condition, we must be guided in our efforts by the desire to improve our communication across social and cultural boundaries. This must also apply to our fieldwork situation and our relationship with the speech communities we want to study.

Fieldworkers' participation in the social life of the community must be recorded as systematically as possible. This is done by writing field notes and by transcribing recordings of social encounters, activities, and events. Field notes are important because they provide researchers with a chance to document important information (which is soon forgotten if not written down) and reflect on what they have just experienced. Transcription is equally important because it allows researchers to fix on paper (or on a computer screen) salient aspects of interactions that can then be interpreted, translated, collected, and compared. Transcription is thus a particular type of what Ricoeur called 'inscription,' that is an abstraction and a fixing of something that by nature is or was moving across time and space. Linguistic anthropologists strive to produce rich transcripts by relying on native speakers who have the necessary cultural background to provide the information necessary to make sense of what is being said. There are many different ways of transcribing speech and nonverbal communication, and it is important for researchers to become familiar and experiment with more than one way before choosing the one that better fits their research goals and needs. For example, those who are interested in grammatical analysis must provide word-by-word glosses; for those who are interested in the relation between speech and the spatial organization of the event, visual representations of the settings become crucial; a transcript that utilizes phonetic symbols is appropriate when writing for linguists, but would be too hard to decipher for anyone else. Similarly, a transcript that tries to cover most of the information available to the participants at the time of speaking would be too cumbersome and equally hard to interpret. More generally, a transcript is always work in progress. It constitutes a first analysis of the data collected. It forces us to make important decisions about what is salient in an interaction and, at the same time, while being produced or once completed, it can reveal phenomena that we might otherwise have missed.

Linguistic Fieldwork

1. History

The history of linguistic fieldwork began in the nineteenth century when linguists started to explore the dialects of European languages. The most famous fieldworker of this time was Edmond Edmont who helped the Swiss dialectologist Jules Gilliéron to collect data for the *Atlas linguistique de France*. Cycling to 639 locations, he interviewed 700 dialect speakers (Chambers and Trudgill 1980, p. 20). Non-European unwritten languages were first systematically investigated on a large scale by the anthropologist Franz Boas (1858–1942), who started to do fieldwork on American Indian languages at the end of the nineteenth century. Boas was also the teacher of a number of influential twentieth century anthropologists and linguists, e.g., Margaret Mead, Edward Sapir, and Leonard Bloomfield.

Until recently linguistic fieldwork on unwritten non-European languages did not attract much attention in mainstream linguistics. It is only since the early 1990s that the linguistic departments of universities and the professional societies have become increasingly aware of the need for researching these languages, about 90 percent of which are endangered (Grenoble and Whaley 1998, Krauss 1992).

2. Learning and Analyzing Unresearched Languages

Fieldwork on languages which have not yet been described differs from other kinds of linguistic fieldwork in that the linguist comes to the speech community with no or only marginal knowledge of the language (called field language). The process of analyzing its structure and use is therefore closely tied to the process of language learning. This means that the choice of research topics, the sequence in which they are studied, and the research methods and techniques depend on the fieldworkers' progress in learning. The better they understand and speak the language, the higher the quality of their data will be, because they will have to rely less on translation. Although the progress of learning a field language depends on the structure of the language and the talent of the researchers and their teachers, experience shows that the methods which have been developed for learning and analyzing a field language work well for very different types of languages and people.

Since languages are never homogenous systems, but show regional, societal, and situational variation, the linguists and the speech communities they work with have to decide which variety should be the object of their first investigation. Only when they have a good command of one variety can they endeavor to study another.

3. Time Plan

Before leaving for fieldwork, the researchers gather as much information as possible about the field language, and the political and sociocultural situation of the speech community they are going to visit. If no information of the structure of the language is available, they should try to access information about related languages in order to get an idea of what to expect. For the work in the field itself, the ideal time plan consists of at least three field trips. The first trip is used for establishing contact and collecting the first samples of data. On the second trip the main body of data is collected, while the last trip will be used for filling gaps and checking what has remained unclear after the analysis and description of the results of the previous trip.

Data collection during the fieldwork is not confined to audio or video recording of spoken language and taking notes during interviews. Rather, all recordings need to be transcribed and translated with the help of native speakers who understand exactly the context of the speech situation and what the people are talking about. In addition, the fieldworker should at least draft a rough analysis of the data, as only analysis and description reveal gaps and unclear items in the data. If for practical and financial reasons it is not possible to visit the fieldwork site several times, the fieldworker has to structure her/his stay into comparable phases of work, so that phases of interviews and recording, translation, and transcription alternate with phases where the researcher steps back from data collection in order to concentrate on analysis and description.

The question of how much time has to be planned for doing fieldwork with the purpose of writing a grammar, compiling a dictionary, or editing a reason-

able number of texts cannot be answered as it depends on the situation of the fieldwork, how the fieldworkers and the speech community cooperate, the availability, talent, and the training of the people they work with, the complexity of the language and culture, etc. In other words, the course of fieldwork is influenced by numerous things that cannot be predicted, but which nevertheless have to be planned. In order to cope with all kinds of unexpected difficulties, the research plan has to be structured in such a way that even in the event of a premature abandonment of the project, the data are sufficiently processed to yield at least some useful output. With regard to dictionary work this means, for instance, that you do not start with the letter A and then work through the alphabet letter by letter, because if the project stops for whatever reasons, a dictionary comprising only a limited number of letters is completely useless.

4. *The Relationship between Linguists and Informants*

The outcome of fieldwork always depends on how well the researchers are accepted by the community, and on which people they can work with. The ideal fieldwork situation is to live in a family or similar kind of group, and be exposed to the field language most of the day. This, however, presupposes that the researchers can adjust to a different standard of food and hygiene, accept their rules of behavior, and can tolerate less privacy than most academics are used to. After having settled, the most difficult task is to find people who can work with the researcher on a regular basis. Especially at the beginning, these people, traditionally called informants, must be able to communicate with the linguist in a second language; but they should also be good speakers of their native language and enjoy studying it together with the linguist. Which people whom the speech community considers to be suitable informants do not exclusively depend on what kind of skills are required for the work, but may also be determined by the linguist's age and sex, by family relations, prestige, or political matters (Grinevald Craig 1987, pp. 9–13)

As in Western societies, work relationships can be of very different kinds. But what makes it more difficult is that fieldworkers do not know beforehand how the speech community will define the roles of the linguist and the informants. None of the recently suggested terms for 'informant,' e.g., 'language helper,' 'native expert,' or 'consultant,' can cover all these types of relationships. Therefore, instead of inventing seemingly politically correct terms, the traditional term 'informant' is given preference in this article.

The relationship between linguists and speech communities should be based on a collaborative approach in which the linguists not only research indigenous languages, but also become involved in the training of native linguists and in language maintenance projects (Grinevald Craig 1997, Wilkins 1992). Apart from their work relations, it is desirable that fieldworkers cultivate friendly relationships within the speech community; in an atmosphere of mutual trust, native speakers will be more ready to advise them on culturally appropriate behavior, and allow them to gain deeper insights into the culture and language.

5. *Types of Method*

The methods used in linguistic fieldwork depend on the research topic, the progress in the linguist's ability to communicate in the then field language, and the kind of work that informants regard as being worthwhile. The best way to ensure the interest and cooperation of informants is to explain to them what one is doing and why. The more the informants understand the linguist's work, the more they can contribute. Thus linguistic fieldwork should be understood as a process of mutual learning in which the linguist learns something about the structure and the use of the field language, and the informants learn something about linguistic methods and the structure of their language.

In particular, linguists employ three kinds of methods: participant observation, interviews, and the recording of narratives, conversations, and other kinds of verbal interaction. Participant observation means that linguists take part in the activities of the speech community so that they can observe how the people communicate and, if they are allowed to play an active role, can also learn to communicate themselves. In the early stages of fieldwork, for instance, games are a good occasion for active participant observation, as the vocabulary used in games is restricted and repetitive, and the grammatical structure of what is said is usually simple.

Participant observation is an excellent means of learning the rules of verbal conduct and the appropriate speech formulas in various situations. It also helps to extend one's vocabulary, as it is easy to memorize new words and their contextually bound meaning when they can be associated with a particular activity. But for the analysis of grammatical structure it is less useful; in order to capture various types of grammatical constructions, one needs to write down hundreds of examples, which is hardly possible while being engaged in activities.

Inexperienced fieldworkers might think that interviews are the easiest and fastest way to obtain all the information you need for grammatical analysis and the compilation of a dictionary. This is an error. Before even thinking of an interview, the linguists need to study 'the local ecology of questioning,' i.e., 'to find out who is allowed to question who, when and how'

(Duranti 1997, p. 104). If it is all right to ask questions, the researcher must be careful only to ask those questions the informants can easily answer; not being able to answer a question about their mother tongue can be so embarrassing that they will try to avoid further interviews, or invent a false answer in order to save face. Questions must be worded in such a way that informants can spontaneously answer without being influenced by what they think the linguist wants to hear.

Two types of interview can be distinguished: the metalinguistic interview and the direct elicitation of language data such as words and sentences. The main purpose of the metalinguistic interview is to help with the transcription and translation of recorded texts, and to provide the necessary background information for understanding their content. Before recording the first texts, however, the linguists should learn the basic vocabulary and grammatical structure of the language. Usually they will do this by elicitation, although there are reportedly cases where the speech community appoints one or two people to teach the linguist in their own way (Wilkins 1992).

All grammatical descriptions must be based on texts which have been recorded, transcribed, and translated, because the function of many grammatical constructions only becomes clear when the wider context of their use is known. In interviews the informants only produce isolated sentences; how these would fit into the natural flow of narratives or other genres of speaking will remain unclear. Nevertheless, elicitation remains necessary in all phases of fieldwork, because even a very large corpus of texts does not contain all wordforms and grammatical constructions which belong to a systematic grammatical description. Similarly, the lexicography of a field language relies on elicitation and the recording of texts.

6. *Fieldwork for Grammatical Descriptions*

If the field language is an unwritten language, the very first thing that needs to be done is to investigate the sound system and develop an orthography. A good method which has been practiced by many linguists starts with a minimum dictionary (Foley 1991, Kibrik 1977, pp. 35–9, Nida 1949, pp. 175–91). This minimum dictionary contains 200–500 words of a maximum length of two syllables which denote different kinds of people, bodyparts, animals, concrete objects, every day activities, states of being, and properties (e.g., words for 'child,' 'dog,' 'house,' 'eat,' 'walk,' 'sleep,' 'sick,' 'big,' 'small'). As these words can be combined to form meaningful utterances, they do not only serve for the investigation of the sound system, but will also, later on, be used to form the first phrases and sentences (e.g., 'the small dog,' 'the child is sick,' 'the child is sleeping,' etc.).

In order to avoid translations from the second language into the field language, the informants are asked to answer questions like 'Could you tell me the names of the most common animals here? What are the basic food items?' and so on. If the word is not too long, the linguist writes it down in a phonetic transcription and asks the informant to translate it or describe its meaning. After at least 200 words have been recorded, the informant's pronunciation of these words are recorded on a tape or disk. First the linguist says the translation equivalent, or the paraphrase, of each word, then the informant repeats the word in question two or three times in the field language. Afterwards the linguist makes a more refined phonetic transcription which is used for a phonological analysis and the design of a practical orthography, both of which will probably have to be revised later on. If there are people in the community who know to read and write in the regional lingua franca, they should help with the development of the orthography to make sure that it is also acceptable and practicable from a technical point of view.

Once the orthography has been designed, the fieldworker can start with the elicitation of short utterances. Again translations should be avoided, as they could result in interferences from the second language and, for example, show an unnatural word order. One strategy to overcome this problem is to give the informant only the idea of the meaning and present it in a way that it cannot be directly translated. For instance, instead of asking to translate the sentence 'Eat the rice!,' one can ask: 'Tell me, what a mother would say to her little son if she wants him to eat up his rice?' In order to elicit utterances of the most natural wording, the linguist should help the informant to imagine a realistic scenario. The linguist writes down the sentences given by the informant and later, preferably not on the same day, reads the sentences to informants and asks them to correct the pronunciation and translate the sentences into the second language. These short sentences should also be recorded; while the recording helps the informant to get used to the tape recorder, the linguist can use the recordings for learning the language.

As for the various components of grammar, it is most difficult to elicit the inflectional paradigms of verbs, since paradigms like 'I ate, you ate, he ate, …' do not make sense to informants who are not trained in linguistics. But later on, after they have become more familiar with language work, at least some of them will understand what such paradigms are. Since it is impossible to identify all morphemes of complex verb forms in the very beginning, the elicitation should start with plain imperatives as they are used by adults when addressing little children. Probably these are, as in many languages, the least complex forms.

After having captured the basic sentence structure, one should start to record, transcribe, and translate short texts, and use them as the basis for further

elicitation by asking the informant to paraphrase certain expressions or to transform sentences. If, for example, the text is about a third person, one can ask the informant to repeat it in the first person: 'How would you say this sentence if it was you who did this?'

7. The Collection of Texts

Which kinds of texts fieldworkers collect depends not only, of course, on the focus of their research, but also on what the speech community regards as both worthwhile recording and suitable for publication. The language a speech community uses for their various communicative interactions is not a homogeneous system, but consists of many styles differing in their phonology, grammar and lexicon. Since it is impossible to handle extensive variation when investigating a language from scratch, the fieldworker should start with one well-defined style and at first, if possible, stick to speakers of the same generation and background. As for transcription, translation, and grammatical analysis, the easiest types of text are narratives of personal experiences. Narratives are usually told at a moderate speed, and contain fewer elliptical sentences and a larger variety of grammatical constructions than casual conversations. Furthermore, the recording of conversations is often impaired by several people talking at the same time, which is very difficult to transcribe. Legends and folk tales, on the other hand, are less suitable than personal narratives early in research, as they may contain archaic words and proverbs which require a deeper knowledge of the language and culture. If, however, members of the speech community ask for a particular text to be recorded and written down, the linguist should never refuse.

In order to guarantee that the informants speak as naturally as possible, and do not simplify their language in reaction to the linguist's low degree of communicative competence, the linguist should ask them to tell the stories in the presence of other native speakers. Ideally, the topic should get the informants so emotionally involved that they forget the tape recorder and the linguist. Since our ethics forbid recording people without their knowledge, emotional involvement can help to overcome the 'observer's paradox,' formulated by Labov (1972, p. 113) 'To obtain the data most important for linguistic theory, we have to observe how people speak when they are not being observed.'

For the representative documentation of a language, the editing of narratives is not sufficient. In order to give a comprehensive picture of how the language is used across a large variety of speech events, it must also contain casual conversations, ceremonial events, political speeches, jokes, poems, and whatever else might count as a distinct genre in this culture (Duranti 1997, pp. 96f). The recording of such speech events is, however, only useful if the linguist and her or his team of native speakers are able to transcribe and translate them. Sometimes it is difficult to get the informants to speak on the recorder because they cannot find a topic which they think would be suitable for recording and publication. In this case it can be helpful to show them a film or a picture story and ask them to describe what they have seen. A short film which was especially designed for linguistic purposes is the so-called Pear-Story (Chafe 1980). Employing the same film for the recording of a number of people can, amongst other things, reveal recurrent patterns of discourse structure which are significant for the respective language and culture. Linguists interested in cognitive anthropology have designed fieldwork kits for highly specialized cross-linguistic investigations such as the conceptualization and expression of spatial relations and the structure of events. Besides questionnaires and video clips, these fieldwork kits also contain materials for language-related games in which native speakers have to fulfill certain tasks while being recorded.

8. Lexicographic Fieldwork

The dictionaries of field languages are usually bilingual dictionaries in which the meaning of the words of the field language are translated into an international language. Some dictionaries are trilingual and have, in addition, translations into the regional lingua franca. Both the fieldworker and the informants must be aware that writing a good comprehensive dictionary takes years, if not decades. If their time is limited, it is more reasonable to plan a glossary to accompany the edition of texts and smaller specialized dictionaries on selected topics such as the terms for food, parts of the house, animals, or speech-act verbs.

The work on a dictionary starts with compiling lists of those words which become the headwords of dictionary entries. There are two complementary methods of compiling word lists: the extraction of words from texts, and elicitation. The extraction of words from texts has the advantage that the words are embedded in sentences which can be used as natural examples in the dictionary. The disadvantage is that even the most common words may be missing. Therefore this method has to be complemented by elicitation. Elicitation begins with the identification of subject areas which should be covered by the dictionary and which are most suitable to start with because the meaning of the words is easy to understand and explain.

The biggest problem of lexicographic fieldwork is that informants are usually not fluent speakers of the second language, whereas the linguist only has a limited knowledge of the field language and culture. Furthermore, many words cannot be translated by single words of a European language because they denote very different concepts. In such cases a translation should be accompanied by a definition. If space

does not matter, the definition can be given both in the indigenous and the second language so that the semantics of the headword as understood by native speakers is clearly shown.

A good example for the usefulness of definitions are animal and plant names. A dictionary which only gives their translations would not show the taxonomy of animal and plant names in the indigenous language and culture, as the semantic relations between generic and specific terms would not be explained. In Samoan, for instance, all fishes, dolphins, whales, and turtles belong to a single category of animals which is called *i'a*. A bilingual dictionary would translate the word *laumei* as 'turtle,' but not explain that it belongs to the class of *i'a*, which is mostly misleadingly translated as 'fish.'

Linguistic Presupposition

Presuppositional information is information that is taken for granted by the participants in a discourse or a conversation. As such it has a different status from information the participants present as new or relevant. The latter information is said to be asserted. This distinction between presupposition and assertion is reflected in the linguistic structure of sentences. For example, by his use (1) a speaker typically indicates that he takes for granted that Adam ate the apple, and asserts that Thomas regrets that.

Thomas regrets that Adam ate the apple. (1)

The information that Adam ate the apple is called a presupposition of (1). This presupposition is said to be linguistically induced by the use of the factive verb 'regret.'

This way of introducing the notion of presupposition calls for a distinction. And the basic distinction that should be made is the distinction between presupposition as information taken for granted and presupposition as induced, invoked, or triggered by a linguistic expression. The first notion is the notion of presupposition as background information, that is information which is already given or taken for granted in a conversation. Stalnaker and Karttunen call it the common ground. The second notion is the notion of presupposition as information that is conventionally associated with linguistic expressions or syntactic constructions. It is found in the literature under a variety of names, potential or pre-supposition (Gazdar 1979), conventional implicature (Karttunen and Peters 1979), or elementary presuppositions (Van der Sandt 1988). Though the two notions of presupposition are fundamentally different there is a straightforward connection. If a linguistic element induces a presupposition, the sentence containing the inducing element will typically be appropriate in a context which already contains the presuppositional information. Thus (1) will normally be judged appropriate in a context in which the information that Adam ate the apple is somehow established or taken for granted. If not, one should rather convey this information in an assertoric way as in (2).

Adam ate the apple and Thomas regrets that. (2)

1. Linguistic Encoding of Presuppositions

Linguistic presuppositions can thus be seen as pieces of information triggered or induced by certain linguistic structures. Such triggers can be identified by using specific tests. These tests rely on the fact that presuppositional information tends to escape from environments which block ordinary entailments. The

traditional test is constancy under negation. Other tests are embedding under epistemic modals, embedding in the antecedent of a conditional construction and questioning. Of these the negation test is the least reliable since negative sentences can in many cases be interpreted in a metalinguistic way so as to defeat the presuppositional inference (see *Negation, Linguistics of*).

Applying these tests to the verb *stop* identifies it as a presupposition inducer.

Hubert stopped smoking (at t). (3)
Hubert used to smoke (during some period preceding t). (4a)
Hubert did not smoke (after t). (4b)
Hubert didn't stop smoking. (5a)
It is possible that Hubert stopped smoking. (5b)
If Hubert stopped smoking, he must be saving a lot of money. (5c)
Did Hubert stop smoking? (5d)

The presuppositional content of (3) is given in (4a), the non-presuppositional content in (4b). Only the presuppositional information is preserved as an inference from the embeddings in (5a) through (5d).

The following linguistic structures are widely recognized as presupposition inducers. The presuppositional information that is triggered by the relevant items is given in the b-sentences.

(a) Definite NPs (definite descriptions often including proper names and indexicals; they induce a presupposition to the effect that there is some entity satisfying the description)

The King of France is bald. (6a)
There is a King of France (6b)

(b) Cleft constructions (including 'that-' and pseudo-clefts; they trigger an existential presupposition that there is some entity satisfying the VP)

It was Adam who ate the apple (7a)
Someone ate the apple. (7b)

(c) Focal stress (induces the same existential presupposition as clefts, though many authors want to account for this inference by an independent theory of focus)

ADAM ate the apple (8a)
Someone ate the apple. (8b)

(d) 'Wh'-questions (the presuppositional material is obtained by existential quantification over the variable introduced by the 'wh'-expression)

Who ate the apple? (9a)
Someone ate the apple. (9b)

(e) Quantifiers (the strong quantifiers 'all,' 'most,'… ; weak quantifiers like 'some' are considered to be ambiguous between a presuppositional and a non-presuppositional reading; the presupposition induced is that the domain of quantification is non-empty (see *Quantifiers, in Linguistics*)

All of John's children are bald. (10a)
John has children. (10b)

(f) Factive verbs ('realize,' 'discover,' 'regret,'… ; they induce a presupposition that the presuppositional complement is true)

Thomas regrets that Adam ate the apple. (11a)
Adam ate the apple. (11b)

(g) Temporal clauses ('before,' 'while,' 'since,' 'after,'… ; as in (f) they induce information of a propositional nature.

After Adam ate the apple, he was expelled from Paradise. (12a)
Adam ate the apple. (12b)

(h) Sortal restrictions on predicates ('bachelor,' 'close,'… ; the presuppositional information consists of the requirement that the arguments of the predicate are of the appropriate sort)

John is a bachelor. (13a)
John is male, adult,… . (13b)

(i) Implicative verbs ('manage,' 'succeed,'… ; put a presuppositional requirement on the action denoted by the VP)

John managed to open the door. (14a)
It took some effort to open the door. (14b)

(j) Verbs of transition ('start,' 'stop,' 'continue,'… ; see (3) above)

(a) through (d) are examples of existential presuppositions. They all involve an existential quantification over some individual- or set-variable. In (f) and (g) the presuppositional information is of a propositional nature. (h) through (j) involve requirements on the applicability of a predicate. This is only a small sample of the linguistic structures that have been identified as presupposition inducing. Further examples include focus particles ('only' and 'even,' adverbs of repetition ('again,' 'too,' 'back'), but also, more controversially, counterfactual conditionals, non-restrictive relative clauses, and discourse particles like 'because' and 'although.'

2. *Projection*

The presuppositions induced by simple sentences tend to survive under embedding, that is whenever a subsentence of a compound φ induces the presuppositional information χ this information will surface as an inference of φ. Karttunen (1973) was the first to note and catalogue numerous exceptions to this generalization. Here are some examples. In the a-

sentences the presupposition that John has children escapes from its embedded position, in the b-sentences the same presupposition does not surface as an intuitive inference.

If baldness is hereditary, John's children are bald. (15a)
If John has children, John's children are bald. (15b)
Either baldness is not hereditary, or John's children are bald. (16a)
Either John has no children or John's children are bald. (16b)
It is possible that baldness is hereditary and that John's children are bald. (17a)
It is possible that John has children and that John's children are bald. (17b)

In the terminology prevalent in the 1970s and 1980s it is said that, in the a-sentences, the presupposition that John has children is projected to the main sentence, whereas it is said to be filtered or cancelled in the corresponding b-sentences.

3. *Semantic, Pragmatic, and Discourse Presupposition*

We may distinguish between three main types of theories that deal with presupposition and projection: semantic, pragmatic, and discourse theories.

3.1 *Semantic Theories*

The semantic view originates in Frege and was revived by Strawson. It construes presupposition as a binary relation between sentences (or propositions). A presupposition is a requirement that has to be fulfilled for a sentence to have a truth-value. Thus ψ is taken to be a presupposition of φ just in case ψ has to be true in order that φ has a truth value. This requires a semantics that allows truth-value gaps. Assuming the standard definition of negation as an operator which maps truth onto falsity and vice versa, semantic presupposition can then be defined as follows:

φ semantically presupposes χ if φ entails χ and not-φ entails χ.

The defining characteristic is constancy under negation. The projection behavior of presuppositions in other embeddings follows from the definitions of the logical connectives and other operators. One problem for such theories is that they cannot handle the presuppositions triggered by adverbs like 'too' and 'even.' Here presupposition failure arguably does not affect the truth-conditions of the sentence, but the appropriateness of the utterance. It also turns out that no definition of the logical connectives can be given which accounts for all the projection data. Defenders of the semantic account are thus forced to either postulate an ambiguity in the logical connectives or transfer the burden of explanation to pragmatics.

3.2 *Pragmatic Accounts*

Pragmatic accounts (see *Pragmatics: Linguistic*) view presupposition not as a semantic relation between sentences. Instead presupposition is viewed as a property of utterances. The basic notion is that of a speaker presupposing a proposition in a context of utterance. This allows for certain variability of presuppositions with the context of utterance. The first formally developed theory of this kind is found in Gazdar (1979). The basic idea here is that a presupposition of a sentence is preserved unless it conflicts with contextual information or with an implicature invoked by its utterance. In the case of (15) through (17) this amounts to the following. A typical utterance of one of the b-sentences will invoke the implicature that it is possible that John has no children. This implicature conflicts with the presuppositional assumption that he does and so the latter is cancelled. Since no such implicature is invoked for the a-sentences, they will be interpreted as presupposition preserving.

3.3 *Dynamic Theories*

A different style of modeling is found in the dynamic approaches. The two main variants are the so-called satisfaction theory and the anaphoric or binding theory. The first derives from Stalnaker (1974) and Karttunen (1974) and has been developed in particular by Heim (1983) and Beaver. The anaphoric account is found in van der Sandt (1992) and Geurts (1999). Comparisons and different assessments of their relative merits are given in Beaver (1997) and Geurts (1999).

Both accounts start off from the idea that an utterance changes the context in which it is made. The basic requirement of the satisfaction account is that the presuppositional information should be entailed by the context of utterance. If so, the input context is incremented with the information contained in the inducing sentence. An utterance of (1) thus requires a context which entails that Adam ate the apple. If this requirement is not met, the input context is not a suitable one. In this case a mechanism of accommodation is invoked. This means that the input context will (under appropriate conditions) be revised so as to incorporate the relevant presuppositional information thus restoring interpretability.

The anaphoric or binding account is formulated as an extension of discourse representation theory. The basic tenet is that presuppositions are anaphoric expressions (see *Anaphora*). Presuppositions only differ from pronouns and other attenuated anaphors in that they have internal structure and semantic content. The basic requirement is not that the presuppositional information is entailed by the context of utterance, but that the presuppositional anaphor should find a suitable antecedent. If no such antecedent is available, the semantic material carried by the presuppositional anaphor will be accommodated in the discourse structure so as to provide an antecedent after all.

The context-change semantics of the satisfaction theory generally yields weaker predictions than are found in the anaphoric account. This is due to the different status that presuppositional material has in both theories and to the different ways in which this material is processed. For example, for a conditional of the form $\varphi \rightarrow \chi_{\langle \psi \rangle}$ where ψ is triggered by χ the satisfaction theory will predict $\varphi \rightarrow \psi$ as presupposition for the whole sentence. This yields for (15a) not the presupposition that John has children, but the presupposition that he has children *provided* that baldness is hereditary. Just like the classic semantic account, the satisfaction theory has thus to appeal to some pragmatic strengthening mechanism to derive the stronger presupposition that John has children. On the anaphoric account, presuppositional information is never transformed into a new semantic construct. Consider (15a) again. The presuppositional anaphor associated with the consequent cannot be bound to some preestablished antecedent. So some entity representing the set of John's children will be accommodated in the main context, thus yielding the stronger prediction that the utterance of (15a) presupposes that John has children.

Linguistic Turn

'The linguistic turn' generally designates in the social sciences a movement away from positivist or historicist accounts of social and historical phenomena toward analyses of the structures of representation that are understood to have helped shape those phenomena. The phrase is frequently (and sometimes loosely) used to characterize contemporary forms of the critique of ideology and the critical 'demystification' or 'demythologization' of historical and socio-political representations that offer themselves as transparent or natural accounts. Since such critical work often proceeds by way of attention to the rhetorical and conceptual articulations of representations that tend to efface their very character as representations, and since it frequently draws from philosophical and even literary theories of language and representation, it is understood to participate in a turn from socio-historical 'realities' to their linguistic presentation.

The phrase is used so broadly, however, that its strong meaning for theoretical methodology is frequently lost. Frequently, the critique of representational structures proceeds without a consequent attention to the question of language, and even some of the strongest versions of 'linguistic constructivism' fail to interrogate their own presuppositions. Thus, the linguistic turn will be defined here fairly strictly from the basis of its foundations in order to recover its meaning and implications for the social sciences. It will be defined as beginning when language is no longer understood as an instrument in social practice, but rather as the site or 'ground' for such practice. It

will be understood to have been fully undertaken when such a fundamental understanding of language shapes the procedures of the sciences themselves.

The beginnings of the linguistic turn may easily be traced to the eighteenth century and seen to be lurking in the very rich debate concerning the origins of language. It is clearly occurring in the research of Wilhelm von Humboldt and in the writings of the German Romantics, and then actively recognized—some would say, practiced—in the later works of Friedrich Nietzsche. Thus, when the official occurrence of a linguistic turn is registered in Vienna for philosophy of language, a more 'fundamental' turning is already long underway in the tradition of German philosophy that Walter Benjamin and Martin Heidegger brought to the fore in their remarkably convergent speculative writings on language. Indeed, if Ludwig Wittgenstein himself was ready to grasp in 1929 the import of Heidegger's still largely latent meditation on language and the significance of Heidegger's own linguistic practice, it is because the philosophical ground was well prepared for Heidegger's subsequent turn (his famous *Kehre*) from an existential philosophy still marked by the metaphysics of the human subject to a thought of what is given of Being in and by language.

Historians of the social sciences will provide ample testimony of methodological tremors linked to the developments noted here in philosophy of language—in short, a displacement of the human subject or human consciousness as the grounding source of meaning in signifying practice, and the requirement of rethinking the subject/object relation and relation itself. However, it may well be argued that the strong turn realized by authors such as Benjamin and Heidegger is not assumed in the social sciences in Europe until the period of the structuralist movement (a movement that explicitly unseated human consciousness from its founding role in favor of broader structures of determination: kinship systems, linguistic structures, and the laws of sexuality or desire). Even here, however, the turn to language remained frequently at no more than the level of analogy, and systems of myth or kinship were shown to be formalized equally effectively with recourse to mathematical logic (another form of appeal to a *logos*, some would argue). Thus, while structural linguistics functioned as a kind of 'point science' for the initiatives throughout the human sciences in Europe for over a decade, only the endeavors of 'post-structuralist' authors such as Michel Foucault, Jacques Lacan, Jacques Derrida, or Gilles Deleuze actually carried the notion of the linguistic constitution of being to its full import for the social sciences. Only from the time of post-structuralism did it become possible to entertain thinking the social relation from language.

The linguistic turn has thus occurred, for example, when Michel Foucault, in his methodological treatise *The Archaeology of Knowledge* (1969), announces that the fundamental element for his study of discursive formations will be the *énoncé*, the statement. In an effort to displace the governing categories of the history of thought (totalizing categories that establish continuity and that all lead back, in Foucault's view, to the sovereignty of the human consciousness), Foucault attempts a theoretical elaboration of a discursive 'object' that is always relational and always to be thought from its material emergence. 'Object' must be left here in quotation marks because the statement, as Foucault understands it, is the 'modality' or 'function' of existence of discursive facts, what 'gives' them or enables them to occur as language and thus as (a) a relation to a domain of objects; (b) a set of possible positions for an enunciative subject; (c) an element in a coexisting discursive field; and (d) a repeatable materiality. A statement, in Foucault's definition, cannot be understood as a sentence that lends itself to hermeneutic investigation or logical analysis, but must rather be seen as the material, always relational, condition for something like a sentence or a proposition. Historical analyses that seek the 'signified' of any group of signs (reading any document for the meaning it bears, any text for its 'allegorical' sense), like linguistic studies that seek rules of formation, invariably efface the irruptive, eventful character of the fact of language, returning all linguistic events to their organizing conditions. Thus they participate in what Foucault calls, in his famous *Discourse on Language*, the 'ancient elision of the reality of discourse.' Foucault's effort in thinking the *énoncé* as the material function of existence of any discursive act or organization is directed at honoring the 'anarchic' character of language—a potential for disruption which 'disciplinary' and institutional formations seek to channel and control. At the heart of his project is an assumption that the orders of knowledge and the social institutions in which they are embedded are organized by a fear of the undermining, or even violent dimensions of discourse for the orders in which it emerges (undermining for the mere fact that it can reveal the inherent lack of foundations for the social order, violent for the fact that it can carry the irruption of desire):

> 'There is undoubtedly in our society, and I would not be surprised to see it in others, though taking different forms and modes, a profound logophobia, a sort of dumb fear of these events, of this mass of spoken things, of everything that could possibly be violent, discontinuous, querulous, disordered even and perilous in it, of the incessant, disorderly buzzing of discourse.'

Of course, Foucault's own study, fiercely abstract in its unfolding design, is not without its own violence. Indeed, his *Archaeology* sometimes reads as a veritable storm of theoretical elaboration; its winds tear unrelentingly at the foundations of the history of

thought. But a glimpse at the virulence of reaction on the part of proponents of rational norms of 'communicative transparency' and/or pragmatic 'consensus' provide a clue to the explosive potential of Foucault's effort to honor the disruptive dimensions of language.

Numerous authors have pursued Foucault's 'archeological' analyses of discursive formations; in fact, significant currents in the growing field of cultural and 'post-colonial' studies principally draw upon Foucault for their understanding of the discursive constitution of social reality. Theories of social construction are deeply indebted to his analyses of 'disciplinary' knowledge and mechanisms of control. Far fewer authors have carried forward his understanding of the subversive dimensions of the enunciative act, though one sees its impact in the fields of gender studies and sexuality or in a topic such as the study of 'the practices of the everyday' by Michel de Certeau. It is for this reason that one might regard the 'linguistic turn'—which many would undoubtedly anchor in the widespread acceptance of the theory of linguistic or social 'constructionism'—as incomplete and even faltering. Theories of social construction, and even theories that stress the necessary 'performative iteration' of social norms, almost inevitably turn short of the engagement with language that marks Foucault's work (or that of the other 'post-structuralist' authors to which I referred). They fail, in particular, to attend to the materiality of discursive usage in that dimension that involves what I might term an enunciative experience with language. This avoidance is easily attributable to Foucault's own wariness regarding the 'ontologizing' and 'transcendentalizing' sources upon which he silently draws (principally Heidegger), not to speak of his strictures against anthropomorphism and humanism. But Foucault's own turn to ethical questions in his late work point firmly to the necessity of an exploration of the subject's engagement with the fact of language at the fundamental level evoked in the *Archaeology*—with the fact and manner of the way the *énoncé* is given in its material singularity. What dimension of experience is engaged with this 'gift,' and what engagements (to evoke a motif pursued throughout Jacques Derrida's late work) does it presuppose if the relations offered by the *énoncé* must be thought from the way they are brought into existence in singular instances of usage?

Heidegger had attempted in his later meditations on language to name with precisely the term 'usage' the human relation to the fact of language. To avoid turning language into a kind of transcendental horizon (a trap into which many 'linguistic constructionists' inevitably fall), and to hold to a thought of its finitude, Heidegger attempted to think through the necessity of a human 'accession' to language—i.e., the conditions for any 'interpellation' of the human subject by language, and any human response. He did not avoid a certain anthropocentrism in this undertaking, but he also pointed beyond the purview of the metaphysics of the human subject. Unfortunately, few authors have followed through Heidegger's thinking on this crucial point, though among them we may count the French psychoanalyst Jacques Lacan (whose thought of the category of the 'real' presupposes this understanding of the 'human relation to the signifier') and the French writer Maurice Blanchot, whose enormous influence on 'post-structuralist' thought still remains to be measured. But their work, taken together with that of the distinguished Jewish philosopher Emmanuel Levinas and the more recent work of authors such as Jean-François Lyotard and Jean-Luc Nancy, make it possible to pursue a thought of the manner in which the social relation opens in and with language. From a notion of the human engagement with language, they elaborate an understanding of the event by which human speech communicates a form of 'finite transcendence': a transcendence of determined orders of meaning that is first of all an exposure to the other human being. They thus make it possible, in effect, to return to a thought of the social relation like that approached by Hannah Arendt in *The Human Condition* (1998) in her effort to rethink the notion of public space and the political act itself.

This latter thought of 'communication' (not a transparent communication of signified meaning, but rather, as Walter Benjamin argued so powerfully, a communication of the very possibility of relation) clearly carries with it the obligation of defining the conditions for its engagement in critical or theoretical practice. For it is clear that the pertinence of a traditionally 'theoretical' mode of inquiry must come into question once language is engaged at levels that exceed that of its representational or instrumental function. Once a 'saying' that bespeaks the irreducible presence of an enunciating subject becomes the object of a meditation on the grounds and possibility of community (but this can be no 'object' for description), theory can no longer claim an exclusive purchase on the question of the social relation. Or it must rethink its own discursive modality and its relation to others (to the language of literature, for example). The challenge of the linguistic turn for the social sciences thus bears upon the discursive practices of the sciences themselves. It is not a challenge that requires the social sciences to abjure their commitment to clarity and rigor in analysis, but it does require them to entertain the question of their own discursive usage and the possibility of translation between discursive modes or between their own usage and that of a singular event of language. Here, it becomes clear that a fundamental reflection on linguistic usage is the very condition for a consequent engagement of the social relation—a relation that is not reducible to its linguistic determinations, but also not thinkable apart from the site of its emergence and articulation. The 'linguistic turn' is not a methodological 'given,' a path already secured; it is a required turn to the grounds of meaning that must

be repeatedly undertaken if social analysis is to achieve concreteness in its effort to regain the social itself.

Linguistic Turn and Discourse Analysis in History

1. The Linguistic Turn and the Post-modern Epistemological Crisis

The term 'linguistic turn' emerged as common currency in discussions among historians during the 1980s and 1990s to designate a sweeping, but vehemently contested, shift in the framework within which both the object or content of historical investigation (the 'past') and the methods of achieving historical knowledge of this content were defined. In its weaker, least contentious, form the linguistic turn referred to a more intense and focused attentiveness to the opacity and complexity of the linguistic forms through which all evidence of the past was mediated, and the 'truth' of the past represented, reconstructed, and communicated. The term itself was appropriated from discussions among philosophers, where it had been used as a general description of the turn in twentieth-century philosophy toward reformulating the epistemological problem of the relationship between thought and reality in terms of a relationship between language and reality. In the stronger and more contentious form that surfaced in debates among historians, however, the linguistic turn came to designate a shift away from the conventional view that language was a passive, potentially transparent instrument for transmitting content, for organizing, representing or expressing the truth of a reality outside of itself, and toward a view of language as the dense, fertile and autonomous site in and through which the objective reality of the world as well as the subjective reality of language users was actively produced or constructed. From this latter perspective, the act of taking the linguistic turn was synonymous with the claim that the production and communication of historical knowledge was inextricably entangled in the epistemological crisis associated with the transition from a modern to a 'postmodern' cultural condition.

As a particular disciplinary expression of this epochal transition to postmodernism the linguistic turn in history was grounded on three major premises. First, it accepted the ultimate futility of the historical quest to reconstruct a single, coherent narrative of human history whose pattern or structure could somehow be grasped and mapped in its totality from a transcendent position outside of the particular, contingent meanings that human beings in specific times and places had imposed on the material traces of the past, a quest most recently articulated in the national liberation narratives, global modernization theories, and Marxian historical dialectics of the Cold War decades. Second, the linguistic turn appropriated from poststructuralist theory the sweeping critique of residual beliefs in the existence of noncontingent stable identities (whether natural kinds or metaphysical essences) whose fates might be traced historically through paths of accident, evolution, repression, resistance, and liberation. National, ethnic, racial, sexual, gender, and class identities were not treated as material or metaphysical realities expressed in language and culture, but contingent, constantly changing, constructions produced in language and culture. Third, this dissolution of essential identities implied a transformation in the methods of historical representation. Access to a reality not already shaped and constructed by the linguistic medium in which it was always presented to the knower, either as subjectively lived experience or objectively perceived external object or event, was considered impossible. The historian could only interpret interpretations, could only redescribe and thus reconstruct in his or her own language the linguistic constructions of others.

Various elements of the epistemological crisis associated with the linguistic turn had been present in muted and sometimes more extreme forms within the Western historical tradition since the beginnings of the modern professionalization of history in the early nineteenth century. During the post-World War II era the disconcerting relativist implications of self-consciousness about the density and relative autonomy of the linguistic medium that mediated reality as meaningful was reined in by a broadly shared disciplinary consensus concerning the reality of the past and the methods that provided access to its truth. The more radical linguistic turn of the 1980s, with its implications that the historian's past was a construction grounded on ethical and political choices, rather than on epistemological criteria, was associated with the breakdown of this consensus, as the increasingly effective voices of previously excluded perspectives, particularly those of women, ethnic minorities, and former colonial subjects, mounted a powerful critique of established professional conventions. The linguistic turn was embedded deeply in the feminist, multiculturalist, and postcolonial 'turns' among dissident members of the disciplinary community, and connected to a new series of interdisciplinary liaisons with literary theory, cultural anthropology, and philosophy.

A major difficulty standing in the way of providing a concise description of the linguistic turn in history stems from the diverse meanings assigned to the term 'language.' The everyday conventional meaning of language as a native or vernacular language is rarely what contemporary historians have in mind. In fact, the use of the term has been extended broadly beyond the rules and practices of verbal communication in speech and writing to include nonlinguistic structures of exchange and all signifying practices through which meaning is produced, transmitted, and communicated. As the totality of meaningful action or signifying practices, 'language' becomes virtually indistinguishable from 'culture.' The favored model for organizing discussions of language by proponents of the linguistic turn during the 1980s and 1990s was the semiotic model derived from the linguistic theories of Ferdinand de Saussure and Charles Sanders Pierce, in which language is conceived as a structured system of 'signs' whose meanings are determined by their relations to each other rather than their relation to a 'transcendental' object or subject. Most influential for historians has been the development of this semiotic model in cultural anthropology and especially the French structuralist and poststructuralist theory of Louis Althusser, Roland Barthes, Jacques Derrida, Jacques Lacan, and Michel Foucault. Although 'language' and 'discourse' are still often used interchangeably in debates concerning the linguistic turn, the attempt to provide some kind of theoretical focus on the analysis of language in history has increasingly been organized around the term 'discourse.' Historians who have taken the linguistic turn tend to define the distinctiveness of their own signifying practice as 'discourse analysis.'

2. *Discourse Analysis: Enabling Structures and Communicative Practices*

Despite the widespread use of 'discourse' as an organizing concept within a variety of the humanistic and social scientific disciplines, its meanings have remained fluid, flexible, and often indefinite. However, the two general meanings of the term in common usage—(a) a formal speech or treatise that presents a theme or object in a systematic and authoritative manner, and (b) a conversation or discussion involving a communicative exchange among a number of speakers—provide a framework for the more technical, disciplinary uses within current historical work.

2.1 *Discourse as the Historical* a priori *of Thought, Speech, and Action*

The more formal, systematic, and authoritative dimension of discourse is articulated in historical studies in the attempt to outline the formal structures of rules, codes, categories, and procedures (the relatively stable aggregate of conventions, usages, idioms, tropes, vocabularies) that define a particular communicative space, delimiting the field of possible statements and actions, enabling what can be meaningfully and effectively articulated. Historical discourses in this sense are impersonal formal structures operating anonymously behind the backs of speakers and actors, constituting the world of objective reality and subjective agency by making certain types of speech or behavior possible and other types impossible, by recognizing certain speakers and actors as legitimate or effective, and excluding others as illegitimate or ineffective, by defining certain objects and events as real or objective, and others as fictional and subjective. Different discourses constitute the world of experience in different ways, and are thus incommensurable with each other. They produce homogeneity (within their field of power) and heterogeneity in relation to other discursive fields. Specific statements or actions are only meaningful as instances of the rules and regularities governing the discourse in which they occur. Discourses become markers of the stable, synchronic, self-contained, incommensurable, discontinuous dimension in historical systems of meaning or cultural formations. For the historian, mapping the structures or codes of particular discourses defines historical action and historical actors as determined by those structures, as events and agents in a foreign world that has its own criteria for determining what is true or real, who is an effective agent, whose speech is meaningful. Discourses may thus, in Foucault's terms, create

specific historical 'regimes' of truth and systems of power.

Discourse analysis can be a way for the historian to establish the otherness of the past, as it has been by practitioners of the new cultural history who imagine the past as a 'foreign country.' Textual traces from the past can be provided with their own reality, differentiated from the realities of other times and places, by inserting them into the discourses that originally defined their significance. By recognizing the strangeness, the alien character of the 'voices' or 'traces' from the past deposited in the archival record, the present also comes into focus as a particular historical moment with its own sets of systematic enabling and limiting conditions. In this sense the deployment of an ahistorical, formal conception of discourse can produce a very concrete historical consciousness, an awareness of the contingent historicity of present existence. It provides few guidelines for reconstructing the developmental processes that lead from the past to the present.

2.2 Discourse as Communicative Process

As a constitutive system of categories and codes that differentiates historical worlds or cultures from each other, discourse becomes a tool for the reconstruction of past as different, for marking historical distance and avoiding anachronism. But it also freezes systems of meaning into static cross-sectional snapshots that allow analysis of the self-relating structures of individual systems, but do not illuminate the interaction among systems or the processes of transformation from one system to another. Moreover, the employment of the structural definition of discourse as a closed semiotic system seems to dissolve historical agency. The identity of agents is called forth or constituted by the discourse itself and their statements and actions remain mere instances of the discursive rules that produce the reality in which they operate. A second dimension of discourse analysis, however, breaks apart the apparent stasis and structural determinism of this stance. Conceived on a conversational or dialogical model in which signifying practices operate in continuous processes of confrontation, exchange, and transformation, discourse becomes a term for conceptualizing historical change, communicative interaction, and the dynamics of historical agency. From this point of view, linguistic or signifying actions are not authorless events in language but actions on language by individual and collective agents who appropriate inherited possibilities contained in existing discursive structures in order to both modify those structures and to transform themselves as agents. But how could the agents, the individual, and collective identities contingently and historically constructed within the structures of discourse, become themselves the creative transformers of discourse? One possible answer to this question could be constructed from within discourse theory itself, but ultimately it does raise the issue: what is the 'other' of discourse? and how is discourse changed and transformed in its relationship to its other?

3. Discourse and Discourses: Pluralism and Heterogeneity

In an early manifesto of discourse analysis, Foucault (1972) distinguished between a general domain that included all meaningful or signifying actions and their formal or structural conditions, and more individualized, singular groups of signifying practices organized in a focused disciplinary fashion around the construction of a coherent regime of truth. Historians have not been completely disinterested in the more sweeping, universalizing or totalizing notions of discourse that define the historical *a priori* of whole epochs or cultures, like the discourse of 'man' or secular historical humanism that rules over the 'modern' epoch, but they have tended to gravitate toward a practice of discourse analysis that emphasizes both the plurality of discourses and the conflict among discourses within a general discursive domain. Three forms of such heterogeneity in discourse analysis are particularly obvious. First, discourses can be differentiated in terms of the social and cultural dimensions or spheres in which they operate or are effective. Thus, one might differentiate among public, official, popular, literary, elite, urban, or religious variants of discourses of class or madness or justice or gender at any particular time or in any particular geographic area. Second, discourses obviously are differentiated in terms of the specific domains of meaning and action—the objects, subjects, and rules of relationship—which they construct. Thus, orientalist discourse constructs 'the east' as well as the 'orientalist'; psychiatric discourse constructs the psyche and the psychiatrist. Differentiations of this type are often imagined as analogous to academic disciplines that produced their putative objects of analysis in the way that the discipline of history constructs 'the past,' or sociology constructs 'society' or 'the social.' Third, historians tend to differentiate competing or alternative discourses that operate within these various dimensions and domains. Within the dimension of public discourse, for example, there may not only exist separate discourses pertaining to the spheres of political authority, citizenship, social hierarchy, or legal structures, but also dominant and oppositional, liberal and conservative, patriarchal and feminist, bourgeois and working class discourses that delineate the boundaries of this sphere and organize and define its contents and relations in competing and conflicting ways.

This proliferation of difference in the discursive realm is one of the major conditions of creativity and historical change. At any particular moment in time

an historical actor will inhabit a heterogeneous compound of discourses, dissolving the apparent formal disassociation of discourses from each other, allowing for creative performances in which the inner logics of different discourses are brought in contact with each other in transformative ways. Just as a scholar can inhabit an interdisciplinary space in which various disciplinary discourses can be brought into interaction in order to transform conventional, dominant discourses about a particular issue or problem, an actor in the public sphere might exploit the plurality of existing constructions of citizenship in various inherited discourses to imagine and act out innovative forms of membership and responsibility in a political community. The first task for the historian engaged in discourse analysis is to identify a discourse within a given body of evidence, to map out its boundaries, and reconstruct its inner logic or structure. A discourse is not simply a synoptic summary of the aggregate of statements that refer to some specific theme, like references to the work of women in France between 1815 and 1848. To identify the discourse in such thematically associated material would be to reconstruct the formal dimensions within the signifying practices informing the evidence. Discourse would be the organizing power that constructs the 'world' the evidence assumes and provides effective power to certain statements. Once such a discourse has been mapped or reconstructed, the map can be used, like an 'ideal type' or 'paradigm' to identify or discover its presence in other texts or bodies of evidence. Such reconstructive mapping of historical *a prioris* establishes historical difference, marks off the conditions of possible action and expression in different worlds. The second task of the historian of discourse, however, would be to cut through or modify the radical difference produced in the first operation—to describe the ways in which the specific actions—linguistic and nonlinguistic performances with communicative intent—within the formal conditions of a discourse create changes in that discourse and reveal the porous, contingent nature of discursive boundaries. This model of discourse analysis as a constant oscillation between the reconstructions of formal contexts and concrete, innovative performances in a dialogical, communicative context has been highly developed within specific realms of intellectual history—like the history of political theory, public opinion, and ideology, but its expansion into a broader analysis of the whole range of historical practices has highlighted a number of problems, problems that have become the center of the controversies dividing historians about the validity of discourse analysis *per se*.

4. *Discourse and its 'Others'*

Discourse and discourse analysis only attain distinctive, specifiable definition if they are placed in relation to something which they are not. What are the 'others' of discourse? This question is directly relevant to two questions that are of particular interest to historians: How can one explain the stability and/or hegemony of certain discursive formations among specific populations over extended periods of time, and how can one explain changes within specific discourses, the shifting relationships among discourses, and the emergence of new discourses in time?

4.1 *Discourse and the Material World*

The polemical thrust of discourse analysis when it emerged as an articulated position in debates among historians during the 1980s was directed primarily against dominant conventions of historical analysis which portrayed the realm of the production, reproduction and transmission of meaning in linguistic and other signifying actions as a product, effect or expression of the structures and transformations of material practices. Despite the complexities within and obvious differences among class oriented British cultural Marxism, the sociologically grounded modernization narratives prevalent in the US and Germany, or the structuralist 'total histories' of the French Annales school, all were viewed as ultimately reducing the production and transformation of meaning to an effect, however indirect, of changes occurring outside of the linguistic and more broadly cultural sphere. Concepts like 'ideology' or 'collective mentality' were criticized and often rejected outright because of their implication that the production of meaning in language could only be grasped with reference to a reality or truth that was situated in material social practices outside of language. In its initial stages the linguistic turn often appeared as an attempt to resist the absorption of the cultural into the social, to insist on the autonomy of processes of meaning production, to assert the autonomy (no longer 'relative') of intellectual and cultural history. More serious tensions among historians developed, however, when the realm of discourse was conceived as creating the categories and identities through which people lived their social being and defined their social interests. Class identities were not defined as public expressions of the ways in which groups articulated social interests grounded in the way they lived their relation to nature in systems of production, but identities produced in discourse that determined how interests were defined and the ways in which economic and social relations were experienced. Gender differentiation in public discourse, or medical discourse, or class discourse was not conceived as representing the contrasting realities of social experience of physically differentiated bodies but as constructed forms in which bodies were experienced as sexually different. Histories of the experiences of classes, of the sexes, of races, ethnic groups, nationalities, colonial subjects, etc., were transformed into historical reconstructions of the discursive processes through which class, sexual,

racial, ethnic, national, and colonial identities were constructed.

It would be misleading however, to treat this new cultural history, grounded in discourse analysis, as some historians have tried to do, as a new form of idealism based on a belief that language makes the material world, that thought creates existence. First, in discourse analysis, discourse itself is conceived as a dense network of signifying practices, a material activity embedded in the communicative interactive relations between producers and consumers of meaning and articulated in institutional structures. The linguistic turn did not simply exalt the status of language but changed the conception of what language is and how it works in history. Second, the 'other' of discourse analysis is not the empirical analysis of concrete evidence: discourse analysts certainly are as attentive to archival evidence as any social historian. The other of discourse analysis is a belief in the ultimate accessibility of an 'unmediated' meaningful reality on the other side of discourse which determines the truth of the meanings produced within discourse. Discourse analysts restrict the historical task to reconstructing the conflicted process of the cultural mediation of meaningless 'reality,' the practical human activity of meaning construction, transmission, and transformation.Yet the actual practice of discourse analysis may raise doubts about historians' ability to finally extirpate the metaphysical impulse to represent a truth beyond the represented 'truths' of human cultural practices. In the work of Michel Foucault and many of the historians who follow his lead, for example, one finds an assumption that the actual workings of discourse are determined by a prior will-to-power, by a universal drive to impose meaningful order on meaningless 'reality,' to narrativize the disassociated fragments of experience, to stabilize the endless proliferation of contingent identities. Discourse analysis, thus, not only marks a turn from the social to the cultural, but also a turn toward the political in the ubiquitous sense that all practices in the world have a political intent, that the legitimation, expansion, and consolidation of power is not a particular sphere of historical action, but the form of all historical practice. Discourse analysis has also been characterized by a renewed and transformed interest in the history of the body and of nature. Both the human body and the world of external nature are constituted within discourse, but at the same time are primary sites of resistance to any particular discursive construction. Within the framework of discourse analysis human and nonhuman physicality cannot have a positive unmediated reality of their own, a reality capable of self-representation within its own nondiscursive, transcendental 'language.' Bodies may be constantly inscribed and re-inscribed as meaningful in various discursive networks, as laboring organisms, as reproductive mechanisms, as emblems of spiritual content, but their sheer intractable existence also marks the limits of discursive constitution and thus fuels an infinite process of re-inscription and re-constitution.

5. *Discourse Analysis and the Problem of Historical Agency*

Discourse analysis is premised on the claim that effective historical agency, and thus the existence of individual and collective subjects who are capable of productive, creative, transformative action in the world, is produced in history rather than expressed in history. It is not subjects who produce meaning, but the networks of meaning that create subjects. In some earlier forms of discourse analysis, which was heavily tilted toward an analysis of the homogenizing, totalizing regularities in discursive structures, subjects, or authors often appeared as nothing more than anonymous, replaceable bearers (*Träger*) of the structures that defined them. In many ways this conception of discourse as a systematic process of meaning production mirrored the position of social historians who defined individual and collective agents in history as the inhabitants of social functions, or as bearers of the process of material production. Historians who took the linguistic turn in the 1980s and 1990s, however, were concerned with revealing the historical contingency of determining structures, with deconstructing systems of meaning production that allowed certain identities—of class, race, gender, ethnicity, and so on—to be experienced as natural realities or metaphysical essences. Attentiveness to the conflictual, dialogical, communicative dimensions of discourses in which historical identities were constantly constructed, modified, dissolved, and transformed did assume the effective agency of historical subjects (both individual and collective) who were able not only to negotiate among conflicting, multivocal, sometimes contradictory discourses, but also to redefine themselves as subjective agents.

Discursive agency, however, was decentered and contingent, the agency of constantly shifting 'identities' that were the creations of discursive practices themselves. Historical subjects were 'subjected' to the logics of the various discursive networks that they inhabited. But within the limitations defined by historical situation and status they made choices that might ultimately change that situation and status, and thus also their own identities. The question of agency in discourse analysis was not so much whether or not agency was possible within its terms, but what kind of agency was imaginable. Within the complex heterogeneous compounds of any cultural or discursive formation, a particular individual might simultaneously inhabit a whole series of dispersed, fragmented subject positions. Within each of them—as parent, worker, consumer, or as sexual, racial, or national subject—the individual could act, either

individually or by identifying himself with other individuals similarly positioned in various discourses, to shift the hierarchical relations among identities, and to change the identities themselves. In discourse analysis, human agency, the identity and effectiveness of the individual and collective subject, was construed as an always coming-to-be in worldly particularly, as historical through and through.

This historicization of agency was at the same time a politicization of agency. The effective construction of specific collective identities, like nation, class, or race was described as a conflictual political process in which certain subject positions were excluded or privileged, became dominant or were repressed, attained stability through forceful imposition on others, or were negotiated in a more consensual fashion. The historicization and de-centering of human agency in the many historical works devoted to the cultural or discursive constructions of class, gender, national, or racial identities written during the late 1980s and through the 1990s did not fully expunge questions concerning the extralinguistic, culturally 'transcendent' grounding or foundation of human agency among historians. The writings of intellectual mentors of the linguistic turn, like Foucault, Walter Benjamin, or Jacques Lacan (and, in the1990s, Slavoj Zizek), were replete with references to the problematic nature not only of the physicality of the body but of the transcendent autonomy of some form of unmediated subjectivity—that which sought or was given shape and identity in the various 'subject positions' constituted in discourse—which appeared to be a necessary condition for the historical differentiation and transformation of subject identities. Historians might modestly decline professional competency in addressing such questions. But that which was outside discourse analysis inevitably shaped what occurred inside discourse analysis. The metaphysical limits of discourse analysis suggested that discourse analysis was itself a historical, that is, contingent and particular identity, a 'subject position' for historians of a particular place and time.

6. *Discourse Analysis and the Discourse of Historians*

The linguistic turn in history began with, and has continued to be characterized by, an intensive self-reflexive focus. With the publication of *Metahistory*, White (1973) introduced many historians to discourse analysis as an analysis of the discourse of historians. The primary object of concern was not so much the reconstruction of the way past identities were produced in language, as the construction of the individual and collective identities of historians through their discourses about the past. Stories historians told about the past were unveiled as stories in which they fashioned themselves, and possibly their readers, in the present. In the discourse on historical theory and historiography instigated by White's work, historians' texts are analyzed as linguistic artifacts akin to the rhetorical and fictional texts of literature, in which the structures of the linguistic form determine the 'objectivity' of the content. The discourse of objective realistic representation that had conventionally legitimated entry into the disciplinary community devoted to knowledge of the past was displayed as a mystifying, self-deceiving attempt to portray the subjective (that is, based on ethical and political considerations) construction of its object as a true representation of its object. The goal of such analysis was self-recognition and emancipation.

Once the burdens of determination by the putative objective reality of the past were recognized as self-imposed limitations, historians were free to imagine and construct alternative pasts in terms of their ethical and political commitments in the present and their visions of alternative futures. Moreover, as soon as the texts inherited from the past were grasped as historically contingent discursive constructions of meaningful identity in time, the inhabitants of the present could recognize themselves in them, not just constitute themselves through them. History could become a discovery of the 'reality' of the human past which was in itself a constantly reformulated attempt to represent reality as meaningful.

Two major questions continue to fuel the debate instigated by the analysis of the historical discipline as a discursive community. The first concerns the politics of this disciplinary community. How should the boundaries of legitimate historical discourse be determined in relation to other disciplinary discourses, or what are the limits of interdisciplinary crossing if history is to maintain a distinctive identity? Within the terms of discourse analysis this question must be decided through the communicative practices of historians rather than through an appeal to the object of analysis. The question then becomes one of defining the discursive process in which historical reality and truth are represented. Who is recognized as a 'subject' with rights to participate fully in the discourse, and how are the negotiations within this discourse to be regulated? The problem of reconstituting a common past becomes a political issue of extending membership and of democratizing power within the profession. Solidarity and objectivity are inextricably bound up with each other. One of the reasons that the linguistic turn and discourse analysis have become such contentious issues among historians is that they pertain directly to the identity of history and the identity of historians.

The second issue raised by the reflexive moment in historical discourse analysis relates to the more general issue that troubles the whole debate surrounding the linguistic turn. What are the ethical (and political) implications of construing the past as a construction of discourse? Is the creation of an inclusive, demo-

cratically negotiated consensus about the nature of the past adequate to the goal of recreating the reality of the object of historical investigation and defining the criteria of historical knowledge? As the ongoing debates about historicizing the Holocaust have suggested, discourse about the truth of the past must involve the dead as well as the living. To converse with the dead entails a recognition not only of their physical existence, their extradiscursive 'reality' as bodies that transcend all the meanings inscribed on them, but also their status as actual or potential subjects of a discourse of their own that must be taken into account in any discourse we might construct about them. It would seem that an adequate conception of historical discourse would need to include some recognition that historians' discursive production of the past can be interrupted by the voices of the dead, and that a part of the ethical obligation of the historian is to listen to those voices.

Linguistic Typology

The term typology in linguistics, as in other fields, is generally understood to mean the classification of languages in terms of structural types. However, from the very beginning in the history of typological investigation, classification itself has never been the ultimate goal. For the grammarians of the early nineteenth century, exhaustive classification of the world's languages was a way to answer the question of what is possible variation in human language. For modern linguists typological classification is part of a method for discovering the constraints governing possible human languages or possible grammatical constructions.

Typological classification is frequently contrasted with the genetic classification of languages and is often characterized as ahistoric in its orientation. This was also not the case in the beginning of the typological studies in the early nineteenth century, when genetic and comparative approaches were not clearly distinguished from the typological one. Indeed, it was in the context of developing a program of comparative-historical research in his 1808 book *Über die Sprache und Weisheit der Indier* (On the Language and Wisdom of the Indians) that Friedrich Schlegel (1772–1829) developed a typological framework most famous in the history of typology. It was mainly due to the structuralist context, in which modern typology arose, that it countenanced a synchronic outlook. In contemporary typological scenes dynamicization of typology, as propounded most forcibly by Greenberg (1969, 1995), is fast obliterating the view that typology is a purely synchronic discipline.

1. Classical Typology

In the above-mentioned book Friedrich Schlegel proposed what is believed to be the first typological framework, according to which the languages of the world are classified into two types—flexional (or

inflectional) type and affixing (or agglutinative) type. Though later typologists, most notably August Wilhelm Schlegel (1767–1845) and Wilhelm von Humboldt (1767–1835), elaborated on his bipartite classification, Friedrich Schlegel, alluding to the ultimate goal of typological classification, made a bold claim that the opposition between *Sprachen durch Flexion* and *Sprachen durch Affixa* represents the two main categories of language, all other cases being mere modifications and variants of these.

The typological studies of the early nineteenth century are also known as morphological typology since the classificatory basis was the morphological structure of words. A beginning linguistics textbook typically introduces four types of language from this early endeavor: (a) inflectional (or fusional) type: relational meaning is expressed by internal modification of the lexical base such that component parts are not easily isolable (e.g., Indo-European languages, English *sing:sang:sung*); (b) agglutinative type: words consist of easily segmentable parts, each indicating a distinct grammatical meaning (e.g.,Turkish *ev-ler-im-de* house-PL-1SG.POSS-LOC 'in my house'); (c) isolating type: words do not give overt expression of relational meaning or else do so by employing to the end the same kind of unit as is used for encoding lexical concepts (e.g., in Chinese the verb *gěi* 'to give' is used also as an indirect object marker); (d) incorporating (or polysynthetic) type: nominal arguments (typically objects) and pronominal forms referring to them are incorporated in the verb form (e.g., Ainu *a-wakka-ta-re*1SG-water-draw-CAUS 'I make someone draw water').

Classical typology embodied system internal inconsistencies and had associated value judgements that caused its decline in the second half of the nineteenth century, when the study of genetically related languages was viewed as the only possible scientific comparative study of languages. Different languages were thought to represent different stages of the development of the languages and language families with the belief that the inflectional type, which fused distinct morphological information into single morphemes, represented the highest degree of linguistic sophistication. This assumption put classical Indo-European languages at the top of the evolutionary ladder and isolating languages of Asia, e.g., Chinese, at the bottom, contradicting the long history of the Chinese language and the advanced civilization associated with Classical Chinese.

The quadripartite classification has shortcomings as a true classificatory scheme in that a language may have morphological characteristics of several types simultaneously. English, for example, shows an inflectional characteristic in some irregular forms (e.g., *bring:brought, man:men*), an agglutinative characteristic in regular verbal and nominal inflections (e.g., *walk:walked, book:books*), an isolating characteristic in certain modal expressions (e.g., *can not walk*), and an incorporating feature in some compound forms (e.g., *to hand-knit a sweater*). Edward Sapir's multidimensional typology developed in his 1921 book *Language* (Sapir 1921) was in part response to the need to accommodate gradient characterizations of linguistic types, as he saw that languages in their entirety could not be neatly pigeon-holed into a given type, the matter being a question of tendency. While classical typology saw the culmination in Sapir's highly elaborate classificatory scheme, his followers have not generally put it into practice. Indeed, the only place where classical, morphology-based typology has been seriously pursued is Prague, where Vladimir Skalička (1909–1991), who recognized five types of languages (the four previous types plus the introflexive type), was a pillar of the so-called Prague School of Typology (see Sgall 1995).

While morphological typology as formulated by the nineteenth century grammarians is no longer considered to be adequate in meeting the ultimate goal of language typology, classical typology saw several developments of contemporary relevance. It is perhaps even fair to say that the followers of classical typology have contemplated most contemporary issues of language typology. For example, August Schleicher (1821–1868) recognized the possible connections between morphological characteristics and the manner in which grammatical relations are expressed, thereby pointing to the current view that a language type is to be defined in terms of a combination of properties that exhibit correlative patterns. The evolutionary chain of isolating-agglutination-inflection envisioned earlier is now recast as a cyclic development and such a model is integrated in the current study of grammaticalization (see Bybee 1985, Hagège 1988). The Humboldtian claim that the structure of a particular language reflects its speakers' *Weltanschauung* has stimulated a line of research on the relationship between language types and the speakers through the nineteenth century leading up to the so-called Sapir–Warf Hypothesis in the early twentieth century. This hypothesis claims a connection between the linguistic structure and the way the speakers perceive the outside world. As typological studies take on more cognitive outlook (see DeLancey 1981), a reappraisal of the Humboldtian tradition may be in order. An interesting development along this line is the recent revival of interest in ethnopsychology and the development of what is dubbed as 'ethnosyntax' by Wierzbicka (1992) and others.

2. *Modern Typology*

A major difference between classical typology and modern typology, developed in the middle of the twentieth century, lies in its scope and methodology. Classical typology sought a global characterization of

the entire language according to a small number of typological characteristics. This holistic approach has proved to be too ambitious, and modern typologists practice partial typology, where specific phenomena or individual grammatical constructions are studied. Methodologically, modern typology heavily relies on cross-linguistic distributional patterns. Implicational universals are drawn from the distribution of existing types and non-attested types.

Roman Jakobson (1896–1982) is generally regarded as the founding father of modern typology. In his seminal paper, Jakobson (1958/1971) recognized that typological analysis leads to the discovery of the dependency relation between two elements such that the presence of one element, X, implies the existence of another element, Y, in the same system (but not vice versa). For example, the parameters of voicing and aspiration in consonants yield the following four types of consonant system (illustrated with dentals); (1) /t/, /d/; (2) /t/, /t^h/, /d/; (3) /t/, /t^h/, /d/, /d^h/; (4) /t/, /d/, /d^h/. Of these four logically possible types, only the first three are actually observed—no language has voiced aspirates in the absence of voiceless aspirates, i.e., the fourth system. From this, it is possible to formulate an implicational statement that the presence of voiced aspirates implies the presence of voiceless aspirates. This statement constitutes a universal on human language if no language indeed violates the pattern implied by this statement—that no consonantal system can contain voiced aspirates in the absence of voiceless aspirates.

Developing Jakobson's insight in a systematic and over-arching manner, Joseph H. Greenberg (1915–2000) has changed the whole perspective of linguistic typology transforming it into a new method of universal research. Greenberg's (1966) study on word order typology drew a large number of implicational universals encompassing both morphological and syntactic levels, and some transcending them. That languages differ in word order is a common place experience of those who are exposed to foreign languages. English is an SVO (Subject-Verb-Object) language, while Japanese is an SOV language. The less frequently observed VSO order is instantiated by Welsh. The impact of Greenberg's work was very strong because of the far-reaching predictions it made on the basis of this kind of simple, basic feature of language. For example, it has been shown that if a language has dominant VSO order, (a) it has prepositions (G's *Universal 3*); (b) the genitive follows the governing noun (G's *Universal 2*, originally formulated in terms of the presence of prepositions); (c) question particles which are specified in position by reference to a particular word in the sentence do not occur (G's *Universal 10*); (d) it always puts interrogative words or phrases first in interrogative word questions (G's *Universal 16*); (e) an inflectional auxiliary precedes the main verb (G's *Universal 16*); and (f) adjectives come after the noun (G's *Universal 17*).

Greenberg's universals have the following two characteristics. They are implicational, such that they are restricted universals. The universals cited above obtain only with regard to VSO languages, and they have nothing to say about those languages having a different word order. Secondly, Greenberg recognizes statistical universals or high cross-linguistic tendencies, which do not obtain absolutely. For example, Greenberg's *Universal 4* is formulated as: 'with overwhelmingly greater than chance frequency, languages with normal SOV order are postpositional,' which allows a language like Persian, which has SOV order with prepositions. Beside implicational and statistical universals, linguists in general recognize unrestricted universals, which are believed to obtain absolutely; e.g., all languages have vowels and consonants; all languages have nouns and verbs.

Implicational statements are also obtainable from hierarchies that grammatical categories exhibit. The most well known grammatical hierarchy is that of grammatical relations formulated by Keenan and Comrie (1977): Subject > Direct Object > Indirect Object > Genitive > Oblique Object > Object of Comparison. This hierarchy, derived from the cross-linguistic relativization patterns, predicts, for example, that if a language allows relativization on an oblique object (i.e., an object of a preposition), then it also allows the same relativization strategy to apply to all those nominals holding the grammatical relations higher in the hierarchy than the oblique object.

Another hierarchy with far-reaching ramifications is the so-called animacy hierarchy: first/second person > third person > pronoun > human noun > animate noun > inanimate noun. In a language such as the Australian language Dyirbal, where an agentive nominal of a transitive clause may receive either ergative or nominative marking—split-ergative marking—those high on the hierarchy tend to be marked nominative, while those low on the hierarchy tend to be marked ergative, such that we can draw implicational statements to the effect that if an agentive nominal X in the hierarchy is marked nominative, all those higher in the hierarchy are also marked nominative. The animacy hierarchy is also at work in voice phenomena such that an agentive nominal high in the hierarchy tends to be expressed in subject position, i.e., in the active voice, while when a patient nominal is high in the hierarchy, passivization tends to occur. A corollary of these tendencies is that those nominals high in the hierarchy are less likely to be expressed overtly as an agentive phrase (as in the English *by* agentive phrase) in the passive clause.

Recent studies of prototype categories have revealed that grammatical categories and constructions form continua rather than exhibiting rigid category boundaries. For example, studies on transitivity have shown that the traditional binary distinction between intransitive and transitive verbs (or constructions) needs to be recast as a multi-valued continuum (see Hopper

and Thompson 1980). A simpler and much coarser form of this continuum yields the following hierarchy: Transitive > Active intransitive > Inactive intransitive, where active intransitive verbs/constructions are those expressing activities (e.g., 'to dance'), and inactive intransitive verbs simple processes (e.g., 'to fall'). An implicational statement can be also derived from this hierarchy; e.g., if a language permits passivization of an inactive intransitive, then it also permits active intransitives and transitive verbs to undergo passivization. Also noun incorporation (see above) basically follows this hierarchy such that the object of a transitive clause is the easiest to incorporate, followed by the subject of an inactive intransitive clause, the subject of an active intransitive clause, and finally the subject of a transitive clause. Thus, if a language incorporates the subject of an active intransitive clause, then it is likely to incorporate the subject of an inactive intransitive clause and the object of a transitive clause.

3. *Functional Typology*

The term typology is used in reference to a theoretical and methodological approach that contrasts with other, especially Chomskyan generative, approaches. The Chomskyan generative approach is said to be formal in two senses. In one sense, Generative Grammar is formal in dealing with the 'abstract formal skeleton' (Chomsky 1975p. 55) of syntactic structures as an autonomous system independent of semantic or functional factors. In another sense Generative Grammar is formal in that its explanations are in terms of the system internal elements and structural relations. The typological approach sharply contrasts with these two characteristics of Generative Grammar. Its basic orientation is functional in that it assumes that the central function of language is to represent cognition and to communicate experience and thought. The task of typology is to determine the range of variation that language permits in achieving this central function. In this framework a language is seen as a problem-solving system; how languages conceptualize a given cognitive domain and express the concepts by linguistic means (see Seiler 1995). Studies dealing with specific constructions such as causative and possessive constructions thus start out with the formulation of the concepts or the cognitive domains to be expressed and typologize the relation between grammatical form and semantic function (see Shibatani 1976 and Seiler 1995). This cognitive-functional stance has a long and venerable history linking the current works with Sapir's and ultimately with the Humboldtian conception of language as an *'enérgeia'* (a creative activity) rather than an *'érgon'* (a product).

The term 'functional typology' is used in recent years in order to underscore the functional orientation the current typological research countenances. This approach also differs from Generative Grammar in its recourse to external explanations. Explanations for cross-linguistic patterns of linguistic structure are sought in functional motivations such as iconic motivation—preference for the structure of language to reflect and the conceptual structure in a parallel manner (see Haiman 1985). Haiman has shown that conceptual distance is reflected in grammatical distance. Thus, inalienable possession, which involves an inseparable or a closely connected whole-part relation, is expressed by a more tightly integrated form than inalienable possession; e.g., *m-pôlu* 'my back' vs. *ŋa pɛ́rɛi* 'my house' (Kpelle). Similarly, in causative expressions, shorter forms tend to express direct causation and the longer forms indirect causation, e.g., *kill* vs. *cause to die*. Another line of research along the functional typological premise has been developed by Hawkins and his associates in which processing mechanisms are invoked as an explanation for observed linguistic patterns (see e.g., Hawkins 1990, Hawkins and Cutler 1988).

4. *Typology and Language Change*

The importance of typology to one of the major concerns of historical linguistics, namely reconstruction of proto-languages, has long been demonstrated. The basic idea here is that where a reconstruction conflicts with the known typological facts, there is a *prima facie* reason to suspect its validity. The most celebrated phonological example of this use of typology as a control on reconstruction is concerned with the Proto-Indo-European consonant system. The standard reconstruction posited a three-fold system of voiced and aspirated consonants (illustrated with dentals) /t/, /d/, /dh/. However, Jakobson (1958/1971) noted that typological investigation revealed that no language would contain /dh/ in the absence of the voiceless counterpart /th/, casting doubt on the validity of the Proto-Indo-European system reached by the standard reconstruction. This has led to either reinstating the Neogrammarians' earlier four-point stop system of /t/, /th/, /d/, /dh/, or developing alternative hypotheses. The so-called glottalic theory, which replaces the traditionally reconstructed voiced stops with ejectives, has also been informed of typological results. Phonological systems comprising a voiceless, a glottalized, and an aspirated series (/t/, /t$^{?}$/, /t^{h}/) conform to synchronic typological findings, but the system arrived at by the conventional reconstruction does not (see Gamkrelidze and Ivanov 1973).

The move to bring typology to the heart of diachronic linguistics, namely linguistic change itself, has been spearheaded by Greenberg (1969, 1995), who advocates the dynamicization of a synchronic ty-

pology. Greenberg offers what he calls the 'state-process model,' which views attested language types as possible stages through which languages can pass and non-attested language types as impossible stages into which a language can change. In other words, just as synchronic typology puts constraints on language types, constraints on typological change can be viewed as limitations on language change.

The connection between synchronic typology and possible change can be illustrated by the typology of number categories in the noun. It has been shown that the category of dual is only found in a system having a singular/plural distinction—no language has a singular/dual system or a plural/dual system. When a language with no number distinction develops a number system, it involves a singular/plural distinction; no language develops a system with a tripartite singular/dual/plural distinction without going through a stage in which a singular/plural distinction has been established. In this way, diachronic typology seeks to identify allowable and non-allowable transition from one state to another so as to determine possible paths of language change.

In the Greenbergian diachronic typology, typological states and transitions between states are characterized by two logically independent factors—stability and frequency. Stability represents a probability that a language, which is in a particular state, will exit from that state, while frequency is the likelihood that a language will enter a particular state. For example, a state of having nasal vowels is characterized as having high frequency but low stability, because a vowel frequently acquires the nasality feature from an adjoining nasal consonant, but once a system acquires nasal vowels, it tends to retain them. The dimensions of frequency and stability of typological states render the state-process model a probabilistic one, which countenances the gradualness of the transition from one language state to the next. In this model synchronic exceptions are accounted for as transitional states arising from gradual diachronic process of change from one state to another.

The two main concerns of diachronic typology—gradualness of historical change and its directionality—have received focused attention in the recent developments in grammaticalization theory (see Bybee 1985, Heine et al. 1991, Hopper and Traugott 1994, Lehmann 1982). Grammaticalization refers to the process by which lexical items come to take on grammatical functions such as marking of tense, aspect, grammatical relations, definiteness, modality, etc. In Chinese the verb *gěi* 'to give' is used as an indirect object marker, and the verb *iru* 'to be/to exist' in Japanese has developed an aspectual usage of indicating an on-going activity, the progressive aspect.

Grammaticalization typically involves synchronized change in several different grammatical dimensions. As a lexical item gets grammaticalized, it tends to undergo phonological reduction, which in turn renders the form less independent, downgrading it to a morphologically dependent status as in the case of enclitics and affixes. Semantically, a lexical item gradually loses its original referential meaning and acquires such relational meanings as those previously noted. As in the case of the Chinese verb *gěi* and the Japanese verb *iru*, Grammaticalization is a gradual change such that these forms co-exist as verbs along with the newly developed grammatical functions. The two main concerns of grammaticalization theory are the relationship between the input and the output of grammaticalization—what kind of lexical items give rise to what kind of grammatical functions?—and the directionality of change—is the change unidirectional from concrete to abstract?

The gradual nature of historical change brought to the fore by diachronic typology and grammaticalization research has an important implication to the matter of definition as well as the synchronic characterization of a language. Many phenomena are in transition from one state to another, and as such they are not amenable to categorical definitions. For example, whether Chinese has prepositions or not is not an easy question to answer, as forms such as the indirect object maker evolving from the verb *gěi* 'to give' can be construed either as verbs or prepositions. The existence of transitional phases of this kind calls into question the traditional distinction between synchronic linguistics and diachronic linguistics. Dynamicization of a synchronic description is the next logical step that diachronic typology suggests.

5. *Typological Differences in Clausal Organization*

As described in Sect. 4, modern typology typically examines specific domains or individual grammatical constructions in order to ascertain possible variation in human language. This leaning toward partial typology stems from the difficulty encountered in attempting to typologically characterize languages in their entirety. Despite this, there is a lingering sense among typologists that a holistic characterization of a language is a desideratum. Georg von der Gabelentz most eloquently expressed this feeling at the beginning of the twentieth century:

> But what an achievement would it be were we to be able to confront a language and say to it: "you have such and such a specific property and hence also such and such further properties and such and such an overall character"—were we able, as daring botanists have indeed tried, to construct the entire lime tree from its leaf. (Gabelentz 1901, p. 481)

Whether or not the ideal state entertained by Gabelentz can ever be reached remains to be seen. However, one area that merits further investigation is

the differences that languages show in the organization of clause elements. In compensation for the emphasis on methodological matters in the preceding *exposé*, the following allows a glimpse of what actual typological investigation or comparison of languages in general involves.

In expressing a transitive situation involving an agent and a patient participant, languages typically distinguish these in some way, so that who is acting on whom is made clear. English, for example, achieves this by using different pronominal forms; e.g., 'He hit him.' In the case of intransitive clauses, its sole nominal argument (S) can be assimilated either to the form of an agentive nominal (A) or that of a patient nominal (P). English assimilates it to the nominal form of A—'He fell, He ran.' A clause that treats S and A alike and distinguishes P from these is said to display the nominative-accusative coding pattern ($S = A \neq P$), and the languages possessing such clauses predominantly are called nominative-accusative type languages.

Some languages organize clauses differently from the nominative-accusative pattern. Many Australian aboriginal languages follow the absolutive-ergative pattern, whereby S is identified with the P nominal a transitive clause, while distinguishing A from these; i.e., the $S = P \neq A$ pattern. Clauses may be organized in yet another way. The American Indian language Lakhota, for example, splits S nominals into an agent-like category (S_a) and a patient-like category (S_p), yielding the coding pattern, known as active-type: $S_a = A \neq P = S_p$.

All of these languages have a single type of dominant transitive clause, where the coding of A and P is fixed. Some languages have more than one type of transitive clause making a unique comparison of intransitive clauses with transitive clauses problematic. Philippine languages are such languages, where a simple transitive clause comes in two variant forms. Cebuano, for example, renders the sentence 'Juan read the book' in two ways; *Ni-basa si Juan sa libro* (AF-read TOP Juan the book), *Gi-basa ang libro ni Juan* (GF-read TOP book ACT Juan). That is, either A or P can be coded as what is called Topic (marked *si* for proper names and *ang* for common nouns) of a transitive clause. The S nominal of an intransitive clause is coded as a Topic as in: *Ni-dagan si Juan* (AF-run TOP Juan) 'Juan ran.' (AF = ctor-focus marking; GF = goal-focus marking; TOP = Topic marker; ACT = Actor marker).

The focus marking in the verb indicates what semantic role is being coded as Topic, such that the prefix *ni-* in Cebuano indexes an agentive Topic, and *gi-* a patient topic. This applies to both transitive and intransitive clauses such that an intransitive clause with a patient S Topic would trigger *gi-* marking; *Gi-kapoy si Juan* (GF-tired TOP Juan) 'Juan is tired.' This split treatment of S Topic marking in the verb is reminiscent of the active-type-coding pattern. However, Philippine languages are not active-type languages in that the nominal marking is consistent for S—it is always realized as *si/ang*-marked Topic—and that there are two competing forms of a transitive clause (see Shibatani 1985 on the Philippine voice system).

The four types of coding pattern examined have important implications for some basic grammatical categories. First, the notion of Subject is problematic in those clause types displaying coding patterns other than the nominative-accusative pattern. Subject, as found in European languages, refers to the category obtained from the $S = A$ grouping in the nominative-accusative pattern. It is a category deriving from the assimilation of S to A, and accordingly is agent-based.

Morphological identification of S and P obtains in an ergative-type language. A long-standing question in typology is whether this grouping of S and P should be identified as Subject. One obvious problem with this move is that whereas Subject is an agent-based category, the $S = P$ grouping is a patient-based category, since it obtains by assimilating S to P. Thus a conservative view is that the $S = P$ grouping forms a category distinct from Subject. Since S and P typically involve zero marking, the term Absolutive suggests itself as the label for this category.

In active-type languages, there is no unique identification between the totality of S and A or P; and therefore, neither Subject nor Absolutive category obtains. In Philippine linguistics, Topic is often likened to Subject, but since it is based on neither A nor P—either can be Topic and S can be identified with either kind of Topic—it is neither an agent-based nor a patient-based category.

While different clausal types of the world's languages may display grammatical relations resembling Subject, they are not entirely identical. Subject is agent-based, whereas Absolutive is patient-based. Philippine Topic is neutral in its alignment with the semantic roles. These different grammatical relations, however, can be identified at a functional level, in that they are the essential relations that a nominal must bear in clause formation. That is, Subject, Absolutive, and Topic are an indispensable nominal category in a clause over which a verb predicates. Predication will not be complete without a nominal category about which the verb says something. The primary status of these grammatical relations is reflected in the primacy they enjoy in such grammatical processes as relativization and focusing. Subject, Absolutive, and Topic, in other words, can be identified as a Primary Relation at the functional level, despite the differences at the substantial level.

The differences in grammatical relations have some additional implications. Firstly, it predicts that those languages that do not have the Subject category do not show the active-passive voice opposition. Active voice (as expressed by 'John hit Bill') is defined in terms of the alignment of A and Subject, while passive voice typically involves the alignment of P and Subject, as in

'Bill was hit by John.' From this it is obvious that languages without the Subject category cannot have the active-passive opposition. Still, other languages may show a different kind of voice contrast. Ergative languages often display ergative-antipassive voice opposition, characterized by the realignment of the absolutive category over P and A.

In both active-passive and ergative-antipassive oppositions, there is a basic voice associated with the basic form of the verb. In the former, active is the basic voice, and in the latter, the ergative voice is basic. Thus, a transitive situation is normally expressed either as an active form or as an ergative form in the languages having these systems. Derived voice forms, the passive and the antipassive, contain derived verb forms, and they are used far less frequently than the unmarked, basic voice forms. Philippine-type languages, in contrast, have no unmarked voice category—the alignment of Topic with A or P is equally marked in the verb. A characteristic of the fluid-voice system of this kind is that both A-Topic form and P-Topic form are used with equal facility such that there is no lop-sided distribution of voice forms as in the other two systems discussed previously. In contradistinction to these types of languages, active-type languages are known to lack voice opposition of the kind discussed here. The three voice mechanisms studied—the active/passive system, the ergative/antipassive system, and the fluid-voice system of Philippine languages—are different in their substance. Yet they are comparable at the functional level in that they all involve diathetic realignment of a Primary argument.

Languages can differ with respect to the nature of grammatical relations and voice mechanisms depending on the way clauses are organized. Besides these, cross-linguistic differences in other grammatical phenomena have been reported, some of which may be attributable to the typological differences outlined here. The question of whether these differences have profound implications for the overall organization of grammar aside, it is becoming increasingly clear that languages are likely to differ at the level of grammatical organization far more greatly than was believed in the latter half of the twentieth century. This suggests that cross-linguistic similarity be sought in the functional equivalence or similarity rather than in the specific manners in which languages define and organize grammatical elements.

Linguistics: Comparative Method

The comparative method is the most important of the various techniques used to recover linguistic history. It is a method (or a set of procedures) which compares related languages, descendants from a common ancestral language, in order to postulate, to 'reconstruct,' the ancestral language. It is commonly considered a major event in the history of ideas; inspired by the success of the comparative method in linguistics, numerous other disciplines in the nineteenth century adopted comparative methods of their own. In this article the comparative method is explained and its basic assumptions and limitations are considered.

1. The Comparative Method and Language Families

Language which belong to the same family are said to be genetically related—this means that they derive from a single ancestral language, called a proto-language. Genetic relationships among languages are talked about in genealogical terms: 'sister languages,' 'daughter languages,' 'parent language,' and 'language families' (definitions below). Through linguistic changes, dialects develop in a language, and then as further changes accumulate in time, these dialects become distinct languages, related to one another ('sister languages') and descendants ('daughters') of the original language (the parent or proto-language). By applying the comparative method to related languages which descend from an original ancestor language, linguists postulate what that proto-language was like—that is, they reconstruct that language. For example, a comparison of English with its relatives, Dutch, German, Danish, Swedish, Icelandic, and so on, reveals what the proto-language, in this case called 'Proto-Germanic,' was like. Thus, English is, in effect, a much changed 'dialect' of Proto-Germanic, having undergone successive linguistic changes to make it what it is today, a different language from Swedish and German and its other sisters, each of which underwent different changes of their own. Therefore, every proto-language was once a real language regardless of whether it is successfully reconstructed or not, and all languages which have relatives have a history which classifies them in language families.

The aim of the comparative method is to reconstruct as much as possible of the proto-language by comparing its daughter languages (the related descendant languages), and to determine what changes they underwent as they diversified from their common ancestor. The comparative method serves two purposes: to show that languages are related, and to reconstruct as much as possible of the parent language. If reconstruction is successful, it shows that the initial assumption that the languages are related was warranted, and it reveals the nature of the proto-language.

Of course, success is dependent upon the extent to which evidence of the original traits is preserved in the descendant (daughter) languages and upon how astute the linguist is at applying the comparative method to them. For example, by comparing Romance languages (Spanish, Portuguese, French, Italian, etc.), the linguist reconstructs Proto-Romance; Proto-Romance is equivalent to the spoken language at the time Latin began to split up into its descendants. If successful, what is reconstructed for Proto-Romance by the comparative method should coincide with the Proto-Romance which was actually spoken at the time before it split up into its daughter languages. In this case, since Latin is abundantly documented, it is possible to check to see whether what is reconstructed by the comparative method accurately approximates the spoken Latin that is known from written sources at that time. However, the possibility of checking reconstructions in this way is not available for most language families, for whose proto-languages there are no written records. For example, for Proto-Germanic (from which English, German, Swedish, etc. descend), there are no written records, and this language is known only from comparative reconstruction.

Often attempts to show that languages are genetically related or to reconstruct a proto-language begin with recognition of similarities among the languages being compared. However, similarities among languages can be due to a number of things, for example to borrowing, accident, onomatopoeia, etc., in addition to inheritance from a common ancestor (see Campbell 1998, pp. 311–26). Therefore, to show languages are related or to reconstruct successfully, similarities which are explained by factors other than common inheritance need to be avoided. The comparative method, aided by regular sound correspondences, helps to eliminate these factors.

2. Application of the Comparative Method

To be able to apply the comparative method, one needs to know some technical terms.

Proto-language. (a) The once spoken ancestral language from which daughter languages descend; (b) the language reconstructed by the comparative method which represents the ancestral language from which the compared languages descend. (To the extent that the reconstruction is accurate and complete, (a) and (b) should match.)

Sister language. Languages which are related to one another by virtue of having descended from the same common ancestor (proto-language) are sisters; that is, languages which belong to the same family are sisters to one another.

Cognate. A word which is related to a word in sister languages by reason of these forms having been inherited by these sister languages from a common word of the proto-language from which the sister languages descend.

Cognate set. The set of words which are related to one another in the sister languages because they are inherited and descend from a single word of the proto-language.

Sound correspondence. In effect, a set of 'cognate' sounds; the sounds found in the related words of cognate sets which correspond among related languages because they descend from a common ancestral sound. (A sound correspondence is assumed to recur in various cognate sets.)

Reflex. The descendant in a daughter language of a sound of the proto is said to be a reflex of that original sound; the original sound of the proto-language is said to be reflected by the sound which descends from it in a daughter language. (Cf. Campbell 1998, p. 112.)

In the application of the comparative method, first potential cognates among related languages (or among languages for which there is reason to suspect relatedness) are sought. It is convenient to begin with cognates from 'basic vocabulary' (body parts, close kinship terms, low numbers, common geographical terms), since these tend not to be borrowed from other languages. Ultimately, it is the systematic sound correspondences discovered in the application of the comparative method which demonstrate which are true cognates. Words which are similar due to accident, borrowing, and other non-genetic factors usually do not exhibit the recurring sound correspondences that true cognates do. Some cognates from Greek, Latin, and English (members of the Indo-European family of languages) are illustrated in Table 1.

Table 1
Indo-European cognates

Greek	Latin	English	
pod-	ped-	foot	'foot'
patḗr	pater	father	'father'

Next, the sound correspondences are sought. For example, in the cognates of Table 1, the first sound in each of the cognate sets exhibits the sound correspondence

Greek *p*, Latin *p*, English *f*

Since the sound correspondence recurs in these (and many other) cognate sets, it is unlikely that it could come about by sheer accident.

When the sound correspondences have been determined, the next step is to reconstruct the original sound. Linguists postulate what the original sound in the proto-language most likely was based on the phonetic properties of the sounds in the daughter languages as represented in the sound correspondence set. General guidelines help determine the most realistic reconstruction. For one, the known direction of certain sound changes is a valuable clue. For example, many languages have changed *p* to *f*, but change in the other direction, *f* to *p*, is extremely rare. In this case, it is said that the expected direction is *p* to *f* (and not *f* to *p*). This being the case, for the sound correspondence of Greek *p*-, Latin *p*-, English *f*-, **p* is reconstructed, since a change **p* to *f*, which would be necessary to derive the English reflex of *f*, is in an expected direction. (Note that the asterisk, as here with **p*, symbolizes reconstructed things.) If **f* were postulated for the proto-sound from which this sound correspondence descended, it would be necessary to assume the change of **f* to *p* in Greek and Latin, a change which goes against the expected directionality. Therefore, **p* is reconstructed in this case, together with the assumption that English underwent the common sound change of **p* to *f*.

Another guideline is the principle of 'majority wins': unless there is evidence to the contrary, for the proto-sound one reconstructs a sound coinciding with the particular sound in the correspondence set which is found in the greatest number of daughter languages. In this example, since *p* is found in both Greek and Latin, but *f* is only in English, 'majority wins' selects **p* for the reconstruction. Common sense is behind this; it is less likely that the same change (here **f* to *p*) would take place independently several times (here in Greek and in Latin) than that a single change would take place only once (**p* to *f*, only in English). The interpretation of the majority, however, can be complicated, requiring caution in the application of 'majority wins.'

This process of reconstructing sounds for the various correspondence sets is repeated until all the sounds of the proto-language have been reconstructed and the changes in the daughter languages worked out.

When all the proto-sounds have been reconstructed, it is possible to reconstruct words of the proto-language. For example, in the cognate set Greek *pod*, Latin *ped*, English *foot* 'foot,' **p* has already been reconstructed as the first sound of this word in the proto-language, based on the *p*-, *p*-, *f*- correspondence set just considered. For the second sound (*o*, *e*, *oo*), **e* is reconstructed on evidence not available in this short example; the correspondences for the vowel are complicated. For the last sound of the word, evidence from other cognate sets shows that the sound correspondence, Greek *d*, Latin *d*, English *t*, recurs and that the best reconstruction for this sound is **t*. Putting these reconstructed sounds together, **p* for the first sound, **e* for the second, and **d* for the third, gives the reconstruction **ped* 'foot,' a word in the proto-language. In this way the vocabulary of the proto-language can be recovered.

The reconstruction of a sound, a word, or large portions of a proto-language is, in effect, a hypothesis (actually a set of interconnected hypotheses) concerning what those aspects of the proto-language must have been like. Hypothesized reconstructions can be tested; sometimes they prove wrong; sometimes they must be modified, based on new insights. These insights may involve new interpretations of the data already on hand or new information that may come to light. The discovery of a previously unknown language may provide new evidence, a different testimony of the historical events which transpired between the proto-language and its descendants, which can change how parts of the proto-language are viewed. For example, with the discovery and decipherment of Hittite (and other languages of the Anatolian branch of Indo-European), the whole picture of Proto-Indo-European phonology changed.

There are numerous general treatments of the comparative method; for some of the clearer accounts, see Anttila (1989), Arlotto (1981), Campbell (1998), Crowley (1997), Hock and Joseph (1996), and Trask (1996).

3. *Assumptions and Limitations of the Comparative Method*

There are limitations on what can be recovered of a proto-language via the comparative method. Traditionally, some of these limitations are called 'assumptions,' since they are inherent consequences of how the comparative method is structured and how it is applied.

There are four main 'assumptions.'

(a) The proto-language was uniform, with no dialects or variation.

Clearly this 'assumption' is unrealistic, since all known languages have regional or social variation, different styles, and so on. However, it is not so much that the comparative method 'assumes' no variation; rather, it is just that there is nothing built into the comparative method which would allow it to address variation directly. This means that what is reconstructed will not recover the once spoken proto-language in its entirety, that is, with all its variation. Still, rather than stressing what is missing, linguists are happy that the method provides the means for recovering as much of the original language as it does. This assumption of uniformity is a reasonable idealization; it does no more damage to understanding of the proto-language than, say, modern reference grammars do which concentrate on a language's general structure, typically leaving out consideration of regional, social, and stylistic variation. Moreover, dialectal variation is not always left out, since in some cases scholars do reconstruct dialect differences to the proto-language based on differences in daughter languages which are not easily reconciled with a single uniform starting point.

Assumptions (b) and (c) are related:

(b) Language splits are sudden.

(c) After the split up of the proto-language, there is no subsequent contact among the related languages.

These assumptions are a consequence of the fact that the comparative method addresses directly only material in the related languages which is inherited from the proto-language and has no means of its own for dealing with borrowings, the results of subsequent contact after diversification into related languages. Borrowing and the effects of language contact are, however, not neglected. Rather, it is necessary to call upon other techniques which are not formally part of the comparative method for dealing with borrowing and the results of language contact. It is true that the comparative method contains no means for addressing whether a language gradually diverged over a long period of time before ultimately distinct but related languages emerged, or whether a sudden division took place with no subsequent contact between the parts of the original language community. Usually, however, reconstruction by the comparative method is reasonably successful, regardless of how slow or sudden the split up of the proto-language may have been.

(d) Sound change is regular.

This assumption is true; it is not a limitation, but an asset, extremely valuable to the application of the comparative method. For example, in the example above, Proto-Indo-European **p* regularly changed to *f* in English in all the words of this kind which formerly contained a **p*. Knowing that a given sound in given circumstances changes in a regular fashion permits reconstruction of what the sound was like in the parent language. If a sound could change in arbitrary, unpredictable ways, it would not be possible to determine from a given sound in a daughter language what it may have been in the parent language, and, for a particular sound of the parent language, it would not be possible to determine what its reflexes in its daughter languages would be. If, for example, an

original *p of the proto-language could arbitrarily for no predictable reason become f in some words, y in others, k in still others, and so on, then it would not be possible to reconstruct it. In such a situation, comparing, say a p of one language with a p of another related language would be of no avail, if the p in each could have come in unpredictable ways from a number of different proto-sounds.

4. How Realistic are Reconstructed Proto-languages?

The success of any given reconstruction depends on the material at hand with which to work, and the ability of the comparative linguist to figure out what happened in the history of the languages being compared. In cases where the daughter languages preserve clear evidence of what the parent language had, a reconstruction can be very successful, matching closely the actual spoken ancestral language from which the compared daughters descend. However, there are many cases in which all the daughter languages lose formerly contrasting sounds and lose grammatical categories through changes of various sorts. It is not possible to recover via the comparative method things in the proto-language if the daughters simply do not preserve evidence of them. In cases where the evidence is severely limited or unclear, reconstruction often results in omissions or mistakes. The comparative linguist makes the best inferences possible, based on the evidence available and on everything known about the nature of human languages and linguistic change. It is necessary to make the most of what is available to work with. Often the results are very good; sometimes they are incomplete, occasionally wrong. In general, the longer in the past the proto-language split up and the more linguistic changes that have taken place in the daughter languages, the more difficult it becomes to reconstruct with full success.

A comparison of reconstructed Proto-Romance with attested Latin provides a telling example. It is possible successfully to recover a great deal of formerly spoken Proto-Romance via the comparative method. However, the modern Romance languages for the most part preserve little of the former noun cases and complex verb inflections which Latin had. Subsequent changes have obscured these aspects of the grammar so much that large parts of Proto-Romance are not reconstructible by the comparative method. On the other hand, a great deal of Proto-Romance is recoverable.

An area of speculation and controversy concerns the outer limits of the comparative method. That is, is there a recognizable time depth beyond which the comparative method ceases to be effective? Some suggest that the comparative method cannot reach beyond the oldest currently reconstructed proto-languages; this cut-off date beyond which the comparative method is assumed not to be able to reach is variously speculated to be 6000, 8000, or 10,000 years. Since there is no reliable means of dating languages splits, these dates are rough guesses. The true issue is not really about dates at all, but rather about how much evidence related languages preserve upon which to base a reliable reconstruction. Typically, languages separated by many millennia have had longer in which to undergo changes, making them more different from one another than languages separated only by a few hundred years. Languages which have undergone many changes conceivably could preserve little of their original vocabulary or grammar; however, at the same time, it is also possible for a language to undergo relatively little change over relatively long periods. Thus, the upper limit of the comparative method is a function of whether accumulated changes have obliterated evidence in related languages, and not directly a matter of how long they have been separated.

Linguistics: Iconicity

Ever since Plato, the majority view of students of language is that anything can stand for anything, the relationship between signans and signatum being determined by fiat or tradition in every manmade code. Within natural languages, in particular, the universal of double articulation ensures that, at the phonological level, individual signs are associated with no meaning whatsoever. At the morphosyntactic level, a distinction may be made between the lexicon and grammar. Challenges to the doctrine of arbitrariness thus fall into three groups.

At the phonological level, the notion of sound symbolism is such a challenge. Although submorphemic constant correlations between sound and

meaning are marginal in languages like English, it has been argued that they are much more pervasive in many languages of Africa and Southeast Asia. At the word level, the corresponding challenge is the notion of onomatapoeia, which has been acknowledged to be marginal in every language. In the artificial registers of poetry, the sound may indeed be made to be an echo to the sense, but this is not the case in flatfooted prose. At the level of compounds and more complex syntagms, however, diagrammatic iconicity in the sense of Peirce (1932) has always been both pervasive and acknowledged: among the staples of linguistic theory which have been strongly iconic are:

(a) The doctrine of semantic compositionality or Saussure's motivation (Saussure 1916): 'the meaning of a complex expression is in some way the sum of the meanings of its parts.'

(b) Behaghel's first law (Behaghel 1932, p. 4): 'conceptual closeness is reflected in physical closeness.' One of the clearest demonstrations of this is in Bolinger and Gerstman's (1957) discussion of the contrasts between phrases like 'light housekeeper' and 'lighthouse keeper,' in which, as they demonstrated, the perceptual phonetic contrast mirrors the orthographical distinction. Other work in the same vein is Greenberg (1966b)—restatements and elaborations of the traditional insight that derivational affixes are closer to the root than are inflectional ones; Givon (1980)—the degree of embeddedness of a complement clause is a reflection of the degree of control exerted by the subject of the containing clause; and Haiman (1985a)—contrasts between direct and indirect causation and between alienable and inalienable possession, and the semantic consequences of coordination reduction. Related is the idea that the physical incorporation of a string into a larger one corresponds to the degree of its conceptual incorporation in the material into the framework represented by the matrix string. Direct quotation resists incorporation, indirect quotation does not. Relevance conditionals (e.g., 'If you're hungry, there's food in the fridge') resist incorporation, ordinary conditionals do not in that the former do not 'count' as constituents in V/2 languages like German.

(c) 'The same form is used for the same meaning.' This is the basis of grammatical analogy (Anttila 1989, p. 89). The somewhat less familiar corollary, that different form is a reflection of different content, is the basis for Bréal's laws of repartition and specialization (Bréal 1897, p. 26). The 'same is same' heuristic also lies behind all the (never entirely successful) attempts to construct a 'notional' definition for parts of speech and grammatical categories in general (e.g., Jakobson 1936, Wierzbicka 1985), as well as for attempts to find explanations for recurrent polysemy of grammatical constructions.

(d) 'More form reflects more meaning.' This is still the most widespread diagnostic for markedness (see Greenberg 1966a, pp. 26–7). The clearest demonstration in typological research in Benveniste (1946) on the most frequent expression of the third person singular. As a creative dynamic principle of perception and interpretation, the 'more is more' heuristic is identified as what has led to the frequently attested restructuring of verbal paradigms (e.g., Watkins 1962). It is probably also what has led to the excrescence of derivational morphology in some less widely attested cases. In Khmer and in Romanian, for example, a reduced pronunciation of a verb was reinterpreted as the verb, the full form being reinterpreted as a derived nominalization or a derived causative.

(e) The order of clauses (e.g., in 'I came, I saw, I conquered') corresponds to the order of events, other things being equal (Jakobson 1965). Elaborations on this '*post hoc*, *ergo*, *post hoc*' heuristic are to be found in the Prague School notion of 'communicative dynamism,' itself a derivative of Behaghel's recognition (1932, p. 4) that the given precedes the new; Greenberg (1966b) on the order of mention of conjuncts, and of the order of protasis and apodosis; and Tai (1985) on the order of constituents within the clause. Hawkins (1994) and others have proposed that Behaghel's second law (that short constituents precede longer ones, as in Malkiel's 'irreversible binomials' (Malkiel 1959)) may also be reducible to this principle, given the tendency to give reduced expression to what is more familiar or given (frequently old) information.

(f) Conceptual symmetry is reflected in formal symmetry in a syntagm. Thus coordinate conjunctions, reciprocals, comparisons, and '*pari passu*' constructions like 'the more the merrier' tend to be symmetrically expressed in most languages. More subtly, conceptual symmetry is sometimes expressed by paradigmatic symmetry. The failure of reflexivization in sentences like 'I like me' and 'I want ME to stay behind' is a reflection of the loss of 'speaker privilege,' and hence, indirectly, a direct reflection of a divided self (Haiman 1998, p. 77): 'me' is treated no differently from (i.e., symmetrically with) any other participant on the perceptual stage. So, too, conceptual asymmetry may be reflected in formal asymmetry. Langacker (1985) argues that the structure 'there's snow all around (sc. me)' directly reflects the subject's inability to see himself, and thus reflects the asymmetry between the perceiving subject and the perceived object directly.

In spite of the opacity and arbitrariness in much of language, there is a sense in which we do not believe in our bones that it is real. In his short story 'Funes the memorious,' Borges showed what a totally arbitrary code would be:

In place of 7,013, he would say (for example) *Maximo Perez*; in place of 7,014, *The Railroad*; other numbers were *Luis Melian Lafinur*, *Olimar*, *suphur*, *the reins*, *the whale*, *the gas*, *the cauldron*, *Napoleon*, *Agustin de Vedia*. In place of 500, he would say *nine* … (Borges 1963, p. 64).

All students of language, however committed they may be to the idea that 'anything can stand for anything,' will probably find this conception of a language to be very alien. What Borges's imaginative and outrageous reductio forces us to acknowledge is the extreme unlikeliness of such willed original opacity. However opaque the signs and combinations of language may seem to us in any mature grammatical system, this system probably owes its present form to an originally iconic code like a pantomime (Donald 1991), modified over the course of time and use by a number of more or less user-friendly transparent signs and rules which 'seemed to be good ideas at the time.'

Given the acknowledged universality of motivation, analogy, markedness, Behaghel's law, and the extreme implausibility of truly arbitrary 'languages' like the number system of Funes, the interesting question is: what muddies the waters?

One obscuring factor is that limitations of the medium lead to competing (albeit impeccably iconic) motivations. For example, 'same form' is motivated not only by 'same meaning,' but by symmetry or 'lack of speaker privilege.' 'More form' is motivated not only by 'more meaning,' but also by 'less frequency' (Greenberg 1966a, on the relative marking of dual and plural), 'less familiarity,' greater surprise (Haiman 1998, on the marking of coreference), and 'more politeness' ('more form' is 'more wrapping,' cf. Geertz 1960). 'First mention' is motivated not only by being 'most familiar,' but also by Jespersen's (1949, p. 54) 'principle of actuality: what is at the moment uppermost in the speaker's mind tends to be first expressed.' Overburdened with too many semantic distinctions, a form may come to seem more or less arbitrary (Bolinger 1975, p. 110). So far, the most promising demonstration of the reality of iconicity in spite of this limitation is that where there are no competing motivations for the 'limited good' of a particular formal expression, there tends to be agreement (Haiman 1985a on word order).

Opacity or the apparent 'autonomy of syntax' is also the result of a number of diachronic factors, of which erosion, routinization, and systematization are perhaps the most important. We can illustrate some of these tendencies in a number system whose iconic origins are still very much in evidence—the Roman numerals.

The first three numbers are of course as iconic as a tally. The numeral V is apparently opaque, but still barely recognizable as a diagram of a human hand. The motivation for the abbreviation was probably no different from the motivation for the sound changes of truncation or assimilation: it is faster and easier to write V than to draw \\\\/. The numeral X can still be seen as a combination of two V's, one on top of the other. The numbers C and M are also icons, but of a different sort: C (entum) and M(ille) are examples of another kind of abbreviation, and illustrate competing iconic motivations coexisting within the same code.

Implicit in even the simplest compound sign, like II, is a rule which seems so natural that it is hardly recognized at first. It is that the combination XY is to be read as 'X' + 'Y.' This is as true of VI, VII, VIII, …, XXXIII, … MMCCCVIII, as it is of II. At some point, an unknown genius recognized and applied analogical reasoning to this natural rule: if XY is read as 'X' + 'Y,' then perhaps, under some (very restricted) conditions YX could be read as 'X' − 'Y.' The result, apparent in numerals like IV, IX, XC, and the like, is motivated within the system. But these numbers, even when they are drawn in the most painstaking and redundant detail, no longer correspond iconically to the quantities they represent. Analogy has led in this case to something that is the opposite of diagrammatic iconicity. The signs within a system cease to reflect reality and take on a life of their own when they are manipulated by rules internal to the system, as well as by the reality they still attempt to represent.

Within language, aspects of this are recognized as:

(a) the substitution of value for signification within a paradigm (the meaning of signs lies not in their relationship to the world, but in their relationship to each other, cf. Saussure 1916);

(b) grammaticalization, or the routinization of fixed structures beyond the contexts for which they were originally motivated; and

(c) the existence of various kinds of context-sensitivity within a syntagm (Haiman 1998, p. 149).

A compact example of systematization in syntax is the stress pattern of thetic sentences such as 'TRUMAN died' (Lambrecht 1988) in languages like English. A stress pattern should iconically reflect the contrast between old and new information, and a word order pattern should do the same. In English, iconic stress has led to sentences such as 'Truman DIED' where the predicate is new relative to the subject, but routinization has led to a fixed SVO word order, which is emancipated from the motivation of functional sentence perspective. Given that low stress … HIGH stress means 'predicate is new,' perhaps (by an analogical leap similar to the invention of the Roman numeral IV) HIGH stress … low stress means not only 'subject is new' (which it still iconically can do), but also 'everything is new.'

The Roman numeral system is far more iconic than the Arabic system, but it is already fully abstract and digitized. A more primitive system, corresponding to those languages in which there are no numerals higher than some 'highest digit' (frequently 2), resorts to subjective and analogic or iconic means of modelling higher numbers, typically {one, two, … many}. More languages resort to this analogical modelling in the domain of fractions, and present series like {one, a half, … a bit}. The digitization process 'colonizes' the analogic domain, substituting fixed quantities for impressionistic assessments like 'many' and 'a bit.' A roughly analogous 'colonization' process cannot be observed in the lexicon, or in morphosyntax, but it is

observed in the conventionalization of intonation (Léon 1993, Fonagy 1977): from being a purely analogical 'more is more' system, it becomes grammaticalized and transformed into an 'all or nothing' system—although never completely so (Bolinger 1961, 1986).

A future project for evolutionalists is to demonstrate that much of the undisputed arbitrariness of human languages, as of other human institutions, can plausibly be attributed to ritual and system: grammaticalization in the broadest sense.

Linguistics: Incorporation

Incorporation is a phenomenon whereby what might be expected to appear as a separate word is in fact part of the word on which it is dependent. The special nature of incorporation has been known to linguists for some time. Although it is known that the phenomenon is not restricted to indigenous American languages, it was first and foremost with respect to these languages that incorporation was, and still is, being discussed. In the following, a three-way distinction between noun incorporation, argument incorporation and grammatical incorporation as a continuum of morphological complexity is introduced.

Traditionally, noun incorporation is understood as a choice of whether arguments are retained on the syntactic level or not. Argument incorporation refers to the realization of the verb's arguments exclusively on the morphological level, i.e., verb internally. Here, no arguments can be identified in syntax, and the basic grammatical relations are realized at the word level. Noun phrases and other supplements have only adjunct status. Going a step further, functional items may be incorporated as well. In such cases of grammatical incorporation, various kinds of grammatical relations are realized verb internally. The term 'incorporation' will be used for all three types, regardless of whether the involved items are independent lexical units, i.e., words, or bound morphemes. Such a distinction becomes instrumental for differentiating the different types of incorporation.

1. Noun Incorporation

Since Kroeber (1909, p. 569) and Sapir (1989/1911, p. 254), noun incorporation has been characterized as stem combination, i.e., the combination of indepen-

dent lexical items into a complex verb. The verb stem determines the newly built form categorically, while the incorporated noun loses its categorical features, as well as any grammatical markings such as plural, if such are employed, see Ex. (3b) below. Nouns do not incorporate as arguments, but as specifiers of the incorporating verb.

(1) (a) Mohawk
/wa?kyvtho? ojì:ja?/ 'I planted a flower'
wa?- aorist modal prefix
-k- 1st person singular agent
-yvtho? 'plant'

(b) Mohawk
/wa?kji?jayvtho?/ 'I flower-planted'
-ji?ja- 'flower'
(Bonvillain 1972, p. 21)

Although the most general features of the construction might at first suggest so, noun incorporation is more than just another variety of compounding. Conspiciously, languages featuring regular and productive compounding, such as German, do not allow for incorporation, and vice versa, incorporating languages do not necessarily allow for compounding.

In many languages, noun incorporation is not a fully productive process, but restricted to certain types of nouns, most often related to the degree of animacy, or it may only be accomplished with suppletive forms. See, e.g., Allen et al. 1984 on Southern Tiwa, Mithun 1984, pp. 863, 876/77.

The incorporating process often entails a loss of referentiality of the incorporated noun and its being backgrounded. From the perspective of the speaker, incorporation represents an option, an alternative way of expression, a strategy to increase the informational content of a proposition, or a focus shift when proceeding with a discourse (cf. Mithun 1984, pp. 869ff. on Mohawk). Thus, the incorporated variant can always be seen in contrast to its nonincorporated counterpart. Being a matter of discourse and style, noun incorporation is expected to be a nonobligatory process. As has been pointed out frequently, it represents an elaborate register and, with bilingual speakers, characteristically is lost with decreasing fluency and competence (see, e.g., Mithun 1984, pp. 879ff.).

It is just this optionality, made possible by the basic lexical independence of the constituents which has motivated the interpretation of incorporation as a syntactic process, as a grammatical function-changing operation (Baker 1988). Incorporation is described as causing the loss of the argument status of the incorporated noun via its vacating its original position in syntax. Such manipulation involves the internal argument (direct object) predominantly.

If at all possible, the incorporation of an external argument typically is restricted to nonagentive noun phrases (Sapir 1989/1911, pp. 252, 266, Mithun 1984, p. 853, Gerdts 1998, p. 87, Cook and Wilhelm 1998).

(2) (a) Chukchee
ŋejə-k ʔəlʔəl təlgə-gʔi
hill-LOC snow.ABS thaw-3SG.S

(b) Chukchee
ŋejə-k ʔələ=lgə-gʔi
hill-LOC snow=thaw-3SG.S
'The snow thawed on the hill'
(Spencer 1995; p. 451)

In its weakest form, noun incorporation simply causes detransitivization, as in examples (1a) and (1b). In its most dramatic version, phrasal constituency is dissolved and the constituents of the former noun phrase become distributed inside and outside the complex verb—the head of the noun phrase is incorporated, while its modifier(s) remain in their external position. This phenomenon is often refered to as 'external modification' or 'classifying incorporation.'

(3) (a) Southern Tiwa
Wisi seuanin bi-mũ-ban
two man:pl 1sB-see-past
'I saw two men'

(b) Southern Tiwa
Wisi bi-seuan-mũ-ban
two 1s:B-man-see-past
'I saw two men'
(Allen et al. 1984, p. 295)

2. *Argument Incorporation*

Baker (1996) extends his syntactic approach of noun incorporation to languages which realize their arguments exclusively verb internally, i.e., which do not exhibit arguments in syntax. Contrary to such an attempt, it must be kept in mind that it is exactly the distinction between syntax and morphology, and the interaction between these two levels, on which the specificity of noun incorporation as compared to other function changing processes, e.g., passives, rests.

The question as to the status of the incorporated noun, i.e., whether it originates as a syntactic argument or not, functions as a crucial and effective criterion for distinguishing noun incorporation from the other types of incorporation. If we consider the implications of the traditional notion 'grammatical,' it is appropriate to distinguish noun incorporation from what was initially called 'pronominal incorporation' by Sapir. Contrary to what the term might suggest, usually no pronoun proper is incorporated. The morphemes under consideration most often cannot even be reconstructed as historically independent forms, but are strictly bound morphemes, obligatory and paradigmatically ordered (Sapir 1989/1911, pp. 250–2). Following Evans (1999) it can also be assumed that their semantic properties are different from those of true pronouns. The more recent term 'pronominal argument' (Jelinek 1984) draws on the relation to syntax again: the arguments of the verb are fully and exclusively realized by bound morphemes, i.e., by

morphological marking. In contrast to the optionality of noun incorporation, argument incorporation does not envisage such a choice. Since the arguments of the verb are realized as bound morphemes joined to the verbal root or stem, no lexical arguments are necessary or even possible outside the verb. The expression of grammatical relations is thus shifted from the syntactic level to the word level, as is illustrated by all examples to come.

As opposed to noun incorporation then, 'pronominal,' i.e., morphological, arguments are not potential syntactic arguments but represent a fundamentally different strategy for the realization of arguments. They fulfill the requirement of representing the fundamental grammatical relations of the sentence, and stand in contrast to inflection, which only reflects the relations constituted on the syntactic level. In order to decide whether a person-marking morpheme has mere inflectional status or whether it actually represents the argument(s) of the verb, careful investigation is needed to decide whether syntactic argument positions are available in a particular language. Such investigations have been carried out only for comparatively few languages, such as the Australian language Warlpiri (Hale 1983, Jelinek 1984, Simpson 1991, see also Austin and Bresnan 1996), the Iroquoian language Mohawk (Baker 1996), Salishan languages (Jelinek and Demers 1994, Jelinek 1995) the Athabaskan language Navajo (Jelinek 2000) and Inuktitut (Eskimo) (Nowak 1996a, 1996b). Discussions of Algonquian languages seem to point in a similar direction, but do not yet cover a broad range of relevant tests. Other languages suggest themselves as promising candidates, but have not been scrutinized, as is, for example, the case with most of the languages discussed by Mithun (1984).

Many morphological argument languages tend to feature a wealth of lexically and/or functionally bound morphemes which have no independent lexical counterparts, and the proportion of roots and stems to bound morphemes is dramatically changed in favor of the bound morphemes (Nowak 2001).

In Inuktitut (Eskimo), whole semantic fields denoting activities, states, events, processes, including 'being' and 'having,' as well as the indication of reported speech and epistemic specifications, are expressed exclusively by bound morphemes which are suffixed to the stem they modify or supplement.

(4) Inuktitut
qimmiqaqtunga
qimmiq-qaq–tunga
dog-have.itr-1s.itr 'I have a dog/dogs.'

(5) Inuktitut
nirijumajara
niri–juma–jara
eat–want–1s.3s.tr. 'I want to eat it.'

In the Salishan languages of the American Northwest Coast, bound morphemes cover the domain of referential expressions and do so exclusively; so-called 'field suffixes' such as -éné, -né, 'ear' in Ex. (6) lack independent counterparts.

(6) Kalispel
na·céné he gets an ear-ring
(Vogt 1940, p. 53)

In cases where items with lexical content are incorporated, no matter whether they are free or bound morphemes, typically the morphological argument and the incorporated lexical items do not exhibit agreement. Yet some cases of such internal agreement relations have been reported. For Southern Tiwa, obligatory incorporation is reported. In this language, person marking on the complex verb also reflects the person, number, and class of the incorporated noun. (Allen et al. 1984, pp. 295–8). The same seems to be the case with Bininj Gun-wok, a language of North Australia.

(7) Bininj Gun-wok
(a) ba-ginje-ng gun-ganj
3/31-cook-PP IV-meat
'(S)he cooked (the) meat.'
(b) Ba-ganj-ginje-ng
3/31-meat-cook-PP
'(S)he cooked (the) meat.'
(Evans 1999, p. 259)

3. *Grammatical Incorporation*

Grammatical relations may also be realized verb internally. Fundamental syntactic operators such as auxiliaries, pronouns, adpositions, complementizers, and other syntactic function words often do not exist at the word level at all.

(8) Inuktitut
(a) niuvirvingmuaqtutit
niuvirvik -muaq–tutit
shop-go.to–2s.itr
'You go to the shop.'

The term *niuvirvik* 'shop' is a lexicalized affix combination, as is *-muaq-* 'go to'; *niuvirvik* is composed of *niuviq-*, 'to acquire' and a nominalizing affix *-vik* 'place where s.th. happens'; *-muaq-* is a highly frequent combination of the (singular) terminalis case *-mut* 'to' and *-aq-* 'go.' Besides these lexicalizations, all affixes are perfectly productive (Nowak 1996a, p. 255).

(8)
(b) niuvirvingmut
niuviq–vik-mut
acquire-place.where-term.s.
'to the shop'

Interestingly enough, the noun marked by the terminalis is not stripped of its plural when involved in such an incorporation.

(8)
(c) niuvirvingnut
niuviq–vik-nut
acquire-place.where-term.p.

'to the shops'

(d) niuvirvingnuaqtutit
niuvirvik -nut -aq- -tutit
shop-term.p-go–2s.itr
'you go to the shops'

Morphological arguments in many instances are fused with other features such as the indication of clause linkage, often referred to as 'switch reference,' or 'anaphoric coreference,' as can be seen in (9).

(9) Inuktitut

tikiniraqtauvutit	piqsiqtillugu

'somebody said that you have arrived while it was blizzarding'

Grammatical incorporation thus can be seen as the morphological realization of functional relators, i.e., as the word internal establishment of relationships which would otherwise demand syntactic spell out. The results are highly complex forms equivalent to full propositions.

4. Conclusion

It must be kept in mind that languages hardly ever represent ideal types. This applies to what has been said about syntax and morphology, and the degree to which they interact. The types of incorporation discussed here exemplify an increasing complexity, or configurationality, in morphology, illustrating a unidirectional relationship between morphological complexity and the morphological realization of arguments. Languages of high morphological complexity also feature the morphological realization of arguments, but it is not necessary that all languages realizing their arguments morphologically must be morphologically complex in other respects.

The morphological strategies employed by such languages range from concatenative (Eskimo) through template (Athabaskan) to morphophonemic and prosodic devices (Salishan), and often exhibit mixtures of all these types. A unified account of such complex and multilayered morphological patterns is a desideratum that must be left for future research.

Noun incorporation on the one side, and argument incorporation and grammatical incorporation on the other, are separated by the optionality vs. obligatoriness of incorporation: with the latter, the speakers do not have a choice. The last type, grammatical incorporation, extends morphological configurations to other than argument relations, i.e., to grammatical relations in general. This is the content of the traditional term 'polysynthetic.'

Linguistics: Information Structure

The fundamentally interactive character of natural language, anchored in communication, is reflected by the impact of context (consituation) on sentence structure. Typically, the sentence is divided not only into syntactic subject, predicate, objects, adverbials, etc., but also into what corresponds to cognitively 'given' and 'new' information. This 'information structure' of the sentence (its 'topic-focus articulation,' TFA, or its division into 'theme' and 'rheme' or 'comment') has been established in linguistic writings of the latter half of the twentieth century as one of the constitutive aspects of grammatical structure, rather than just as an issue of the use of language in communication that would be determined only by contextual conditions of the distribution of sentences.

1. *Topic-focus Articulation, Aboutness and Presupposition*

TFA can be illustrated by the following examples (in which capitals indicate intonation center (IC, main sentence stress, falling), cf. Sect. 4):

I was writing this study on the WEEKENDS. (1a)
On the weekends I was writing this STUDY. (1b)
Yesterday John visited BOSTON. (2a)
JOHN visited Boston yesterday. (2b)
John visited Boston YESTERDAY. (2c)
Jim's brother did not insult MARY. (3a)
Mary was not insulted by Jim's BROTHER. (3b)

As (1) documents, the opposition of focus (F, which carries the IC and in the primary case is placed at the end of the sentence) and topic (T, referring to 'given' information) is relevant for the semantic interpretation of the sentence (even for its truth conditions: there are situations, or 'possible worlds' in which (1b) can be used as a true statement, but (1a) would not be true). Thus, although the information structure (TFA) is closely connected with contextual conditions of the use of sentences (e.g., as answers to different questions), it belongs to the information expressed by grammatical means (sentence prosody, word order (WO), and in languages such as Japanese or Tagalog by specific particles) and relevant for the linguistic meaning of the sentence. The WO shift in (1) can be understood as primary, prototypically accompanied by passivization in English, cf. (3) although it occurs also with the active verb in languages with a higher degree of 'free' WO, cf. e.g., Czech, Marii (Accus.) *urazil Jimův BRATR* (Nomin.). In English, a shift of IC is more or less equivalent: 'Jim's BROTHER insulted Mary.'

In declarative sentences TFA corresponds to the 'aboutness' relation in the sense of F being asserted about T. Thus, in (2a) it is asserted about John (x) and yesterday (y) that what x did at timepoint y was to visit Boston. In (2b) it is asserted about yesterday's visit to Boston that it was carried out by John, and (2c) asserts about John (x) and Boston (z) that x visited z precisely yesterday (or, with the verb being included in T, it asserts about John's visit to Boston that it occurred yesterday).

A positive sentence can be interpreted as asserting that F holds about T, i.e., as F(T). The prototypical negative sentences, such as those in (3), are used to assert that F(T) does not hold, which means that what is under negation is identical to F (the expression 'under negation' will be made more precise in Sect. 3); T then is not under negation and a typical definite noun group in T triggers a presupposition that is not present if this group is included in F, as in (3b): while both (3a) and its positive counterpart entail the existence of Jim's brother, this is not entailed by (3b), in which the entailment can be classified as an allegation, rather than a presupposition or a case of 'meaning proper.' It is not exact to speak of a presupposition of existence; in certain cases, especially in sentences directly concerning existence (in the actual world), what is presupposed is not the existence, but rather the referential availability of the object concerned (an abstract object, a mythical being, etc.), or its presence in the part of the universe of discourse that is assumed by the speaker to be accessible to the hearer(s), cf. 'The gifts are from your parents,' 'Santa Claus does not exist,' or also 'White crows would have red eyes, if they existed.'

It is a specific question under which conditions a difference in TFA has a direct impact on the truth conditions of sentences. A similar situation is known from predicate logic, in which, e.g., the order of 'for every x' and 'there exists a y' is relevant, although the order of two variables bound by the existential quantifier is not relevant ('Every child passed an EXAM' is weaker than 'An exam was passed by every CHILD,' but 'A child passed an EXAM' and 'An exam was passed by a CHILD' share their truth conditions.)

It can be argued that there is a difference between contrastive and non-contrastive F; while the sentences in (1)–(3) can occur as typical answers to questions such as 'When were you writing this study?' 'What were you doing on the weekends?' 'Which town did John visit yesterday?,' etc., the cleft construction in (4) would preferably be used in case of contrast, e.g., after 'I am not sure which of your cousins was in Boston yesterday.'

It was JOHN who visited Boston yesterday. (4)

The concept of contrast (based on choice among alternatives) is also relevant for T, as discussed in Sect. 4 below.

2. *Different Traditions*

In the light of the older European tradition, the pioneering insights of H. Weil, G. von der Gabelentz, Ph. Wegener, and others (cf. also the notion of 'logical stress' in Russian language teaching), V. Mathesius introduced an analysis of TFA into structural linguistics. The sentence has been analyzed as divided into a contextually bound and a non-bound part, i.e., into T and F; while the former can be expressed by weak, unstressed or zero pronominal elements, the latter is stressed. This and similar views have then been elaborated especially by Halliday (1967–8), by J. Firbas (1992), as well as by the research group of theoretical and computational linguistics in Prague (Sgall et al. 1986), by D. Bolinger, W. Chafe, T. Reinhart, then (with the division of T or 'ground' into 'link' and 'tail') by Vallduví and Engdahl (1996), and, in Chomskian linguistics, by R. Jackendoff, M. Rochemont, and others. Recently, centering theory (A. Joshi, B. Grosz, E. Prince) attempts to determine which sentence part probably will occur as (or in) the T of the next utterance.

Some of the approaches based on constituency or configurationality face problems connected with the fact that neither T nor F is, in the general case, a single constituent, as can be illustrated by (5) and (6), where the sign '@' indicates the T/F (F/T) boundary:

(How have you spent the vacations?) We went @ for a week to the ADRIATIC (rather than for the whole month to Mallorca, as we had planned). (5)

(What happened to Mary in the valley?) A WASP bit @ her. (6)

It is then necessary to work either with specific rules of 'focus inheritance' (adding more constituents to F, see Selkirk 1995), or with multiple derivations such as those of Steedman's (1996) combinatory categorial grammar, if the authors do not want to multiply the articulations, differentiating, e.g., between an opposition of background vs. focus, and that of topic vs. comment. It may be seen as more advantageous to use dependency syntax (as known from European structural linguistics) and an elaboration of certain notions originally introduced by J. Firbas: as discussed in Hajičová et al. (1998) and in the writings quoted there (a formal treatment was presented by Petkevič 1995), the scale of communicative dynamism (CD) can be handled as an underlying order, which differs from the surface or morphemic order especially in sentences in which IC (carried by the most dynamic item) occupies a secondary position (not at the end of the sentence), as is the case in (2b), (4), and (6) above; contextual boundness (as a grammaticalized feature of every lexical occurrence) can be understood as a primitive notion. This allows for a subtle classification of notions such as 'broad' and 'narrow' F; the T/F boundary can then be specified as determined by a single edge of the dependency tree (which constitutes the core of the sentence structure).

On the other hand, there is a tradition started by J. Jacobs (1983) and continued by M. Krifka, M. Rooth, K. von Fintel, D. Büring, and others, whose approaches are based on the analysis of the positions and functions of focus sensitive particles (such as 'only,' 'also,' 'even'). The foci and backgrounds of the particles and their contextually conditioned properties are systematically studied by methods of formal semantics. An attempt at a synthesis of the two approaches, offered by B. H. Partee and her co-authors (Hajičová et al. 1998), is summarized in the next section.

3. *The Focus of the Sentence and the Focus of a Particle*

As example (3) above illustrates, what is under negation in the primary case is F. In secondary cases, (a) the negation itself, together with the verb, belongs to T, and only the verb is negated, cf. (7), or (b) negation constitutes the whole F, and (a part of) T is under negation, cf. (8):

My brother didn't come to the party since he was ILL. (7)

(e.g., after 'Why didn't your brother come to the party?')

My brother DIDN'T come to the party. (8)

Jane told me that yesterday she did not SUCCEED. (9)

In the secondary cases, and also if negation is present in an embedded clause, not only the articulation of the sentence into F and T is relevant, but also the focus of the negation particle and its scope: in (7) only T, i.e., the main clause, is the scope of negation and 'come to the party' is its focus (i.e., is under negation); in (9) only the 'that'-clause is the scope and its verb is the focus of negation. It is then possible to define the background of the particle as its scope minus its focus.

This concerns also other focus sensitive particles or operators (focalizers), as can be illustrated by examples from German, the WO of which is more perspicuous than that of English. Prototypically, the focalizer is placed at the T/F boundary:

Er ist nicht/auch/eben/sogar/nur/mit großer Freude/nach PRAG gekommen. (10)
[He – has – not/also/precisely/even/only/with – great – pleasure – to PRAGUE – come.]

Also in the secondary cases, other focalizers occur in a position similar to that of negation: the focalizer belongs to T in (11) and constitutes the whole F in (12):

Er ist wegen seiner FRAU nicht/auch/…gekommen.
[He has due – to his WIFE not/also/…come.] (11)

Dein Bruder war dort NICHT/AUCH …
[Your brother was there NOT/TOO/…] (12)

In English, WO is more ambiguous, e.g., in (13) F has several possible ranges (the positions of the T/F boundary on different readings are again marked by '@'):

Martin only @ gave @ a flower @ to a GIRL. (13)

It follows that it is necessary to distinguish between (a) the sentence focus F, typically placed after the topic, marked by IC and empirically specifiable with the use of operational criteria such as the question test or a test with a negative or adversative continuation, and (b) the focus of a focalizer (ff). In the unmarked case ff is identical with F (cf. (3), (10) and (13) above), but this is not the case in secondary examples (such as (11) and (12)).

If negation is one of the focalizers, then in the absence of an overt focalizer the positive modality of the verb can be interpreted as a focalizer (see Jacobs 1984), which is not overtly present in the sentence, but is relevant for its semantico-pragmatic interpretation (i.e., a procedure leading from underlying representations to an account of the content of the expressed statements, questions, etc.). Two studies on issues of the interpretation of TFA by means of post-Montague semantics—B. H. Partee's investigation of the relationship of 'allegation' to accommodation and J. Peregrin's elaboration of the aboutness relation as that of an argument and a predicate—are included in Partee and Sgall (1997).

4. *Means of Expression of Information Structure*

In the prototypical case, the (surface) WO corresponds to the scale of CD: T proper (the least dynamic item) occupies the leftmost position, and F proper (most dynamic) comes last. In sentences with a marked position of IC, this prosodic feature overshadows WO; F proper is expressed by the bearer of IC, cf. J. Pierrehumbert's H*L accent and also the analyses by Ladd (1996), who outlines how TFA varies from one language to another, and Steedman (1996).

Differing both from IC and from lexical stress of individual words, there are other kinds of stress, which are to be classified and specified as to their positions in several hierarchies. Some of these kinds of stress (phrasal, contrastive, or the rising interrogative contour) are immediately relevant for sentence structure, whereas others express different ('pragmatic,' attitudinal) values, which do not directly belong to the system of language (various kinds of emphasis, wonder, aversion, doubts, and so on).

T proper often has a contrastive value (i.e., refers to an entity chosen from a set of alternatives determined by the context); this is expressed by a certain kind of phrasal stress, denoted here by italics:

Paul's *son* has bought a new CAR and his *daughter* has got an APARTMENT of her own. (14)

It is often assumed that in sentences such as (14) a rising contrastive stress on the subject is present, which differs from IC. Example (14) also shows that compound sentences include separate TFA patterns in their individual clauses.

If a focalizer occurs within T, its ff (perhaps always a contrastive part of T) is marked (according to C. Bartels and others) by a specific kind of stress (which perhaps may be identified with the just mentioned contrastive stress), or at least by some other kind of rhythmic prominence, see Rooth (1992). This concerns also the ambiguous position of 'only' in his example reproduced here with a modification concerning the phrasal stress (cf. the discussion in Hajičová et al. 1998, p. 157) as (15a); its preferred reading is identical with that of (15b), with 'only' in T:

People who *grow* rice often only EAT rice. (15a)
People who *grow* rice often EAT only rice. (15b)

5. *Three Layers of Word Order*

Let us have a look at the following examples (with which the symbols for dependents such as Directional or Locative should be self-explaining):

They flew from Chicago to Boston. (Dir. 1–Dir. 2) (16a)
A B
They flew to Boston from Chicago. (16b)
B A
Jim dug a ditch with a hoe. (Objective–Means) (17a)
A B
Jim dug a DITCH with a hoe. (17b)
A B
Ron cannot sleep quietly in a hotel. (Manner–Loc) (18a)
A B
In a hotel Ron cannot sleep quietly. (18b)
B A

If A precedes B in the examples with normal intonation, then A belongs to T on some readings, to F on others; however, if B precedes A (or if A, preceding B, bears the IC), then B belongs to T. A similar relationship can be found with other pairs of arguments and adjuncts (with certain differences concerning groups of verbs, dialects, or generations), so that a basic scale can be established that determines

their CD, with deviations possible only in case B is contextually bound (belongs to T); the differences between CD and WO (such as in (17b), or those concerning the position of the verb in German, etc.) can be handled by low-level rules. The existence and the basic shape of this 'systemic ordering,' known since the 1970s, has been confirmed by several series of tests for Czech, German and to a certain extent for English, see Sgall et al. (1995).

Systemic ordering in English—a preliminary partial scale:

Temp–Actor–Addr–Obj–Origin–Effect–Manner–Dir.1–Means–Dir. 2–Loc

This ordering can be specified in the lexical entries of verbs (and other head words), especially by the order of the obligatory and optional kinds of dependents in the valency frames. Another layer of order of the lexical items in the sentence is the CD (which within T may differ from the systemic ordering), and the third layer is WO.

It can be concluded that at least the core of information structure belongs to grammar and can be described within frameworks with flat patterns, such as dependency syntax; these representations may serve as input for an interpretation using methods of formal semantics. This holds for languages with the most varying degrees of 'free' WO. In most Slavic languages, Latin, etc., in which the basic syntactic relations are expressed by case endings, WO often is 'free' to correspond to CD. English or French, which express these relations by WO rather than by endings, use more syntactic reshaping (passivization, clefting, secondary placement of IC) to achieve such a correspondence between WO and CD.

Linguistics: Internal Reconstruction

Internal reconstruction is a method for establishing earlier, unattested forms of languages without reference to 'external,' especially comparative, evidence from other languages. In this it differs from the comparative method (see *Linguistics: Comparative Method*), which is based on such evidence, though the aims of both methods are in practice the same. To signal the difference, forms or languages reconstructed by internal reconstruction are designated 'pre-forms,' 'pre-languages,' etc., as opposed to the 'proto-forms' and 'proto-languages' reconstructed by the comparative method. The method can be applied to individual languages in cases where comparative evidence is not available, for example to isolated languages or to reconstructed proto-languages.

Internal reconstruction is an extremely powerful method, and for this reason some of its results can be both speculative and controversial, though a number of the reconstructions arrived at by this method which were earlier deemed too hypothetical have subsequently become accepted, for example the postulation of a set of 'laryngeal' consonants for Indo-European

(the 'laryngeal theory'), whose existence was corroborated following the discovery of Hittite (Lindeman 1987). As in the case of the comparative method, it evolved in practice before it was formally recognized. However, since the method rests on a quite sophisticated formal analysis of language, it did not appear until the late nineteenth century, much later than the comparative method. In a youthful work, for instance, Saussure used aspects of what would now be regarded as internal reconstruction in his study of the Indo-European vowels. However, the method was not firmly established until the 1940s, principally in the work of American structuralist linguists such as Henry Hoenigswald.

Internal reconstruction is not a single, unitary method; the term embraces a number of related but distinct procedures, which we may designate as follows:

(a) historical morphophonemics;
(b) regularization of systems; and
(c) universal and typological reconstruction.

All of these have in common the attempt to work backwards in time by reversing changes that are assumed to have taken place in the language in question, but they differ in scope and in the factors that are taken into account.

1. *Historical Morphophonemics*

This is the most limited of the methods of internal reconstruction. It applies only to the reconstruction of phonology, and works by identifying phonological alternations between grammatically or lexically related forms resulting from the differential operation of phonological changes in different linguistic contexts. By eliminating these alternations and reducing the set of alternants to a single form, it effectively reverses the changes and establishes the form that existed prior to their taking effect. In practice, it is equivalent to the synchronic process of establishing 'morphophonemes,' or the 'underlying forms' of classical Generative Phonology (see *Phonology*; *Morphophonology*)—abstract phonological entities from which the occurring forms can be derived—though it interprets these morphophonemes as historical antecedents.

Consider, for example, the Latin forms given in (1).

Nominative	Genitive		
consul	consulis	('consul')	
genus	generis	('kind')	(1)
corpus	corporis	('body')	

As we see from *consul*, the genitive is formed by adding the affix -*is* to the stem of the word, but in the case of *genus* and *corpus* the final consonant of the stem is -*s* in the nominative and -*r* in the genitive. In synchronic phonology we might regard these two sounds as realizations of the same element, a 'morphophoneme' which appears as /s/ at the end of the word and as /r/ between vowels. But the alternation can also be interpreted historically, if we assume that this morphophoneme was actually an original phoneme, assumed to be /s/, which was changed to /r/ between vowels. We can therefore postulate earlier forms of the genitive: **genesis* and **corposis*.

This method works, therefore, by attempting to undo the effects of the splitting of phonemes in different contexts. Here, the original phoneme /s/ split into two separate phonemes, /s/ and /r/, depending on the context in which it occurred. This split resulted in a synchronic alternation between the phonemes /s/ and /r/ in different forms of the word. By identifying such alternations, and deriving the alternating phonemes from a single source, we reconstruct the earlier form of the words.

2. *Regularization of Systems*

Like historical morphophonemics, this method attempts to reverse changes by eliminating anomalies, but it extends this principle to cover whole systems of linguistic elements.

Consider, for example, the so-called 'strong' verbs of the Germanic languages. These verbs form their principal parts not by the addition of affixes (*walk–walked*; *love–loved*, etc.), but by modifying the vowel of the stem (*sing–sang–sung*; *ride–rode–ridden*, etc.). Strong verbs fall into a number of classes, according to the pattern of alternation of the vowels; only the first three are relevant here. For these verbs, we can identify three stems, whose vowels can be reconstructed by means of the comparative method, for the Germanic languages as a whole: as in (2).

Class I	i:	ai	i	
Class II	iu	au	u	(2)
Class III	i/e	a	u	

It can be seen that there is a certain regularity here, though also some anomalies. By the simple expedient of regarding the *i*: of the first stem of Class I (the colon indicates length) as *ii*, the first two classes become entirely parallel, with the vowel pattern *i–a–zero*, where the vowel is followed by *i* in Class I and *u* in Class II; in the third stem, the *i* or *u* is left as the only vowel. In Class III verbs, the vowel is followed by a nasal or liquid consonant (*r* or *l*), and the *i*/*e* alternation in the first stem depends on the following consonant: *i* occurs before a nasal and *e* before other consonants. We can therefore eliminate this alternation; the standard reconstruction assumes an *e* here, which is also generalized to the first stem of Classes I and II (*e* became *i* before the *i* and *u* of these classes as well as before the nasal of Class III). Thus, all three classes can be reconstructed with the same pattern (*e–a*) for the first two stems.

There remains the third stem, for which, as we have seen, we assume a 'zero vowel' for Classes I and II. If the pattern is the same for all three classes, Class III

should have no vowel at all here, though in fact we find *u*. This *u* thus alternates with the *zero* of Classes I and II, and we can reconstruct a single source for both, which, following the first two classes, is taken to be *zero*. The nasal or liquid consonant of the stem of this class is assumed to have been 'syllabic' (i.e., it had the role of a vowel, as with the *n* or *l* of such English words as *bitten* [bitn] or *bottle* [botl]). It is presumed that these syllabic consonants later developed *u* before them. The result of these procedures is an entirely regular system, with the pattern *e–a–zero*, the differences among these three classes being in the sound which followed the vowel: *i* in Class I, *u* in Class II, and a nasal or liquid consonant in Class III. Such a regularized system can then be regarded as existing at an earlier stage of the language.

It is legitimate to object, of course, that, carried to its logical conclusion, this procedure results in the elimination of all anomalies and irregularities, and thus assumes that earlier languages had no such irregularities—an unlikely state of affairs. However, it should be borne in mind that all reconstruction, by whatever method, produces an idealization rather than an attested reality.

3. *Universal and Typological Reconstruction*

This method attempts to work backwards by invoking known or assumed general attributes of language or processes of linguistic change. This is the most powerful, but also the most speculative form of internal reconstruction, since the evidence we have of such general processes of change is often of a theoretical kind.

The criteria for reconstruction here may be either universal or typological. In the former case, changes are assumed to have occurred which reflect universals, i.e., characteristics of all languages, though these may be diachronic (universal processes of change) or synchronic (universal characteristics of language states which constrain the processes of change). If we therefore encounter a particular feature in the language under investigation which is known to be the result of a certain universal process, then we may assume this process to have occurred and reinstate the form from which the feature may have derived.

Universal processes or constraints have been recognized for all components of linguistic structure: phonology, morphology, syntax, and the vocabulary. One such process, which is currently receiving considerable attention, is grammaticalization (see *Grammaticalization*), the 'downgrading' of lexical words to grammatical words and affixes (Hopper and Traugott 1993); a similar and related process applies in the lexicon, by means of which words are progressively 'bleached' of semantic content. Recognition of such universals allows us to determine the direction of language change, and thus to reconstruct earlier stages in conformity with this direction. Thus, if we assume that all grammatical affixes are derived from original lexical words, then a reconstruction which posits grammatical morphemes as earlier stages of lexical morphemes rather than the reverse would be ruled out.

Reconstruction based on typological criteria relies on the observation that languages fall into a number of more or less distinct types, characterized by co-occurring or harmonizing features (see *Linguistic Typology*). A standard typological grouping, for example, divides languages into VO and OV types, according to whether the object (O) follows or precedes the verb (V). A number of other features of sentence structure harmonize with this: in VO languages (e.g., French) the adjective typically follows the noun, and prepositions are used; in OV languages (e.g., Japanese) the adjective typically precedes the noun, and postpositions are used.

To apply the method, we identify the language as belonging to a particular type on the basis of some major feature, and, making the further assumption that languages are ideally typologically consistent, bring the remaining harmonizing features into line. If, for example, we find a language (such as English) which is VO but has the order adjective + noun, we will assume that at an earlier stage the language will have either been OV (which is assumed for English) or will have had the reverse order of noun and adjective. Various different typological parameters have been put forward, but their use in reconstruction generally follows the above procedure. Again there are potential weaknesses in the assumptions underlying the method, since most languages are typologically inconsistent to some degree, and it is by no means proven that typological consistency represents an ideal or original state for languages.

4. *Conclusion*

The methods of internal reconstruction are extremely powerful, but they rest on a range of assumptions about both the nature of languages and the nature and direction of language change. The accuracy and reliability of the results inevitably depend on the adequacy of these assumptions. Not surprisingly, the results of the method have often been challenged as the assumptions themselves have been called into question.

Linguistics: Markedness

'Markedness' refers to an asymmetry relation between elements of linguistic or conceptual structure. In a marked–unmarked relation, one term of an opposition, or of a set, is taken to be the dominant one while the other(s) are taken to be secondary. The dominant term is known as 'unmarked' and the secondary one(s) as 'marked.' Linguistic markedness ranges over phonological, grammatical, and semantic oppositions and constructions. The concept has been extended to the analysis of cultural relationships as well, with background cultural categories (right-handedness, sightedness, etc.) being taken as unmarked.

1. *Background in the Prague School*

As Henning Andersen (1989) has noted, the idea of asymmetry in linguistics predated the actual coining of the terms 'marked' and 'unmarked' in the 1930s, going back to work in the early 1800s. The modern concept of markedness originated in the Prague School structuralism of Roman Jakobson and Nikolai Trubetzkoy, and was proposed as a means of characterizing binary oppositions. In Prague School structuralism both sound and meaning were analyzed into systems of binary distinctive features representing sound and meaning as the presence or absence of relational properties or features. Binarism suggests symmetry and equivalence in linguistic analysis; markedness adds the idea of hierarchy. The fact that distinctions were characterized as the presence vs. the absence of some property implied an evaluation of any opposition into a mark and its absence. Thus for example, phonological oppositions such as nasal vs. nonnasal were defined as the presence vs. the absence of nasality; nasality was marked, nonnasality unmarked.

Oppositions manifest asymmetry in several ways, most notably for Trubetzkoy in terms of the diagnostic of neutralization, whereby the unmarked term of a phonological opposition was thought to be that which occurred in positions where the contrast was neutralized (i.e., here only one term of the opposition could occur.) In his 1932 article 'Structure of the Russian Verb,' Jakobson extended the concept of asymmetry to a view of grammatical meaning in which the marked element 'announces the existence of [some meaning] A' while the unmarked element 'does not announce the existence of A, i.e., does not state whether A is present or not.' This meant that an opposition like past vs. nonpast characterized three interpretations: past, present (as the opposite of past), and timelessness (the neutralization of the tense opposition). More generally, any semantic opposition involved three meanings: two unmarked and one marked. The breadth of the unmarked terms was extended by Jakobson to oppositions that were not inherently binary. In a 1972 article, Jakobson described language by saying that 'every single constituent of a linguistic system is built on an opposition of two logical contradictories: the presence of an attribute ('markedness') in contraposition to its absence ('unmarkedness').' Jakobson also suggested a role for markedness in language acquisition and loss, in his monograph *Child Language, Aphasia, and Universals of Language* (1941). Jakobson proposed a relationship between a universal feature hierarchy, the acquisition of sound distinctions by children and the loss of sound distinctions during aphasia. Today few linguists or aphasiologists adopt Jakobson's positions literally, though many view them as useful tendencies (see Caramazza and Zurif 1978).

Semiotically oriented work in the Prague School tradition has viewed markedness as a means to investigate the isomorphism of form and meaning. Henning Andersen and Michael Shapiro have linked markedness to semiotic universals and to the work of Charles S. Peirce. The work of Cornelius van Schooneveld, Edna Andrews, Rodney Sangster, Yishai Tobin, and others foregrounds the notion of 'semantic invariance' (understood as the different general meanings reflected in the contextual specific meanings of features). The most well-known semantic invariants are those in Jakobson's analysis of the Russian case and verb systems which attempt to ground semantics in spatial relations and in the relations among participants in the overall speech event (for recent work on invariance, see Waugh and Rudy 1991).

2. *Markedness in Generative Grammar*

Markedness entered generative linguistic theory through Chomsky and Halle's *The Sound Pattern of English* (1968). Following the Prague School view, phonological features were assumed to be part of a universal phonetic vocabulary. In addition, features

were also incorporated into what was known as the 'evaluation metric,' a central concept in early versions of generative grammar. The evaluation metric was a means of selecting the most highly valued grammar capable of describing the facts of a language. In *The Sound Pattern of English* the value of a grammar was the inverse of the number of features required in that grammar. However, Chomsky and Halle realized that their initial approach to phonological features made implausible rules and segment inventories as highly valued as natural ones. To deal with this, they introduced markedness as a means of encoding the intrinsic content of features. Chomsky and Halle proposed a set of 39 universal marking conventions tying naturalness to evaluation. In their system, an unmarked feature value was cost-free with respect to the evaluation metric, while the marked values were counted by the metric. Segment inventories could also be evaluated according to the number of marked features required to characterize them; sets of lexical items could be evaluated for markedness based on the number of marked features they entailed; and a concept of 'linking' reduced the number of features required to characterize processes corresponding to the markedness conventions. However, the use of phonological markedness as part of the evaluation metric was never able to fully account for the fact that some features are more likely than others or for the fact that phonological system must have a certain minimal complexity and symmetry (see Kean 1980).

In syntax, markedness as feature-evaluation did not receive the same attention that it did in phonology. In Chomsky's work, markedness evolved to a view of unmarked properties as an innate preference structure based first in constraints and later in parameters of universal grammar. Beginning in the 1970s, Chomsky attempted to greatly restrict the class of possible grammars, suggesting a relative rather than an absolute interpretation of conditions on rules. In such an approach, rules apply in accordance with the conditions unless specifically complicated to evade them, with Chomsky (1977) noting in his article 'On *Wh*-movement' that 'The logic of this approach is essentially that of the theory of markedness.' In their 1977 article 'Filters and Control,' Chomsky and Howard Lasnik extended to view markedness as part of a theory of 'core grammar':

> We will assume that [Universal Grammar] in not an 'undifferentiated' system, but rather incorporates something analogous to a 'theory of markedness'. Specifically, there is a theory of core grammar with highly restricted options, limited expressive power, and a few parameters. Systems that fall within core grammar constitute 'the unmarked case'; we may think of them as optimal in terms of the evaluation metric. An actual language is determined by fixing the parameters of core grammar and then adding rules or conditions, using much richer resources, … These added properties of grammars we may think of as the syntactic analogue of irregular verbs. (1977, p. 430)

What is unmarked is the entire core grammar of a language, which is then supplemented by a marked periphery. In later versions of his theories, Chomsky has explored various positions on markedness, for example associating the unmarked with a child's initial hypothesis. In a 1986 work, he summarized his views as follows:

> The distinction between core and periphery leaves us with three notions of markedness: core versus periphery, internal to the core, and internal to the periphery. The second has to do with the way parameters are set in the absence of evidence. As for the third, there are, no doubt, significant regularities even in departures from the core principles (for example, in irregular verb morphology in English), and it may be that peripheral constructions are related to the core in systematic relaxing certain conditions of core grammar. (1986, p. 147)

Other researchers in generative syntax have tried to flesh out aspects of markedness, attempting to operationalize the idea of the cost of a marked syntactic construction or integrate markedness into the theory of parameters. Various approaches have been suggested, including tying markedness to an ordering of parameter values defined by subset relations among sentences, connecting it to types of triggering experiences or to default learning strategies, and using markedness to establish a universal syntactic feature hierarchy. Optimality Theory approaches emerging in the 1990s also incorporate markedness. In such approaches, in which constraints are ranked and candidate outputs may violate them to a greater or lesser degree, markedness is encoded in the constraints and ranking (see Archangeli 1997). Some generative researchers have applied markedness to second language acquisition theory, treating it as an inherent learning hierarchy which reflects the sequence in which constructions are acquired, the difficulty of acquiring certain constructions, and the transferability of rules across languages.

3. *Universals*

Markedness has also been applied to typological and function and approaches to language, influenced by Joseph Greenberg's 1966 book *Language Universals*. Greenberg surveyed the correlates and diagnostics of markedness proposed by Jakobson, Trubetzkoy, and others in an attempt to find parallel diagnostic criteria across levels of language. Noting that unmarked grammatical categories in a language show characteristics correlated to the greater frequency of a category vis-à-vis its opposite, Greenberg took frequency to be the primary determining factor of markedness in grammar and suggested that unmarked categories could be determined by 'the frequency of

association of things in the real world.' In addition to emphasizing the role of frequency in determining markedness within a language, Greenberg applied frequency cross-linguistically, taking unmarked categories to be those that are unmarked in a wide number of languages. However, while frequency is an appealing diagnostic, it is also problematic because a phenomenon may be infrequent cross-linguistically but predominant in a particular language (a much-used example is preposition stranding in English, which appears to be marked cross-linguistically but unmarked in English).

Universals have also been proposed on the basis of implicational laws, with a category taken as generally marked if every language that has the unmarked category also has the marked one but not vice versa. Other approaches to universal markedness relations focus on functional economic and iconic motivations, tying recurring asymmetries to properties of communication channels and communication events. Croft (1990), for example, notes that asymmetries among linguistic elements may be explainable in terms economy of form and in terms of iconism between the structure of language and conceptualization of the world. Similarly, Givón (1990) suggests that markedness related to cognitive complexity—'in terms of attention, mental effort or processing time.' And Mayerthaler, Dressler, and other 'naturalists' view markedness relations in terms of the ways in which extralinguistic principles of perceptibility and psychological efficiency determine what is natural in language. (Mayerthaler (1988), for example, defines unmarked as 'in agreement with the typical attributes of the speaker.')

4. *Cultural Markedness*

A main theme of markedness is the information content and information value of an element. Thus many researchers have seen markedness as an encoding of that which is unusual or informative. Conceptual familiarity with cultural norms provided by familiar categories creates a ground against which marked categories provide a figure, opening the way for markedness to be applied to cultural and social categorization. In the 1930s Jakobson had already suggested applying markedness to any oppositions, explicitly mentioning such pairs as life/death, liberty/bondage, sin/virtue, and holiday/working day. Waugh (1982) extended this idea to note that oppositions like male/female, white/black, sighted/blind, hearing/deaf, heterosexual/homosexual, right/left, fertility/barrenness, clothed/nude, and spoken language/written language can all be treated as unmarked/marked cultural oppositions. And McCawley (1985) suggested that aspects of belief systems and even scientific theorizing could be analyzed as systems in which some assumptions are culturally unmarked. The papers in Myers-Scotton (1998) demonstrates ways in which intentionality is conveyed by adopting stylistically and culturally marked choices. Such approaches hold promise as a descriptive technique for domains beyond language, and recent work has applied markedness to music, myth and facial expression, among other things (see Hatten 1994, Liszka 1989).

As is evident, markedness has been extended and reshaped over the past century and reflects a range of loosely connected theoretical approaches. From emerging in the analysis of binary oppositions, it has become a global semiotic principle, a means of encoding naturalness and language universals, and a terminology for studying defaults and preferences in language acquisition. What connects various approaches is a concern for the evaluation of linguistic structure, though the details of how markedness is determined and what its implications are varies widely.

Linguistics: Overview

Linguistics, conventionally defined as the scientific study of language, has generated a wide range of branches, subdisciplines, schools of thought, and applications, many of which are given separate treatment in the encyclopedia. This article provides a perspective within which these and other aspects can be interrelated, insofar as they use the word 'linguistics' as part of their identity.

1. *Linguistics as a Science*

Linguistics achieved its academic identity during the twentieth century, shaped in the first few decades by a series of pioneering and influential personal statements (notably Saussure 1916, Sapir 1921, Bloomfield 1933), consolidated in the middle decades as a university subject at both undergraduate and graduate levels, and reinterpreted in the later decades by a new generation of scholars concerned to give the subject a sound theoretical foundation (notably Chomsky 1957, 1965). In Europe, its origins lay chiefly in a reaction to the philological curiosity about the history and origins of language, which had preoccupied the nineteenth century; in the USA, the primary impetus came from a concern to provide a linguistic dimension to the anthropological investigations of American Indian cultures. But the subject also benefited from an increased general interest in the study of language in relation to human beliefs and behavior (e.g., in philosophy, theology, information theory, literary criticism, communication studies), which manifested itself at both popular and specialized levels. The development of the media, especially broadcasting, further helped to bring language issues to the forefront of national consciousnesses, as did the demands made by foreign-language teachers and other 'language professionals' for more sophisticated information about their subject.

The multiplicity of interests in the subject, each with its own intellectual agenda and methodologies of inquiry, brought a profound appreciation of the range and complexity of linguistic phenomena, and thus of the need to develop a research discipline with its own principles and procedures. Early on, linguistics came to be viewed as a 'science,' and attempts were made to define its axioms and make its investigative procedures explicit (e.g., Bloomfield 1926, Hjelmslev 1943). Linguists emphasized their concern to make their studies systematic and objective, by contrast with the selective impressionism which had characterized much previous literary and pedagogical work on language. A great deal of attention was devoted to making investigative procedures clear and well defined. There was a significant growth, fostered by progress in acoustic technology, of experimental techniques, especially in phonetics. And there was an unprecedented concern for precise definition, clear and comprehensive description, and more powerful explanation. An emphasis in the first half of the century on the procedures for describing individual languages, or the features of language families, changed during the second half into an emphasis on the universal, defining properties of language, and on the nature of language viewed as part of human biology and psychology. Yet there were significant continuities too. Chomsky's focus on the distinction between linguistic competence and performance, and on the status of language as an 'organ of the mind,' echoed Saussure's notions of the collective language system (*langue*) and its concrete manifestation in utterance (*parole*), and of the human language faculty (*faculté de langage*).

Because of its claims to scientific stature, the subject has often been referred to as 'linguistic science,' but sometimes a designation of 'linguistic sciences' will be encountered. The choice hinges on the perceived standing of phonetics. In the 'plural' interpretation, phonetics is seen as a separate discipline, which along with linguistics makes up the linguistic sciences. The reasoning is that the subject-matter of phonetics—which includes acoustics, anatomy, physiology, neurology, and auditory perception—is so different from the 'rest' of linguistics that it cannot sensibly be subsumed under the same heading. Moreover, its

methodology is very different, both in its experimental approach and in its reliance on technology. It is, some argue accordingly, a prelanguage study, and its findings need to be brought into relationship with those of linguistics. Others, however, point to the fact that the bulk of the subject deals only with those aspects of sound production and processing that are relevant to the production of spoken language.

Phonetics focuses on such entities as vowels, consonants, and pitch movements, and not on such noises as whistles, hiccups, and burps, even though these are also made by the vocal apparatus. Its aim is to explicate speech sound, and as it is speech which is the ground of being for all languages (writing being present only in a proportion of instances), this alternative argument sees phonetics as the 'indispensable foundation' (Henderson 1971) for linguistics—one branch of a single linguistic science. (The term 'linguistics,' of course, avoids the need to make a decision.) A similar issue appears when the focus is on speech alone. Speech science (or speech and hearing science) is the study of all the factors involved in the production, transmission, and reception of speech; but speech sciences will also be found, when there is a need to emphasize the constituent disciplines involved.

2. *Classification by Orientation*

These changes of emphasis and direction, which are an inevitable part of the intellectual development of a subject, have given rise to a range of designations for linguistics, each of which captures a particular orientation or 'universe of interest.' The earliest of these, introduced by Saussure, was chronological, distinguishing diachronic linguistics from synchronic linguistics. This terminology reflects his concern to move away from an exclusively historical approach for the study of language to one in which a language is seen as existing at a particular moment (or 'state') in time, 'syn-chronically,' regardless of whatever may have happened to it previously or would happen to it subsequently. Most linguistic research is synchronic, in the sense that linguists are aiming to establish the nature of the system of rules which define a (part of a) language's expressive potential at any one time. For example, the word 'balcony' currently has a stress on its first syllable, and this is what would be noted as part of a synchronic description of modern English stress; the fact that, over a century ago, the stress was on the second syllable, would not be considered relevant. On the other hand, in a diachronic description, the way the stress has shifted is of central relevance—not least because the process is continuing in many other words, such as 'dispute' and 'research.' Saussure saw the two chronological orientations as intersecting—an 'axis of simultaneities' crossing an 'axis of successivities'—and this point of intersection must not be ignored. Uncertainties about usage are one example of the way in which ongoing language change complicates a synchronic analysis. But the point of the distinction is widely appreciated, and Saussure's refocusing has been so successful that it has long been standard practice to interpret the word 'linguistics' as meaning 'synchronic linguistics,' with references to the other orientation requiring a more explicit phrase—usually, these days, 'historical linguistics.'

Another type of orientation relates to the generality of a linguistic inquiry. As already mentioned, a contemporary focus on language is to make statements of maximal generality: the aim is to determine what it is that defines the notion of 'human language.' All languages have a great deal in common in the way they produce sounds, organize their grammars, and construct systems of meaning in words. Identifying the universal principles which govern language, and demonstrating how these principles apply in individual circumstances to produce the languages known to us as French, English, Chinese, Swahili, etc., is the primary aim of theoretical linguistics. The term 'theory' here has its standard scientific application, reflecting the need for explanation of a maximally general kind, and the provision of fruitful models which will generate testable hypotheses about, in this case, linguistic structure and use. Theoretical linguists do not study a language because they are interested in that language *per se*; they study it because of what it can tell them about the nature of language in general. A particular language may be especially 'interesting' because it makes use of a type of sound or grammatical construction that other languages do not. The label 'general linguistics' is often used to capture this breadth of vision. A further consequence of this approach is that, once some linguistic data has been accumulated, a special concern is to find the best way of analyzing it. There are so many variables in pronunciation, grammar, and vocabulary that it is possible to envision an indefinitely large number of ways of showing how these domains are organized. Theoretical linguists spend much of their time searching for plausible and elegant analyses, and identifying criteria for their evaluation.

One of the controversies in the profession relates to this point. According to some linguists, as a result of the above orientation, the subject has become 'too general.' Analyses which try to achieve maximal generality inevitably make statements which are highly abstract, and seem to be far removed from the description of individual languages, and of the way these are used in everyday speech and writing. The emphasis on achieving generality, according to this view, has brought a de-emphasis on individuality—of what it is that makes one language unique, different from all the others. While it is accepted that, in the long term, all the idiosyncrasies of individual languages may be explicable with reference to general rules, there is seen to be no likelihood of this happening

in the foreseeable future. In the meantime, the need to provide descriptions which are as full as possible is as important now as it ever was. Indeed, this focus on the special character of a particular language was given special urgency in the 1990s, when it was realized just how many of the world's languages are near the point of extinction. Of the 6,000 or so languages in the world, it is widely thought that half are likely to die out within the next 100 years (Crystal 2000). The need to make descriptions of the languages most at risk is therefore a priority for the subject, for once a language dies which has never been written down or recorded in any way, it is as if it had never been. This orientation for the subject, where the aim is to make as complete as possible a description of a language, in all its varieties, is usually referred to as descriptive linguistics.

It is not only the endangered languages which benefit from a descriptive approach, therefore. Descriptive accounts of English, German, Japanese, and all the other 'safe' languages are also important. 'Descriptive' here is being seen in contrast with 'traditional,' referring to the tradition of language inquiry which antedated the emergence of twentieth-century linguistics, and which was characterized—especially in the field of grammar—by prescriptive and proscriptive rules about usage, purist condemnation of language change, and the distorted description of modern languages through the use of a model of description derived from Latin. In the field of English, the need for more realistic description was the driving force behind many grammars, pronunciation guides, and dictionaries, especially from the 1950s on (e.g., Jones 1956, Fries 1952, Quirk et al. 1972). A particular consequence of this orientation was the provision, in some countries, of new syllabuses and materials for use in schools and teacher-training courses—a change of direction which in the later decades of the century brought not a little heart-searching, as teachers found themselves engaging in a close encounter with a linguistically based conceptual apparatus and a partly unfamiliar terminology. At a research level, since the 1980s the descriptive orientation of linguistics has been given additional impetus through the use of computational methods of data collection and analysis. Large bodies of data, in some cases consisting of several hundred million words, are now available as sources of evidence for descriptive statement, in a field that has come to be called corpus linguistics.

A considerable conceptual distance separates the description of an individual language from a general account of the properties of human language, so it is not surprising to find orientations which occupy aspects of the 'middle ground.' It is possible to extend the descriptive orientation 'upwards,' bringing individual languages together in specific ways but without the inquiry necessarily bearing on a hypothesis about linguistic universals. This is the motivation behind comparative linguistics, where the purpose is to identify the chief similarities and differences between historical states of a language, between modern languages (e.g., those within a particular family, such as Romance or Germanic) or, in a more ambitious mode, between language families as wholes. This use of 'comparative' in fact antedates modern linguistics, being part of the designation of comparative philology, the subject which grew up at the end of the eighteenth century devoted to the historical comparison of Greek, Latin, Sanskrit, and their hypothetical antecedents, whence arose the concept of an Indo-European family of languages.

Applying the 'comparative method' to other languages which had written records was a natural extension, and philology (as it is today usually called) is practiced still, being distinguished from the orientation of historical linguistics partly by its aims and methods, and partly by the contrasting intellectual background (often from literature or history) of its practitioners. A related designation is typological linguistics, where the aim is to study the structural similarities between languages, regardless of their history, in order to locate them within a classification (or 'typology'). This is the only possible method in cases where there are no written historical records—a situation in which most of the world's languages find themselves.

When linguists talk about the structure of language, they are usually referring to the way a language can be analyzed into several dimensions susceptible of independent study. These dimensions are commonly referred to as 'levels' or 'components,' though terminology varies widely between linguistic models. Most accounts recognize three major levels of linguistic organization: a sound system (or phonology, including its interface with phonetics), a grammatical system (with a division often made between sentence-structure (syntax) and word-structure (morphology)), and a semantic system (typically focusing on vocabulary (the lexicon), though not thereby excluding other ways in which a language's meaning is organized). The study of the written language necessitates the recognition of an additional level: an orthographic system (or graphology). And some linguists recognize other levels of analysis, such as one which extends linguistic inquiry above the sentence (a level of discourse, or text) or one which takes into account the way structure is altered when language is used interactively (pragmatics). Each of these terms has a variety of interpretations, depending on the theoretical approaches involved, but they all have one thing in common: they aim to explicate a domain of language structure, and are thus part of an orientation to the subject that might be legitimately called structural linguistics.

However, this designation has had a controversial position within the history of twentieth-century linguistic thought. In its early use, 'structural' linguistics referred to the particular approaches to phonology

and grammar which were current in the 1940s and 1950s, in the work of such linguists as Bloomfield. There, the emphasis was on finding methods which would establish the contrasting units in a language's sound system (the phonemes), identify the elements of word formation (the morphemes), and analyze sentence constructions into their constituent parts. In a somewhat broader sense, developing the initiatives of Saussure, a 'structuralist' ethos prevailed, which aimed to establish systems of relations between linguistic units—an approach which, under the heading of structuralism, came to influence thinking throughout the arts and social sciences. Within linguistics, it was in due course applied to further areas of linguistic structure (especially semantics), and extended by some linguists (such as Pike 1954–60) to other domains of human communicative behavior. The notion of system continued to play a central role in linguistic theories which emerged during the postwar period, notably in the work of Firth (1957) and his students, and later became central in the systemic linguistics of Halliday (Halliday and Fawcett 1987). It was the perceived limitations of the structuralist orientation, with its focus on the classification of structures and units at a 'surface' level of description within a corpus of data (linguistic 'performance'), which prompted its labeling as 'taxonomic' (with a pejorative implication) by Chomsky, and which motivated his initial formulation of generative linguistics (Chomsky 1957), with its concern to explicate underlying linguistic relations in ways that could account for the creative linguistic abilities (or 'competence') of the individual.

3. *Classification by Interaction*

The generative orientation constituted a revolution in linguistic thought; and although other kinds of linguistic theories and models continued to be devised and developed in the latter part of the century, it was the generative approach, in its various formulations, which provided the subject's center of gravity. At the same time, partly independent of this state of affairs and partly as a consequence of it, several areas of interaction with other academic disciplines emerged. These 'hybrid' subjects were the result of a synergy between two intellectual streams. On the one hand, linguists sensed that they needed to take their subject in fresh directions if they wished to account for everything that influenced the way people spoke and wrote (and also signed, for the analysis of deaf signing was also emerging as a new research field). On the other hand, scholars in other academic disciplines were finding that they needed to provide more sophisticated accounts of language structure and use in order to maintain their own research agendas. The potential for interaction had in some cases been recognized for many years. In the case of the interaction between linguistics and anthropology, it had been there from the earliest days of the subject (Boas 1911). The difference was partly in the way hybrid labels came to be institutionalized as 'recognized' domains for teaching and research (anthropological linguistics, in this case), and partly in the cross-disciplinary climate of the times, which gave rise to nearly two dozen such hybrids by the turn of the century.

There is not always a total meeting of minds in these interdisciplinary encounters: the orientation given to the hybrid subject within a linguistics department is by no means identical with the orientation it is given within the department which constitutes the other half of the hybrid. For example, one of the areas of inquiry in psycholinguistics is the relationship between language and memory. When a linguist investigates how language is affected by memory and a psychologist investigates how memory is affected by language, it might be thought that the two directions of inquiry would 'meet in the middle.' In practice, differences in the researchers' intellectual histories, theoretical aims, and research procedures can produce widely divergent accounts. One need only look at the list of references at the end of journal articles to see how authors, ostensibly investigating the same subject, can come from different directions. There may be a difference of labeling, which may reflect a difference of orientation—as in sociolinguistics (a branch of linguistics) alongside the sociology of language (a branch of sociology), or philosophical linguistics (a branch of linguistics) alongside linguistic philosophy (a particular approach within philosophy). Nonetheless, the shared subject-matter, and a growing mutual familiarization with the intellectual background of the contributing disciplines, produced in the last quarter of the twentieth century a growing number of research collaborations, interdisciplinary conferences, jointly authored textbooks, and shared teaching courses in many of these hybrid subjects, resulting in a growing identity and coherence.

Hybrid subjects can be placed in clusters, on the basis of an overlap in their subject-matter. The earliest clusters to be given clear definition all relate to a concern to see language in its cultural and social context. Anthropological linguistics (or linguistic anthropology) focuses on language variation and use in relation to human cultural patterns and beliefs (in its early years, especially on the Amerindian peoples of North America). Overlapping with this is ethnolinguistics, studying language in relation to ethnic types and behavior, and widely practiced through approaches (variously called the ethnography of communication or ethnography of speaking) which analyze the entire range of variables, extralinguistic as well as linguistic, involved in social interaction. Sociolinguistics, studying all aspects of the relationship between language and society, is the most well established of this cluster of subjects, and is sometimes used as a covering label for all domains of inquiry in which there is a preoccupation with the social func-

tions of language. However, sociological linguistics is sometimes differentiated from it, particularly in mainland Europe, reflecting a concern to see language as an integral part of sociological theory. So too is interactional sociolinguistics, referring to the study of speech in face-to-face communication.

Several other facets of the sociolinguistic cluster have maintained their individual nomenclature. One example is dialectology (sometimes called dialect geography), which focuses on the properties of regional (and more recently social) dialects. Another is areal linguistics, which studies the linguistic properties (languages as well as dialects) of large geographical regions—such as Western Europe or the British Isles. Closely related is geolinguistics (also geographical linguistics), which studies the geographical distribution of languages throughout the world with reference to their political, economic, and cultural status. Pragmalinguistics studies language use from the viewpoint of a language's structural resources; it contrasts with those pragmatic studies which examine the conditions on language use deriving from the social situation (sometimes referred to as sociopragmatics). Finally, there is the study of (linguistic) style, stylistics—a study which, though chiefly concerned with the nature of the personal linguistic identity of individuals (especially in a literary context), has often been extended to include the distinctive linguistic features of group-identifying functions of language, such as are found in advertising, science, and the media. When the focus is specifically on the distinctive language used in social institutions, such as law, medicine, and religion, some linguists use the label institutional linguistics.

Another cluster of hybrid subjects looks at language in relation to human biology. In its broadest characterization, the subject is referred to as biological linguistics (or biolinguisics), focusing on the preconditions for language development and use from the viewpoints of both the history of language in the human race and the development of language in the individual (the latter topic usually being distinguished by the name developmental linguistics or child language acquisition). Its topics include the genetic transmission of language, neurophysiological models of language production, and the anatomical comparison of humans and other species. It also subsumes the study of pathological forms of language behavior (as in aphasia, dyslexia, and language delay), though the complexity of these conditions, and the interdisciplinary nature of their diagnosis and treatment, has prompted the development of separate specialisms. Chief among these is neurolinguistics (sometimes referred to as neurological linguistics), which focuses on the neurological basis of language development and use, in particular aiming to understand the way the brain controls the processes of speaking, listening, reading, writing, and signing. Although its focus is on clinically normal states, much of its evidence comes from the investigation of abnormal language development and language breakdown. It thus overlaps with clinical linguistics, which is exclusively devoted to the diagnosis, assessment, and treatment of all forms of language disability in children and adults.

Any of these domains can of course be studied from the point of view of 'mind' as distinct from 'body,' and psycholinguistics (sometimes called psychological linguistics) has emerged as a major subject, investigating the interaction between language and such topics as memory, perception, attention, and personality, in normal and abnormal states. Depending on the domain of inquiry involved, compound names will be encountered, such as clinical psycholinguistics and developmental psycholinguistics. Psychology shares with education an interest in learning, and there has been special concern to understand how language is dealt with in schools and other educational institutions. Educational linguistics (sometimes pedagogical linguistics) focuses on the way government policies and planning, teacher training, curricula, syllabuses, and pedagogical materials handle the teaching of the mother tongue and foreign languages. The later decades of the twentieth century also saw a growing metalinguistic concern, with researchers investigating the ways in which children become increasingly aware of language and its elements, in a domain which by the 1990s had been labeled language awareness. Within the teaching profession, a corresponding fresh interest in the study of language, largely motivated in the UK by the arrival of the National Curriculum, introduced a new acronym, KAL (knowledge about language).

A further cluster of hybrids relates to the numerical sciences. Mathematical linguistics studies the formal properties of language, usually employing concepts of an algebraic or statistical kind. Its main application has been in the formalization of linguistic theory, as developed in relation to generative linguistics, but several other areas of language study have received mathematical investigation. In particular, statistical (or quantitative) linguistics studies the frequency and distribution of linguistic units in texts, with the aim of establishing general laws concerning the statistical properties of language (such as the relationship between word types and tokens), and identifying the distinctive characteristics of authors (stylostatistics). In the later part of the twentieth century, computational techniques and concepts came to be increasingly applied to the elucidation of linguistic problems, under the heading of computational linguistics. Several research areas have been developed, including natural language processing, automatic speech synthesis and recognition, machine translation, the making of concordances, and the many areas where statistical counts and analyses are required. The provision of large machine-readable texts (computer corpora) was a special development of the 1990s, and gave rise to the domain of corpus linguistics. Linguistic

involvement in the other direction—in relation to such matters as computer programming, information retrieval, document identification, indexing, reference science, and knowledge management—has been limited to isolated projects, and has not yet resulted in a hybrid label, though one imagines that, given the growth in this area, the emergence of Internet linguistics can only be a matter of time.

Not all hybrid terms can be neatly clustered. Some, by their nature, stand outside of classification, because their role is to evaluate aspects of the field as a whole. The study of the history of ideas in linguistics is linguistic historiography. Philosophical linguistics studies the role of language in relation to the understanding and elucidation of philosophical concepts, as well as the philosophical status of linguistic theories, methods, and observations. Critical linguistics emerged in the 1990s with the aim of revealing hidden power relations and ideological processes at work in spoken or written texts. Critical linguists criticize mainstream linguistics for its formalist preoccupations, its lack of adequate social explanations, and its obscuring of ideological and political issues. This 'critical' perspective may be applied to individual branches of the subject. In particular, critical discourse analysis studies the relationship between discourse events and sociopolitical and cultural factors, especially the way discourse is ideologically influenced by, and can itself influence, power relations in society.

4. *Applications and Extensions*

The list of possible hybrid subjects involving linguistics is by no means exhausted by the above itemization, and new ones will doubtless emerge. A similar potential for expansion is also found in the various domains of applied linguistics. In its broadest definition, this is the application of linguistic theories, methods, and findings to the elucidation of language problems which have arisen in other areas of experience. The most established and well-developed branch is the teaching and learning of foreign languages, and sometimes the term is used as if this were the only domain involved. But several other domains of application have emerged since the middle of the twentieth century, including speech pathology and therapy, the teaching of the deaf, mother-tongue education, the writing of dictionaries (lexicography), the analysis of literary texts (literary stylistics), and translation studies. Quite restricted and specialized domains may be encountered. For example, theolinguistics has as its focus the study of the way language is used in theological, biblical, and other branches of religious studies. Forensic linguistics is the use of linguistic techniques to investigate crimes in which language data forms part of the evidence, such as in the use of grammatical or lexical criteria to authenticate police statements. The field of forensic phonetics is often distinguished as a separate domain, dealing with such matters as speaker identification, voice line-ups, speaker profiling, tape enhancement, tape authentication, and the decoding of disputed utterances.

There is an uncertain boundary between applied linguistics and the various interdisciplinary subjects reviewed in Sect. 3, especially as several of those concerns involve practical outcomes (e.g., planning a national language policy within sociolinguistics). On the other hand, as these hybrid subjects develop their own theoretical foundations, the distinction between 'pure' and 'applied' is becoming more evident, and terminological distinctions such as that between (theoretical) psycholinguistics and applied psycholinguistics are now more regularly encountered.

The term 'linguistics' will also be encountered in a wide range of other contexts, where it is often no more than a loosely used synonym for 'school of thought' or 'approach,' or even a stylistic replacement for the word language or grammar. Very general states of mind on the part of the investigator can be given a linguistics designation. For example, mentalist(ic) linguistics is contrasted with behaviorist linguistics. Macrolinguistics, representing a relatively broad frame of reference for linguistic inquiry, is opposed to microlinguistics. In relation to schools, we find such usages as Cartesian linguistics (showing the influence of Descartes), Chomskyan linguistics (from N. Chomsky), Whorfian linguistics (from B. L. Whorf), Saussurean linguistics (from F. de Saussure), Firthian linguistics (from J. R. Firth), and neo-Firthian linguistics (scholars whose teaching derived from Firth's influence, notably M. A. K. Halliday (whose name has, in turn, been given to Hallidayan linguistics).

At this level, there is an appreciable overlap with the relevant aspect of language which is the focus of an approach—for example, the terms Chomskyan linguistics and Chomskyan grammar are often used synonymously, as are Whorfian linguistics and Whorfian semantics. The same point applies to such general approaches as functional(ist) linguistics, which treats the notion of function as central, especially in grammar, and thus allows a terminological overlap with functional(ist) grammar. Systemic and polysystemic linguistics (which treat the notion of system as central) may also be found alongside systemic and polysystemic grammar. Virtually any variety or use of language can be focused in this way, as in creole linguistics (= the linguistic study of creole languages) and paralinguistics (= the linguistic study of paralanguage—tones of voice, facial expressions, etc). But eventually, as increasingly restricted areas of inquiry are encountered, the use of the general term ceases to have a point, and linguists replace it by specific terms such as morphology, phonology, lexicology, semantics, onomastics, and other structural labels best explicated under the heading of 'language.'

Linguistics: Prototype Theory

Prototype theory is a theory of categorization. Categorization is a central issue in linguistics, for several reasons. In the first place, words can be regarded as names for categories, and using a word involves an act of categorization (Labov 1973). In stating that *The cup is in the saucer*, a speaker is categorizing the figure object as a 'cup,' rather than as a mug, bowl, vase, or other kind of object; the reference object is being categorized as a 'saucer,' not as a dish or a plate; while the location of the cup vis-à-vis the saucer is being categorized as an 'in'-relationship, rather than as an 'on'-relationship, or whatever. Knowing these words involves knowing how to apply the words appropriately to entities that fall within the categories that they designate.

There is another way in which categorization impinges on linguistic theory. The moment one pursues even the most elementary linguistic analysis, language itself becomes an object of categorization. Like any intellectual discipline, linguistics requires its practitioners to set up categories for the description of the object of study. In any linguistic description, one will encounter such entities as words and morphemes, phrases and clauses, nouns and verbs, subjects and objects, clitics and particles, phonemes and allophones. 'Doing linguistics' consists, in large measure, in setting up categories such as these, defining them, studying their properties and interrelationships, working out criteria for determining their membership, and applying them to the data at hand. The ontological status of the categories themselves may also become an issue. Where do categories such as 'noun' and 'verb' come from? Are they inherent in the object of study? Are they mere descriptive conveniences? Are they constructs of linguistic theory?

1. Two Approaches to Categorization

Two major approaches to categorization are the 'classical' approach and the 'prototype' approach. On the classical approach, a category is defined in terms of a set of necessary and sufficient conditions for category membership. The set of conditions specifies the essence, as it were, of the category. Any entity meeting all the conditions is, by definition, a member of the category; failure to meet any of the conditions excludes an entity from the category. On this view, category boundaries are discrete (an entity either is, or is not, a member), and the category lacks internal structure (all members are of equal status).

The simplicity of the classical view makes it intuitively appealing. A major problem is that many categories are simply not amenable to classical definition. What, for example, are the defining features of 'chair,' 'vegetable,' and 'love,' or, for that matter, of

'cup,' 'saucer,' and 'in'? In fact, classical categorization probably works best only for 'expert' categories, that is, categories that have been created and explicitly defined (in classical terms!) by experts, whether these be scientists, bureaucrats, administrators, or whoever. For most words of everyday speech, the classical theory is quite inappropriate.

On the prototype approach, a category is understood, primarily, in terms of its good examples. Entities are associated with the category to the extent that they resemble the good examples. Often, the boundary of a prototype category will be fuzzy—it might not be clear whether some entities belong in the category or not. Moreover, prototype categories have an internal structure, in that some entities count as more central members than others.

Prototype categorization came to the attention of linguists largely due to the work of the psychologist, Eleanor Rosch. In a series of experiments, summarized in Rosch (1978), it emerged that the meanings of several very ordinary words, such as *bird*, *toy*, *vehicle*, are structured around good examples. People readily agree that a robin is a better example of 'bird' than a penguin; they can determine the truth of *A robin is a bird* faster than *A penguin is a bird*; when asked to name members of a category, they name more central examples before more marginal examples; and when drawing inferences about a category, people tend to draw on knowledge of central members, rather than on knowledge about the category as a whole. Rosch observed prototype effects both with 'natural kind' categories—that is, categories such as 'bird,' which are, as it were, given by nature—and with categories that are understood relative to human concerns, such as 'vehicle,' 'furniture,' and 'toy.'

Rosch's discoveries were eagerly taken up by linguists, and extended by a wide range of linguistic data (Lakoff 1987, Kleiber 1990, Tsohatzidis 1990, Geeraerts et al. 1994, Taylor 1995). An especially fruitful application has been the study of semantic change (Geeraerts 1997). The prototype notion has also been widely applied to the study of the categories of linguistic description (Langacker 1987), Croft 1991).

2. *Problems and Refinements*

Despite its success in lexical semantics and elsewhere, prototype categorization raises a number of problems.

While not denying the reality of prototype effects, Fodor (1996) argues that concepts cannot be equated with prototypes. The fish prototype (a herring?) and the pet prototype (a poodle?) contribute nothing at all to the complex concept 'pet fish,' nor to the prototype of 'pet fish' (a goldfish?). Generally, as a concept gets specified in greater detail, prototype effects not only shift, they also tend to get effaced. Consider the diminishing role of the 'nurse' prototype in one's understanding of *nurse*, *male nurse*, *retired male nurse*, etc. On the other hand, prototype effects show up even on categories that arguably are subject to classical definition, such as 'odd number.' Armstrong et al. (1983) report that subjects readily agreed that 3 was a better example of 'odd number' than 447, even though, obviously, 447 is no less of an odd number than 3.

On one interpretation of these findings, prototype effects are extrinsic to word meanings as such, and arise only when a person applies a concept to the world. This view draws a distinction between the 'essence' of a category (the 'real' meaning of a word), and 'recognition procedures' invoked when speakers attempt to categorize things and eventualities in the world. On this view, the fuzziness of category boundaries results from the fact that eventualities in the world may not lend themselves to clear-cut categorization, even though the words of a language do have clear-cut meanings. Although it might not be clear whether a particular utterance counts as a 'lie,' the meaning of *lie* might nevertheless be clear-cut.

2.1 *Degree of Membership vs. Representativity*

Before endorsing this exclusion of prototypes from word meaning proper, it is important to distinguish two aspects of prototype categories: fuzziness of category boundaries (a question of category membership), and degree of representativity within a category (a question of category structure).

It is uncontroversial that certain categories are inherently fuzzy, in that it is simply not possible to make a clean distinction between what goes into the category and what does not. This is the case with many adjectival concepts, such as 'old,' 'tall,' and 'bald.' While there is little doubt what a (prototypical) *bald head* looks like, also what it means to be *not bald*, it would be futile to draw a boundary between 'bald' and 'not bald,' e.g., in terms of the number of hairs on a person's head.

However, prototype effects also show up on categories that arguably do have clear boundaries. Although turkeys might not be good examples of the bird category, they are birds nonetheless, albeit not very representative ones. Representativity, to be sure, can be understood in different ways—in terms of frequency of occurrence, cultural or environmental salience, or statistical averaging over category instances. Representative examples are typically invoked in default contexts. Given only the mention of 'a bird,' with no further specification, one would assume a representative example. A person who wishes they were a bird would surely be disappointed if they were transformed into a turkey! The internal structure of a category cannot reasonably be excluded from a person's knowledge of word meanings.

2.2 Prototypes and Background Knowledge

Categories, in order to be viable, need to be conceptually coherent (Murphy and Medin 1985). A category is coherent to the extent that it is based on theories of how the world is, and how it links up with a person's encyclopedic knowledge. A category is not simply a conjunction of an *ad hoc* set of features, the category has to make sense.

Lakoff (1987) discusses this aspect in terms of his notion of the Idealized Cognitive Model (ICM). The concept 'bachelor' is understood against an ICM of marriage practices (which in turn is based in ICM's of sexuality, procreation, and family). One aspect of the ICM is the idea that each person, after reaching the 'marriageable age,' sooner or later marries. Within the ICM, *bachelor* may well be definable in classical-like terms, i.e., as 'unmarried,' 'adult,' and 'male.' Prototype effects arise, because the ICM may not fit the world perfectly. The Pope is not a good example of 'bachelor,' not because of uncertainties about whether the Pope is unmarried, adult, or male, but because Catholic clergy are outside the scope of the ICM.

2.3 Prototypes and Features

On the classical theory, categories are assembled, as it were, out of their features; the features pre-exist the category, they are evaluated independently of the category, and must be simpler than the category they define. A prototype, in contrast, can be perceived holistically, as a gestalt; features are no longer the building blocks of categories, they emerge, as dimensions of similarity, through acquaintance with cat egory members. It is unlikely that people construct their bird-category through conjunction of features such as 'having feathers' and 'laying eggs'; knowledge of feathers and egg-laying emerges from acquaintance with birds, not vice versa. Likewise with linguistic categories. One might propose that ability to inflect for tense is a defining characteristic of verbs (for English, at least). Yet, the very notion of tense inflection rests on a prior acquaintance with members of the verb category.

Given this revised understanding of features, a feature-based view of prototype categories becomes possible, through the differential weighting of the features. Some features may be better cues to category membership than others; some features may be virtually indispensable; others are able to be overridden. The prototype will be a representation that maximizes feature weights; an entity exhibiting highly weighted features will automatically count as a category member; an entity exhibiting less highly weighted features might still count as a member, though a more marginal one. Moreover, it is possible for two entities to belong to a category, even though they have no category-specific features in common. The way also opens up for a reconciliation of classical and prototype categorization—a classical category is the limiting case of a prototype category, i.e., a category understood solely in terms of essential features.

3. Prototypes and Polysemy

It is useful to distinguish between the prototype structure of a concept and the polysemy structure of a word. There is a clear difference, in principle, between applying the word *fruit* to different kinds of fruit, and the use of the word in such expressions as *the fruit of his labors*. The latter usage represents a semantic extension of the word, in a way that is different from the use of the word to refer, say, to olives.

Take the preposition *over* (Lakoff 1987). *Fly over the Atlantic*, *the lamp hanging over the table*, *put your hands over your face*, *come over here*, *there's water all over the floor*, *the party's over*, *do it over again*—these exemplify different senses of the word, rather than more or less representative examples of one and the same sense. To the extent that these senses can be clearly individuated, it is possible to construct a network of sense relations, which links up the different senses according to their similarity. Such an array invites a prototype analysis, with one of the senses selected as central, and the others radiating out from it.

There are, however, different criteria for selecting the central sense, and these do not always deliver the same result. On a diachronic perspective, the basic sense is the historically oldest one, from which the others have been derived over time. On a developmental perspective, the basic sense is the one that children acquire first. Alternatively, the descriptive linguist (or lexicographer) might select as basic the most frequent sense, or the one to which the others can be most economically related. The real question, however, concerns the speaker's mental organization of polysemy. Currently, this is a lively topic in polysemy research (Taylor 1995).

4. Prototypes and Linguistic Categories

The prototype concept may be applied, not only to the study of word meanings, but to the very categories of linguistic description. Many linguistic concepts (including the very notion of 'language' and 'a language') turn out to have a prototype structure, in that they exhibit degrees of representativity, and often have fuzzy boundaries. Uncertainty as to what goes into a category and what does not pertains even to such basic notions as what constitutes a word (as opposed to a bound morpheme, clitic, or phrase), the part-of-speech categories (whether a particular item is a noun, verb, adjective, etc.), constituency (whether a particular string of words is a syntactic constituent), and syn-

tactic relations (whether a particular constituent is a modifier or adjunct, the subject of a clause, or whatever).

Some linguistic theories propose to decide such issues by *fiat*. In practice, however, the linguist's strategy often reflects a prototype conception, even though this might not be explicitly acknowledged. When deciding the category status of a linguistic item, it is usual to apply a set of tests (Croft 1991). The tests are set up on the basis of what, intuitively, count as good examples of the category in question, whereby each of the tests diagnoses a property typical of the good examples. An item which passes all the tests is *ipso facto* a member of the category; an item which fails the tests is not a member. Sometimes, an item passes only some of the tests; it will have to be regarded as a marginal example, or even as an item of uncertain status.

Consider the parts of speech, perhaps better called 'lexical categories,' such as 'noun,' 'verb,' 'adjective,' 'preposition' (see *Word Classes and Parts of Speech*). These can be characterized either in semantic or in formal terms. Semantically, nouns prototypically designate categories of things, i.e., concrete, time-stable, spatially bounded objects (*chain*, *cup*, etc.); verbs designate events, involving rapid changes in state (*explore*, *arrive*); adjectives designate fairly stable properties of things (*hot*, *young*); while prepositions designate a relation, typically a spatial relation, between things (*on*, *at*). It is commonly agreed that lexical category cannot be reliably predicted from a word's semantics. In spite of their reference to rapid changes in state, *explosion* and *arrival* are nouns, just as good nouns, in fact, as *chair* and *cup*. This is because the words exhibit the full range of formal properties typical of the noun category, i.e., they pass all the syntactic tests for nounhood—they pluralize, they take the full range of determiners, they can be modified by an adjective, they can head a subject noun phrase, and so on. There are words which fail to exhibit the full range of properties. *Groceries*, in *I bought some groceries*, looks like the plural of a noun *grocery*—yet there is no such noun (**I bought a grocery*), neither can *groceries* take numeral quantifiers (**five groceries*). Syntactically, *groceries* is a somewhat marginal noun (though still a noun). However, there are words whose status is genuinely unclear. Consider *saying*, in *without my saying a word*. Being the complement of a preposition, *my saying a word* looks like a noun phrase, headed by *saying*, and *saying* looks like a noun, in that it takes possessive *my*. Other determiners, though, are not possible (*without *the/*that/*a saying a word*). Moreover, *saying* is followed by what looks like a direct object (*a word*), and the ability to take a direct object is a distinctly verb-like property, not at all a property of nouns.

Both semantic and formal criteria, then, fail to deliver clear-cut lexical categories. Nevertheless, there is an important sense in which the semantic prototypes have priority. Any language has to provide its speakers with the means to refer to 'things' and 'events,' 'properties' and 'relations,' and the semantic prototypes of the lexical categories, in English and other languages, are understood in such terms. Indeed, without the semantic prototypes, there would be no basis for recognizing the categories 'noun' and 'verb' across the different languages of the world.

Linguistics: Theory of Principles and Parameters

In generative syntax (see *Generative Grammar*; *Linguistics: Incorporation*) principles and parameters are two related concepts introduced to capture both invariance of language and cross-linguistic vari-

ation. *Principles* express universal constraints on language; *parameters* define the space of cross-linguistic variation.

1. Background: The Problem of Language Acquisition

The goal of generative linguistics is that of developing a model of linguistic knowledge (Chomsky 1981a, 1981b, 1986), i.e., to describe the cognitive system at the basis of the language capacity.

1.1 Knowledge of Language

Linguistic knowledge is represented as a system of constraints, a grammar, which defines all and only the possible sentences of the language (Emonds 1980, Ross 1967, Perlmutter 1971). An adequate grammar of a specific language must not generate ungrammatical sentences, i.e., sentences which are not acceptable to the native speakers of that language. For instance, the grammar of English will generate (1a) and must not generate (1b).

(1a) John always eats chocolate.
(1b) *John eats always chocolate.

1.2 Language Acquisition

The generative linguist also poses the question of language acquisition (see *First Language Acquisition: Cross-linguistic*). Linguistic knowledge is acquired fast and at an early age. This leads to the hypothesis that the system underlying it must be relatively simple. The speed and ease of language acquisition is all the more striking because it is achieved on the basis of an input which is deficient in several respects:

(a) The linguistic input is not homogeneous but varies from one learner to the other.

(b) The input contains ungrammatical material (performance errors, hesitations).

(c) The child acquires linguistic knowledge which he or she cannot infer solely on the basis of the input.

The following illustration of this so-called 'negative evidence' problem is from White (1989). In each sentence, the subordinating conjunction *that* may be omitted.

(2) I think (that) John will leave.
(3) Who do you think (that) John will invite?
(4) The woman (that) you met last week is my sister.

If data such as (2)–(4) constitute the input for the acquisition process, the child will be entitled to infer generalization (5).

(5) The subordinating conjunction *that* may be omitted in English.

However, the subordinating conjunction *that* cannot always be omitted in English (6, 7), and, conversely, there are sentences in which *that* is ungrammatical (8).

(6a) That Mary should be invited is surprising.
(6b) *Mary should be invited is surprising.
(7a) She could not get over the fact that Mary was invited.
(7b) *She could not get over the fact Mary was invited.
(8a) *Who did you say that got there first?
(8b) Who did you say got there first?

How does the native speaker acquire the knowledge that (6b), (7b), and (8a) are not acceptable English sentences, while (6a), (7a), and (8b) are acceptable? All the sentences in (6), (7), and (8), including (6b), (7b), and (8a), are compatible with (5). Being ungrammatical, (6b), (7b), and (8a) are not available in the input. The input contains sentences such as (6a), (7a), and (8b), which are all compatible with (5). For the native speaker to infer that (6b), (7b), and (8a) are incompatible with English grammar, and that (5) is thus an incorrect generalization, the input would have to contain negative evidence, i.e., the information that (6b), (7b) and, (8a) are ungrammatical. Such negative evidence is not available in the input: the non-occurrence of example such as (6b), (7b), and (8a) in the input is not sufficient to establish their ungrammaticality. A pattern may be absent from the input because it is ungrammatical (e.g., (1b)), but it may also be absent because it is stylistically marked.

The deficiency of the input leads to the hypothesis that language acquisition is not based simply on exposure.

2. Universal Grammar: Principles and Parameters

The hypothesis was formulated that a theory of language acquisition must assume a genetically-determined language acquisition device, which mediates between the data in the input and the grammar of the language which the child is to attain. In the *Principles and Parameters Theory* (Chomsky 1981a, 1981b, 1986) abstract universal principles which underlie different linguistic patters are factored out and attributed to Universal Grammar (UG), the innate language faculty. UG guides language acquisition by constraining the possible grammars which can be formulated on the basis of the input. Two types of UG principles are distinguished: invariant principles (see Sect. 3) and parameterized principles (see Sect. 4).

Invariant principles are rigidly fixed and hold universally. For instance, the Empty Category Principle constrains omission of constituents in a sentence. Hence, the application of generalization (5), inferred from the input, is constrained by the Empty Category Principle. Other invariant principles are those which

impose constraints on syntactic structure (see Sect. 3), and the (still controversial) principle that all syntactic variation is driven by morphological variation (see Sect. 5).

Other principles of UG are not fully fixed cross-linguistically; their interaction with the input will be at the basis of cross-linguistic variation. The variable components of UG are referred to as 'parameters.' Parameters are binary: each parameter offers a choice between two options or parameter-settings. Depending on the parameter-setting, a language will or will not display the corresponding syntactic property. For example, the pro-drop parameter determines whether a subject pronoun may be omitted in a given language or not (Sect. 4.1), the verb-movement parameter determines if a verb can be separated from its direct object (Sect. 4.2).

The principles and parameters theory thus captures cross-linguistic invariance (in terms of the universal constraints), and cross-linguistic variation (in terms of the language-specific parameter-settings). The theory reduces acquisition of syntax to parameter-setting on the basis of the linguistic input, the so-called 'triggering experience.'

3. *Invariant Principles: Phrase Structure is Endocentric and Binary Branching*

According to one invariant principle of grammar, syntactic structure is characterized by two properties:

(a) structure is endocentric: a syntactic unit or a constituent is organized around a head; and

(b) constituents are always formed by combining two units.

Based on (a) and (b), all constituents have the binary branching format represented in Fig. 1, where XP is the constituent, X is its head. The head X combines with another constituent, here ZP. ZP is itself built according to the X-bar format. The unit formed by X and ZP (X′) combines with the constituent YP to form XP. The format in Fig. 1 is taken to be universal. Cross-linguistic variation in sentence patterns is determined either by the option of omitting certain constituents (cf. Sect. 4.1) or by moving them (cf. Sect. 4.2).

4. *Parameters*

4.1 *The* Pro-*drop Parameter*

In terms of the X-bar format in Fig. 1 the sentence is conceived of as a constituent whose head is the inflection of the verb (I).

The *pro*-drop parameter (see Fig. 2) determines the variation between languages like Italian, in which the subject pronoun can be omitted, and those like

Figure 1
X-bar format of constituent structure

English, in which it cannot be omitted (Jaeggli and Safir 1986, Rizzi 1986).

(9a) *Parla inglese*. (*Italian*)
(9b) *Speaks English.

The *pro*-drop parameter is formulated in terms of the relative richness of the verbal inflection. The inflectional paradigm of the Italian is rich: it has a distinct form for each person/number combination (*parlo*, *parli*, *parla*, *parliamo*, *parlate*, *parlano*, 'speak,' present tense). English inflection is poor, with minimal variation (*speak*, *speaks*). Rich inflection sets the *pro*-drop parameter positively, allowing the language in question to omit subject pronouns.

The concept of parameter should not be taken to mean that each aspect of cross-linguistic variation is related to a distinct parameter. A parameter underlies a cluster of properties. For instance, it is generally held that the *pro*-drop also underlies the contrasts in (10)–(12). As shown by (10), Italian weather verbs such as *rain* cannot have a subject, while English weather verbs must have a subject. While (11) shows that the subject may follow the verb in Italian, an option unavailable in English. Questioning the subject of a subordinate sentence in Italian (12a) is compatible with the presence of the conjunction *che*, while the English analogue in (12b) is unacceptable; (12b) is rendered grammatical by omitting *that* (cf. (8b)).

(10a) *Piove./*Esso piove*.
(10b) *Is raining./It is raining.
(11a) *Arriva Gianni*.
(11b) *Arrives John.
(12a) *Chi credi che abbia telefonato*?
(12b) *Who do you believe that has phoned?

4.2 *Verb Movement*

The distribution of verbs in the clause provides a second illustration for the interaction between verb morphology and syntactic variation. In English (13a), the inflected verb *eats* immediately precedes the direct object *chocolate*. The verb follows the adverb *often*. In French (13b), the finite verb is separated from its direct object *du chocolat* and it precedes the adverb *souvent*.

(13a) John often eats chocolate.
(13b) *Jean mange souvent du chocolat*. (*French*)
*John eats often chocolate.

The verb and its direct object form a semantic unit. While the English verb in (13a) remains adjacent to its

Figure 2
The structure of the clause

object, the French verb *mange* in (13b) is separated from the object. Based on the structure in Fig. 2 it is proposed that French (13b) involves leftward verb-movement from the position V to the inflectional head (I).

The contrast between Icelandic and Danish in (14) is the same as that between English and French in (13). The Danish verb remains adjacent to its object; the Icelandic verb is separated from its object by the adverb *oft*.

(14a) *at Johan often spiser tomater*. (*Danish*)
that John often eats tomatoes.

(14b) *að Jón borðar oft tomata*. (*Icelandic*)
*that John eats often tomatoes.

Verb-movement, as displayed by French (13b) and by Icelandic (14b), is also related to the inflectional paradigm of the verb (Pollock 1989, Holmberg and Platzack 1995). French and Icelandic have a relatively rich inflection, whereas English and Danish have impoverished inflection. In languages with rich inflection, the verb can move away from its direct object.

The kind of paradigm which allows verb movement is related but not identical to the kind of paradigm which triggers a positive setting of the *pro*-drop parameter as discussed in Sect. 4.1. Verb-movement to the inflectional head requires fewer distinct forms in the paradigm than pronoun omission (cf. Vikner 1997, pp. 192ff.). Verb-movement is possible in languages like French or Icelandic which do not allow the subject pronoun to be omitted.

5. *Parameters and Language Acquisition*

The parameter determining verb-movement can be set by the language learner on the basis of inflectional information. However, the inflection is not the only positive evidence that the language learner gets in order to set the parameter. Word-order patterns in the input (i.e., the sequence verb–adverb or adverb–verb) also provide robust positive evidence allowing the learner to determine the parameter-setting. Thus, two types of evidence are available to the language learner for fixing the parameter: syntactic evidence (word-order) and morphological evidence (inflection).

Figure 3
Word-order variation

5.1 *Morphology and the Setting of Parameters*

Both parameters of cross-linguistic variation discussed so far are related to inflection. The question arises whether all parameters can be stated in terms of inflectional variation. One area of cross-linguistic variation whose definition remains subject to controversy concerns the contrast between so-called VO languages such as English, in which the verb precedes its direct object, and OV languages such as Dutch and German, in which the direct object precedes the verb (see *Word Order*):

(15a) I think that John knows this house.

(15b) *Ik denk dat Jan dit huis kent*. (*Dutch*)
*I think that Jan this house knows.

According to the more traditional approach, the variation in (15) is due to a parametric variation in the underlying structure of these languages. In this view, the universal principles of structure (Fig 1) only determine hierarchical relations, leaving the linear order of the constituents to be determined parametrically. Thus the structure of the VP would come out as Fig. 3a for English and as Fig. 3b for Dutch.

The universal base approach, on the other hand, assumes that structure determines linearization and that the verb always precedes the object; (Fig. 3b) is not a possible base structure. In this view, the OV order of Dutch (15b) is derived by a leftward movement of the object. Those adopting the universal base approach define the trigger of the leftward movement of the object in Dutch (15b) in terms of a morphological property of the object. Since the Dutch object does not, at first sight, display any visible properties to distinguish it from its English counterpart, it is proposed that morphological variation need not correspond to an overt manifestation; morphological properties at the basis of cross-linguistic variation may also be abstract.

5.2 *Diachronic Change and the Trigger for Parameter (Re-)setting*

Two types of overt evidence in the input allow the learner to formulate his/her grammar: syntactic evidence (the observed word-order sequence verb–adverb–direct object vs. adverb–verb–direct object, the observed omission of the subject) and morphological evidence (the verbal inflection). The question

arises whether either of these two kinds of evidence is primary in parameter setting.

Inflectional endings in a language get weakened and disappear in the course of time. As a result, the morphological evidence for a given parameter-setting disappears. The development of English (see *Historical Linguistics: Overview*) suggests that the loss of inflectional morphology led to the loss of leftward verb movement (cf. Roberts 1993, Pollock 1989). Changes in the inflection have led to a re-setting of a parameter. Apparently, when the morphological evidence gets lost the syntactic evidence alone is insufficient for triggering the relevant parameter-setting (see Vikner 1997, pp. 205ff. on Scandinavian). The loss of the morphological trigger for a particular word-order does not necessarily lead to an abrupt change in the word-order patterns of the language. A syntactic trigger (i.e., the word-order pattern itself) can maintain the old system for some time, leading to gradual, rather than abrupt change.

Literacy and Illiteracy, History of

The period from the early sixteenth century up to the end of the eighteenth century saw a veritable revolution in European cultural history. In the Middle Ages, it was taken for granted that only a select few knew how to read and write and that many of them made their living out of these skills as scribes and clerks. By the late eighteenth century, however, in the most developed regions of Europe, about 50 percent of men were able to acquire information from reading the newspapers, and the number of people who could write was steadily rising. The skills of reading and writing and, beyond that, the use of literacy, were rapidly gaining ground, to the detriment of oral communication. The body of written documents increased drastically; literacy made its presence felt more and more strongly throughout society. Printed books grew in number while becoming cheaper, and more things were thought worthy of being committed to paper. Literacy extended its power to ever-newer sectors of a developing state administration and bureaucracy in early modern Europe. Surveys and certificates were drawn up, and the use of written documents gradually squeezed out verbal evidence. Inevitably, people's mentality and ways of thinking underwent a simultaneous change.

Orally transmitted knowledge and the memory of the elderly lost a good deal of their former prestige, while respect for information set down in writing, which increasing numbers of people were able to decipher, strengthened. With the spread of calendars and printed maps, the concepts of space and time altered; numerically articulated, measurable time came to replace an image of a past drawn with vague, uncertain outlines. Acquiring writing skills alone did not necessarily involve a change in mentality. Owing to the gradual spread of literacy in society, however, more and more people were able to read the dates on printed works, and this affected their way of thinking. People knew what the date was and how old they were, and tied events to specific days, months and years. The traditional concept of time had rested on oral tradition and memory, associating the passage of time with events such as wars and plagues, and the changing seasons. This slowly gave way to the new concept based on literacy, supported by written documents. This article tracks the development of literacy, especially in Europe and North America in the early modern period, the most important time in history of literacy, marking the period of transition from restricted to mass literacy in the West.

1. Literacy: Definitions and Mutual Relations

Functional literacy, i.e., the capacity to read a newspaper, sign a check and write a short postcard at least,

was an essential and indispensable precondition of the functioning of nineteenth and twentieth century society. These skills were, however, lacking in the majority of the population in early modern Europe.

Literacy is much more than just the capacity to read and write. It is the constant practical use of writing and of the written record. Literacy represents a different way of seeing the world and storing information from that used by illiterate people.

During the 1990s very important research was carried out on literacy in ancient societies, evaluating in a new light data that had been available for centuries, but not regarded as sources of literacy: descriptions of reading and writing, orthography of mural epigraphs, and so on.

Literacy remains a very real problem in large parts of the world outside the West (and in parts of the Western world where there are poor schools, and where the phone and television have completely replaced letter writing and newspaper reading, etc.). However, literacy played a central part in European cultural and social history in the centuries between 1500 and 1800. Literacy is typically a phenomenon of transition—these centuries saw in Europe the transition from a restricted medieval literacy to modern mass literacy. After the invention of the printing press in the mid-fifteenth century, the quantity of written documents, from books to newspapers and leaflets, grew very quickly, and this encouraged more and more people to learn to read and, to a lesser extent, to write.

Illiteracy is by no means a synonym for lack of culture. The oral tradition and the oral culture of traditional societies is as important and precious as the written culture and literate world of modern societies. The oral tradition did not disappear with the onset of literacy: in early modern Europe there was a coexistence of the two cultures. The oral culture was not, however, an isolated island in the dominating literate world; illiterate people using orality lived very much in the middle of a society where the most important decisions were put into a written form, and where more and more people could read and write. There was a continuous interaction between the two worlds. Illiterates used written documents that they could not decipher, e.g., passes and documents concerning ownership of their houses and land. Often the content of lost written documents was conserved only by orality, e.g. those concerning the migration of population or the origin of settlements. Such information was often kept in memory only by the tales of the old people in the villages who may once have read such lost documents.

General illiteracy influenced the exchange of information, making it difficult for the masses to maintain contact with the world outside their town or village. In the twenty-first century it is natural for a literate man to write a letter and read a notice or a brochure. For the unlettered, though, this causes grave difficulties and requires the assistance of others. Until the widespread use of the telephone, large sections of society practiced writing mainly through corresponding with relatives. Even illiterates tried to exchange letters, which meant sharing their innermost thoughts with those who offered to commit them to paper.

2. *Measuring Literacy: Problems of Methodology*

The best sources for measuring literacy are census records. During a census every citizen was asked if he or she could read and write, or only read, or neither read nor write. However, such censuses were carried out only from the second half of the nineteenth century. As literate people generally came from the upper, richer strata of society, they had a higher general life expectancy than illiterates. For this reason we should not draw retrospective conclusions on literacy from the age-groups of censuses, as it is not absolutely certain that literate and illiterate people died in the same proportion.

We can estimate the rates of literacy before the beginning of censuses by consulting descriptive sources and statistics of crosses and signatures. Descriptive sources such as travelogs, reports of state officials, data on elementary education, book production, and book ownership, cannot furnish reliable quantitative data on the literacy rates. However, these are valuable indirect sources because we can analyze the competence of the writing. It is only exceptionally recorded that someone had authenticated a document 'by alien hand, not knowing the letters'; in most cases, only a cross by way of signature or some characters suspiciously identical with those in other signatures show that somebody was illiterate. In sources such as witness depositions, however, hundreds of nobles, peasants and burghers declared that they could not read, or this fact about them was recorded by travellers, state administrators, etc.

Good statistics on literacy rates in early modern Europe can be drawn up, however, only on the basis of enumeration of people who signed their names or who could only make a cross instead of a signature. For this purpose we need a representative cross-section of the society where the social rank and geographical position (and if possible, age) of the persons in question can be determined. Often, however, only males and only the better-off figure in the documents, or only one professional group is represented.

Statistical data hardly reflect the real state of affairs concerning literacy. The method of counting crosses and signatures rests tacitly on the supposition that all those whose signatures have been found could indeed write, while those who left merely a cross on documents were all lacking the skill of even writing their names. Both suppositions could be erroneous, because examples abound of counterfeit signatutes being

entered on behalf of illiterate people and of crosses made by people well trained in penmanship. This reflects the mentality of a given society: if literacy has already acquired prestige, even illiterates try to fake writing capacity; however, if the great majority in society are illiterate, handwriting has no authentication function and thus even village notaries make only a cross, even if they can write properly. This would not come to light unless we have more than one sample of the signatures or crosses left behind by the same person, which in turn presupposes a recurrence of the same name, whose bearer gave a signature at one time and a cross at another. The statistical data concerning crosses and signatures, therefore, reveal the attitudes of a community toward literacy, rather than the concrete spread of literacy: they speak about the community expectations concerning literacy, the pressures on semi-literate persons to sign the documents themselves, and on the genuinely unlettered to forge a signature. Such mentality only emerged, though, if literacy was on the rise in a society. In their totality, therefore, these statistics more or less do mirror the advance of literacy. There is no doubt that if we divide society strictly into literate and illiterate people, the major part remains concealed: the semi-illiterate layer of society that did learn something of the alphabet and later, in accordance with the community's wishes, either made crosses or wrote their name on official documents. The same applied to reading, too: those who were taught the letters at school but hardly ever read, could profit from the printed prayerbooks whose text they knew by heart (extensive reading). However, they did not fare well when they had to read a handwritten circular whose contents were unknown to them (intensive reading). The unlettered and the literate were in fact never separated as sharply as may be suggested by the rows of crosses and signatures. No clear-cut distinction can be made between fully illiterates, who could neither read nor write, and semi-literates, who could read but not write: both groups left crosses on documents. Yet there is no greater gap in levels of education than that separating those able at least to read, to gather information from written texts, from those to whom the world of letters is literally a closed book.

The greatest number of written sources and of sources on literacy are to be found where the levels of literacy were the highest, and obviously this greatly influences research on literacy overall. In England from the seventeenth century onwards witnesses authenticated their testimony by putting their signature or mark on the records, and people signed oaths of fidelity en masse. In several Western European countries, spouses and their witnesses also confirmed a marriage by signing or marking the marriage register. This explains why the marriage register is a major source for the spread of literacy. In France marriage registers had to be signed from 1686, in England from 1754. The city of Amsterdam, one of the most literate places of the world in this time, required marriage registers to be signed from as early as 1578. In 1630, 43 percent of bridegrooms and 68 percent of brides made a cross; 100 years later in 1730, the proportion is 24 percent and 49 percent respectively. In 1780 only 15 percent of men and 36 percent women could not sign their names at their marriage.

The conquests of Napoleon Bonaparte open up new possibilities for the historians of literacy in Germany and Italy. These two countries, so important for the cultural history of early modern Europe, lacked similar mass sources in the sixteenth to eighteenth centuries for evaluation of literacy levels. After they became part of Napoleon's empire, however, the French system was introduced—thus, around 1800, we have a statistically relevant quantity of crosses and signatures from many regions of Germany and Italy, as they were parts of France at this time. In Central and Southern Europe, however, only the minister conducting the marriage ceremony was expected to write in the register, and it was not compulsory for eyewitnesses to sign their accounts in court. Witnesses confirmed their accounts only by taking an oral oath, without signing the document. This fact in itself is indicative of the lesser role literacy and writing played in these regions compared to Western Europe.

Reading, in contrast to writing, leaves no traces behind; that is why researchers into literacy almost invariably examine the ability to write—or more specifically, to produce a signature—and give up trying to gauge reading abilities as a hopeless venture. In several European countries, however, an extraordinary source lends scope for the examination of reading skills en masse: the Lutheran pastors in those areas made an annual survey of reading skills in their flock from the late seventeenth century. In the history of European literacy, a position of eminence is certainly due to Sweden (with Finland and Latvia, which still belonged to it at the time), Zurich and vicinity in Switzerland, and certain regions in northern Germany (seventeenth and eighteenth centuries) where the Lutheran faith thrived. In the course of Lutheran church visitations in these territories, records were made of, among other things, the reading skills of all adults, even indicating the grades—so an otherwise non-manifest skill can be examined on the basis of a large sample. The Lutheran church believed it to be of great importance for believers to read the catechism and the Bible. Those reluctant to learn to read were denied communion at Easter. The Swedish model is especially interesting, as the church was pushing for better reading skills without enforcing writing capacities. As a result there was a huge gap between reading and writing abilities—in the eighteenth century almost everybody (around 90 percent) was able to read, but only few (around 10 percent) could write. Female literacy was rising, too, and the role of the mother as a teacher at home became very important, especially in the nineteenth century.

The Lutheran church records are, however, not the only sources for examining reading capacities before the age of censuses. In Hungary, when the county administration investigated claims to noble title, it asked the nobleman making the claim whether he had read, or only seen, the lost letters patent that would prove his nobility. In three different regions of eighteenth-century Hungary, 71 percent, 74 percent and 55 percent respectively of the lower noblemen declared that 'as they cannot read at all' they had only seen, but not read, the lost document.

3. *Literacy in Europe*

England together with the Netherlands, was the most literate country in the world during the period. In the mid-seventeenth century, during the stormy years of the Civil War, Englishmen were required to sign oaths of allegiance several times; consequently there are ample data available concerning the state of literacy in various parts of the county, in the form of thousands of signatures and signs. On examining these, David Cressy (1980) has found that in England in the 1640s, some 70 percent of men and 90 percent of women were illiterate. As regards the sixteenth-century situation, only estimates can be made. Cressy avers that in the middle of the sixteenth century, 80 percent of men and 95 percent of women could neither read nor write. The percentages around 1500 may have been 90 and 99 respectively, though this is a mere surmise as even in England no statistical data about literacy can be culled so early. The situation in eighteenth-century Britain is much better known. According to David Cressy's estimates based on the available sources, at the beginning of the century 55 percent of men and 75 percent of women could write their own names. In 1754, it was stipulated by law in Britain that the marriage register had to be signed by both the bridegroom and the bride. From that time onwards, therefore, the development of literacy can be traced on the basis of precise data. By the middle of the eighteenth century, the majority of men knew how to write, only 40 percent being unlettered, while the rate amongst women was 60 percent. In the second half of the eighteenth century, however, this dynamic progress came to a sudden halt. Until the early nineteenth century, illiteracy stopped falling in Britain. The social transformation that was taking place as a consequence of the Industrial Revolution was probably to blame for this—inner migrations and early child labor were not really conducive to literacy. In the second half of the nineteenth century, though, illiteracy in Britain all but disappeared. Between 1850 and 1911, the proportion of illiterate men decreased from 30 percent to one percent, and that of women from 45 to less than two percent.

France is the best researched of all countries in terms of literacy in the early modern age. From the age of Louis XIV, it was compulsory for brides, bridegrooms and witnesses to put their signature in the register at weddings, thus leaving a wide scope for researches into literacy. In France in the eighteenth century the number of literate people almost doubled, even though at the time of the outbreak of the French Revolution they were in the minority, the proportion of literate people in France grew from 21 percent in 1686–90 to 37 percent in 1786–90. Frenchwomen also lagged behind men—literacy among them grew from 14 to 27 percent within 100 years, while amongst the men it rose from 29 to 47 percent. However, averages that apply to entire countries hide what is really relevant—the huge regional differences that were so characteristic of this large country. That imaginary dividing line connecting Geneva and Saint Malo, which in the seventeenth century separated the literate northern and eastern parts of France from the more backward western and southern parts, was still clearly visible on the map of literacy at least a century later, and in the case of women's literacy, as late as 1866. This indicates that regional imbalances in the spread of literacy, as an important index of development, take a long time to change. When the French Revolution broke out, there were huge regional differences in the literacy of men. In Normandy and in the countries north and east of Paris, 90 percent bridegrooms signed the register in Brittany and on the Atlantic coast, their proportion was less than ten percent. In the secluded regions of the Massif Central, the percentage of men who put their signature in the register was 16, of the women a mere four while in Alsace-Lorraine the percentages were 83 and 44 respectively. The differences did not diminish until the second half of the century.

By the end of the nineteenth century, illiteracy had in effect been wiped out in France. While in 1854, 13 percent of bridegrooms were unable to sign the marriage register, the number decreased by 1900 to a mere five percent. Within the same period the proportion of illiterate brides decreased from 46 to six percent. Compulsory schooling put an end to the difference between male and female literacy, which had been a marked feature in earlier centuries.

The newly unified Germany presented a very mixed picture from the point of view of literacy, too. In the Prussian kingdom in 1871 10 percent of men above 10 years could neither read nor write. However, this average was calculated again on the basis of very different regions: the proportion was only 2 percent in Hessen and 3 percent in Bradenburg, while in the Polish-inhabited region around Posen (Wrocław) one-third of the males (32 percent) could not even read.

For lack of relevant researches, there are no statistical data on literacy available from the Austrian provinces of the Habsburg Empire in the sixteenth to eighteenth centuries. After the modern census had

been introduced, the available data testify to huge discrepancies between the provinces, dwarfing the differences between the various French or Prussian regions. In 1900 in the most developed provinces of the Habsburg Empire, in Upper and Lower Austria, and in Bohemia and Moravia, the rate of illiteracy in the population aged 10 years and above was less than 4 percent. In the same time, in Galicia 56 percent, in Bukovina 66 percent and in Dalmatia no less than 73 percent of the population above 10 was illiterate.

There are ample sources in Italy on the spread of education and culture and on schools in the early modern period; however, except for the provinces conquered by Napoleon, no statistics are available about literacy before the introduction of censuses in the second half of the nineteenth century. In the vicinity of Turin in 1710, excluding the town itself, 94 percent of brides and 81 percent of bridegrooms were illiterate; by 1790, the percentages had decreased to 70 and 35 respectively. In the Neapolitan kingdom in Campania province, in the mid-eighteenth century, 76 percent of those submitting tax returns could put only their cross on the document, even though only the well-off, and then only men, were expected to prepare such a return at all. The marked difference between the northern and the southern provinces is evident even from this single piece of information. Censuses reveal, on one hand, that in the whole of Italy in the late nineteenth century, illiteracy, which earlier had reached astonishingly high proportions, was rapidly diminishing; on the other hand, however, the gap between northern and southern Italy was huge. It had not disappeared by the early twentieth century—in 1901 in the northern region of Piedmont 18 percent of the population above six was illiterate, in Lombardy 20 percent, in Veneto 28 percent, while in Sicily the figure was 71 percent, in Sardinia 68 percent and in Calabria 79 percent.

In Poland we can observe huge regional differences, too. In the Voivodeship of Cracow at the end of the sixteenth century, the landed nobility was largely literate: 96.7 percent of the nobles who bore the title *generosus* and usually owned several villages, could sign their name, and the percentages remained unchanged over the next two centuries. Among women, however, literacy rose rapidly in the same period: while in the late sixteenth century, 51 percent were unlettered, by the seventeenth century only 22 percent remained so. Women continued to catch up with men in the eighteenth century, when a mere 15 percent put a cross on documents instead of signing their names. In the lower ranks of landed gentry or *nobilis*, who owned one or at most two villages, the proportion of illiterates made up 24 percent in the sixteenth century and 16 percent in the following century. In another study, the literacy of Polish noblemen was examined on the basis of tax returns submitted in and around Cracow. In 1564–64, 43 percent of the noblemen were illiterate. The vast Polish kingdom, however, comprised regions with very different levels of development. In the Voivodeship of Sandomierz in the seventeenth century we find circumstances very similar to those of the Voivodeship of Cracow: 99 percent of the noblemen bearing the title of *generosus* and 75 percent of the *nobilis* could write. On the other hand, the Voivodeship of Lublin lagged behind: while those titled *generosus* were almost entirely literate, only 65 percent of the women could write. Of the *nobilis*, compared to the 84 percent in and around Cracow, only 70 percent signed the documents, while barely one out of 10 women could write their names. Even this proved to be a highly developed state of affairs when compared to Eastern Galicia, where eight percent of the magnates (*magnifici*), eleven percent of the *generosi* and 72 percent of *nobili* put a cross instead of their names as late as the early eighteenth century. In 1764, two-thirds of the participants of the diet called *sejm* held here could not authenticate documents by signing them.

In Vas county, Hungary, in the eighteenth century, only 2.5 percent of peasants could sign their names, and among the lower strata of the gentry only 26 percent could sign their names with 74 percent putting only a cross on documents. The first census to give an overall picture about the literacy of the population in the Hungarian kingdom was carried out in 1870. At this time three-fifths (58 percent) of the population aged above six in the historical Hungarian kingdom (part of the Habsburg Empire, consisting of Hungary, Transylvania, and Croatia) could neither read nor write. The figure for Hungary alone was 51 percent; 78 percent in Transylvania; and over four-fifths of the population (84 percent) in Croatia and Slavonia. There were huge differences between the various nationalities, however, in 1890 63 percent of Germans and 53 percent of Hungarians could read and write, but only 9.7 percent of Ukrainians living in Hungary, 14 percent of Romanians and 30 percent of Serbians. If Central Europe was lagging very much behind the developed Western parts of Europe, the difference between Central Europe and Russia, and the countries of the Balkan peninsula, was as huge.

No reliable data are available on the measure of illiteracy in Russia for the sixteenth to eighteenth centuries, but Jeffrey Brooks, historian of Russian literacy, gave his 1977 work on the period between 1861 and 1917 a telling title: *When Russia Learnt to Read*. At the 1897 census, only 21–29 percent of men and 13 percent of women could read. Literacy attained the highest proportions in the Polish provinces of the empire, even though this favorable position was relative indeed: 29 percent of men and 23 percent of women had a passive knowledge of the letters. In the European part of Russia, 28 percent of men and 10 percent of women could read, while the relevant percentages in Siberia were only 16 and three respectively. Development in the 50 years preceding World War I was rapid, however while in 1880, four-

fifths of new conscripts did not know the letters, in 1913 only 32 percent of these young men, who were just above school age, were illiterate.

The line of the River Danube and the Carpathian Mountains, which separated Hungary from the Balkan peninsula, was also a demarcation line between two worlds as regards literacy. Missionaries and travelers in seventeenth century Moldavia and Wallachia noticed that hardly anybody knew how to read or write, and even some of the Greek Orthodox bishops could read only with difficulty. 'Of the nobles and the tradesmen, few know the Ruthenian or the Slav script,' and even the majority of priests were illiterate according to the Jesuits, although they may not have been impartial. The population of Serbia was largely unlettered as late as the early nineteenth century. Hardly any of the leaders of the Serbian uprising could read or write; the ruling Prince Milos was probably the only illiterate head of state in Europe at the time. According to contemporaries, when Serbia became independent, neither the priests nor the monks could read and write. There was little improvement in this situation in the following decades: even the 1866 census found that 96 percent of the population was illiterate; at the turn of the century, the number was 83 percent. The Balkan Peninsula remained very much a region of illiteracy even at the turn of the twentieth century: around 1900, of the population above six, 72 percent in Bulgaria, 60 percent in Greece, 78 percent in Romania, and 87 percent in Bosnia were illiterate.

For these parts of Europe, literacy remained very much a problem of the twentieth century—the Bolshevik Party launched huge literacy campaigns after coming to power in Russia. In North America there were very high levels of literacy for New England—male literacy rose here from 70 percent in 1710 to 90 percent at the end of the eighteenth century. However, as these data were calculated on the basis of the wills of the wealthy, doubts must be raised about this very high proportion of literates. The 1840 census showed huge differences within the country: around four percent illiterate in the state of New York, compared with 20–28 percent in Georgia, North Carolina, Tennessee, and Arkansas. However, the African-American population showed high levels of illiteracy even after slavery had been abolished: in 1870 some 80 percent of adult blacks were illiterate, and the figure was 44 percent in 1900. Massive immigration into the USA from Europe before the World War I, imported mass illiteracy: in 1909 99 percent of Danish or Scottish workers in the United States were literate, but only 45 percent of Portuguese and 43 percent of Polish workers could read and write at this time.

In other parts of the world, literacy is a problem of today and tomorrow. Around 1960, the time of dissolution of the colonial empires, 81 percent of the population of Africa, and 55 percent of Asia's population were illiterate. According to various estimates, at this time roughly 40 percent of the world's inhabitants still could not read or write. There remains much to do in 1992 the illiteracy figures for Burkina Faso were 86 percent, in Bhutan 85 percent and in Afghanistan 76 percent. Illiteracy remains a problem for mankind even in the third millennium.

Literacy and Orality

1. Definitions

Notions which are mutually dependent are called dialectical. This label applies to orality and literacy, 'literacy' cannot be conceived of without 'orality,' nor orality without 'literacy.' Hence, their respective meanings depend on how the opposite notion is assessed: if orality is given a positive value, literacy appears as negative, and vice versa.

To give some examples: Marshall McLuhan (1962) started from an oral society which was originally closed, which attached importance to the spoken word, and in which social roles were relatively fixed. He opposed this idealized form of community to Western literate societies which, having transformed oral language into a visible code, were seen as depreciating the spoken word, compelling us at the same time to cope with different social roles. In this context, a particularly negative influence is attributed to the invention of printing. Whereas Jack Goody and Ian Watt (1962) saw the transition from orality to literacy more in the sense of a profit-and-loss account, Walter J. Ong (1982) took an opposite stance underlining the positive aspects of literacy, thus suggesting the positive kind of innovation McLuhan was only willing to attribute to the New Age of television which, in his view, already occupies the place of literacy (Raible 1994).

The rash and overgeneralized judgments to be found in scholarly discussion of the 1990s suggest a more cautious attitude. The first question to be asked in this context is: what do 'orality' and 'literacy' mean? Here we need to distinguish a *medial* from a conceptual or cognitive aspect: the medial one is trivial—something we utter is either spoken or written. The conceptual aspect is a continuum, intertwining orality and literacy. This conceptual side needs some more consideration.

Communication by language is based on social convention. Hence, the utterances we engage in or exchange with others always reflect a socially accepted activity: somebody has to be welcomed; we engage in small talk with her or him, ask questions, give answers, make jokes, engage in gossip, and so on. Some more privileged individuals may pass judgment on somebody, make an injunction, or pronounce a verdict.

The terms in the preceding paragraph describe social activities accompanied—or even only made possible—by the use of language ('speech acts'). They represent a continuum of text types which can best be arranged on a scale, one end of which can be termed 'interactive text,' and the other, 'edited text' (Biber 1988); other labels are 'conceptually oral' and 'conceptually written,' i.e., highly planned and edited text (Koch and Oesterreicher 1994). For a similar distinction, Karl Bühler (1934) had already introduced a pair of Greek terms used by Wilhelm von Humboldt in the nineteenth century: language as *enérgeia* vs. language as *érgon*—i.e., language as an activity or process (involving present partners), as opposed to language as something created, produced, edited, e.g., a book. Increasing from one end of this scale to the other are, among other things, the degree of structuring and, at the same time, the degree of intersubjectivity. Conceptually scriptural texts should be accessible to a large and unspecified public.

The implications of the conceptual scale can best be shown within a three-level approach to language (see Table 1). Each one of these three levels should be conceived of as a scale, reflecting exactly the conceptual and cognitive scale holding between orality and literacy: on level (b), we encounter *text types* with an ever increasing degree of editing and planning. Stylistics and rhetoric belong to this level, rhetoric being, indeed, the art of planning effective texts in subsequent steps. It starts with a general idea and a global strategy: then come linear organization and memorizing; even the delivery is planned.

On level (a), we find the respective realizations, i.e., *utterances* occupying—like small talk—one end of the scale, or, in case of a judgment, a patent specification, the other one. Level (c) is the level of the corresponding *systematic prerequisites*: composing texts belonging to elaborate text types demands a much higher mastery of language than buying bread or joking with our neighbor.

Hence, conceptually speaking, orality and literacy are thoroughly intertwined. The often postulated 'great divide' between orality and literacy, between 'oral' and 'literate' societies, simply does not and cannot exist (Hornberger 1994).

2. Transitional Aspects

This holds all the more as the existence of a script does not change or achieve anything by itself. Beyond doubt there is an immense creative and changing potential in literacy. But in order to unfold it, literacy has to meet the appropriate cultural—e.g., institutional—conditions.

There are, nevertheless, some evolutionary tendencies. One of them is that literate societies are likely

Table 1
The conceptual continuum and its representation on three levels of 'language'

	Cognitive scale		
	Wilhelm von Humboldt		
	enérgeia	↔	*érgon*
	P. Koch and W. Oesterreicher		
	conceptually oral	↔	conceptually written
	Douglas Biber		
	interactive text	↔	edited text
(a) 'language' as utterance	e.g. dialog with neighbor	↔	e.g., The papal encyclical *fides et ratio*
(b) 'language' as speech act types	e.g., small talk, gossip, joke	↔	e.g., judgment, textbook, novel
(c) 'language' as system	makes possible a dialog, etc.	↔	makes possible a judgment, etc.

to develop a greater number of textual genres, along with new—e.g., legal—institutions. This enlarges the conceptual space, shifting considerably the societal acquisition of conceptual scripturality (and augmenting the time it takes us to acquire it). There will be neither essays nor editorials, patent specifications, nor testaments in an oral society.

The augmentation of textual genres and the extension of the conceptual scale automatically means new demands on the systemic side. This is shown, among other things, by the fact that a considerable number of English speech act verbs appear for the first time in Early New English: to acknowledge, to advocate, to assert, to concede, to remind, to apologize, to question, to request; or even only in New English: to remark, to retort, to state, to accept, to guarantee, to volunteer (Traugott 1987). Together with the speech act types already mentioned, these examples enhance institutional aspects of literacy.

One further general tendency, which is illustrated below, is the slowness of all processes bringing about cultural change.

2.1 Alphabetic Writing, Orthography, and the Invention of Printing

There are two kinds of writing systems: those representing formal aspects of speech (syllabic, alphabetic script), and those rendering content (ideographic script). Writing proper names is a task that regularly leads to syllable or even alphabetic elements in ideographic script, whereas alphabetic script tends to become ever more ideographic. By reflecting essential aspects of spoken language, early Greek script is characteristic of early alphabetic writing in general: since we do not hear pauses between words, *scriptura continua* is (with some exceptions) a quite natural outcome. It prevails in Western texts up to the eighth century AD and is linked with reading out loud. By 1200, all the achievements of what most of us would call modern layout are present in scholastic texts: spaces between words, punctuation, capitals at the beginning of a new sentence, paragraph indention, emphasis by means of different colors and different script (all of them ideographic features), chapter headings, short summaries in the margin, footnotes, a table of contents, alphabetic registers. As a result, the reader is not lost in an amorphous text. It is only at this time that the general practice of silent reading can begin (Parkes 1992).

Such developments are due to a feedback loop: the higher the number of readers, the more will their needs be taken into account by the invention of features facilitating the reading process—such as ideographic elements. This explains why such phenomena can be observed at the end of the twelfth century: it was not until then that lay literacy developed to any significant extent.

By this time, we observe an incredible increase in the production of written documents. In the State Archives of the Italian city of Siena, there are, for instance, about 500 documents from the twelfth century, but nearly 17,000 from the thirteenth. This acceleration of text production coincides with major changes in social, commercial, and agricultural organization. Thanks to doings and dealings, the city states of Northern Italy already had a population surplus; this required them to organize life and everyday supply very strictly by written statutes. A similar evolution can be observed in large parts of central Europe (for England, see Clanchy 1993).

As a consequence, there was an immense need for knowledge—how shall I write a letter? make a speech? a treaty? how do I behave well?—in short: 'how to win

friends and influence people?' This was the time when, at Bologna, Roman Law was rediscovered; when the great encyclopedias of the Middle Ages were written; when Italian merchants came to invent paper money as well as the new juridical forms of joint stock companies and insurances. In Art and Science, this was the epoch of Gothic architecture and scholasticism (1100–1450), mediated by contact with Arabic culture, and by the discovery of Aristotle. From this perspective, the invention of printing presents itself much more as a necessary consequence than as an agent of change in the domain of literacy.

There was, nevertheless, at least one topic fostered by printing: discussion on orthography. On the one hand, printing books for a great variety of unspecified readers inspires thoughts on standardization. On the other, it goes without saying that all the achievements made in writing and layout increase the intellectual and the practical effort of the writer. This is why discussions on orthography have tended to be dominated, since the sixteenth century, by elementary school teachers who would like to reduce—for those learning to write—the difficulties brought about by the ideographic tendency under discussion.

2.2 Material Aspects of the Written Text

The evolution of layout has an aspect which merits further attention. Unlike spoken language, written text presents itself in two dimensions. Layout makes use of the respective possibilities in making visible chapters, paragraphs, and so on. There is one further possibility which leads to modern mathematics. Thirteenth-century mathematicians were far from being familiar with the system of notation their successors use today. This system only took shape in a slow process between the thirteenth and the seventeenth centuries. Most of the symbols are the outcome of an intermediate stage presupposing alphabetic literacy: the stage of abbreviation. This led not only to most familiar signs such as & ('et'), but also to the plus and minus (+, −), the symbol for the square root, etc. It was Descartes who, at the beginning of the seventeenth century, introduced the conventions that are still followed for the symbolization of the unknown element; they facilitated the highly momentous discoveries made during the seventeenth century: analytic geometry and calculus, resulting in a new ideographic system.

Mathematical ideograms, consequently exploiting the two dimensions of the page, are accessible to simultaneous rather than to linear perception—provided one knows the system. This enormous progress made mathematics the most important complementary discipline to natural sciences, contributing in a decisive way to their role in our modern world (Krämer 1991). This is why, at the beginning of the seventeenth century, Galileo Galilei tells us that the Book of Nature is written in cipher and that those intending to read it have to master the language of mathematics.

In recent times, this role has partly passed to a new branch of mathematics, informatics. Texts written in programming languages not only are at least as demanding as complex written texts in natural languages (Raible 1999). At the same time, their influence on modern life is pervasive. Retrospectively, the second part of the twentieth century is likely to appear as the age of Claude E. Shannon (1916–2001).

2.3 The Written Text as a Metaphor

The use of written language as a metaphor also has a long history—witness the Book of Nature (Blumenberg 1999). The metaphorical use starts with the early atomists, Leucippus and Democritus. Their basic idea was that the whole complex, manifold world surrounding us is nothing but appearance, whereas in reality all was thought to consist of atoms and the void between them. According to what Aristotle tells us in his *Metaphysics* (985b, 15ff.), their visible model for the invisible structure of matter was alphabetic script. The variety of the visible world would be due to the fact that the atoms are differently shaped—just as an A differs in shape from an N; that their order may be different—as the sequence AN is different from NA; finally, their relative position in space may differ: a rotation of 90 degrees makes an N out of a Z. The central idea behind this conception is the reduction of numerous varieties to a restricted set of elements (here the 20-odd letters of the Greek alphabet combining for a possibly infinite variety of written texts).

While the Book of Nature has been a powerful and influential metaphor since the Middle Ages, the idea of the alphabet as the basis of a code reappears at the end of the nineteenth century in cell biology (Friedrich Miescher, 1844–95). It was again put forward in 1943, this time by the Austrian physicist Erwin Schrödinger, (1887–1961), in a series of lectures entitled 'What is life?' where he suggested a genetic alphabet similar to the Morse code. This idea was confirmed in 1953 by Francis Crick and James Watson who showed that the long strands of DNA (Schrödinger's punched Morse tapes) have the structure of a double helix, and by the series of important discoveries that followed this breakthrough.

Since that time, the metaphor of language in the form of alphabetic script has become omnipresent in molecular biology. The four nucleotide bases abbreviated by A, T, G, and C were called letters of the genetic alphabet. RNA-polymerase is reading DNA-sequences with their reading-frames. This process is called transcription, and it happens thanks to transcription factors; transcription is accompanied by an immediate process of proof-reading. The result is called a copy subject to further editing. The resulting

string of mRNA will be translated into a polypeptide. This is made possible because the triplets of DNA encode or are coding for amino acids. The whole process is called gene expression. It presupposes a grammar of biology. As the genome of humans and of other species is being deciphered, the result is stored in large databases modeling the sequences of nucleotides as sequences of the letters A, T, G, C. In this context, molecular biologists are speaking of gene libraries. Recurrent sequences of nucleotide 'letters' as well as recurrent sequences of amino acids in proteins are called motifs, and the genome itself is seen as an encyclopedia (Raible 2001).

2.4 Some Other Processes of Transition

One of the disadvantages of 'oral' cultures is what was called a 'collective censorship.' Texts the audience dislikes fall into oblivion. In literate societies all written texts can be preserved and rediscovered by future generations. This advantage, however, changes into a serious problem with mass media, including the Internet—this is, above all a true consequence of printing.

Unless the public simply refrains from reading, there are at least three reactions. Long texts are transformed into shorter (and cheaper) versions. A lot of these text types were created in antiquity or in the Middle Ages—e.g., epitomē, summarium, argumentum, catechismus, breviarium, compendium. Other genres make a new text out of parts of others—e.g. anthology. Modern literary scholars cannot but use one of the vernacular versions of Valentino Bompiani's *Dizionario delle Opere di tutti i Tempi e di tutte le Letterature*.

A second reaction is an institutional censorship as embodied by all systems of education. They make use of specific curricula, syllabi, textbooks, introductions, primers in order to transform youth into fully-fledged members of society. Making texts as attractive as possible, at the same time making their content easily accessible, is a third answer to the problem. The most radical changes in writing can be observed in the history of mass media, i.e., in journalistic writing and in the corresponding genres of television. Scientific writing is another good example: the articles published in the respective journals are structured according to an identical model and endowed with tables, schemes, and pictures, whose captions and legends, together with the obligatory abstract of the article itself, swiftly inform the readers. The last point shows one of the problems, though: it holds only for those who are already experts in the subject, with the cognitive demands of such texts increasing at the same time.

The presentation of information in the Internet repeats an evolution that took place in the layout of written text. Witness the plethora of new elements in subsequent releases of hypertext markup language (it corresponds to the third level in the above scheme) and the introduction of meta-tags leading, for web crawling machines, to the equivalent of subject catalogues in our libraries. The web pages of the Internet basically exploit the acquisition of literacy (in traditional texts, 'footnotes,' page references, a table of contents, etc., correspond to 'links.' The only major difference is the ready availability of the objects referred to). New features are the availability of color, sound, and moving items.

3. A Precarious Equilibrium

There is no great divide, then, between 'oral' and 'literate' societies, orality and literacy being intertwined on the conceptual level. In addition to this, there is another factor of cultural variation: a social community can dispense with script, but not with spoken language. Apart from entirely oral cultures, we are thus always confronted with more or less literate societies. Given the dialectical relationship between orality and literacy, this means a steadily changing state of equilibrium.

There are indicators showing that the precariousness of this equilibrium is felt. As the evolution of culture in general may lead to the slogan 'back to nature,' the increase in literacy may make us long for the lost paradise of 'innocent' orality. This desire may materialize in a motto like 'let us write the way we speak' (Bader 1994). First examples were Plato's critique of literacy (*Phaidros* 275 d) and the effectiveness of highly planned Sophist rhetoric which made the public suspicious.

Anyhow, the consequence of such reactions is even more literacy. Since antiquity, theoreticians of rhetoric know that among the genres of speech *ex improviso*, speech is the most artful one. Baldassar Castiglione (1478–1529), whose *Courtier* was a model for Europe from the Italian Renaissance on, tells us that true art means dissimulation of art. The same thing holds for the impression of orality called *skaz* that was discovered and recommended by some of the Russian formalists.

What at first sight might appear as paradoxical is quite clear at a closer look. Given the dialectical relationship, in a literate society orality has to be artificially created—just as seventeenth-century authors conceive of Nature (in literature and in the Fine Arts) as 'the negation of the negation of nature.' Once a culture has adopted literacy, returning to 'authentical' orality is impossible.

Literacy, Cognitive Psychology of

Once oral language was evolving, humans needed to code and decode it for purposes of storage, transmission, and tradition. Thus, writing systems (scripts) were invented and literacy, that is, competence with a written language, evolved. Cognitive psychology of literacy studies how the cognitive processes underlying (de-)coding oral language function in reading, spelling, and writing and how humans learn to become skilled literates. It uses a variety of cognitive models (e.g., boxological, mathematical, and computational; for a classification see Jacobs and Grainger 1994) and methods (e.g., psychophysics, mental chronometry, brain imaging) to explain how humans (learn to) perform the fundamental processes underlying literacy: (a) code elementary speech sounds as written symbols (e.g., phonemes as letters in alphabetic scripts) and vice versa, (b) transform information about those symbols (e.g., phoneme/letter identities and their relative position) into information about meaning, and (c) transform information about meaning into written symbols.

1. Major Issues

Most of the cognitive research on literacy studies the question how humans learn and apply the alphabetic principle in perception and action, that is, the fact that in many languages letters (or letter groups) symbolize elementary speech sounds. Other major issues concern: (a) the functional units of learning/processing spoken and written language (e.g., letters vs. words; phonemes vs. syllables), (b) the question which role phonological awareness, that is, explicit knowledge of the sound structure of words, plays in acquiring literacy, or (c) the causes of individual differences and deficits in the acquisition of literacy and methods to remedy such deficits.

1.1 Learning and Processing Scripts: A Question of the Right Mapping

Literacy involves the mapping of multiple symbols and mental representations of symbol-related perceptions and actions on to each other. Cognitive psychology provides models for necessary and possible mapping processes and methods for testing those models. Since a single script can represent speech at more than one level of representation and different scripts represent different levels, an elementary task for learners of scripts is to detect the basic (i.e., most fine-grained) level at which visual and phonological representation meet (identity relationship) and to develop efficient cognitive processes for discriminating between them and for generalizing from known representations to new ones. About 10 levels of representations are possible: logogen, morpheme, syllable, onset, rime, nucleus, coda, phoneme, phon, and articulatory feature. By hypothesis, in logographic/morphophonological languages like Chinese, the basic processing level is the word. In syllabic languages (e.g., Japanese kana), the same vowels or consonants (phonetically) are represented by different graphic features, depending on the syllable in which they occur. Therefore, the basic level is the syllable. In alphabetic orthographies (phonographic languages) the basic level is the phoneme, because letters code phonemes, not phones (e.g., [p] vs. [p^h]). In such languages, a necessary condition for literacy is to

detect the alphabetic principle and to develop both stable and flexible representations of the critical spelling-sound/sound-spelling relations.

The task of inducing the right relations is made difficult by a number of learning/processing problems that differ across alphabetic languages. First, language users have to deal with the inconsistency of sound-spelling and spelling-sound mappings: identical visual units can represent different sounds and identical sounds can represent different visual units, as illustrated in the famous 'Beware of HEARD a dreadful WORD, it looks like BEARD and sounds like BIRD.' Thus, acquiring literacy should be easier in languages with more consistent mappings (ideally, one-to-one mappings, as in Serbo-Croatian) and more difficult in languages with more inconsistent ones (many-to-many mappings). Indeed, quantifiable differences in the consistency of languages lead to differences in learning and processing performance. In English, whose spelling system was developed to keep morpheme (root meanings) spelling constant (e.g., heal/health), about 40 phonemes have to be represented by 26 letters: thus, distinctive letter groups (i.e., graphemes) are required to represent all phonemes. Furthermore, about a dozen vowel segments in speech have to be represented by only five letters (in comparison: in Italian seven stressed vowels code five letters, any of which is pronounced uniquely). As a consequence, approximately 31 percent of English words are spelling-to-sound inconsistent. Basically, this inconsistency is due to vowel ambiguity: in contrast to initial and final consonants that have the same pronounciation in about 96 percent to 91 percent of words, in only about 50 percent of the words, vowels are pronounced the same. Learners of English adapt to this fact by using higher units of processing than the basic level: by using onsets and rimes, the spelling-to-sound mapping becomes more consistent (vowels are now pronounced the same in about 80 percent of the words) and performance in a variety of psycholinguistic tests improves.

In contrast to English, there is evidence that learners of languages that are more spelling-to-sound consistent use basic-level representations (i.e., phonemes) in perceptual and motor processing (i.e., reading, spelling, writing): German (in which approximately 90 percent of words are spelling-to-sound consistent) or Italian children detect the alphabetic principle earlier and exhibit better decoding skills than English (Cossu et al. 1995, Wimmer and Landerl 1997). There is also evidence that even in skilled adult readers word recognition performance is affected by both the spelling-to-sound and sound-to-spelling mapping: words that are consistent both ways (e.g., duck) are processed better than words that are inconsistent both ways (e.g., swarm) with words being inconsistent either way yielding intermediate performance levels (note that approximately 80 percent of English and French words are sound-to-spelling inconsistent, as compared to 50 percent of German words). A simple and reliable predictor of skilled adult reading performance in English, as measured by the naming task, is the ratio of consistent pronounciations to all pronounciations of a given orthographic segment. The (type) consistency ratio of the orthographic segment-ave, for example, is $1/(1+12) = 0.08$, because there is only one word (have) with the/Av/pronounciation compared to 12 (monosyllabic) words with a different pronounciation (save, gave, cave, etc.). Taking word frequency into account, the consistency ratio is very much increased to 0.89, because the token frequency of have is very high in relation to the summed frequency of its orthographic neighbors.

This notable asymmetry in the consistency of languages can be used to explain the observable asymmetry in the difficulty of reading and spelling: according to Bosman and Van Orden (1997) spelling is more difficult than reading for speakers of English because the sound-to-spelling mapping is more inconsistent than the spelling-to-sound mapping and because the sound-to-spelling inconsistencies must be resolved by the semantic-spelling dynamic, which is relatively weak in comparison to the semantic-sound dynamic that develops earlier in language learning. In contrast, sound-spelling inconsistencies are resolved by the stronger semantic-sound dynamic. This fundamental spelling-reading asymmetry is enhanced by the fact that reading is a more frequent activity than spelling.

A second problem in acquiring the alphabetic principle is that higher-level representations are more accessible than lower-level ones. English-speaking kindergarteners have better access to the number of syllables in a word than to the number of phonemes in a syllable. They also have better access to rimes than to phonemes.

A third problem is the dominance of meaning over form. An example from children is the observation that common semantic features of two words (e.g., the fact that tiger and clown are associated with a circus) can mask phonological differences between them (e.g., that tiger and clown have different onsets). An example which should be familiar to all adult readers is that one has better mnestic access to semantic features than to form features (e.g., upper- vs. lower-case) of words.

1.2 Functional Units in Orthographic and Phonological Awareness/Processing

Which units are functional in learning and processing scripts? All of the above-mentioned 10 representation levels are possible, in principle, but some have been studied more extensively than others and seem to play a predominant role. As concerns visual units, the majority of studies suggest that reading is letter-based (e.g., Nazir et al. 1998), but some evidence favors the hypothesis that in addition it can also be word-based.

However, intermediate units, such as graphemes (i.e., letter clusters representing a single phoneme) have also been found to play a role in word recognition performance: Identification times are longer for words that have fewer phonemes than letters (e.g., beach is composed of five letters and three phonemes, i.e.,/biJ/) as compared to words with equally many phonemes and letters (e.g., crisp-/krIsp/) suggesting that graphemes can be functional reading units (Rey et al. 1998). In addition, onset and rime can play a role in processing written English, as discussed above.

As concerns the problem of phonological awareness, the standard assumption is that three levels play a role: syllable, onset-rime, and phoneme (Byrne 1998).

As concerns the problem of meaning computation from written words, the debate revolves around the alternative: Phonological recoding of written words (i.e., the translation of visual units into sound codes in reading) as a necessary condition for meaning extraction vs. direct reading, that is, the computation of meaning without involvement of sound representations and processes. A related open question is whether orthographic and phonological processes are interactive or independent, and whether they develop interactively or sequentially (see Sect. 2). Many studies suggest that written words automatically activate their sound representations and there is increasing evidence for strong interactions between orthographic and phonological processes even in skilled adult readers (Ziegler et al. 1997).

1.3 Deficits

Reading, spelling, and writing disorders are complex, as evidenced by the postulated existence of at least seven types of dyslexias (peripheral: neglect dyslexica, attentional dyslexia, and letter-by-letter reading; central: nonsemantic reading, surface dyslexia, phonological dyslexia, and deep dyslexia) and about the same number of dysgraphias.

The standard position is that the basic problem underlying developmental disorders of literacy is a phonological processing deficit both in alphabetic and non-alphabetic scripts (e.g., Chinese; Siegel 1998), as efficiently diagnosed by the pseudoword reading test (see Sect. 3). However, possible deficits in temporal and visual processing including eye movements must also be considered.

2. Methods

A wealth of cognitive methods allows to study the multiple processes involved in the investigation of literacy. Pragmatically, they can be classified on various dimensions, such as modality (auditory vs. visual presentation), cognitive aspect (perceptual, mnestic, motor) and task (detection, discrimination, classification, identification), or dependent variable (error rate vs. simple or choice reaction time).

Figure 1
Schematic illustration of the variable viewing position technique: the letter string is briefly presented by the computer such that the eye fixates at a different letter (or viewing zone) on different trials. In general, optimal performance for words is obtained for the viewing zone slightly left of the word middle (e.g., the second to third letter of a five-letter word) with accuracy rapidly decreasing outside this zone

Apart from standard classroom reading and writing tests, tests of phonological awareness are most important for discovering potential developmental disorders in literacy acquisition. Adams (1990) classified the enormous set of tests into five difficulty classes (selected examples are given from difficult to easy): phoneme deletion, addition, or exchange; phoneme tapping; syllable splitting; oddity task, that is, detecting the odd item in a set (e.g., *lot, cot, hat, pot*); and rhyming task.

More sophisticated, computer-controlled tests from psychophysics and mental chronometry (i.e., measurement of reaction times) should complement standard (paper–pencil) classroom reading tests more often in the future. Among the multiple perceptual identification tests, such as the classical Reicher paradigm for properly measuring the word-superiority effect, the grapheme detection (Ziegler et al. 1997) and word fragmentation tests (Ziegler et al. 1998) or the variable viewing position (see Fig. 1; Nazir et al. 1998) and luminance increment procedures (Rey et al. 1998) are recent promising examples for quantifying potential perceptual disorders. For example, children who do not show a word-superiority effect (i.e., the fact that letters in words are processed better than letters in other conditions, such as in pseudowords or in

isolation) in the Reicher task may have a deficit in phonological recoding or lexical processing. Deficits in phonological recoding can be assessed with the grapheme detection test using the absence of a pseudohomophone effect as diagnostic: normal readers yield suboptimal performance for pseudohomophone stimuli (e.g., brane) as compared to control stimuli (e.g., brate), presumably because of an automatic phonological recoding of letter strings. Deficits in lexical processing can be quantified and computationally modeled with the fragmentation test in combination with an interactive activation model of performance in this test. The variable viewing position procedure in combination with the mathematical model of Nazir et al. (1998) allows parametrization of the capacity to integrate letters into words which is an important element for the acquisition of literacy.

The standard alphabetic and lexical decision tasks (i.e., decide as quickly and accurately as possible whether a single sign is a letter or not, or whether a letter string is a word or not, respectively) allow to assess how well alphabetic and lexico-orthographic knowledge can be accessed without a necessary involvement of phonological or semantic processes (Grainger and Jacobs 1996). The naming task (i.e., pronounce a letter string as quickly and accurately as possible) can measure the ease of accessing knowledge about grapheme-phoneme relations. This task is especially interesting for diagnosing problems in acquiring literacy when using pseudowords, because difficulties with reading aloud pseudowords are a reliable indicator of dyslexia (Siegel 1998). For example, to assess whether children have (implicit) knowledge of and access to the rule 'a final e in a one-syllable (English) word makes the vowel long,' pseudowords like rike, fute, or mose can be used.

3. *Models*

As a rule of cognitive psychology a given cognitive test should be accompanied by a falsifiable cognitive (process or task) model that makes explicit the processes and structures underlying performance in the test and allows qualitative and quantitative predictions about performance to assess its validity. Contemporary cognitive models relevant to studies of literacy and reading can be distinguished according to about a dozen criteria (Jacobs and Grainger 1994). Three basic lines that separate them are: (a) prequantitative vs. quantitative, (b) rationalist vs. associationist, and (c) learning vs. performance models.

Prequantitative and quantitative models complement each other: Modeling a given aspect of reality in a prequantitative manner, such as the ubiquitious 'boxological' (i.e., boxes-and-arrows) models of cognition, allows to summarize a wide variety of data obtained with different methods in a static, informal, abstract way. Macroscopic boxological models can be tested at the level of qualitative predictions of off-line data, such as behavioral errors in neuropsychological studies. In order to allow falsifiable predictions, such prequantitative models have to be made more explicit in the form of either mathematical or computational models. Mathematical models use closed-form expressions to describe general functions of dependent vs. independent variables in order to detect lawful relations and are mainly static and very abstract. An example is Nazir et al.'s (1998) model of visual effects in word recognition that can be used to parametrize reading disorders. Computational models allow testing of quantitative predictions of on-line behavioral data that takes into account complex, nonlinear, dynamic interactions between many cognitive processes at different microscopic levels of representation. Prominent examples relevant to research on literacy are interactive activation (Grainger and Jacobs 1996), activation–verification (Paap et al. 1999), dual-route (Coltheart et al. 1993), and parallel distributed processing models of word processing (Zorzi et al. 1998).

Most cognitive models in this field follow the basic rationalism vs. associationism distinction in the philosophy of mind, that is, viewing the mind as a modular system in which rules manipulate symbols vs. the mind as an association machine that detects and acts on correlations between events. Currently open questions addressed by such models are: (a) whether grapheme-phoneme relations are represented by rules or associations or both, (b) whether reading aloud requires access to whole-word representations in a hypothetical mental lexicon or simply involves grapheme-phoneme associations, or (c) whether spelling requires two processes or only one.

A third difference between cognitive models concerns the focus on learning vs. processing/performance. There is a variety of prequantitative models attempting to model the acquisition of literacy, some of which postulate independent stages, while others assume interactive development of orthographic and phonological processes. Increasing evidence favors the latter view (Ehri 1997). As concerns quantitative models, basically, distributed connectionist models allow to study learning problems, while localist connectionist models allow to simulate processing problems (Grainger and Jacobs 1998). Both can complement each other in simulating the main learning/processing problem in acquiring literacy: Analyzing oral speech in a way compatible with the symbols and representations composing the script.

4. *Applications*

For more than a century, teaching literacy has been the battlefield of advocats of different forms of the whole-word method (also known as meaning-based approach) competing with advocats of different forms of the 'phonics' approach. In the former method the

mapping between written and spoken words is taught explicitly at the expense of making explicit letter-phoneme mappings. In the latter approach, children are taught to break words down into their component letters and 'sound them out.' More studies support a superiority of phonics approaches (Byrne 1998), but, of course, an exclusive choice of one or the other method is not necessary: many kinds of mixture approaches are possible. Note, however, that the optimal method depends on the particular spelling-to-sound and sound-to-spelling mappings of a language (Wimmer and Landerl 1997).

5. *Challenges*

In a world full of illiterates and dyslexics, the biggest challenge for cognitive psychology surely remains to provide the applied disciplines with the necessary and sufficient fundamental knowledge allowing to design efficient and reliable methods for diagnosis, teaching, training, and rehabilitation. Given the enormous, heterogeneous set of models and methods in the cognitive literature on literacy, another challenge is theoretical and methodological unification. For example, fundamental research on speech perception still remains relatively disconnected from research on reading and writing; research on implicit learning and working memory is still widely separated from research on literacy; more research on standards for model building and evaluation, as well as for evaluating diagnostic and teaching methods is needed, if we want to fully explain the conditions favoring optimal acquisition and mastering of literacy; finally, so far, too little effort has been spent on developing a formal framework for evaluating the sensitivity, reliability, or validity of cognitive tests relevant to literacy research, such as the ubiquitious lexical decision or the naming tasks.

Literacy Education

Literacy is a relatively recent human invention, and goals of universal literacy within societies are even more recent. Furthermore, although a goal of universal literacy is in place in modern nation-states, it is far from universal, when one considers the vast number of languages for which writing has either not

been developed or for which literacy values have not been firmly established. Studies of the historical contexts of literacy within Western societies make clear that the development of literacy has been embedded in specific cultural 'transactions' (e.g., Resnick and Resnick 1985). The establishment of literacy values in 'developing' non-Western societies occurs within cultural contexts that vary greatly in a number of ways affecting their movement toward literacy (Olson and Torrance 2001).

Where universal literacy goals have been established, the manner of literacy instruction has been subject to change and debate. Although literacy instruction is an issue as inseparable from cultural contexts as the development of literacy itself, it is helpful to focus on the general components of the issue that derive from the distinctive technical nature of literacy—the fact that it has to do with the use of written language. This fact warrants a central place in questions of literacy instruction.

1. *The Definitions of Reading and Literacy*

Reading has been defined both narrowly and broadly. The narrow definition honors an important fact about the dependence of reading on language: *reading is the conversion of written forms into spoken language forms*. With this definition comes the concept of *decoding*, the process of converting printed word forms to spoken word forms. On the narrow definition, then, reading instruction is primarily about the teaching of the code—how the writing system encodes the spoken language system. This can be considered the system-based definition.

By contrast, broader definitions entail literacy as a concept distinct from reading in the narrower sense. In this broader definition, the concept of *literacy* entails the achievement of a broad range of skills embedded in cultural and technological contexts. In this extended culture-centered definition, reading may not even be a critical part of literacy. Thus, a person who can recite religious texts from memory without being able to read them may be included in such a definition (Wagner 1986). Other extended definitions imply functional, rather than cultural, norms. Literacy is 'using printed and written information to function in society, to achieve one's goals, and to develop one's knowledge and potential' (Kirsch and Jungeblut 1986). An extended functional definition is practically useful in specifying expectations for achievement and in helping to make clear the wide range of literacy tasks a society might present to its members. Further extensions of literacy are entailed by such phrases as 'computer literacy,' 'historical literacy,' 'scientific literacy,' etc. In effect, literacy in its broader senses refers to a level of achievement in some subject or specialty, an extension of basic skill to reasoning and discourse in a domain. This amounts to making 'literacy' co-extensive with 'education.'

Intermediate between the narrow definition of reading and the extended definition of literacy is the definition of literacy as reading and writing. This definition may entail the narrower decoding concept, but it adds comprehension, or the attainment of meaning, as the main feature of literacy. In the USA and Europe, reading as obtaining meaning from print has become the most common definition applied in the pedagogy of reading. Thus it may be considered the standard pedagogical definition.

In the face of these various definitions, some clarity is achieved by noting that the common meaning-based definition is *outcome* based, whereas the narrower decoding-based definition is *system*- and *process*-based. Thus to say that reading is the conversion of written forms into language forms, is to appeal to the relationship between *writing systems* and *language systems* and to the process of decoding elements of one system into elements of the other. By contrast, the pedagogical definition is focused on the outcome of comprehension, without regard to the system relationships or the process. The extended literacy definition is neither outcome- nor system-based, but rather is a culturally embedded definition that can complement either the system-based or the outcome-based definition.

In considering the most universal aspects of early reading instruction, it is useful to adopt both the pedagogical definition and the systems definition. The pedagogical definition is useful because it emphasizes a consensus on the major goal of reading, including children's reading. The systems definition is useful because it reflects accurately both the systemic foundation of reading and the related decoding ability that must be acquired by children to learn to read. The treatment of literacy in the sections below center on these two definitions.

2. *Reading and Writing Systems*

Writing systems, which are the result of human invention and refinement, vary according to their design principles even after centuries of convergent development. Conventionally, one distinguishes among alphabetic, syllabic, and logographic systems (Gelb 1952). Thus, English, Italian, Russian, and Korean are examples of alphabetic writing systems, in which graphic units associate with phonemes. Arabic, Hebrew, and Persian represent modified alphabetic systems, in which vowels can be omitted. Japanese Kana is a syllabary system, in which graphic units correspond to spoken language syllables. The logographic system is, at least among current systems, uniquely represented by Chinese (along with the Japanese Kanji adaptation of the Chinese system). In

such a system, the graphic units associate primarily with whole words or lexical morphemes.

Although Chinese approximates this logographic concept, its partial representation of morpheme level pronunciation suggests a different classification, as morpho-syllabic (DeFrancis 1989). Thus, in Chinese the compound character Ñó (pronounced yang 洋 and meaning 'ocean') has two components: the left component signifies that the character meaning has to do with water, while the right component is a character that when it stands alone is also pronounced as yang 羊 (Ñò, meaning sheep). This combination of meaning and pronunciation information inside a character is very far from perfect, but it is frequent enough to challenge the assumption that it is a pure logographic system. Indeed, pure logographic systems seem not to exist among current writing systems.

The significance of writing system analysis for literacy education lies in the following: the fact that writing systems vary in systemic design principles means that children must learn how their writing system works. Do the elementary units correspond to meanings? They do not in an alphabetic system—and not in a syllabary system. The child learning either of these systems must focus some attention on meaningless print units that correspond to meaningless spoken language units. Only in the case of Chinese is there the potential for learning mainly form-meaning mappings. And, as noted above, this mapping is only part of the Chinese system. It is fair to say that there is a universal challenge in learning to read that requires the learning of a relationship between form (written) and form (spoken) rather than between form and meaning.

It is important to note that this challenge is not a consequence of bad writing-system design. It is merely the price to be paid for system efficiency and productivity. Speech-based writing systems are productive in that they make infinite use of finite means (an inventory of syllable signs, an inventory of letters) to express all words and all possible words in a language.

3. *Learning to Read in an Alphabetic Writing System*

In learning an alphabetic writing system, a child comes to learn that letters and strings of letters correspond to speech segments. In principle, this learning might occur implicitly (through the extraction of print-speech correspondences in text) or explicitly (through direct instruction). The problem that has confronted reading instruction is how much success is to be expected from strictly implicit learning.

Complicating the picture is that the consistency of the mappings between letters and phonemes varies within the family of alphabetic systems. The specific manner in which a writing system is instantiated is its orthography, which provided the details of the mapping system. Within the family of alphabetic writing systems, orthographies can be characterized as relatively deep or relatively shallow (Frost et al. 1987). A shallow system provides reliable mappings between letters and phonemes, whereas a deeper system sacrifices some reliability in its mappings, instead preserving more underlying morphology in its spellings. European languages, including Romance, Germanic, Slavonic, and Finno-Ugrian languages, tend to be coded by shallow orthographies. The letters reliably map onto phonemes.

English presents a problem of deep orthography to the learner: many letter patterns in English associate with more than one pronunciation. For example, the letter string 'ow' is read as /ow/ in the words *how* and *cow* and as /o/ in *low* and *tow*. Although the irregularity of English is widely lamented, many of the 'irregularities' turn out to be quite predictable, provided one takes into account more than a single letter. The rime unit—the vowel plus the syllable ending together—turns out to be pronounced very reliably in English (Treiman et al. 1995).

In either a shallow or a deep alphabetic system, the learner needs to grasp the alphabetic principle: letters are associated with meaningless speech segments, or phonemes. Deeper orthographies merely present more context-dependency in these associations.

3.1 *Phonological Sensitivity*

A major link to discovering the alphabetic principle is the child's phonemic awareness, the understanding (more or less explicit) that the speech stream can be segmented into a set of meaningless units (phonemes). Although awareness of phonemes is central to the alphabetic principle, researchers may speak more generally of 'phonological' sensitivity, which entails an appreciation of a broader range of information in the speech signal. Phonemic awareness, variously measured, shows a strong correlation with early reading success. Furthermore, training studies in which children receive explicit instruction in phoneme segmentation produce gains in reading. The research thus supports a strong causal link between explicit knowledge of phonemes and reading in an alphabetic system.

However, the causal relationship between reading and phonemic awareness appears to be reciprocal. First, adults whose cultural context does not include formal schooling may fail to show phonemic awareness (Morais et al. 1979). Second, Chinese children who learned to read Chinese without first learning the Chinese alphabetic (pin-yin) system fail to show phonemic awareness (Read et al. 1986). Third, longitudinal studies of first grade children learning to read

English find a reciprocal relationship, such that initial gains in simple phonemic awareness precede gains in reading, which in turn lead to further gains in phonemic awareness (Perfetti et al. 1987).

For fuller discussions of phonological sensitivity, see Rieben and Perfetti (1991), Liberman and Shankweiler (1991). For a summary of the evidence on the role of phonemic awareness and other factors in learning to read, see the National Research Council Report (1998).

3.2 Theories of Learning to Read

Progress in acquiring reading skills has been viewed typically as a series of stages (e.g., Ehri 1991, Frith 1985). Among the shared ideas across at least some of these theories is the assumption that the earliest stage of reading is characterized by an attempt to learn associations between visual features of graphic forms (not complete orthographic word forms) and spoken words followed by a subsequent stage of graphic-phonological decoding that brings on a truly productive capability in reading. The use of letter names as a bridge to phonology is an important beginning step (Ehri 1991).

Alternative theoretical accounts emphasize the incremental acquisition of decodable lexical representations, rather than discrete stages (Perfetti 1992, Share 1995). Important in these theories is the role of phonology in helping to establish word-specific orthographic representations.

The relationship between spelling and reading comes into the picture quite early. The initial expression of the alphabetic principle appears more often in spelling than in reading (Frith 1985). Indeed, children's attempts at spelling prior to formal reading instruction typically reveal a real understanding that the sounds of a word are to be found in the letters (Read 1971). This early realization forms the basis for later alphabetic reading, even if the earliest stages of reading—as opposed to spelling—appear to be based on partial visual cues or 'logographic' strategies (Frith 1985). Eventually, in nearly all languages, the learner confronts an important fact about spelling: typically, the mapping from pronunciation to spelling is less consistent than the mapping from spelling to pronunciation. Reading is more reliable than spelling. For a collection of papers on spelling in different languages, see Perfetti et al. 1998.

4. Teaching Reading in an Alphabetic System

Given the theoretical understanding of learning to read and the wealth of data that supports central features of these accounts, especially the role of phonological awareness and the need to acquire letter string–phoneme string mappings, the goal of beginning reading instruction for alphabetic systems seems clear. Children need to learn that the letters of their alphabets map onto speech segments of their language; if they lack phonemic awareness, then some instruction in phonemic awareness as part of reading instruction is implied. Phonemic awareness instruction linked to reading instruction seems to be more effective than isolated phonemic awareness instruction.

However, in English-speaking countries—and to some extent in European countries—there has been a history of assertive ambivalence about teaching directly what the child needs to learn. This history is captured in the phrase 'The Great Debate,' the subtitle of a review of teaching methods by Jeanne Chall (1967). The question has been, to what extent—if at all—should beginning instruction focus on teaching directly the correspondences between letters and 'sounds' (phonemes)? The logical answer to this question appears to be that these correspondences, and the alphabetical principle that they instantiate, should be the central initial focus of instruction. However, the tendencies of actual practice have been otherwise. A variety of alternative pedagogies have emphasized instead meaning-focused struction built around story reading, exposure to print, and enhanced language environments. These alternatives are too varied to capture with a single characterization. For example, in the original Great Debate, the alternative to direct instruction was 'whole-word' (also called 'look-say') teaching (Chall 1967), in which basal readers and limited (and later) 'phonics' instruction were typical components. In the last 20 years, the dominant alternative has been 'whole language,' a broad philosophical approach without specified components, except for prohibitions against direct teaching of decoding.

Chall's original conclusion, based on a careful analysis of some 22 programs, classroom observations, and reviews of published studies, was that children who were taught in direct code-based instruction (i.e., decoding-emphasis or 'phonics') classrooms tended to have higher achievement in the first three grades than did children in whole-word classrooms. Although initially whole-word classrooms showed better on measures of comprehension and reading rate, the advantage of decoding-based instruction became highly general, encompassing spelling, word recognition, and comprehension. This conclusion, in its general form, was confirmed in later, less comprehensive reports.

Adams (1990), in a study requested by the US Office of Educational Research and Improvement, provides a review of a number of these research reports and, more generally, an evaluation of teaching methods in the context of a review of the research. Furthermore, Adams (1990) puts the Great Debate in its historical context and helps to explain why there has been so much resistance to the direct teaching of decoding. An emphasis on meaning and comprehension not only

coincides with the main goal of reading, it is also appeals to beliefs that the child's experience in school learning should reflect purposeful learning in authentic contexts. In that spirit, a use of commercially published children's literature as the main or exclusive reading material has become characteristic of whole-language classrooms. Modern advocates of direct instruction point out that there is nothing incompatible between these meaning values and good decoding instruction (often called 'phonics'), which aims to provide the child with the basics of the letter-sound system quickly, while introducing real reading with comprehension at the same time.

The US National Research Council (NRC; the research arm of the National Academy of Sciences) revisited this issue in its report, *Preventing Reading difficulties in Young Children* (National Research Council 1998) The NRC report concluded that research shows that beginning reading 'depends critically on mapping the letters and the spellings of words onto the sounds and speech units that they represent.' Directly counter to the idea that somehow comprehension can proceed on its own, the report adds that 'Failure to master word recognition impedes text comprehension' (p. 321). An additional feature of the NRC report is its emphasis on early language and literacy experience prior to school. It is clear that coming to school with certain relevant skills (e.g., some degree of phonological sensitivity) and dispositions (e.g., an interest in books and stories) eases the burden of school instruction. It is equally clear that if schools are to retain the major responsibility for literacy instruction, they need to organize their efforts to level the variability among children in at-home literacy preparation. Such efforts, organized along the lines supported by research, would aim to ensure that children acquire the ability to decode words and have sufficient opportunity to gain fluency and to read with comprehension.

Although the debate about teaching reading may appear to be about methods of teaching and the research that helps decide which methods are effective, this appearance is probably misleading. Arguments for a whole-language approach (and against the teaching of decoding) have embraced philosophical stances and professional advocacies that have little to do with effective teaching and learning and their research basis. Traces of these philosophical and professional advocacies issues can be seen in the professional teaching publications. The effect of this has been to make research appear irrelevant to the debate. See Stanovich (2000) for a researcher's perspective on this problem.

However, at the close of the twentieth century, there are indications that a stronger consensus has emerged in favor of research-guided practice. There is also an emerging consensus that teaching preparation has been a neglected part of the problem. Strong recommendations to improve both the college education and the 'in-service' training of teachers in the USA have come from recent studies suggesting low levels of teacher preparation in the foundations of reading. Improved teacher training, including more knowledge about the research foundations of reading, was a major recommendation of the NRC report.

5. *Reading Instruction in an International Context*

The questions of how to teach reading are general across languages, writing systems, and national and cultural contexts. However, the English language case is special to some extent. Among alphabetic systems, English is exceptional in its depth and its vocabulary, both its size and its mixed linguistic origins. These two facts are related—a large vocabulary from mixed roots can be expected to produce more spelling variability and hence a less reliable spelling-to-speech mapping. One might wonder whether the facts of English spelling have contributed to the debate on how to teach reading.

In non-English-speaking countries, the debate either has been lacking or appears in a milder form. Among European countries speaking Germanic languages, the tendency is toward the teaching of letter-sound correspondences, although there appears to be variability; e.g., Denmark has placed less emphasis on decoding, the Netherlands and Germany somewhat more. Among Romance language areas, decoding instruction has an important part of beginning reading instruction in Italian and Spanish but not in French.

Indeed, there may be at least a superficial relationship between the reliability of an orthography (its shallowness) and the approach to instruction. Where the mapping from graphic unit to speech unit is highly reliable, whether syllabic or alphabetic, decoding tends to be taught—in Japan, as well as in Korea and most Romance, Germanic, and Slavonic language areas of Europe. In general, children in these language areas are explicitly taught grapheme–phoneme or grapheme–syllable correspondences and are encouraged to use phonological recoding (i.e., 'sounding-out') as their primary word recognition strategy (Feitelson 1988, Mayringer et al. 1998, Reitsma and Verhoeven 1990). The high consistency of these orthographies reinforces the use of phonological coding, allowing most attempts at decoding to produce an accurate word pronunciation.

It is in English-speaking countries, including the USA, the UK, Australia, and New Zealand, where the debate on reading education has been the most heated and where nondecoding methods (particularly whole-language) have been prominent (Turner 1995). This is not an exclusive quirk of English, however. France and French-speaking Switzerland have also tended to emphasize non-decoding approaches. On the orthographic reliability continuum, French orthography

can be characterized as somewhat less reliable than Italian and Spanish, especially in the direction of sound-to-spelling. With these examples, one might be tempted to conclude that the reliability of the spelling-to-pronunciation mapping is a major influence on whether education emphasizes decoding. Certainly, arguments against phonics instruction have sometimes used observations about the 'irregularity' of English spellings as a reason not to teach spelling-sound correspondences. However, it would be misleading to conclude that it is the reduced reliability of an alphabetic orthography that explains failures to teach decoding. Teaching practices are strongly determined by traditions that develop around professional (teacher training), philosophical (child development beliefs), and the marketing of instructional materials. One needs to examine the specific influences that have guided practice contexts within a political region.

In the light of a resistance to teaching decoding, the case of Chinese is especially interesting. Chinese writing presents a high contrast to alphabetic systems—even those with reduced reliability in letter-sound mappings. Even with the presence of phonetic compounds, only a minority of characters give fully accurate information about their pronunciation. Furthermore, for a learner to use this information, he or she must already know the pronunciation of the character that serves as the phonetic cue. Thus, the basic learning procedure is to memorize characters (and the radicals), relating them to spoken words and their associated meanings. This means a logical approach to teaching reading in Chinese would be whole-word or look-say methods. Indeed, until after World War II, this whole-character method was how Chinese children learned to read. Students were taught to recognize individual characters by means of flash card drills and writing practice.

However, in implementing goals of universal literacy, the Chinese added an initial bootstrapping alphabet-based procedure. Children now spend their first eight weeks of school learning a 26-letter alphabet (*Pin Yin* in mainland China, including Hong Kong, and *Zhuyinfuhao* in Taiwan). The instruction focuses on learning grapheme-phoneme correspondences (and phonemic awareness), so that after the first eight weeks of school, the child can read words and sentences written in the alphabet. Then, individual Chinese characters are introduced, accompanied by their Pin Yin counterpart. Gradually, the Pin Yin are removed for familiar characters and then for all characters (Sheridan 1992). A similar system is employed for teaching Japanese children to recognize the Chinese characters (Kanji), which are used together with the syllabic scripts in standard written Japanese. When the kanji are first introduced to children, their pronunciation is written out below the characters in the syllabic script. In both the Japanese and Chinese cases, even with Pin Yin, children spend substantial time with individual characters, including practice at writing characters. One of the most dramatic differences between the educational practices of both China and Japan and those of the North America and Europe is the amount of time children spend on 'homework' (Stevenson and Lee 1990).

It is interesting that the Chinese use an alphabetic system for no other purpose than as an initial teaching device to help children acquire the Chinese system. Not only does this illustrate the value of a speech-based system, its brevity suggests the possibility that preparation for basic decoding can be accomplished in a relatively short time.

6. *International Aspects of Functional Literacy*

Finally, in considering international contexts, it is useful to reconsider the definitions of literacy. The foregoing has assumed the systems and pedagogical definitions of reading. Instruction has been about how to enable children to learn how their writing system maps onto their language. Implicitly, the issue is also about how children can learn to obtain meaning from printed language. The reasonable assumption is that, with the acquisition of decoding skill, a reader's ability to comprehend printed language will be limited only by his or her ability to comprehend spoken language.

However, consistent with broader definitions of literacy, expectations about communicative functioning increase in literate contexts. It is implicit in schooling in Western societies that learning to read enables a broader range of communicative competencies and literate interests. These competencies then become expressed not just in print but in spoken language. Literacy becomes more than being able to read. Its acquisition promotes a range of behaviors, dispositions, and skills that represent broader individual and cultural interests.

These broader aspects of literacy—part of its extended definition—are a source of widespread concern internationally. As local and national expectations for 'functional literacy' become identified, gaps between achievement and performance become visible. Questions of equal opportunities for participation in the economical and social benefits of literacy become salient. Certainly, coming to know the details of how one's writing system represents one's language is the central prerequisite for literacy, even in this broader sense. But both within the technologically advanced countries of Europe and North America and within developing and recently autonomous regions of the world, the development of functional and participatory literacy faces serious obstacles. One shared problem is the target language for reading instruction. Both in developed and developing countries, instruction in a single national language—either the politically privileged or majority language (in the case of Europe, North America, and some countries of South America and Asia) or the language of the former

foreign occupying country (in the case of African countries)—may present cultural and cognitive obstacles to literacy goals.

For additional discussions of functional literacy in this broader sense, see Verhoeven (1994). For papers specifically addressing the obstacles faced in countries without a long history of universal literacy, see Olson and Torrence (2001).

Literary Texts: Comprehension and Memory

Nothing seems more effortless and automatic than being swept up in the pages of a good book. In reality, the cognitive processes that underlie the comprehension of literary texts are quite complex, and discourse psychologists are beginning to expose some of these

factors in their theoretical models and empirical work. Some of the relevant variables are common to all types of texts, but others seem to be the special province of literary texts.

1. Literary Texts

In general, literary texts may be differentiated from other types of texts with regard to the identity of the author, the purpose(s) of the author, and the presumed reader. Many literary texts are narratives—their goal is to tell a story. Narratives can be differentiated from expository texts, in which the primary aim is the transmission of information. Encyclopedia articles, or the directions on the back of an aspirin bottle, are narrative texts, and as such lack aesthetic dimensions typically found in literary texts.

1.1 Characteristics of Literary Texts

Many literary texts were originally composed as oral texts—stories transmitted by word of mouth before literacy became widespread. Such stories have features that make them easier for the storyteller to remember. These features include formulaic exposition (e.g., 'Once upon a time … ') and repetition (e.g., the number three in *Goldilocks and the Three Bears*). In addition, literary texts typically have a moral or 'message' for the reader. These morals may be explicit, such as an adage following one of Aesop's fables, or implicit, as in the antiwar message of Heller's *Catch 22*.

Some literary texts, however, contain devices that are designed to sidetrack normal comprehension processes (Zwaan 1996). In poetry, for example, rhyme and alliteration cause readers to focus not only on the content of the poem, but also on the words and their relation to each other. In prose writing, temporal events may be presented out of order, or a whole story might be told in reverse order. Literary writing is also more likely to include figurative language, such as novel metaphors and exaggeration. The purpose of these devices is to achieve the aesthetic effect of defamiliarization—to focus the reader on the linguistic surface structure of the text rather than the situation described by the text. Such texts can be described as 'inconsiderate,' and special control processes may be developed and employed by readers to deal with them.

2. Empirical Study of Literary Texts

The scientific examination of literary texts is a relatively new area of research. Many of the issues that are currently studied in the laboratory were originally raised by literary critics and students of rhetoric. However, these insights were often very general in nature, and could not be related systematically to a large body of texts. Experimental psychologists, however, have been very interested in the processes of reading and comprehension, but have shied away from the complexities of literary texts in favor of simple, experimenter-derived 'textoids' (Graesser et al. 1997). These impoverished texts afforded a great deal of experimental control over variables like sentence length and word frequency, but they cannot shed much light on the aesthetics of literary texts.

Attempts to study literary reading in the laboratory, however, are hampered by the artificiality imposed by the process of measurement. For example, a reader may be asked to read individual sentences on a computer screen, and to press a key after reading each one. In other studies, readers must wear heavy apparatus that allow their eye movements to be tracked. Although much can be learned from such studies, it is difficult to argue that these conditions mimic the process of reading for pleasure.

3. Comprehension of Literary Texts

3.1 Models of Text Comprehension

One influential model of text comprehension suggests that readers combine the textbase (propositions derived directly from the text) with propositions contributed from longterm memory to form a situation model for that text. This construction—integration model has been the focus of much experimentation in cognitive psychology (see van Dijk and Kintsch 1983, Kintsch 1998).

Another cognitive model of comprehension is the CAPS/READER model (Just and Carpenter 1992). This approach employs a production system approach (if ⟨state⟩ then ⟨action⟩) for adding, changing, and removing propositions in both working memory and longterm memory as comprehension takes place. Both the construction—integration and the CAPS/READER model assume that the reader is willing to do the work necessary to make sense of the text, and this process is crucially dependent upon inference generation.

3.2 Inferences

There has been some debate about which inferences are generated as a consequence of processing narratives. Graesser et al. (1994) suggest that there are 13 classes of inferences that might be drawn during narrative processing. Some of these, such as referential inferences, are necessary to establish local coherence,

while others, such as thematic inferences, are required for establishing global coherence. These authors have proposed a constructionist theory of inference generation, which states that readers attempt to construct representations that address the goals of the reader, local and global coherence, and explanations for why particular events, states, and actions appear in the text. As a result of this construction, readers make many inferences on-line (that is, during comprehension), and some inferences off-line (after comprehension).

Although the constructionist model was developed to explain inferential processes in all types of narratives, certain types of inferences may be especially germane for literary texts. These include inferences that involve reader emotion and author intent, such as figuring out the attitude or motivation of the writer. If, for example, a reader encounters a satire or a parody, the reader must make inferences about why the author chose to express his or her ideas in this way.

The constructionist approach makes different predictions than the minimalist hypothesis, proposed by McKoon and Ratcliff (1992). These researchers suggest that the only inferences encoded automatically during reading are those based on information that is explicit, and those that are necessary for establishing local coherence. Strategic inferences, however, are more time consuming to construct. They may be drawn when local coherence cannot be established, and there may be important individual differences that affect whether they are made at all.

Magliano and Graesser (1991) have proposed a three-pronged method for studying inferences generated during the comprehension of literary texts. They suggest that verbal protocols are useful because they reveal inferences generated during the comprehension process. In addition, well-articulated theories of discourse processing allow predictions to be made about which kinds of inferences might be drawn during reading. Finally, behavioral measures, such as reading time or eye movements, may be collected to explicitly test whether certain kinds of inferences are generated.

3.3 Participatory Responses

Gerrig (1993) uses the term participatory responses (or p-responses) to refer to noninferential responses to narrative texts. P-responses can refer to a wide variety of psychological states, such as emotional reactions and imagery. Gerrig's research has suggested, for example, that hopes and preferences are generated as readers process narratives, and that these p-responses can affect decision times to stimuli and the mental representation of the narratives.

Suspense is one type of p-response that is common in literary texts. This reaction will occur in readers when an outcome that they care about is uncertain. Even more interesting is the case of anomalous suspense, or suspense in the absence of uncertainty. For example, when one rereads a favorite novel in which a beloved character dies, it is possible to feel suspense about this outcome even though the fate of the character is not in doubt. Gerrig (1993) suggests that anomalous suspense is the result of an expectation of uniqueness, incorporated within cognitive processes that guide how narrative texts are experienced.

3.4 Control Systems

People read different types of texts with a variety of purposes and goals in mind. Newspaper articles, for example, are often skimmed by readers in order to quickly obtain specific information. The structure of news stories accommodates such an approach: important information appears at the beginning of an article, and background information may appear at the end. Literary texts are very different in their organization, and Zwaan (1991) has suggested that readers have developed different types of control systems for reading different kinds of texts.

Zwaan presented college students with texts that could be read either as news stories or as literary stories. Participants who believed that they were reading a news story read the texts more quickly than those who believed they were reading a literary story. This suggests that a literary-comprehension control system induces slower reading speeds than a news-comprehension control system, and that such control systems influence the on-line processing of texts independently of the features in the texts themselves. It may well be the case that the different control systems exist to accommodate the wide variety of text genres that readers encounter.

4. Memory for Literary Texts

The participants in the Zwaan study described in the previous section also showed differences in their memory for the texts that they read. Subjects who believed that they were reading a literary story had a better surface structure representation (i.e., they more accurately recognized the original wording of the texts) than subjects who believed they were reading a newspaper article. This suggests that the literary-comprehension control system focuses upon the stylistic aspects of a text, at least in comparison to the news-comprehension control system. Since many of the aesthetic effects used by authors occur at the word level (e.g., alliteration, metaphor, and oxymoron), it follows that the literary control system is attuned to such features.

The formulaic nature and repetition of some literary texts can play an important role in being able to

remember them on a later occasion. Freedle (1996), for example, asked college students to recall the folktale of *Goldilocks and the Three Bears*. On average, the participants had last encountered the story 10 years earlier. Recall was greatly aided by the triadic nature of episodes in the folktale (e.g., too hot, too cold, and just right bowls of porridge). The causal connectedness of the propositions in the folktale also predicted recall – events that are linked to many other events in the story are better remembered.

5. Future Directions

Literary texts differ from nonliterary ones in important ways, and researchers are still evolving methodologies that will allow processing and representational differences to be captured. These methodologies will be used to evaluate theories of literary comprehension that have become more finely articulated in the past few years. It also seems likely that physiologically-based measures, such as brain imaging techniques and evoked potentials, will allow even greater temporal precision in the study of on-line comprehension.

Lithics and Archaeology

In archaeology, the term 'lithics' refers to all stone artifacts fabricated by humans from the beginning of prehistory until the present time. Stone artifacts have always played a major role in our understanding of prehistory. Stone is the most abundant, and often the only, human-worked material preserved in prehistoric sites. In addition, stone artifacts retain traces on their surfaces that allow us to identify how they were made and used. From an evolutionary perspective, stone-tool making is an essential criterion used by anthropologists to distinguish humans from other hominid species, and to follow the process of human evolution. For the Paleolithic, and along with ceramics and metal for later periods, they are a fundamental source of information concerning past human societies and their economic systems.

1. Historical Aspects

1.1 The Significance of Lithics in the Discovery of Prehistory

At the end of the sixteenth century, Mercati recognized the human origin of polished stone axes, which were previously believed to have been created by lightning bolts. In 1723, Jussieu compared stone axes to ethnographic objects from Canada and the Caribbean. Most notably, as early as the beginning of the nineteenth century, Thomsen classified objects from the Royal Museum of Copenhagen into three successive phases: Stone Age, Bronze Age, and Iron Age. In 1866, Lubbock divided the Stone Age into the Paleolithic, or knapped stone age, and Neolithic, or polished stone age. Meanwhile, the Stone Age, which encompassed all of humanity, and had even been mentioned in biblical and ancient texts, remained undated until the development of absolute dating methods (see *Chronology, Stratigraphy, and Dating Methods in Archaeology*).

However, the notion that stone tools were very ancient was suggested as early as the late eighteenth

century when John Frere identified stone tools in association with the bones of pachyderms at Hoxne (Suffolk, England). Soon after, the first excavations of caves in France, Belgium and England allowed for arguments of a great antiquity of humanity. In 1859, Boucher de Perthes, with support from British geologists, finally succeeded in convincing the intellectual community of the existence of an ancient, 'antediluvian' epoch of humanity. He demonstrated that flint hand axes could be found in situ with the bones of extinct animals deep within gravel quarries in northern France. The idea of very early prehistoric humans equipped with only stone tools was born.

1.2 Lithics as a Criterion for the Definition of Early Humanity?

Chimpanzees, our closest primate relatives, can use natural objects as tools (stone hammers and anvils to break nuts), and even alter natural objects to make tools (removing leaves from twigs to capture termites or ants), but they do not fabricate stone tools in the wild (Berthelet and Chavaillon 1993). The production of stone tools is thus a tempting criterion for distinguishing the earliest species of *Homo* (*Homo habilis*, *Homo rudolfensis*, etc.) from their ancestors and from other contemporary hominids, the australopithicenes, who became extinct between 3 and 1 million years ago. Unfortunately, this criterion remains putative, since it is rare to find stone tools and early hominid fossils in direct association. There is as well no *a priori* reason to believe that some of the australopithecines did not also make stone tools.

To date, the oldest known assemblage of knapped stones, discovered by Helene Roche (1980) at the site of Kada Gona in Ethiopia, and dated to at least 2.6 million years ago, already shows mastery of conchoidal fracture (the basis of controlled stone knapping), perhaps indicating that stone tool technology had already existed for a considerable time.

1.3 The Role of Lithics in the Construction of a Prehistoric Chronology

Once the great antiquity of humankind was finally accepted, researchers put their efforts into developing a chronological classification of the Stone Age. After the first paleontological subdivisions of E. Lartet (1858: Cave Bear Epoch, Reindeer Epoch), classifications were based on stone tools, along with bone tools for more recent periods (G. de Mortillet in 1869, E. Piette in 1889, H. Breuil in 1912, D. Peyrony in 1933). These classifications emphasized the most characteristic tools found in strata of different sites. Following a paleonto-geological perspective, these tools were called 'index fossils'. This procedure led to two excesses that sometimes persist in current research. First, these 'index fossils' were regarded as exclusively representative of distinct time periods and 'cultures,' which were believed to represent different human groups in an ethnic sense, following an overly simplistic historic schematization (see *Ethnic Identity/Ethnicity and Archaeology*). Much work has since been devoted to determining precise dates and geographic origins for these cultures and groups, which are seen to follow a rigid succession of 'evolutionary cycles' based on the appearance and disappearance of a few tool types. Second, these successive cultures, which were originally defined in France following the excavation of numerous stratified sites, were abusively extended to other European regions, thus masking the originality of archaeological data over broad areas.

1.4 A Slowly Developing Technological Perspective

As early as the nineteenth century, some archaeologists were becoming interested in what stone tools could tell us about the daily activities of our ancestors. They asked a first, seemingly accessible, question: how were these tools made? This question led immediately to attempts to reproduce stone tools. However, early experimental procedure lacked rigor and the results remained superficial (Johnson 1978). Numerous prehistorians observed modern gunflint knappers at Meusnes, France and Brandon, Suffolk at the beginning of the twentieth century. However, an extreme production standardization, and exclusive use of iron tools, limited the utility of the comparison. Other prehistorians turned to early accounts of Native Americans manufacturing stone tools. However, many of the descriptions they consulted were second-hand, and thus too imprecise to be useful. Nonetheless, the record in the Spanish Codex of obsidian pressure debitage by the Aztecs permitted D. Crabtree in 1968, and then J. E. Clark in 1982, to reproduce this production process successfully.

Some prehistorians, such as J. Evans, were able to synthesize numerous observations of archaeological collections, ethnographic records, and their own knapping experiments. As a result, the three major knapping operations (shaping, debitage, retouch) and several knapping techniques (direct, hard stone percussion; indirect 'punch' percussion; pressure retouch) were recognized very early (1870). The research of W. H. Holmes (1919) concerning the lithic production activities of prehistoric North Americans was also remarkably modern in its approach to and interpretation of technology. Meanwhile, the functions of stone tools remained hypothetical, except for a few objects such as polished axes and certain arrow heads, the form of which suggested their potential use. Lacking other methods for determining function, the principal categories of stone tools were named after their

similarity of shape with traditional tools (e.g., scrapers, borers, knives, etc.).

2. Recent Methodological Developments and Research Orientations

In conjunction with the genealogical perspective described above, early research was aimed essentially at identifying the major evolutionary stages of the Paleolithic cultures. It was not until the middle of the twentieth century that broader and more analytical perspectives were developed.

2.1 The Typo-Technological Approach

During the 1950s, the French prehistorian, François Bordes, developed a method of studying and comparing assemblages of lithic artifacts, as opposed to single objects, which was both quantitative and qualitative (Bordes 1950). The technological understanding of the objects that he gained through personal knapping experience enriched the methodology he developed. While in the past it had been considered sufficient to discuss only the 'index fossils,' this new method entailed study of all the tools, as well as the technological processes by which they were made. The objective of this broader characterization of lithic industries was the identification of the conceptions of the prehistoric groups that produced them. This became the basis of what is referred to as the 'cultural' approach, which has since been subject to long debates. In particular, Bordes distinguished several different, contemporaneous 'facies' in the Late Mousterian of southwest France. He interpreted these as being representative of different human groups, with different technological traditions, occupying the same region at the same time. L. and S. Binford contested this interpretation, proposing instead that these different facies represented different functional, perhaps seasonal, activities. Other researchers have proposed that these facies could be chronological phases or that they reflect the differential availability of raw materials. None of these interpretations has received unanimous acceptance. In addition, Bordes' method of distinguishing tool types was rather intuitive; some have suggested that several of these tool types actually represent different stages of use and resharpening of a single type of tool (see Renfrew 1973, Mellars 1990, Dibble and Mellars 1992).

Meanwhile, advances in computer technology that have allowed for more elaborate statistical analyses permitted H. L. Movius to confirm the reality of several tool types distinguished by Bordes and D. de Sonneville-Bordes, particularly for the Upper Paleolithic. The 'reality' and meaning of types (especially by Sackett), and the possible use of typological analysis continue to be debated (see *Classification and Typology (Archaeological Systematics)*).

2.2 The Paleoethnological Approach

André Leroi-Gourhan, a French contemporary of Bordes, implemented a paleoethnological approach to prehistoric human groups. This perspective stems from his more general studies of techniques in ethnographic contexts, following a broad anthropological perspective (Leroi-Gourhan 1943, 1945, cf. 1993). Along with other members of his research team, his objective was to reconstruct the spatial dimensions of human activities, which are represented principally by the remains of their technological activities and the organization of the artifacts in relation to various structures (fireplaces, traces of huts or tents, etc.).

Such spatial analysis could be performed only at those rare sites where occupation floors are well preserved. In addition, excavation techniques had to be modified from the primarily vertical, or 'telephone booth' approach that was well adapted to the chronological perspective described above, to a more horizontal approach to allow for exposure of contemporaneous objects on an occupation floor. Under these conditions, this research objective led to two important methodological developments. The first was classification of all lithic remains, including waste-products of production, finished tools, and used and abandoned or broken tools, following the technical process of production and use. This method, which was originally developed in ethnological research, is called *chaîne opératoire* (operational sequence) analysis. The operational sequence is composed of the succession of technical actions beginning at the moment of raw material acquisition and continuing to the abandonment of the tools (cf. Inizan et al. 1999).

The second development was the systematic search for refits between broken objects, retouch flakes and the tool from which they originate, and between lithic objects successively removed from a single core. In this way it became possible to reveal the spatial and chronological relations between isolated objects. Refitting analysis was also developed to detect disturbances within and between archaeological levels, as well as to interpret certain archaeological structures such as different activity areas (cf. Cahen, in Sieveking and Newcomer 1987).

2.3 The Processual Approach

Beginning in the 1960s, L. Binford, and other American archaeologists, developed the approach called

'processual archaeology' (see *Theory in Archaeology*). According to this approach, archaeological artifacts must be considered in terms of the dynamic cultural and natural processes by which they reached the state in which they are found by archaeologists—rather than as static end-products, as they are when a typological approach is used. As with the paleoethnological approach, questions can thus be asked concerning the technological behavior of prehistoric peoples, and we can attempt to situate this behavior within its environmental context. The concept of 'middle-range theory' was borrowed from sociology to provide a link between static archaeological remains and the dynamic processes responsible for them.

This involves the development of explanatory 'models' based primarily on ethnographic references (see *Ethnoarchaeology*) and experimentation. In addition, processual archeologists placed a new emphasis on the natural formation processes (geological, biological, chemical, etc.) of archaeological sites and objects, as well as on the rigorous application of the hypothetico-deductive method to archaeological interpretation. This led to a more critical view of our ability to interpret the past than that espoused by most European archaeologists, and thus to a divergence of research orientations. In terms of lithic studies, American archaeologists became concerned increasingly with the broader contextual aspects of the objects, including the role of lithic technology within the entire technological system of a cultural group. This approach, known as 'technological organization,' addresses issues such as group mobility, tool design needs and constraints, time allocation, risk factors, and degrees of technological investment (see Binford 1983, Odell 1996, Torrence 1989). It is the dominant approach followed by American archaeologists as they enter the twenty-first century.

2.4 Developments in Technological Analysis and Classification

Simultaneously, and until the present time, continental European archaeologists, the French in particular, continued to develop their inductive approach to lithic artifacts. This perspective is based on profound practical knowledge of Old World lithic industries, whose high variability and informational value (due to an abundance of complex and sophisticated technologies) is particularly well adapted to this type of approach.

As early as 1963, Tixier had made the pertinent distinction between method and technique in stone knapping. Technique designates the modes of execution in tool fabrication, including how force is applied (direct percussion, indirect percussion or pressure), the tool employed (e.g., stone cobble, wood, antler or bone hammer, copper point, etc.), and the gestures that are used (e.g., direction of blow, manner of holding the stone and tools, etc.). Method, which is performed according to a systematic and more or less reasoned processes, concerns the organization (order and placement) of series of removals from the object being worked, and thus forms the structure of the operational sequence of production. Systematic experiments are essential to the recognition of techniques, which can be identified based on particular stigmata seen on the objects. In contrast, the knapping method can be identified only through a technological 'reading' of all the objects that entails determination of the direction and order of removals from each piece.

An experienced lithic analyst can perform this technological reading mentally, even in the absence of refit pieces. It is thus possible to classify an assemblage of lithic artifacts according to their original order in the operational sequence of tool fabrication, and distinguish between the products desired by the stone knappers and the waste resulting from their production (Inizan et al. 1999).

2.5 Economic Perspectives

The analytical principles described above, along with the technological classification of lithic artifacts, have revealed that in certain assemblages particular types of 'blanks' were selected for the fabrication of particular types of tools. This realization led to the concept of debitage economy (economy of the products of knapping) (Inizan et al. 1999). This concept was extended to the end of the operational sequence to include tool economy, via which certain blanks were used successively, and/or resharpened in different ways (e.g., work by Binder, and by Perlès). At the beginning of the operational sequence, in a single lithic assemblage, different stone raw materials were often differentially acquired and/or used. This led to the concept of raw material economy (by Perlès, and by Geneste). These perspectives are especially useful for identifying possible choices and decisions made by prehistoric peoples during technological activities (Perlès 1992, Inizan et al. 1999).

Archaeologists also recognized the need for precise determinations of the geographic origins, and modes of acquisition, of the stone materials found in archaeological sites. Following Renfrew's research on the circulation of obsidian in the Near East, surveys and petrographic characterizations were conducted in many regions of the world where diverse workable stone materials are found. The identification of these materials in prehistoric lithic assemblages allows the extent of the territories frequented by foragers to be determined: From several kilometers for the Early Paleolithic human groups, to several hundreds of kilometers during the Upper Paleolithic (Féblot-Augustins 1997). Later, during the European

Neolithic, stone axes and long blades produced in specialized workshops were exchanged over distances up to 1000 km (e.g., Bradley and Edmonds 1993) (see *Trade and Exchange, Archaeology of*).

2.6 The Development of Methods for Determining the Function of Stone Tools

In 1964, with the English publication of his long-standing research, the Russian archaeologist S. A. Semonov (Semonov 1964) demonstrated that the use of stone tools left different macroscopic and microscopic traces on their surfaces. V. E. Shchelinskiĭ and later L. H. Keeley further developed Semenov's results using a high magnification method that allows for identification of the materials worked (e.g., wet or dry skin, bone, antler, meat, plants, etc.) on the bases of comparison with experimental samples. In addition, lower magnification methods can indicate the manner in which the tool was used (e.g., scraping, drilling, sawing, striking, etc.), and how it was possibly hafted, according to the direction of striations and location of polish and micro-removals (Keeley 1980).

Unfortunately, these time consuming methods are not completely reliable. Traces of use are quite often altered, especially on older tools. Another problem is the lack of understanding of some of the physical processes involved in use wear. Nonetheless, certain important results have been obtained, e.g., the recognition of woodworking during the Middle Paleolithic (Anderson, Beyriès; ref. in Dibble and Mellars 1992), and the illumination of harvesting techniques in the Near East (Anderson 1992) (see *Food Production, Origins of*). Other studies, also based on experimentation, have focused on confirming the function of stone and bone points as hunting weapon heads. Such analyses attempt to determine how weapon heads were hafted and used (e.g., thrust or thrown by hand, or with a spear thrower or bow, from long or short distance), and test their durability and performance capabilities (see Knecht 1997).

2.7 The Evaluation of Skill in Lithic Technology

Stone tool fabrication also can be analyzed in terms of cognitive processes (see *Cognitive Archaeology*). Being an acquired ideomotor activity, stone knapping requires a period of apprenticeship, and involves the operation of certain psychomotor capacities. Research questions such as the following can thus be addressed: (a) the development of psychomotor capacities during the course of human evolution: For example, it has been proposed that the production of bifacial handaxes with regular edges and a symmetrical form, by evolved *Homo erectus*, required a propositional level of reasoning (Pelegrin), and/or Piaget's rational degree of intelligence (Wynn); (b) the recognition of different skill levels within a Paleolithic human group, indicating the activities of children and adolescents at different stages of apprenticeship, or a sexual division of activities (Pigeot, Ploux); (c) the recognition of different degrees of technical specialization during the more recent periods of prehistory, from an evaluation of apprenticeship duration based on ethnographic and experimental references (Roux) (cf. Berthelet and Chavaillon 1993, Sinclair and Schlanger 1990, Gibson and Ingold 1993, Renfrew and Zubrow 1994).

3. Conclusion

Since the 1950s/1960s, approaches to lithic artifacts have undergone a genuine revolution. Starting from the early antiquarian perspective, wherein the most 'characteristic' tools were selected *a priori* for the purpose of constructing 'chronocultural' sequences, our approaches to lithic technology have become both more refined and broader. They have been refined by considerable progress in methods of technological analysis of individual objects and of assemblages of objects. The development of practical knowledge through experimental analyses has played a major role in this progress. Approaches have broadened due to the ambition of archaeologists to enhance their field as a human science. From a more ecological and social perspective, researchers are interested in tracing the extraordinary diversity of human behavior since the dawn of humanity, and in understanding its underlying evolutionary mechanisms.

Litigation

1. Definition

Litigation is a highly structured process of dispute resolution that invokes the power of the state, or a contractually agreed to private decision maker, to provide a means to authoritatively adjudicate a dispute between two or more parties. In many countries in a large proportion of disputes or cases involving litigation, the parties reach resolutions without completing the full litigation process, either by voluntary settlement, abandonment by one party, or some intermediate authoritative decision that short circuits the full process. Unless there is some legal requirement that the adjudication process be invoked, there is typically an even larger set of disputes that never enter into the formal litigation process but which are resolved with the knowledge that the process could be invoked. Most cases of litigation involve disputes among private parties, either individuals or organizations (businesses, corporations, etc.). Some cases involve the government as a party to the dispute, and, especially in federal systems, the parties on both sides of a case can be governmental entities.

Adjudication involves three key elements: (a) authoritative resolution of a dispute, (b) by a neutral third party, and (c) through the application of pre-existing norms or rules. While the courts customarily are associated with adjudication, there is nothing that limits adjudicatory dispute resolution to courts or other governmental bodies; private adjudication systems are common in many countries and transnationally. Also, while the pre-existing norms or rules most often associated with adjudication comprise what is normally called 'law,' there is nothing that precludes adjudication relying upon any agreed upon set of norms or rules, including those derived from custom or religious texts.

Litigation is a particular form of adjudication that is based on a set of formalized procedures. Formalization is a matter of degree. There are forms of adjudicate dispute resolution that dispense with most aspects of formalized process; examples include small claims courts, qadi courts, or other kinds of community-based courts. On the formality continuum, there is no bright line separating what is appropriately labeled litigation and what is not.

When a governmental entity serves as the adjudicator and oversees the litigation process, it is most often a court. In some governmental systems, the courts are formally independent of the other branches of government, while in other systems the courts are more integrated into the executive. Even in systems where the courts are independent of the executive, there are often specialized adjudicatory forums within the executive, possessing varying degrees of independence. What is labeled a 'court' in one system, may be labeled a 'tribunal' or a 'commission' in another. For example, in Germany, there is a system of 'labor courts' to handle litigation involving many types of disputes arising from the workplace; in Britain some of the cases that would go to labor courts in Germany go to 'Industrial Tribunals' and in the United States the forum is called a Labor Relations or Employment Relations 'Commission' or Workers' Compensation Board. Even within a single country, one finds entities labeled as 'courts' (the US Tax Court) or as something else ('Tax Appeals Commission') where both are

involved in similar adjudicatory activities. Thus, while the 'court' label is usually linked to litigation, that need not be the case.

For a dispute-resolution process to be a form of litigation it only requires that the method of resolution be adjudication as defined above and that there is a formalized, structured process governing the forum's activities. Litigation involves a wide range of issues, and the cases range from the most routine, mundane disputes, to mega-disputes involving large numbers of people or huge sums of money, or both. Because of this range, generalizations are difficult, and it is best to think in terms of multiple worlds of litigation reflecting differing scales of activities and issues.

2. *Theoretical Issues in Understanding Litigation*

The highly structured nature of litigation derives form a combination of rights, procedures, and incentives. Each of these elements influences who uses litigation, when they choose to use it, and the specific nature of the litigation process.

2.1 *Rights*

Rights refer first of all to who is granted access to the mechanism of litigation. In the United States and Canada there are complex rules governing who has 'standing' to bring an action in (federal) court, and under what circumstances they may bring that action; under the US Constitution, the jurisdiction of federal courts is limited to 'cases and controversies,' and only those who are in fact affected by the case or controversy may bring an action. In other countries (e.g., Israel or Germany) many kinds of actions can be brought by persons who have only a tangential connection to harm or the issue in dispute. In still other countries litigation is used regularly as a means of obtaining advisory opinions from judicial bodies, and there need not be any immediate case or controversy in the American sense.

The legal rules and norms within a country or jurisdiction control the kinds of substantive issues subject to litigation. For example, in England tenants often have what amount to a property interest in their tenancy; this can lead to costly disputes and litigation over whether or not a property owner can obtain the use of property held under such a tenancy. In the United States there are very detailed protections afforded certain categories of employees, and there is significant litigation over those protections; in England there are many fewer specific protections, but a more general limitation on an employer's ability to discharge employees without just cause.

In addition to whether or not there are issues that are subject to litigation, the question of whether there are avenues of redress other than litigation is extremely important. In England, consumers may bring claims for defective goods, but they may also turn to authorities to enforce criminal laws vis-a-vis the duties of sellers of consumer goods (i.e., consumer protection can be dealt with under criminal as well as through civil litigation). Despite substantial social and cultural similarities, litigation over torts arising from auto accidents is lower in the Netherlands than in neighboring areas of Germany in part because insurance companies in the Netherlands have institutionalized mechanisms for resolving claims without litigation.

The remedies available also have a great deal to do with whether or not litigation is invoked. In the United States, mass disasters such as fires, airplane crashes, and the like typically result in litigation because American law provides substantial remedies to the victims of such events. In contrast where remedies are severely limited, litigation is less likely. For example, in 1987, an English cross-channel ferry capsized due to crew negligence resulting in almost 200 deaths; English law strictly limited damages, and the ferry company and its insurers quickly resolved the victims' claims. A second example of the impact of available remedies involves persons in the United States claiming job discrimination on some basis other than race. Until the early 1990s civil rights laws limited remedies to lost wages and/or reinstatement; this typically made litigation an unattractive option. In 1991 legislation was passed permitting punitive damages in intentional discrimination cases making redress through litigation more feasible.

2.2 *Procedures*

A set of rules of procedure govern litigation, whether in a court, an administrative tribunal, or a private setting. These rules determine the form by which litigants initiate claims, provide for mechanisms to inform and establish jurisdiction of defendants/respondents, set procedures for gathering the information necessary for the adjudicator to reach a decision, and establish decision-making rules (standards of proof, who makes the decision, etc.). Procedural rules also determine the availability of aggregation procedures (e.g., class actions), who bears the burdens of the cost of litigation (i.e., fee shifting), and who actually serves as the adjudicator of issues of fact and issues of law (professional judges, lay juries, some mixed form). Specific rules may be set by the forum, by the parties, or by some combination of the two, depending upon the structure of the forum.

While there are many variations in specific rules, there are two very broad approaches to litigation which are associated with the two dominant legal traditions: common law systems and civil law systems. The former is built on a model of party adversity, with the adjudicator playing an umpirial role; the parties

and their agents primarily control the flow and process of litigation, with the adjudicator receiving what is offered and forming a decision based on what the parties present. The latter is built on a model variously described as 'inquisitorial' or 'investigatory,' where the primary responsibility for determining and requesting information lies with the adjudicator. Under the common law system, the formal adjudication tends to be concentrated around an event called a trial when the two sides bring in their evidence and witnesses for presentation to the adjudicator. Under the civil law system, the formal proceedings are more episodic with the adjudicator determining what additional evidence he or she would like to see based on what transpires at a particular session. A second major difference between the two traditions is the relative balance placed on oral vs. written processes, with common law procedures involving a heavier oral component while civil law countries emphasizing written materials. Developments in recent years have moved the two systems closer together, with more effort in civil systems to reduce the episodic nature of adjudication procedures and reduce the burden or producing written materials, while common law systems have moved toward increased reliance on written materials.

The specific rules create a vehicle for analyses of litigation by social scientists. These analyses may be process-based, building on the flow of litigation; one approach models litigation as a series of stages and transitions, with litigation progressing from the initial harm through the initiation of a dispute into the formal litigation process culminating in a trail and possibly and appeal. Other analyses rely on tools such as game theory and economic modeling. These latter analyses provide predictions of relative advantages and disadvantages created by the rules, and provide models of how the parties and their agents should behave under assumptions of economic rationality and uncertainty.

2.3 Incentives

Litigation frequently has significant financial implications, in terms of the costs of litigation and/or the resulting remedies. The result is a set of incentives which serve to structure the decision-making of the parties and their agents. The first incentive is the likelihood of success, both in terms of 'winning' and in terms of obtaining the desired redress; those who must bear the cost of litigation are sensitive to whether or not the litigation will succeed. The second incentive is the size of potential remedies, which is a function of the severity of the alleged harm, the law or rules governing the awarding of remedies, and possibly the nature of the adjudicator of the remedy: professional, lay, single, or group, expert, or nonexpert. The third incentive is the costs associated with litigation: institutional fees, costs of representation, and expenses for investigation, experts, etc. The fourth incentive is the nature of the payment system for legal representation: *private payment* based on effort, *payment contingent on success* either on a percentage/commission or some other basis, or *third party payment* such as legal aid, legal insurance, or some other type of group assistance; closely related to payment system is whether or not there is a system of partial or full fee shifting ('loser pays'), and how the level of attorneys's fees is set (relation to size of case, outcome, amount of processing involved).

As with procedure generally, incentive structures lend themselves to economic analyses. Extensive formal analyses have been made of rules governing cost allocation and their expected impacts on decisions to litigate, decisions to go to trial or to settle, the likelihood of frivolous litigation, and the role of attorneys. In addition, to theoretical analyses, procedural rules and the resulting incentives have been the subject of extensive empirical analyses, most heavily in the United States, but also in England.

2.4 The Role of Uncertainty

One of the central features of litigation is uncertainty, and the decisions of actors in the litigation system must be made in light of this uncertainty. Both the degree and source of uncertainty vary depending on rules, the substance of the case, and the general structure of the system. Key elements of uncertainty include: which side will the adjudicator favor, the size or nature of the remedy that the adjudicator will award, the length of time the litigation process will take, and the costs that will be incurred. Part of the uncertainty reflects the strategic nature of all conflict, and part of it reflects the introduction of a third party neutral decision-maker, combined with formalized procedures for influencing that decision-maker. Uncertainty creates risk, and the parties involving in litigation differ significantly in their ability and willingness to bear the burdens created by risk.

3. Empirical Results Concerning Litigation

The most extensive empirical research on litigation has been carried out in the United States, although there are also bodies of empirical litigation focusing on litigation from other common law countries, many European civil law countries, and countries from other regions of the world (Japan, India, the Phillippines, etc.).

3.1 The Likelihood that Disputants will Turn to Litigation

Research from a variety of countries consistently has shown that relatively small proportions of most disputes eventually invoke formal litigation pro-

cedures. The exceptions involve certain types of cases which by law require formal court action (e.g., dissolution of marriage in many countries), but those types of cases frequently involve only *pro forma* court action. Particularly in common law countries, the image of the filtering process has often been cast as a 'Disputing Pyramid,' with 'injuries' lying at the base of the pyramid, and final adjudicatory resolution at the top. The base of the pyramid is broad and the upper areas are narrow; most of the variation whether by type of dispute or country, tends to come in the middle regions of the pyramid, reflecting a combination of incentive structures and alternative avenues of redress.

The initiation of litigation presupposes that an injury is perceived, that responsibility for the injury is externalized, and that a grievant (or an agent of the grievant) seeks redress. Most research in common law countries shows substantial attrition from potential claims to act claims, often reflecting that injured parties are never aware that they have suffered an injury, do not attribute to someone else the responsibility for the injury, or do not initiate a claim because of a belief that redress is not practical or it is not needed given alternative sources of compensation. As suggested above, even if litigation is initiated, most cases end before final adjudication. Settlements occur in what has been dubbed the 'shadow of the law' and they reflect anticipations of what judges or juries will decide.

In civil law countries, the adjudicator plays a more central role and multilevel review is a more integral and usual part of the process. As a result, there are many more adjudicators in civil law countries; the perceived quality of judges making the initial decision is lower in civil law countries compared to common law countries where judges are relatively small in number and are chosen selectively after years of legal practice. In civil law countries, it is relatively easy to get an initial court decision because the judge controls the process; in common law countries, obtaining an initial court decision is more difficult and costly because the parties can fight each other every step of the way. However, in civil law countries, appeals are more common, making the economic advantage of one system over another unclear. In common law countries the emphasis in the civil justice process is on proof provided by the parties; in civil law systems the emphasis is on logical reasoning by the judge.

3.2 Cross-national Patterns in Litigiousness

The United States has a reputation as particularly litigious. This in part reflects the important role of law and courts in the United States from its beginning. However, systematic evidence indicates that the supposed exceptionalism of the United States is either changing or is overstated. Fig. 1 shows estimated litigation rates circa 1990; clearly there is substantial variation among countries in the use of litigation, and the US, while at the higher end of the distribution, does not stand out as exceptional.

Figure 1
Litigation rates around the world. (Source: Wollschlager C 1998 Exploring global landscapes of litigation rates. In: Brand J, Strempel D (eds.) *Soziologie des Rechts: Festschrift fur Erhard Blankenburg zum 60. Geburtstag*. Nomos, Baden-Baden, Germany, pp. 587–88)

Many explanations for the variation have been advanced. These include stage of economic development, institutional structures, national cultures, alternative remedy systems, and incentive structures. For example, Japan frequently is cited as a country with a very low litigation rate. One explanation for this is that within Japanese culture there is an imperative to avoid conflict, and hence litigation. An alternative explanation is that events such as automobile accidents are dealt with in a way that avoids the need for litigation. A third explanation is that the Japanese elite intentionally has restricted access to litigation as a form of redress.

One general problem with comparing litigiousness is the baseline that should be used. Almost all studies rely on per capita litigation rates. However, litigation arises out of very specific types of events the number of which is not simply a function of population. For example, product liability litigation arises from events involving products that are purchased; a country with a higher rate of material consumption may have a higher per capita rate of product liability litigation simply because the transactions that might give rise to such litigation are more common. The problem of using baselines other than simple population is almost never addressed because of the difficulties of developing such alternative baselines.

3.3 The Role that Litigants and their Agents (Lawyers) Play

Decisions to initiate litigation typically are made by litigants in consultation with their legal advisors. Two elements dominate the decision to litigate. The first is the need to finance the litigation. The second is the likelihood of success, both in terms of whether the desired decision can be obtained, and whether the decision will be enforceable. Research throughout much of the twentieth century has shown consistently that a key element in obtaining redress in tort cases is the availability of a source of payment, either a wealthy defendant or insurance coverage.

Where the potential litigant must directly finance the litigation, the decision to initiate litigation will lie almost entirely with the potential litigant. Lawyers may seek to dissuade potential litigants from pursuing the claim, citing the financial, time, and emotional costs as well as the uncertainty inherent in the process. Where the cost, or at least the risk, of the litigation is to be borne by some other actor, these actors will typically be more involved in the decision to proceed. For example, in the United States where much litigation is funded by the lawyers through the mechanism of a contingency fee, the lawyers' decisions whether or not to accept cases are crucial, and lawyers turn down at least as many cases as they accept. When some third party will cover the litigation expense, such as an insurance company (through litigation expense insurance) or legal aid or a trade union, the third party will need either make the decision whether or not to proceed or require that it be allowed to review and veto any decision to proceed. These decisions are determined by a combination of likelihood of success and the amount at stake.

3.4 Nature of Litigants

The nature of litigants typically varies depending on the type of case. Tort (injury) cases are dominated by individuals as plaintiffs while contract cases more often involve businesses as plaintiffs. Defendants in tort cases are often nominally individuals, but most individual defendants are insured and the insurance company becomes the effective defendant. In contract cases defendants are distributed among individuals and organizations, with variations depending on the exact nature of the issue at stake.

Litigants are not created equal. Litigation typically requires resources and expertise, and analysts have argued that this advantages the wealthy. Galanter (1974) distinguished between 'one shot' and 'repeat players' in litigation, arguing that the repeat players should be expected to win more often than 'one shotters.' While some of the advantages of repeat players reflect resources, other advantages reflect the ability of the repeat player to take a long-run view of litigation. The result is that repeat players are more able to 'play the odds' (i.e., they can act as risk neutral participants), and more able to 'play for rules' (i.e., try to establish precedents that will work to their advantage over the long run).

The importance of the one shot versus repeat player distinction for understanding how litigants behave is further enhanced by dividing the repeat player into the 'government player' which may have even fewer economic constraints than other repeat players, and the 'routine player' for whom litigation is genuinely a part of doing business (e.g., the liability insurance company) and who cares little about the outcome of individual cases as long as it is able to comfortably predict the likelihood of winning and losing. Yet another type of 'repeat player' is the political interest group which uses litigation for explicitly political purposes. While this is most often discussed in the American context, it is by no means unique to the United States; particularly as politics becomes more judicialized, these types of litigants are becoming both more common and more important. Developments such as the increasing role of the European Court of Justice reflect and encourage these changes. Notably, while there has been an increase in 'interest group litigation,' the evidence is inconsistent on whether interest group involvement increases the likelihood of success or whether when successful in court interest groups achieve their ultimate goals.

3.5 Litigation Process

Research on the process of litigation is generally nation specific because the process is so closely tied to the rules governing that process. Some of the research focuses on the handling of specific types of cases, such as injury cases or divorce cases. Much of this research focuses on the role of the lawyer in the litigation process, and how lawyers relate to their clients; there is disagreement over the degree to which lawyers domi-

nate in the decision making process. Other studies focus on specific aspects of litigation, such as the impact of specific rules, the role the judge plays in questions other than adjudication, or problems in aggregating claims. There is no theoretical framework or argument tying together this disparate research which is heavily concentrated in the United States.

3.6 Winning and Losing in Litigation

A natural issue in the study of litigation concerns the outcome: who wins and who loses, and why? The definition of winning and losing is problematic: should outcomes be measured in absolute terms or relative terms? If a plaintiff (the initiator of litigation) obtains some redress from the court, has the plaintiff 'won'? What if that very same result could have been achieved without litigation, and what the plaintiff sought was something more which it failed to achieve? What if the only reason it could have achieved that lesser result was that the option of litigation existed? With relatively few exceptions, studies of litigation outcome ignore these complications. A second problem is that, particularly in common law countries, the final resolution of litigation is most often a private agreement among the parties. Those cases resolved through formal, final adjudication tend to be a small, nonrepresentative subset. Some scholars argue that the cases resolved through trial are those where uncertainty is high or there are strongly conflicting views of the likely outcome. Others argue that some types of parties avoid adjudicatory outcomes intentionally when the result will produce unfavorable results, and concentrate their adjudicatory efforts on cases that will produce favourable precedential outcomes.

Many studies have looked at the relative success of different types of litigants, and while the majority of studies have found that repeat players are more successful than one shot players, the patterns reveal major complications. First, the largest gaps tend to come not between repeat players and one-shot players but between government litigants and nongovernmental litigants. Second, few researchers ask the question of whether one shotters are better off with or without litigation as a means of dispute resolution, that is, litigation must be assessed not just internally but externally vis-a-vis its alternatives. For example, are persons injured through medical negligence better off with litigation as the means of redress, or relying upon the goodwill of medical providers, or with a system of insurance that provides for medical expenses, loss of wages, etc.?

In the United States there has been substantial research on the outcomes of civil trials, particularly those trials decided by juries. Some of these studies focus on civil cases generally, while others focus on single areas such as medical malpractice or products liability. Typically, these studies show a large proportion of verdicts or decisions involving modest amounts of money, but with a distribution showing an extreme tail (i.e., a small number of very large verdicts). While over the broad range of cases, plaintiffs win about half the time and defendants win about half the time, the studies also show a range of plaintiff success depending on the nature of the case reflecting in part whether the uncertainty is over liability or the amount of damages. Research looking at decisions of American trial judges vis-a-vis questions such as liability and damages is much less common; what research there is shows that judges are more likely to find for the plaintiff although the typical judge's award is about 20 percent less than the typical jury's. A danger in all of these comparisons between decisions by judges and decisions by juries is that the cases decided by judges and juries are probably not comparable because litigants themselves choose between the two types of trials.

Another line of research in the US focuses on the substantive decisions of judges in civil cases. This research typically relies upon the examination published decisions by federal trial judges, and distinguishes between decisions described as 'liberal' or 'conservative' (using contemporary American notions of this continuum). The core results of the research demonstrate that there are measurable differences in outcomes depending on whether judges are identified with the Republican or Democratic parties based on either their own affiliation prior to appointment or the affiliation of the President who appointed them. One recognized problem with this research is that published decisions differ from the full population of decisions made by federal district judges in civil cases, and results differ when unpublished decisions are included in the analysis, reducing or eliminating the relationship between decisions and partisanship.

While substantial attention has focused on formal adjudication by judges and juries, less attention has been directed at the outcomes of cases resolved short of adjudication. Part of the reason for this is that determining outcomes is more difficult because they are not part of the public records. A number of empirical studies have focused on the settlement process, both in the United States and elsewhere, generally showing that economic considerations (likelihood of success, who is bearing costs, the magnitude of costs both absolutely and relative to stakes) combined with risk preference are central to understanding settlement. Simply put, cases will tend to settle when the plaintiffs net expected gain (recovery discounted by probability of success *minus* expected costs) is less than or equal to the defendants expected loss (pay out discounted by probability of plaintiff success *plus* costs). When stakes are relatively small, this is almost always true, and it is frequently true for larger cases even when there is substantial disagreement about the likely outcome. It is less clear to what degree the intervention of court officials can influence

the settlement process, in no small part because such a large proportion of cases settle regardless.

Litigation: Effects on Medical Research

Litigation, broadly defined, is the process where two parties attempt to settle a dispute by court action. The general objective is to obtain a judicial decision about which party's claim is legally stronger. This article considers how litigation has affected medical research. It highlights the concerns of researchers and research subjects about court decisions regarding their rights and liabilities, and how this may have affected their approach to research. The main regions in focus are the USA, Europe, and the Commonwealth countries.

One general area of concern is the nature of dispute resolution in the courts. The ability of parties to argue fairly in an atmosphere that is competitive, stressful, and expensive and the efficacy of legal norms about justice and truth have been widely discussed in critical legal studies literature as well as in media reports. There is a common view that litigation better suits the strategies of powerful, well-resourced parties, and hence has a tendency to determine justice according to their interests. These issues are not addressed in detail in this article as they are not peculiar to the research relationship. This article examines, from a sociolegal perspective, the content of court decisions about medical research and the way that judges have developed legal rules that govern, and hence shape, the experience of research. It considers the claims that judges' decisions have led to legal defensiveness in research and participants' unwillingness to volunteer.

A significant point to note is that there is no clarity about the effect that litigation has had on medical research. On the one hand it is claimed that while court decisions have been aimed at justice, the law in practice has led medical researchers to be anxious and disillusioned, and consequently have limited their innovativeness and medical progress. On the other hand it is claimed that research subjects are concerned about the strength of their legal rights and this makes them reluctant to participate in medical research. There is little empirical data to support either the view that the quality of medical research has diminished, nor whether the effect is due to direct or indirect court-imposed constraints on innovativeness or participants' rights. Thus the competing accounts of the effects of litigation on medical research are inconclusive. Nevertheless it is informative to consider the main areas of law that are reported as being structural evidence for litigation's impact on the relationship between researcher and subject.

1. Compensation for Harm Caused by Medical Research

Medical research inevitably results in some injuries and harm to research subjects irrespective of the care and caution taken. It is a natural consequence of the search for new knowledge. Some researchers have insurance cover, and funding bodies occasionally have a policy of offering limited payment for injuries that were caused by the research, but this is far from universal. However, to receive large sums of compensation, research participants have needed to litigate in the courts.

The compensation cases are usually based on product liability laws, the law of negligence, or insurance contracts. To win their case, the injured person has to prove as a bare minimum that their injury was 'caused' by the medical research and not due to any alternative causal agent like environmental pollutants or underlying disease. 'Causation' has a technical meaning in the law. Suffice to say that it can be difficult to prove legal causation because the typical side effects complained of can be caused by many things and, in therapeutic research, patients are ill to begin with.

Research participants feel that courts require them to prove too much in order to get compensation. They think that their altruism in being a research subject entitles them to easier access to compensation. Researchers feel that they carry the burden of legal liability and that it should instead be spread across the whole community through health insurance or no-fault compensation schemes since medical progress benefits everyone, not just the researcher. They are also alarmed by the variety of legal rules through which they can be called to account, and would prefer more integration and certainty.

This sort of experience could naturally be expected to cause a degree of tension in the research relationship. For example, researchers might be increasingly defensive in their work, and volunteers reluctant to participate. However, the extent to which compensation cases have affected medical research is open to doubt. In the USA, there have been a substantial number of compensation cases about innovative treatment (Siegler et al. 1987), and widespread calls for reform of this area of law. However, there is little evidence of an actual impact on the quality of research, medical progress, or the relationship between research and subject. Furthermore, while liability for compensation has been a significant topic of debate in the USA, it has had a much lower profile in most other countries, which have seen far fewer compensation cases.

2. *Informed Consent*

A shared concern for researchers around the world is the courts' interpretation of 'informed consent.' All research guidelines emphasize the need to obtain prior informed consent from research subjects. Additionally researchers are anxious to avoid liability for assault or bodily trespass for failing to have legally valid consent prior to research involving internal or external body contact.

Court decisions have caused researchers considerable concern because of the demanding levels of communication that they require. A participant must not only be provided with information about the material risks, but steps must also be taken to ensure that they understand that information. Furthermore, consent must be sought without any coercion or inducement, otherwise it will not satisfy the legal requirements of a decision made by free will. The courts have justified these standards on the basis of the importance of individual autonomy. In medical law cases the court has noted that the community expects a less paternalistic relationship with medical professionals than existed in the past.

The medical and research professions complain that this interpretation stifles medical research by imposing impractical and unrealistic standards of consent, and by failing to recognize the utilitarian justifications that exist in the context of medical research. Put briefly, in some cases research participants do not have sufficient scientific understanding to understand the risks, regardless of how much information is provided to them. In other situations, research will inherently have an element of inducement because the mere fact of participating in the study will mean that the patient will receive medical attention that they would not have otherwise had (e.g., where the research methodology involves frequent monitoring or is set in Third World countries).

Researchers are concerned that the effect of court decisions is to rest a heavy burden of potential liability on them. Despite obtaining apparent consent from participants, they may not have met the strict tests of the law. Furthermore, researchers argue that there are certain research studies where obtaining consent would skew research results (e.g., in population studies, or in behavioral studies where subjects' lack of awareness of the research is a critical factor). Therefore, certain exceptions to the consent requirement should be recognized. The exceptions recognized in ethical guidelines are not necessarily recognized by the law.

It is said that the risks of liability for failing to obtain legally valid consent threaten the continuation of research in these areas, albeit they are important research projects with potential benefits for many more people than just the research subjects themselves. Two points should be noted. First, what is a consent burden on researchers is a consent protection for research participants. Thus the effect of litigation about consent cannot be easily categorized as negative or positive. Secondly, there have been very few cases decided where the facts related to medical research rather than consent to treatment (cf. the Canadian case of *Halushka vs. University of Saskatchewan* (1965) 53 DLR (2d) 436). Thus the law relating to consent in medical research is unclear. Researchers could be anxious about a form of liability that the courts will not enforce in view of the public interest in research. This points, though, to one of the general difficulties of court-made law, namely that prior to a binding precedent being set, the law is often ambiguous and uncertain.

3. *Confidentiality and Privacy*

For many years, laws about confidentiality have been largely established by court decisions, as there was very little legislation on this topic. It is clear that legal obligations of confidentiality apply to the doctor–patient and researcher–participant relationship. Researchers have been particularly concerned about the effect of these laws for research that evaluates personal information in medical records. Frequently, a researcher will wish to use information that has already

been collected from individuals for a purpose other than research (e.g., during a general medical consultation). Consent to disclose the information for research purposes will not have been obtained at the time the information was collected. It can be very impractical, sometimes impossible, to work within the courts' interpretation of confidentiality and contact the individuals for their consent to use their record in the research project. For a start the researcher must locate records that belong to a doctor who is willing to spend time identifying and contacting relevant patients, because this process involves looking through confidential details and may not be carried out by an external researcher. Secondly, the contact details will often be long out of date. To proceed without the individuals' express consent leaves the researcher open to liability that is said to be sufficient to deter many.

Research participants, on the other hand, have been getting increasingly concerned that the courts are too lenient about privacy rights beyond nondisclosure. For example, they argue that there ought to be additional standards about data security and aggregation of data held in databanks. In recent years, the privacy movement has successfully motivated governments to enact statutes and protocols with standards for the collection, use, disclosure, security, personal access, and linkage of personal health information. There are limited concessions for medical research in these rules. In many jurisdictions privacy commissioners or data protection commissioners have been established.

4. *Property Rights and Patents*

Court decisions have also had a major impact on the way in which researchers collect tissues and organs for research. One of the most influential cases that has been discussed extensively across the world was *Moore vs. Regents of the University of California* 793 P. 2d 479 (Cal SC1990). In this case a doctor at a university hospital developed a cell line from cells he took from his patient's spleen during an operation. Although the patient had consented to the spleen operation, he had not consented to the use of his cells in research. The cell line was patented and the patient claimed a right to the profits. The court rejected the argument that the patient owned his own body cells. This aspect of the court judgment reinforced the legal norm that patients have no claim to the profits of research despite the fact that they 'invest' their bodies in research. Only those who invest money or professional skill have a claim. This case highlighted the commercial tensions that exist between researchers and participants and dispelled any myths of pure altruistic motivation on the part of either.

The case also had an impact on the relationship between a research subject and a researcher who is also that subject's treating doctor. Although the court said that Mr. Moore did not have property rights in the medical invention, he was nevertheless awarded compensation. The court held that if a doctor treating a patient simultaneously pursues his or her own research for economic gain, the doctor breaches the special legal duties that doctors owe their patients (called 'fiduciary duties'). This decision thus put 'doctor-researchers' on notice that they have a particularly strong obligation to obtain the consent of their patients prior to research, not only to permit interference with their bodies and use of their personal information, but also to keep control of subsequent intellectual property rights and to avoid a serious breach of their professional standards.

The Human Genome Project, which aims to map human genes, has heralded a new wave of controversy about social distribution of biomedical research profits. There have been many court challenges about patents that have been granted by patent offices for human gene sequences. The decisions of US courts have had a global impact. Courts in the USA have upheld the validity of these patents, notwithstanding technical legal arguments about novelty and inventiveness, and submissions that the practice was unethical. This has put considerable economic pressure on other countries to follow suit.

A significant question is whether research participants ought also to profit from a patent that is based on the participant's body but which relies on the researcher's skills and ingenuity. The orthodox position is that research subjects are instruments of research that have rights to human dignity but not to financial profits. It is argued that to change this would radically change the incentives to invest in research to the point of threatening its continuation. Others claim that legal protection of property rights over gene sequences stymies research because new knowledge is disseminated more slowly and small firms are priced out of the market since they cannot afford to license patented knowledge. The empirical evidence is entirely inconclusive.

These landmark court decisions about property rights in human tissue continue to have major reverberations. There have been several recent and highly controversial inquiries in the UK to investigate reports that hospitals have been routinely compiling banks of human tissue and organs from deceased patients (including babies) without the consent of the patients' families and using these for research purposes. The public's shock at the prevalence of this practice has had significant implications for the community's trust in the medical and research professions.

5. *Subpoenas*

Further areas where litigation has generated concern is the ability of parties who are suing or defending a

claim to issue subpoenas for oral and documentary evidence to be given by researchers (Fischer 1994). Not uncommonly the effect of the subpoena is to coerce the researcher to disclose confidential research to a party whose motivation for seeking the information may be questionable. Not only is cross-examination in the courtroom a harrowing experience, but compelled disclosure under subpoena also affects the researcher's ability to release 'fresh' results for publication or intellectual property rights. Some believe that the strategic use of subpoenas to compel release of research has the potential to discourage research in economically or politically sensitive areas. This has been a concern reported in US literature, but less so in other countries despite the similarity of laws on subpoenas.

6. *Putting the Concerns in Perspective*

The discussion above has highlighted the main ways in which it is claimed that court interpretations of the law have affected the practice of medical research. It is important, however, not to form an exaggerated view of the effect of litigation.

There are in fact relatively few court cases about medical research. One US study that systematically reviewed the incidents of medical research litigation in medical faculties and academic medical centers found only 43 cases in 41 years in all US state and federal courts (Helms and Helms 1993). Also the frequency of medical research cases would seem to be considerably less in other countries. Books and articles about legal issues in medical research rarely refer to more than a handful of court decisions.

As noted in the introduction, there is little empirical evidence to sustain the view that the court decisions are actually stifling medical research. The concerns of researchers and patients about the effects of litigation reported above are generally based on anecdotal experience. Naturally, to reinforce their concerns, researchers and patients argue that there is, or is likely to be, a causal link between their concern and the future progress of medical research. However, this has not been established.

Litigation is, in fact, only one part of the regulatory framework for medical research, and its impact cannot be assessed without considering it relative to other forms of regulation. The reality is that medical research is regulated mainly through a system of self-regulation largely controlled by the medical profession with very little involvement by the courts (Moran 1993). The principal avenue of regulation is the process of review by a research ethics committee (sometimes called an institutional review board or human subject committee). This local level of regulation has the most direct and frequent impact on medical research. It determines which projects proceed, which types of patients are recruited, and how the recruitment and research takes place.

The courts are rarely involved for several reasons. The ethics committees are nonstatutory and owe no statutory duties. While they are arguably required to follow rules of administrative law, these relate mostly to procedural breaches rather than substantive rights. Information to establish court cases is also scarce because the committee proceedings are generally held in private. The ethical guidelines enforced by the ethics committees are generally policy documents of professional associations, regulatory agencies, or central government and are not generally reproduced in legislation. Therefore, they too fail to sustain any substantive legal rights and obligations that might be litigated in a court. There are few, if any, sanctions in legislation for breaching the guidelines. Instead, non-compliance is deterred, because it might cause funding to be cut, journals to refuse publication, or give rise to a finding of professional misconduct. However, having noted the limited court involvement in enforcement, it would be an oversight to fail to note the profound influence of one court in propagating the ethical guidelines, namely the Nuremberg Military Tribunal whose decision in the Nuremberg war crime trials in 1946 was transposed into the international treaty on medical research known as the Declaration of Helsinki (adopted by the 18th World Medical Assembly, Helsinki, in 1964 and revised by the Declaration of Tokyo, adopted by the 29th World Medical Assembly, Tokyo in 1975), and subsequently into many self-regulatory research guidelines (Kennedy and Grubb 2000).

The self-regulatory system of medical research has been frequently criticized and may explain (any) disillusionment in medical research more than the effects of litigation. For example, it would seem that the committee review is often cursory and rarely extends beyond examining issues of informed consent because the committees are underresourced. The process rarely requires researchers to submit regular follow-up reports to confirm compliance with the approved research protocol. It is not uncommon for the committees to have too many members, too few, or a pattern of representation that does not accord with government guidelines. The enforcement mechanisms are weak and have limited application to research whose success does not depend on state funding or publication. There can also be an extraordinary degree of bureaucracy for research involving a broad geographical ambit, if the researcher must approach several local ethics committees (Nicholson 1997, Jamrozik 2000).

Although there are frequently calls for reform of the primarily administrative review of research, the proposed alternatives do not include greater court involvement. Most propose a stronger form of self-regulation with legislation, policy guidelines, the backing of state agencies, and more accountable research

review committees. This has also been the case with privacy and confidentiality in medical research (see Sect. 3).

7. Conclusion

In summary there are many reasons to consider that litigation may have had a significant impact on medical research and altered the approach of both researchers and research subjects. This article has explored the principal court decisions that underpin the view that litigation has had such an effect. However, it has also noted that courts are involved in just a few pockets of the mainly self-regulatory framework of research, and have had more particular impact in North America. Further empirical field research is necessary before the claims that litigation is stifling research could be substantiated. In fact this work may well support the contrary view that recourse to litigation is an important safety net for the protection of fundamental human rights and enhances the experience of medical research.

Llewellyn, Karl Nickerson (1893–1962)

1. Biography

Karl Nickerson Llewellyn was born in Seattle, Washington on May 22, 1893, though the family soon moved to Brooklyn, New York. At age 16, he went to Germany to study for 2 years, before entering Yale College in 1911. When World War I broke out, he was studying in Paris. Staunchly Germano-philic, he joined up with the 78th Prussian Infantry, was wounded later in 1914, and subsequently received the Iron Cross! Returning to Yale, he completed his undergraduate studies and enrolled in Yale Law School, from which he graduated in 1918. Wartime absences of faculty and students led Llewellyn to stay on at Yale for 1918–19 as editor-in-chief of the *Yale Law Journal* and as a part-time instructor teaching, due to curricular needs, commercial law—the field in which he would later become the most influential American figure of the twentieth century. He began working as a lawyer for a New York City bank in 1920, soon joining the prestigious corporate law firm of Shearman and Sterling. He joined the Yale faculty in 1922, moving to Columbia Law School in 1925; Columbia was then a fertile ground of the new 'Legal Realism,' a movement in which Llewellyn soon emerged as the major figure. He taught at Columbia until 1951, though he spent the academic year 1928–29 once again in Germany, as a visiting professor at Leipzig. During this time, he became better acquainted with the German 'free law' movement, which influenced Llewellyn's conception of Legal Realism. In the 1930s, he worked with an anthropologist doing fieldwork on American Indian law, as well as producing voluminous scholarship in commercial law. From the 1940s until his death, he made his seminal contributions to the Uniform Commercial Code. He moved to the University of Chicago Law School in 1951, which also hired his second wife, Soia Mentschikoff, herself an accomplished legal scholar. He spent the remainder of his career at Chicago, where he died of a heart attack on February 13, 1962.

2. Llewellyn and American Legal Realism

Llewellyn was the most important and famous figure associated with the American Legal Realism of the 1920s and 1930s, a movement that transformed the way both academics and lawyers thought about law. The Realists argued against the dominant 'mechanical jurisprudence' or 'formalism' of the day, which held that judges decide cases on the basis of distinctively *legal* rules and reasons, which justify a unique result in every case. The Realists argued, instead, that a careful look at how judges *really* decide cases reveals that they decide not primarily because of law, but based on their sense of what would be 'fair' on the facts of the case.

Legal rules and reasons figure simply as post-hoc rationalizations for decisions reached on the basis of non-legal considerations.

2.1 Legal Indeterminacy

The Realists argued that the law was 'indeterminate.' By this, they meant that the available class of legitimate legal reasons did not *justify* a unique decision, especially in those cases that reached the stage of appellate review. Llewellyn argued for indeterminacy based on the existence of conflicting, but equally legitimate, canons of interpretation for precedents and statutes. So, for example, courts had endorsed *both* the principle of statutory construction that, 'A statute cannot go beyond its text,' but also the principle that 'To effect its purpose a statute must be implemented beyond its text' (Llewellyn 1950, p. 401). But if a court could properly appeal to either canon when faced with a question of statutory interpretation, then the 'methods' of legal reasoning (including principles of statutory construction) would justify at least two different interpretations of the meaning of the statute. In that case, the question for the Realists was: why did the judge reach that result, given that law and legal reasons did not require him to do so? Llewellyn (1930) made a similar argument about the conflicting, but equally legitimate, ways of interpreting precedent, which he called the 'strict' and 'loose' views of precedent. According to Llewellyn, a judge almost always had the latitude to characterize the decision of a prior case in a highly fact-specific way, so as to distinguish it from the present case, or to characterize its holding in a way that abstracted from the specific facts of the earlier case, so as to make it binding in the present case. Thus, a precedent never really constrained a judge in a later case, because he could construe it 'strictly' to distinguish it, or 'loosely' to treat it as binding.

2.2 Two Branches of Realism

All the Realists agreed that the law and legal reasons are often indeterminate, so that the best explanation for why judges decide as they do must look beyond the law itself. In particular, all the Realists endorsed the following 'core claim': in deciding cases, judges respond primarily to the stimulus of the facts of the case, rather than to legal rules and reasons.

There was, however, a division among Realists over the question of how to explain why judges respond to the underlying facts of the case as they do. The 'Sociological' Wing of Realism—represented by Llewellyn (1930, 1960, 1962)—thought that judicial decisions fell into *predictable* patterns (though *not*, of course, the patterns one would predict just by looking at the existing rules of law). From this fact, these Realists inferred that various 'social' forces must operate upon judges to force them to respond to facts in similar, and predictable, ways. These social forces might include the economic background of the judges and their professional socialization experiences. It was these factors, rather than rules of law, that account for decisions and determine the responses judges have to the underlying facts of the case.

Llewellyn's focus was on the professional socialization and background of judges that would lead them to be sensitive to the norms of ordinary commercial practice. Focussing primarily on commercial law disputes, Llewellyn argued that what judges really do in these cases is try to enforce the uncodified but prevailing norms from the commercial culture in which the dispute arose. Llewellyn (1960, pp. 122–4) gave this famous example: a series of New York cases applied the rule that a buyer who rejects the seller's shipment by formally stating his objections thereby waives all other objections. Llewellyn notes that the rule seems to have been applied rather harshly in the NY cases, since either the buyers may not have known at the time of rejection of other defects or the seller could not have cured the defects anyway. A careful study of the underlying facts, however, revealed that in each case where the rule seems to have been harshly applied what had *really* happened was that the market had gone sour and the buyer was looking to escape the contract. The judge, being 'sensitive to commerce or to decency' (1960, p. 124) applies the unrelated rule about rejection to frustrate the buyer's attempt to escape the contract. Thus, the commercial norm—buyers ought to honor their commitments even under changed market conditions—is enforced by the courts through a seemingly harsh application of an unrelated rule concerning rejection. It is these 'background facts, those of mercantile practice, those of the situation-type' (1960, p. 126) which determine the course of decision.

Llewellyn's seminal work on the Uniform Commercial Code was informed by his Realist perspective (cf. White 1994). For example, the Code imposes an obligation of 'good faith' in all contractual dealings, which is defined as requiring not only honesty but also 'the observance of reasonable commercial standards of fair dealing in the trade.' But for a judge, then, to enforce the rule requiring good faith is just for the judge to enforce the norms of commercial culture! The reliance of the Code throughout on norms of good faith and 'reasonableness' is a constant invitation to the judge to do what he would, on the Realist theory, be likely to do anyway: enforce the norms of the prevailing commercial practice.

The 'Idiosyncracy Wing' of Realism, by contrast—exemplified most prominently by Frank (1930)—claimed that what determines the judge's response to the facts of a particular case are idiosyncratic facts about the psychology of that individual. Thus, Frank notoriously asserted that 'the personality of the judge

is the pivotal factor in law administration' (1930, p. 111). This view is hard to square though with lawyers' ability to predict rather well what judges will do (if they could not do that, litigators, at least, would be out of business). Despite its extreme nature and limited appeal to most Realists, Frank's view has come to dominate the current picture of Realism, to the extent that Llewellyn's far more typical 'sociological' approach is often neglected.

3. *Impact and Current Importance*

By calling attention to the role of nonlegal factors in judicial decision-making, Llewellyn and the Realists initiated the interdisciplinary turn in American legal education, and made clear the need for lawyers to draw on the social sciences in understanding the development of law and what judges do. Much contemporary political science literature on law and courts takes its inspiration from Realism by seeking to explain decisions not by reference to legal reasons (which are assumed to be indeterminate) but by reference to facts about the politics, background, and ideology of the judges (Cross 1997). Recently, it has even been argued that Llewellyn's own approach to commercial law anticipated the now dominant economic analysis of the business law fields (Schwartz 2000). This should hardly be surprising, though, since the economists seek to structure legal rules to maximize efficient outcomes, but efficiency is surely an important norm of all mercantile practice: thus, if judges enforce the norms of mercantile practice (as Llewellyn claims they do and should do), it will turn out that judges will try, among other things, to produce efficient outcomes.

Llewellyn's work on Native American law and dispute resolution practices (Llewellyn and Hoebel 1941) remains an anthropological classic, while his introductory lectures to Columbia law students (Llewellyn 1930) may lay claim to being the most widely read book on law by generations of American law students. While the Uniform Commercial Code (UCC), the single most influential piece of commercial law in the US, bears Llewellyn's imprimatur, it is often lamented in recent years that revisions to the UCC have moved it away from Llewellyn's original vision of a Code sensitive to actual commercial practice. Even so, the lawyers and scholars effecting these changes continually feel the need to grapple with Llewellyn's conception.

Within jurisprudence, Llewellyn's ideas have been subjected to extensive criticism by analytical philosophers (notably H. L. A. Hart), though more recently a philosophical defense has been mounted (Leiter 1997). Among legal scholars, however, Llewellyn's ideas remain influential, both in scholarly movements (like 'Critical Legal Studies' and 'Law and Society') that emphasize law's indeterminacy and the need to look at extra-legal factors to explain law, but also in the work of judges, who now attend to the specific facts of cases (the 'situation-types' as Llewellyn called them) and general nonlegal policy considerations much more openly than before the triumph of Realism in American law.

Lobbying

Lobbying describes the effort of organized interests to inform policy makers and to try to persuade them to choose particular policy choices. The term derives from an earlier time when legislators did not have their own offices. Representatives of organizations would station themselves in the corridors and lobbies to intercept legislators as they walked toward the legislative chamber. On one level lobbying is a communications process, whereby group representatives (lobbyists) or group members send messages that give those in government information favorable to the group's

cause. At another level lobbying is the exercise of a fundamental democratic freedom: the right of citizens to organize and to ask those in government to respond to their preferences. In the US, that right to lobby is enshrined in the First Amendment to the Constitution, which guarantees Americans the freedom to 'petition the government.'

Although lobbying is a basic freedom, it is not without controversy. In no society do all citizens possess equal resources, belong to equally effective organizations, or are equally well represented before government. Interest groups with more resources and higher status constituents are advantaged in the political process. They can lobby on more issues and they can lobby more extensively on the issues they choose to take up.

Citizens look unfavorably upon lobbying because they recognize that interest groups pursue policy goals which are best for their constituents, not necessarily what is best for the nation. Every time an industry group lobbies government for a tax break, that policy change comes at the expense of taxpayers who must make up the shortfall in revenue. Every trade advantage granted to lobbyists works to the detrimient of consumers who must pay the higher costs associated with reduced competition. In one poll of Americans, 64 percent said they regarded lobbying as a threat to democracy in their country. People conveniently ignore that the lobbies they belong to pursue selfish goals as well, believing instead their groups are working for the public good.

1. *Strategies and Tactics*

In studying lobbying political scientists have tried to determine what works best. They have looked at both strategies—broad plans of attack—as well as the tactics—the specific means of communicating with policy makers. Yet in spite of a considerable amount of research, scholars have made limited progress in assessing lobbying effectiveness. Such studies run into three difficult methodological problems. First, policy makers are loathe to admit that they were influenced by lobbyists or interest groups. An affirmative answer diminishes them and could even call into question their integrity. John Kingdon found that legislators he talked to discounted the importance of lobbyists in influencing their voting decisions, but said they were highly influenced by their constituents. On highly visible and important issues, legislators can easily determine how their constituents feel. On complicated and less salient issues, lobbyists help inform legislators and agency officials how their constituents and attentive publics feel. In short, we cannot take this rejection of lobbyists' influence at face value.

Second, much if not most lobbying is directed at policy makers who are already sympathetic to the group's goals. The most critical issue facing lobbyists may be getting sympathizers to actively work on an issue. Lobbying is also directed at fence sitters and those who may have even expressed some doubts about what the group is doing. Sometimes policymakers approach interest groups and lobby them to back a proposal they want to initiate. What is the common metric to measure these different kinds of endeavors, each of which is hard to measure on its own?

Third, the world is a complicated place and lobbying never takes place in a vacuum. Legislators and agency officials are influenced by many different factors including public opinion, political party leadership, the president, and the media. Distinguishing interest group influence from all these other sources has proved to be an intractable methodological problem.

Despite the lack of success in measuring lobbying effectiveness, scholars have succeeded in mapping out the array of tactics used by groups and at developing rich explanations of the underlying strategies. At the risk of oversimplifying the interest group world, lobbying tactics fall within two broad categories. Direct lobbying includes those tactics which involve immediate contact between interest group lobbyists or members and policy makers. This is what we usually think of when we see a reference to lobbying: lobbyists meeting with legislators or administrators. Filing a court suit or an administrative petition also falls within this category as it is a direct effort to persuade policy makers with an argument presented by a group representative. Direct lobbying of policy makers is ubiquitous—98 percent of Washington-based lobbies use it. All lobbyists have their set of the facts and summarizing them in conversation with harried policy makers who have little time to read the substantive literature is seen as critical. Once the European Union began making important decisions, lobbyists began to crowd Brussels. By one estimate there are over 10,000 lobbyists who work the EU parliament and the number is surely growing.

Lobbying the public utilizes a second set of tactics. It is frequently the case that interest group leaders come to the conclusion that policy makers will not do the right thing until the climate of public opinion changes. This is particularly true when key decision makers hold views at odds with the interest group, or don't see the problem as a high priority. In large countries reaching the whole public is difficult and expensive, so efforts are usually tailored to attentive publics—segments of the population that are more likely to respond to tactics such as advertising, direct mail, and membership alerts asking individuals to write to their legislators. Lobbying organizations also make concerted efforts to gain journalists' attention in the hopes of stimulating them to do a story and, thus, generate publicity for the cause. Animal rights groups in the UK, for example, have often resorted to histrionics to generate coverage of their issue.

Interest groups will often mix the two basic strategies in trying to influence government decisions. Members of an organization will receive a letter, fax, phone call, or email asking them to write to their legislators, usually asking them to vote to pass or defeat a piece of legislation before them. At the same time lobbyists for the same group are talking to legislators, reinforcing the message being sent by constituents who are group members. Scholars have long argued that organizations with large memberships are advantaged in the legislative process. This advantage grows when the constituency is one that is easy to mobilize. Memberships that are easy to mobilize are, of course, those which are composed of individuals high in education, status, and income. But it is not just high status individuals who are advantaged. Some lobbying 'groups' are corporations and they have deep enough pockets to fund substantial lobbying operations. Other interest groups are trade associations composed of corporations and are thus able to draw on the substantial resources of many companies within their organization.

2. *Money in Politics*

The advantage of social class in interest group politics goes beyond the help lobbyists get from having members who are cooperative when asked to write to policy makers. Interest groups go to members and donors and ask them for money to be used to strengthen the organization's lobbying efforts. Donations can be translated directly into resources which can be used in their advocacy campaigns. Money can buy more lobbyists, more researchers, more advertising, and more issue alerts sent to members asking them to communicate with legislators.

Money can also be used by interest groups to donate funds to political parties and individual candidates for office. The underlying philosophy here is that the best lobbying tactic is not to try to influence legislators or prime ministers who are already in office, but to put people in office who are already poised to work on behalf of the issues the group cares about. Each country has its own rules governing interest group donations. In Japan, business interests are the principal financial support for various factions within the Diet.

In the USA, interest groups channel contributions in two ways. First, money to candidates for Congress comes from political action committees, most of which are tied to existing lobbies. Second, interest groups can contribute directly to political parties. Despite the controversy over campaign money and its role in elections, political scientists run into the same kind of methodological problems when they try to determine how effective this tactic is. Legislators who receive donations from an interest group are more likely to vote the way the group wants, but that can't be taken as evidence that they were influenced. Most contributions are given to incumbent legislators or candidates who the group has reason to believe are sympathetic to at least some of the goals of the organization. Can we say that labor unions in the UK buy the votes of Labour Party MP's? The unions provide the financial support for the party, but what type of people choose to run for office under the Labour Party banner? In the US scholars have had a particularly difficult time sorting out the complexities of linking PAC contributions to voting behavior by members of Congress. Summarizing the research, political scientist John Wright concluded that 'Empirical evidence about the influence of PAC contributions on congressional voting is filled with ambiguity and apparent contradiction' (Wright 1985).

3. *Stability or Change?*

Although interest groups are an enduring and persistent part of democratic politics, they frequently face significant changes in their political environment. In parliamentary systems with proportional representation, for example, new political movements can quickly metamorphize into new political parties. The lobbying organizations for that cause may have to switch quickly from protest politics to campaign politics. In the American context, with its stable two-party system, the challenge more recently has been the unprecedented growth of interest groups. Looking back on his career, one member of the House remarked 'When I first came to Congress there were five major financial trade groups, but now there are at least five times that. Now if you're trying to satisfy all the trade groups, it's pretty hard to do.'

For present-day lobbyists the most significant tactical decision may be figuring out what to do just to get noticed. With so many lobbyists working on the same issue, how do the lobbyists from a single organization convince legislators and their staffers that their organization is one to consult with and to work up drafts of legislation with? The competition between lobbyists has put an even greater premium on expertise. Although well-connected lobbyists are always helpful, policy expertise is a particularly important trait of effective lobbyists.

An interesting question that has emerged is whether the new technologies are changing interest group politics. The new technologies have certainly made it easier for interest group organizations to reach their members and attentive publics. Today communication can be virtually instantaneous. If events change rapidly lobbyists in the capital can mobilize their members quickly to let policy makers know that voters back home have noticed what's going on and they are upset about it. Interest groups have also taken advantage of the Internet, establishing their own web sites to serve as vehicles for soliciting members, advertising their

views, and facilitating the retrieval of documents by sympathesizers around the country. Another use of the Web is that it facilitates the organization of new groups. Small constituencies with modest resources can use the economies of the Internet to reach those concerned with their issue and to generate communication among themselves.

Yet for all the changes that have taken place in government and in telecommunications, the fundamental nature of lobbying remains relatively stable. At its core lobbyists work assiduously to mobilize their followers and to bring information to the attention of policy makers. Although how those tasks are carried out changes over time, these changes have not revolutionized the process.

As political science has become increasingly sophisticated and the discipline has placed greater emphasis on precise measurement of complex phenomena, lobbying has remained a particularly difficult nut to crack. Assessing the effectiveness of different types of lobbying or different lobbying campaigns continues to be a formidable methodological problem. We know a lot more about many facets of interest group politics, especially in understanding how and why people join organizations. Research on lobbying, however, has made only limited progress.

Local Economic Development

Local economic development is concerned with the well-being of a place, a locality. Distinct from 'economic development' more generally, local economic development focuses on particular contexts, which vary across space. 'Context' refers to the constellation of endogenous behaviors and formal and informal institutions that have evolved in a place and interact with exogenous cross-currents that may be social, cultural, economic, political, ecological. Approaches to local economic development vary substantially, and are themselves context-specific. 'Local' has different meanings relative to the broader context in which places are conceptualized. 'Economic development' also has different meanings; that is, the nature of 'well-being' is variously interpreted, relative to researchers' theoretical perspectives. Accordingly, 'local' and 'economic development' are addressed separately, and approaches to local development as a field of study are elaborated subsequently.

1. The Term 'Local'

'Local' can mean a neighborhood, town, or metropolitan area in the context of a region or nation; it can refer to a region in the context of a nation; and it can signify a nation or even a multinational region in the context of the global economy. 'Local' is relative, referring to scale specificity and relations among processes at different scales, although it is not itself specific to a particular scale. Examples of local development within the USA illustrate the point. In the 1960s and 1970s local development typically entailed subnational, regional units, such as Appalachia, which were recognized as problem areas amid general national prosperity. The US South was compared to a Third World country because it hosted footloose branch plants of multinational corporations (MNCs) that did not invest locally in institutions or in people, via upskilling (Cohen 1977). By the end of the 1980s and in the context of profound economic restructuring nationwide and globally, economic volatility, a large federal deficit, and reduced federal funding to states, 'local' in the USA continued to refer to regions, but also to urban areas, some of which confronted problems of industrial decline and out-migration of people and capital (Rodwin and Sazanami 1989). At the same time, 'localized distress' also referred to problems of defense conversion in cities and towns in several regions in the aftermath of the Cold War (Markusen and Yudken 1992). Further, 'local' referred to slums in cities in all regions of the country (Goldsmith and Blakely 1992).

What is 'local' about each of these situations is the conceptualization of problems specific to a particular place in relation to a broader context. Although the

problems are local, the broader context is critical in understanding the structures, agents, and processes that affect local contexts: for example, MNCs and related corporate strategies and spatial divisions of labor; the pressures of competition in the global economy on places that must survive or thrive via entrepreneurialism and local funding; changes in power relations among the superpowers and the changing geopolitical map that affects defense-based economies; the changing geography of urban employment and residential patterns in relation to changes in migration, interethnic relations, and firm strategies and their spatial divisions of labor.

The localness of problems does not mean that they are unique. Similar problems may emerge in different places during economic upturns and downturns that sweep across space. What varies among places experiencing similar effects of economic change are the political, economic, social, cultural, and ecological processes and (local) state–society relations associated with locally specific configurations of institutions and behaviors, and their histories. A round of investment is likely to affect places differently in light of different histories of labor-management relations, gender relations, industrial foci, and so forth. Massey (1984) used a geomorphological metaphor to convey this idea: each round of investment brings its own division(s) of labor and related distribution of economic activity—a stratum—that is overlaid on previous socioeconomic 'strata' and impacts a locality relative to the characteristics and combinations of previous strata. Massey conceptualized places in terms of their respective histories of successive layering of socioeconomic strata in relation to wider divisions of labor at national and international scales in association with multilocational firms, often MNCs.

While local problems can vary substantially within nations, the parameters of variation may vary from nation to nation in the context of different modes of state regulation and state–society relations, as well as nationally based systems of production and innovation (Porter 1990). Local economic development issues in the USA, for example, rarely involve an interventionist state at the national scale. In contrast, states in Western Europe or East Asia are much more directly engaged in development processes, although in different ways. Western European countries, with long histories of independence in the global economy, tend to focus developmental efforts internally to resolve problems of regional imbalance, whereas East Asian countries, being 'late developers,' have focused more on asserting a national position in the global economy as a matter of survival (Gershenkron 1962). Thinking about national development as 'local' is especially common in discussions about the role of the state and state–society relations in East Asia, and more generally among countries characterized either as late developers, or nations whose relative position of power has declined and which are confronted with regaining and sustaining competitiveness. Similarly but from a somewhat different vantage point, early dependency theory saw former colonial territories as being actively *under*developed in the modern world system (Gunder Frank 1967)—a situation of local underdevelopment (as opposed to development) relative to national or supranational agents such as MNCs.

2. *The Term 'Economic Development'*

What constitutes economic development depends on perspective. Neoclassical approaches measure economic *growth* in terms of aggregate indicators such as population, employment, productivity, and income. Political economy orientations distinguish economic *development* by focusing on qualitative changes in conditions of living and opportunities for work. At issue is not just employment, but *type* of employment and whether work situations offer opportunities for skill improvement, upward mobility, and appropriate compensation. Qualifying principles have, however been interpreted differently.

Especially in the 1970s and early 1980s, researchers focused on the effects of corporate strategies (notably of large, multilocational firms such as MNCs) on conditions of work. Scholars were concerned with people—workers—and how firms' locational strategies for different types of facilities (e.g., branch plants, administration, or research and development—R&D) signified different consequences for wages, type of work, human capital investment, and so on. During this period traditional Anglo-American corporate strategies prevailed worldwide, which competed on the basis of price (as opposed to quality or innovativeness) such that branch plants routinely employed cheap, low, or unskilled labor. Consequently, the places hosting branch plants were generally considered sites of exploitation and underdevelopment.

Later in the 1980s and throughout the 1990s, Schumpeterian-inspired approaches predominated, offering a view of development with reference to innovative capacity. This perspective developed in the USA in the context of growing numbers of small firms and a concern with how to foster entrepreneurialism; the larger context was one of increasing numbers of competitors in the global economy and, relatedly, new corporate strategies emanating from different sociocultural contexts and entailing different systems of human relations. People, from a Schumpeterian perspective, are of interest insofar as they are useful to firms in establishing and sustaining competitiveness, which generally signifies economic development. Schumpeterian thinking tends to be firm-oriented because analysis typically focuses on the competitiveness of firms or industries (measured in terms of technical advance, productivity, and the like),

generally in relation to skill-based production—a departure from prevalent corporate strategies in the 1970s and 1980s. Ironically, Schumpeterian and neoclassical analyses implicitly converge on the assumption that the well-being (competitiveness) of firms and industries signifies positive conditions for workers, that is, it 'trickles down.'

A recent concern has been the exclusionary and politically charged character of development studies, whether people or firm-oriented. Scholars have recognized researchers' own biases that underlie what appear as simple and value-neutral representations of reality. One important byproduct of those concerns is the identification of differentiated processes relative to different types of people, as well as different yet related dimensions of change (e.g., social, cultural, economic, political, ecological). From this perspective, the constituent components of economic development cannot be aggregated into a single, essentialized assessment.

3. *Context and Approaches to Local Economic Development*

Understandings of local economic development have stressed exogenous and endogenous processes or the articulation of the two.

3.1 *Exogenous Processes*

Consider the 'branch plant economy,' which is characterized by a significant percentage of employment in branch plants of MNCs. Critically at issue are corporate strategy and related management principles. During the 1970s and early 1980s, for example, MNCs commonly produced in large volume for mass markets using cheap and low or unskilled labor. The effect on localities was dependency, especially when corporate strategies were focused on price competitiveness (rather than, say, quality control). In this context, firms routinely relocate as wages or union or other pressures increase. The resultant capital mobility renders localities and their employable populations hostage to the impulses of exogenous corporate decision making, which typically is detached, physically and otherwise, from the localities in question. Moreover, places become pitted against each other in a zero-sum game of wage competition, thereby hampering cohesive resistance among workers across space.

Conditions of high capital mobility and exogenous domination of localities have been approached in various ways. Some scholars viewed processes at different scales as interacting—for example, local histories, industrial configurations and production ensembles with national and international corporate strategies, and industrial change (Markusen 1987, Massey 1984, Storper and Walker 1989). Others in different ways saw localities as objects of corporate processes at larger scales. Although there was general consensus that branch plant economies associated with Taylorist management connoted underdevelopment, some scholars focused on the corporate decision-making component with reference to firms' product and innovation cycles (Malecki 1981), whereas others researched the underdevelopment and dependency components in the context of what had become known as a 'new international division of labor' (NIDL) (Froebel et al. 1980).

3.2 *Endogenous Processes*

Not all local economies are dominated by large firms (Taylor and Thrift 1983) and, moreover, spatializing industry and management is not necessarily neatly hierarchical. Whereas under the model of high capital mobility and exogenous domination scholars interpret change with reference to large firms' locational strategies, *in situ* industrial change or development suggests important endogenous processes. Local economies evolve in various contexts that are neither wholly dependent on, nor the object of, exogenous processes in the sense described in Sect. 3.1.

One of these contexts is a localized version of what Schumpeter called 'creative destruction,' in reference to small, innovative firms successfully challenging the pre-existing corporate order in a region and founding a new wave of economic development. The genesis of Silicon Valley is a case in point.

From another perspective, Scott (1988) developed a theory of local development based on corporate restructuring, specifically the termination of many activities in large, multilocational corporations that had been spread out across regions and the move to subcontract previously internal activity to local independent firms. Borrowing from the 'new institutional economics,' Scott suggested that the cost-effectiveness of externalization strategies during times of market instability (and given the condition of a highly segmented local labor market) would engender dense and cost-competitive interfirm interaction in a local economy, thereby signifying local development based on a new production system. More generally, scholars explained uneven development with reference to new production systems (Storper and Walker 1989) or industrial configurations (Markusen 1987) in new industrial spaces.

But what of old industrial spaces? These are not necessarily subject to decline, as well evidenced by the reindustrialization of the US industrial heartland following deindustrialization. In this context, subcontracting to firms from other sociocultural contexts, such as Japan, gradually changes local corporate culture and social relations from Taylorist (where subcontractor–client relations are typically antagonistic and short run) to collaborative (where, in long-

run relationships characterized by trust, client firms help subcontractors develop knowledge and problem-solving skills to enable increasing independence). Regional restructuring occurs through transnational corporations (TNCs) that become locally embedded and committed to training workers in new, upskilling proceses (Florida 1996).

Another type of context departs from hierarchical models of interfirm relations and is focused on lateral or horizontal networks. This type of context entails communities comprised of a large informal economy, or small firms in mature as opposed to new and strategic industries, or communities that are not major hosts to TNC facilities. Localized small-firm networks can evolve either in the absence of policy to achieve this end (as in the case of the Emilia Romagna region in Italy) or as a result of proactive brokering and assistance via local governance (such as communities in the USA in the 1980s and 1990s reacting to lack of federal funds and industrial decline, or countries such as Taiwan that have institutionalized programs for small firms). Constrained by their size, small firms or informal organizations are unable to achieve the efficiency that is possible for large firms. Scale economies can be achieved by pooling resources, that is networking. As in the case of industrial revitalization, competitiveness lies in an appropriate (inter-organizational) human relations system, one that emphasizes collaboration and cooperation—'social capital' (Cooke and Morgan 1998). Some research focused on understanding how networks achieve competitiveness (e.g., Sengenberger et al. 1990), while other research focused, from a local policy perspective, on how to foster such networks in places where they may not already exist (Rosenfeld 1992). Policy-conscious research interfaced with growing interest on the part of local politicians to assist in the development of entrepreneurial economies to foster change via local and regional institutions (Osborne 1990).

At the national scale, among 'developmental states,' endogenous change may occur through state-assisted industrial development in which foreign capital is effectively manipulated to restrict branch plants (and thus dependency) and encourage subcontracting with local, independent firms, sometimes via networks of entrepreneurs (as in the cases of Hong Kong, Taiwan, and South Korea) (Wade 1990).

3.3 Connecting Exogenous and Endogenous Processes

Researchers interested in endogenous development who are attuned to globalization focus on the connections between particular places and global agents. Unlike the model of capital flight (Sect. 3.1), in which global agents are necessarily 'dominant' and capital is mobile, at issue is how local and global competitive forces may be connected to develop entrepreneurial economies (Storper 1997).

Most MNCs, which produce in one country and market products elsewhere, have evolved into TNCs that functionally integrate marketing and production of different components in a wide variety of countries and localities therein. Global production in this context has become more complex than a strategy of establishing branch plants in diverse locations.

Many TNCs withdraw wholly or partially from production itself and focus energies on coordinating a global system of subcontracting via tiers of networks of firms across nations and world regions (Gereffi and Korzeniewicz 1994). This type of production system can result in positive local change, if the state is developmentally oriented and invests in upgrading of production processes and upskilling of workers regarding the local component of a global commodity and knowledge chain. Alternatively, such networks entail uneven power relations across regional divisions of labor, and some regions remain trapped in a Taylorist-oriented low-skilled, low-cost production component (Hart-Landsberg and Burkett 1998).

Other TNCs remain production-oriented and sink costs into localities by establishing plants that become locally embedded (Amin and Thrift 1994). This is a possibilist perspective in which the long-run investment of foreign capital (capital fixity as opposed to capital mobility) is contingent on: the synergy of preexisting local structures (revisiting Massey's geomorphological metaphor), strategies of TNCs specific to facilities in each place of production, and agency (social interactions, leadership). Questionable, however, in this rosy, albeit possibilist picture, is the partiality of so-called 'development.' Embeddedness itself is partial and usually confined to elite circles; workers, if empowered, are only partially empowered and are disempowered in other respects; and workplaces often remain homogeneous and exclusionary (Ettlinger 1999).

4. The Relevance of Reflexivity

The question 'development for whom?' underscores the partiality of all research on local economic development. Poststructuralism calls for reflection on our biases and assumptions with attention to the consequences of our frameworks, and it opens researchers' minds to questions and information precluded by traditional paradigms. A case in point is the assets based community development (ABCD) approach to local development that considers local assets in ways previously considered unthinkable (Kretzmann and McKnight 1993). The unemployed, for example, may be seen as an untapped and extremely valuable local regional resource. Critically at issue is understanding that developing industries and regions are not coincident because people in places outside of firms are as central to local development as those who are fully employed. This highlights the multiple realities in places, requiring a

conceptualization of local development as a hybrid phenomenon that cannot and should not be essentialized (Escobar 1995).

Local–Global Linkages, Environmental Aspects

One of the 'grand queries' in science is understanding linkages between macroscale and microscale phenomena and processes. Biologists, for example, seek to understand linkages between molecules, cells, and organisms; ecologists between patches, ecosystems, and biomes; and economists between firms, industries, and economies (Wilbanks and Kates 1999). In the environmental and ecological sciences, broadly defined, this challenge embraces such profound issues as relationships between local ecosystems and global climate change; relationships between local land use and global economic restructuring; and relationships between the sustainability of local environments and global political change.

Pursuing understandings of such linkages is complicated by the fact that processes at one spatial scale tend to be studied by different communities of scholars than processes at another scale. The respective literatures speak different academic languages, arise from different bodies of theory, and are accustomed to very different units of measurement, even when the subject matter is within a single discipline. When, as is often the case, the linkages cross the boundaries of disciplines, the challenge is much greater—and less often attempted as a matter of careful research rather than qualitative assessment by diverse panels of experts.

The reality, of course, is that global changes in climate, environment, economies, populations, institutions, and cultures converge in localities; and their impacts play out at local and regional scales. At the same time, global changes result from an aggregation

of decisions, actions, innovations, mutations, and other changes that arise in specific localities. Examples of the interplay between global and local scales range from AIDS to ecotourism. Macroscale and microscale are linked intrinsically, and neither can be fully understood without considering the other.

1. How Scale Matters

In understanding environmental systems, the issue of global–local linkages would be relatively insignificant if the local scale were merely microglobal, in other words if a phenomenon or process studied at any one scale could be expected to tell the observer essentially the same thing as study at any other scale. There are a number of reasons, however, why scale matters and why understanding linkages between scales is therefore an important part of the search for knowledge (Wilbanks and Kates 1999).

Several of the reasons have to do with how the world works. First of all, the forces that drive environmental systems arise from different domains of nature and society. For example, population ecology operates at a smaller geographic scale than national or global demographic patterns (Clark 1985). Within this universe of different domains, local and regional domains relate to global ones in two general ways: systemic and cumulative (Turner et al. 1990). Systemic changes involve fundamental changes in the functioning of a global system, such as effects of emissions of ozone-depleting gases on the stratosphere, which may be triggered by local actions (and certainly may affect them) but which transcend simple additive relationships at a global scale. Cumulative changes result from an accumulation of localized changes, such as groundwater depletion or species extinction; the resulting systemic changes are not global, although their effects may have global significance. A second reason that scale can matter is that the scale of *agency*—the direct causation of actions—is often intrinsically localized, while at the same time such agency takes place in the context of *structure*: a set of institutions and other regularized, often formal relationships whose scale is regional or global. Land use decisions are a familiar example. This kind of local–global linkage is especially important where environmental impact mitigation actions are concerned, analogous to hazards behavior. A third reason that scale can matter is that the driving forces behind environmental change involve interactions of processes at different locations and areal extents and different time scales, with varying effects related to geographical and temporal proximity and structure. Looking only at a local scale can miss some of these interactions, as can looking only at a global scale. For instance, geographers have shown that processes of change involve patterns of spatial diffusion that can be generalized, and ecological modelers

Figure 1
Scale-dependent distribution of impacts of climate change (adapted from Environment Canada 1997)

such as Holling have found that managed biomes are characterized by landscapes with lumpy geometries and lumpy temporal frequencies related to the size and speed of process interactions, shaped by the fact that processes operating at different scales tend to show faster or slower dynamics (Holling 1995).

Several additional reasons have to do with the how we learn about the world. One of the strongest is the argument that complex relations among environmental, economic, and social processes that underlie environmental systems are too complex to unravel at any scale beyond the local. A second reason is that a portfolio of observations at a detailed scale is almost certain to contain more variance than observations at a very general scale, and the greater variety of observed processes and relationships and relationships at a more local scale can be an opportunity for greater learning about the substantive questions being asked. For instance, net benefits/costs from global climate change vary more widely for small areas than large ones (Fig. 1). A third reason is that research experience in a variety of fields tells us that researchers looking at a particular issue top-down can come to dramatically different conclusions from researchers looking at that very same issue bottom-up. The scale embodied in the perspective can frame the investigation and shape the results, which suggests that full learning requires attention at a variety of scales. As one example, Openshaw and Taylor (1979) have demonstrated that simply changing the scale at which data are gathered can change the correlation between variables virtually from $+1$ to -1.

These reasons, of course, do not mean that global–local linkages are salient for every question being asked about environmental and ecological systems. What they suggest is more modest: that examinations of such systems should normally take time to consider linkages between different scales, geographical and

temporal, and whether or not those linkages might be important to the questions at hand. Consider two examples:

(a) *Land use change and climate change*. Obviously, anthropogenic causes of climate change arise from location-specific activities: points, such as a coal-fueled electric power plant; areas, such as a forest or a farming region; and flows, such as interstate highways. Local and regional land use shapes climate change; and reductions in pressures toward climate change are rooted in changes in land uses, although some of the largest contributors occupy relatively small geographical areas. At the same time, climate change affects land use. For instance, it can cause hardwood trees to displace pines or vice versa. It can lead to changes in agricultural cropping patterns. And sea level rise leads to shoreline retreat and coastal land loss. One example of a linkage between the scales is that concerns about impacts at a local level can lead to efforts to promote greenhouse gas emission abatement in order to reduce the likelihood or magnitude of those impacts. An important program of the International Geosphere–Biosphere Program is concerned with land use and land cover change (LUCC), including linkages between very local processes and a variety of larger scales (Turner et al. 1995).

(b) *Biodiversity protection*. Likewise, biodiversity protection has both local and very large-scale dimensions. Most endangered species exist within localized ecological niches with a rather narrow tolerance for change. Other than through zoos or gene banks, their protection requires action at a very local level. On the other hand, many of the forces that endanger them, from environmental pollution to economic and demographic growth, arise at a much larger scale. In addition, where species are migratory, their survival depends not only on a single local biosphere but on a viable migration corridor between seasonal biospheres as well, at the scale of a region or beyond.

2. Tracing out the Linkages

Our understanding of global–local linkages in the environmental and ecological sciences is still poorly developed and is a promising subject for further research. As few hypotheses based on rather fragmentary evidence, however, can suggest some directions for discussion.

It appears, for instance, that whether global change is likely to cause local change depends on how significant and discontinuous the global change is, whether localities are substantially subject to external driving forces, and whether global processes are relatively closely linked with local processes. It appears that whether local change is likely to cause global change depends on the magnitude and force of the local change, whether the local change is focused on a key driving force in a global process, and whether the local change either (a) is associated with structures/processes for dissemination or (b) is associated cumulatively with similar local changes elsewhere. It appears that whether a global–local link is likely to be disruptive depends on existing stress levels in localities and their adaptability and coping capacity. It also appears that divergences between local and global optimality are affected by mobility, which is clearly increasing in many global networks; in some cases the divergence can be greater where mobility and other adaptation mechanisms are limited, while in others it can be magnified by a loss of control at the local level over the nature and speed of change.

3. Linking the Global and the Local

In seeking to improve the understanding of macro–microscale linkages, a common conceptual approach has been to depict the systems operating at different scales as hierarachies: classes of processes in which each smaller unit is nested within a larger unit, which can be associated with bodies of theory about interactions within and between scales (e.g., Allen and Starr 1982). Examples include ecosystems and economic markets. Such approaches have often been fruitful, but they are often criticized for arbitrarily dividing complex systems into a limited number of levels of 'organization.'

Current efforts to improve the capacity to trace out, understand, and if appropriate modify linkages between the global and the local in environmental and ecological systems include attention to five central problems:

(a) Downscaling global and other large-scale models to understand issues at a regional or local scale, such as implications of global environmental change. Recognizing the limitations of top-down paradigms based on global or near-global scale modeling, the research community is increasingly active in moving toward more detailed geographic scales and topical richness, using both numerical (i.e., model-based) and empirical (i.e., statistical-based) approaches. Challenges include data availability at detailed scales, the complexity of process relationships as models become more like the real world, and in some cases computational capacity (although advances in computing have reduced this constraint considerably). Appetites on the part of model users for downscaling appear insatiable; as a result, this trend is expected to continue.

(b) Upscaling data from points or very small areas to understand issues at a regional or global scale. Many kinds of data pertinent to macroscale issues are gathered at specific points, ranging from meteorological observations to crop production; but in many cases these data cannot simply be aggregated to estimate larger-scale values, such as regional agricultural production or climate processes. For instance, the data may fail to meet standards for valid sampling, and they may fail to represent stochastic and geographic variability in representing how processes

work. As one example, it has been shown that an estimated response to an 'average' environment can be a biased predictor of a 'true' aggregate response (Templeton and Lawlor 1981).

(c) Integrating top-down and bottom-up perspectives to arrive at a comprehensive understanding. Where downscaling and upscaling come together is when the two approaches are merged to attain an integrated understanding of processes, benefiting from the strengths of both perspectives. This kind of integration is usually done in one of three ways: (i) by converting both perspectives to a common metric, usually a 'meso' or intermediate scale such as one-half degree of (equatorial) latitude and longitude (e.g., Easterling 1997); (ii) by comparing the two different answers and adjusting the approach used in arriving at each, iterating until a single answer is derived (applied, for instance, in the integrated environment/economy model of the International Institute for Applied Systems Analysis); and (iii) by comparing the two different answers and seeking a meta-understanding, incorporating both perspectives but arriving at a third answer (e.g., the multidisciplinary Susquehanna River Valley study conducted by the Pennsylvania State University: see Abler et al. 2000). In many cases, integration is partly a matter of bridging between analytical styles, for example, top-down models and bottom-up case studies. In addition, it is often a matter of reconciling differences in process assumptions, theoretical foundations, and perceived standards as to what constitutes the best science.

(d) Resolving differences in scales between relevant processes. Because different interacting processes may operate at different scales, for example, between the scale of ecosystems and the scale of governmental units making decisions about them, efforts to incorporate a variety of linkages in a single analysis or action must often confront problems of 'scale discordance.' Among the avenues being investigated are adaptive approaches to analysis and management, which permit modifications of the scale as more is learned about the relevant processes and their interactions.

(e) Accounting for cross-scale dynamics. Because so much data collection and analysis occurs at a particular scale, data are often scarce about cross-scale relationships and interactions. Strategies for reducing this gap are being considered through the establishment of richer information infrastructures, especially regarding longitudinal data sets, but assuring continued financial support for data collection structures is a continuing challenge.

Much of this growing effort to improve the understanding of global–local linkages is motivated not only by scientific curiosity but also by social needs to deal with environmental problems such as reducing environmental pollution, coping with possible impacts of global climate change, and responding to threatened losses of ecosystem quality and variety.

Location: Absolute/Relative

Location refers to the relationship of a place to other places in a space. The space can be absolute or relative. Imagine absolute space as a container, or an array of containers, in which elements are found. To move an element means to change its position among the locations available. Locations remain fixed; elements repositioned have changed location. In contrast, relative location is defined by the positions of the places relative to each other. Places are nearest their neigh-

bors where they share a boundary. An intervening nearest neighbor separates a place from its second nearest neighbors. Places are remote from one another where connecting them requires crossing many boundaries. Some boundaries and territories are more easily crossed than others, which means that the intervening places affect the extent of separation or relative location.

The distinction between absolute and relative location has both philosophical and practical importance (Couclelis 1992). At the philosophical level, there are two prevalent views of geographic space: space as a plenum, fixed, and continuous with elements contained within it (absolute); and space as neighborhood, defined by the interaction and exchange between places (relative). The issue will not be resolved in favor of one or the other view, because each is valid and useful in different applications—not unlike the wave and particle views of electromagnetic energy.

In practice, the difference arises in the way geographic space is depicted as either a fixed array of pixels (smallest distinguishable grains) in a raster database, in which spatial elements are distinguished by differences in values of individual pixels, or as topological relationships between spatial objects in a vector database. Satellite images, aerial photographs, newspaper pictures, and art portfolio prints are all raster images, in which spatial elements are distinguishable by differences in value, intensity, or color of individual pixels. The size of the pixels defines the resolution of the images. By contrast, objects in vector models are defined by their edges or end points, and by adjacency and containment relationships with other objects. A road network may be modeled as a set of points (intersections and end points) and lines (road segments). You can travel through the network by moving through a sequence of lines connected by points of intersection. Attributes of the street segments and intersections, such as number of lanes, direction of travel, posted speed limits, signal lights, and turn restrictions, affect the measure of separation between locations. Changes in any of these attributes change the relative location of places. The reference above to spatial resolution is germane, because space has other attributes that affect the notion of location, including scale, distance, and dimension (see *Scale in Geography*; *Place in Geography*).

1. Place or Location: Scale Dependent

A place is a fundamental spatial element, spatially undifferentiated within and positioned relative to other places beyond. The dichotomy *site and situation* establishes this level of spatial abstraction and is scale dependent. It distinguishes what is within a site from what is exterior. The site or place may be any size, such as that of a nation, a city, or a residential neighborhood. Situation or location refers to the external relations of places. Ullman (1956) noted that linkages beyond the borders of a place require exchange or movement between locations. Consequently, as transportation and communication technologies evolve, the relative locations of places change. The familiar expression that the world is shrinking alludes to this trend (see *Access: Geographical*; *Spatial Interaction*).

A sense of place is evocative of an emotional attachment to a locale. Normally this requires repeated and deep experience in a place, be it home or wilderness. In the writings of structuralists, exemplified by works of Sack (1986) and Curry (1998) and by humanists such as Yi-Fu Tuan (1977) and J. B. Jackson (1994), place trumps location in the processes in which society attaches sentiment, value, and power to socially constructed places. Unlike in Ullman's works, maps do not play a prominent role in these traditions, because consideration of place takes president (see *Territoriality: Geographical*; *Humanistic Geography*; *Geographic Information Systems: Critical Approaches*).

Gatrell (1983) defines space as a relation defined on a set of objects. Keeping in mind that places are spatial entities, the set theory view of locations allows consideration of topological relations between places, such as nesting, clustering, and adjacency, without reference to distance (Worboys 1995) (see *Geographic Information Systems: Critical Approaches*; *Spatial Pattern, Analysis of*).

2. Metric Space and Dimensions

Distance is the defining relationship between places in a metric space. The concept of distance in a metric space has very specific characteristics, including: that the distance from a place to itself is zero; that distance to any other place is a positive real number; that distance between places is the same in each direction (symmetry); and that the shortest distance between two places is the direct path between them (triangular inequality). Being able to use a metric space in an analysis is useful because familiar geometry and algebra hold. However, spaces often do not possess all the properties of metric distance. In city street networks with overpasses and one-way streets, neither symmetry nor triangular inequality holds. A finite network of points and lines is an appropriate model for city street space.

Location in a metric space can be specified by a Euclidean coordinate system, in which the number of axes defines the dimensions of the space. In a flat, two-dimensional surface, ordered pairs of real numbers (x, y) specify locations. An ordered triplet of numbers is required to specify location in a three-dimensional space. To complicate matters further, although imbedded in a three-dimensional space, the earth's

surface is itself two dimensional, and two numbers (latitude and longitude) are sufficient to locate a place on it. It is also a closed space, which means there is a finite maximum distance separating places (see *Spatial Data*; *Cartography*).

3. Applications

Location is a central theme in a class of practical location–allocation problems in which the best location for sources and volumes of flows are investigated. Specifying the locations of warehouses, so minimizing the total cost of delivering food to supply a chain of supermarkets, is an example of an application of location–allocation models. Determining the arrangement of emergency vehicle stations in an urban area, such that no place is more than a certain number of minutes from help, is another example (Ghosh and Rushton 1987) (see *Spatial Optimization Models*; *Spatial Interaction Models*).

The notion that space can be defined by an ordered n-tuple of real numbers leads to many interpretations. The spatial properties of a place may be defined by the triplet (x, y, $\mathbf{a}$), where x and y are spatial coordinates and $\mathbf{a}$ is a vector of attributes of the place. When $\mathbf{a}$ is elevation, displaying $\mathbf{a}$ at all locations creates a terrain model. If $\mathbf{a}$ is a collection of attributes, $\mathbf{a} = (\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3 \ldots \mathbf{a}_n)$, displaying each separately creates a series of overlays that show spatial juxtaposition of the variables. In *Design with Nature*, an early well-known application of this method, Ian McHarg used multiple attributes of places, including physical, social, economic, and historical conditions, to assess the suitability of territories for land use development (McHarg 1967).

Alternatively, each element in the vector $\mathbf{a}$ could be considered a dimension. For example, an n-dimensional ecological space might include soil moisture, temperature, slope, and direction of exposure as dimensions of the space. Places could be located in a moisture/temperature space or in an n-dimensional space that includes all the site variables. Clusters in this space represent multidimensional similarity of places. Studies of spatial behavior—that is, studies of how people perceive, move about, and use space—have employed this type of multivariate analysis (see *Behavioral Geography*).

4. Locational Referencing

There are many practical ways of specifying location. Street addresses and zip code zones are used to locate homes and businesses. Cadastral surveys establish ownership of land parcels for tax purposes. The Census Bureau uses a nested hierarchy of areal units to report demographic data. Police use road intersections and mileposts to locate emergency incidences along roadways. State plane coordinate systems and global referencing systems are used to specify locations referenced to the earth's surface— in particular, the familiar latitude and longitude reference system. When locational referencing systems are based on different models of space, problems arise in the process of comparing or converting locational information between systems, because not all the attributes of spaces are likely to be preserved in the transformation. Providing a Rosetta stone for transferring locational information between locational referencing systems involves using standardized symbols and proper map projections, but semantics and purpose also dictate what is needed.

More broadly, whenever location of places enters into consideration, the nature of the spatial–temporal context rises to importance. The issue is more than a technical and semantic matter. The user's purposes and fundamental views of space as absolute or relative, whether realized or not, will underlie understanding and actions.

Location Theory

1. The 'Where' Question: Space is Crucial

Location theory is concerned with the intriguing question where economic activity can be found. It addresses the geographic dimension of economic

decision and analyses both the behavior of firms and of households. Thus the locus, the geographic place, is of prime interest in location analysis.

More specifically, the main question in location theory is: which are the motives to choose a particular location and which are the geographic implications? And clearly, there is not a single, conclusive answer. A student who has just left the university will usually have different aims in mind when seeking for a residence than his parents who have just retired. But despite variety in motives and goals, there are many things which are common to anyone seeking a residential location (such as affordability, accessibility, quality of life, etc.).

The same applies to business firms. An ice-cream vendor will not open a shop in a dead-end street, and a diamond seller will not opt for a location in an underground station. Both may have profit motives, but their decisions where to locate may be totally different. But also here, if one observes the actual location patterns of business firms, there are some similarities. The location of households and firms does not exhibit a random pattern worldwide, but displays many regularities. For instance, all over the world we find a population concentration and business concentration in river basin areas and delta areas, a phenomenon already observed by Adam Smith more than 200 years ago.

Location theory does not only investigate the spatial point decision of an individual actor (household, business firm), but looks also into the regularities (patterns, geographic structures) that emerge out of the decision of individual actors. Locational decisions are usually influenced by so-called externalities, which means that the decisions made previously by a group of actors impact on the current decisions of new market entrants. This explains why cities emerge as a spatial conglomerate of many individual actors seeking urbanization economies, or why industrial complexes arise as a consequence of agglomeration advantages (such as a joint use of infrastructure). Thus, location theory does not only have a micro aspect, but also a macro (collective or social) aspect; locational decisions are at the end usually interactive decisions.

Clearly, once a spatial pattern of economic activity has been realized, it will influence other patterns as well. Consumers tend to be attracted by the proximity of shopping facilities, business centers tend to orient themselves towards the presence of a critical mass of clients with a high purchasing power, etc. Thus, there is interactivity in location at both the micro and the meso/macro scales.

The next section offers a very concise presentation of some highlights from traditional location theory, followed by an exposition of some modern developments. After a discussion of firms' location decisions, households' decisions will be looked at. The impact of the modern network economy and of information and communication technology (ICT) will be dealt with as well. The article will be concluded with some prospective remarks.

2. *Conventional Wisdom on Location Decisions of Firms*

Location theory forms a central element in regional economics and economic geography. Location and trade were already regarded by the grandfather of economics, Adam Smith, as two interwoven phenomena: location impacts on trade flows and trade impacts on location decisions.

In the history of economics a great variety of contributions on the nature, motives, and implications of the location of production can be found. We will offer only a few examples here from this rich history.

The location and land use in agricultural production was studied extensively by Von Thünen (1842), by using a simple profit maximization scheme for spatial product choices, as a function of revenues, product types, and transport costs. He was able to demonstrate the existence of a set of concentric rings of agricultural products, based on Ricardian comparative cost theory leading to product specialization. Von Thünen's rent theory has formed the basis for the urban land rent theory, which has become a central focus in urban economics

The location of industrial firms was investigated by Weber (1909) by looking for a cost minimizing location solution of a new firm on the basis of resource inputs (and other material inputs) and product outputs (to be shipped to the market). This intriguing and complex question was solved by Weber (1909) by using a triangular force field of input and output points, within which the optimal location has to be found.

The spatial concentration of economic activity in a city has also been studied intensively, starting from the work of Marshall (1925), who argued that agglomeration benefits are central for city formation. He referred to externalities which caused such benefits, in particular better information and skills, trade growth, specialized equipment, and availability of skilled labor.

The shift towards multiproduct economies and the spatial inter-relationships between multiple products received due attention some 50 years ago in the context of the so-called central place theory, developed by Christaller (1933) and Lösch (1954). The basic idea is that the location of economic activity is subject to agglomeration advantages. As a consequence, economic activities are not spread randomly, but manifest themselves in clusters. Moreover, in the light of product diversity, price elasticity, and the existence of daily and non-daily goods, a spatial hierarchy is a logical outcome of a series of profit-maximizing location decisions of firms. This hierarchy means that a place with a certain ranking order also includes firms

producing goods with a lower order. This theory has become a landmark in location theory and has had far-reaching implications for spatial planning.

In the postwar period, a wide range of new and refreshing contributions has also been offered, such as the growth pole theory, the cumulative causation model, and the forward–backward linkage view on regional development.

The complexity of location decisions in a continuous space or in a discrete network configuration has also prompted a rich research field in the operations research discipline, where many attempts have been made to derive mathematically the optimal site of public facilities or private goods, especially in the context of a multiproduct location decision. It should be noted that in a discrete space with a finite number of location options the number of combinatorial possibilities may be formidable, so that rather advanced mathematical software has to be developed.

In the 1990s much attention was given to a rigorous analysis of the link between trade and locations, especially in the spirit of the monopolistic competition approach advocated by Krugman (1991). In this analysis, spatial accessibility does not only favor transport and trade, but geographical clustering is also positively influenced by a strong critical mass of local demand, by increasing returns to scale in the production sector and by a good transportation system in the area. This will be discussed in more detail in Sect. 3.

3. *Location and Growth*

Locational decisions are usually not stand-alone choices of a firm, but are part of a broader set of firm decisions, e.g., on market areas, marketing channels, technology to be used, image, etc. Against this background transport—and thus trade—plays an important role. This fact was already recognized in the well-known Hecksher–Ohlin theory on international (or interregional) trade flows, where trade intensity between two countries is dependent on the comparative advantage of the use of factor inputs. Clearly, also the degree of homogeneity of products to be traded plays a role here. Based on the assumptions of monopolistic competition, Dixit and Stiglitz (1977) have tried to make the Hecksher–Ohlin theory more realistic, inter alia by allowing for product differentiation. In this way, both inter- and intra-industry trade flows and locational patterns can be analyzed. This integration of trade theory and location theory forms one of the main characteristics of modern growth and trade theory.

In this context there is also a need for a more dynamic perspective to spatial equilibrium phenomena. This presupposes a more integrated view on locational decisions and emerging market patterns, thus necessitating an economic growth perspective. Consequently, trade and location are endogenously determined in modern economic growth theory, as developed inter alia by Krugman (1991). This also means that factor mobility, transportation costs, and transaction costs become an integral part of modern theories on location and urban or regional growth.

In a recent study by Fujita et al. (1999), the authors offer an attempt to re-track economic geography (and regional science), while they also aim to build a 'new economic geography' based on a few vigorous economic principles. The authors signal a regrettable dividing line between mainstream economics and the economics of location. They aim to build a bridge on the basis of a few simple (certainly not universally valid) concepts, in particular the imperfect competition model marked by increasing returns to scale (originating from Dixit and Stiglitz 1977). In an open (multiregion or multicountry) system various types of spatial agglomeration patterns may emerge, depending inter alia on transport costs, forward and backward linkages, and immobility of resources. The authors offer a new perspective in their effort to bring general economics closer to regional economics. They illustrate their arguments by referring to core-periphery phenomena, agriculture, urban systems, city size, transportation, international trade, and industrial clustering. The book forms a clear manifestation of the rigour of solid economic analysis for the explanation of the spatial patterns and evolution of economic activity.

The two pillars of regional economics are certainly formed by agglomeration economies and generalized transportation costs. Much emphasis is made in the book on the economic analysis of urbanization and scale advantages, but less on transportation costs. In our era of ICT development where many economists advocate the 'death of distance,' it would have been necessary to pay more attention to both psychological and virtual distance costs, and their implications for the spatial organization of our world (see Sect. 6).

It is clear that a further integration of location theory, transportation science, trade theory, and industrial organization seems to be a necessary condition for a rigorous way forward.

4. *Where Do People Wish to Live?*

The locational choices of households can be looked at from many perspectives exemplified by a great variety of historical, cultural, social, economic, and geographical views. The most prominent and visible pattern in the spatial distribution of households is the clustering of people in the vicinity of firms that demand workers for their economic activities. For example, the Industrial Revolution, based on new, steam-driven technology, created mass-produced goods at particular geographical locations where the inputs for the indus-

trial production process were found. The workers needed for this new mass production of goods were forced to settle near the factories, given the limited transport facilities at the time and their low financial means.

The ultimate example of spatial clustering of economic agents (firms and households) is observed through city formation and city growth, both in developed (industrialized) countries and in developing countries. Nevertheless, some people do not live in the urbanized areas with the main employment centers, but commute from their home regions to their workplace in the city. This travel distance of households from home to work forms the principal focal point in the classical urban location theories that were developed to explain the spatial structure of agglomerations (see Alonso 1964, Muth 1969, Mills 1972).

The old economic wisdom on urban location decisions of households builds on the functioning of the market for land from which the urban location patterns were derived through the application of standard economic laws of supply and demand. The classical, elementary model for the urban location of households considers the decision-making process of households as a place—utility maximizing process in which a crucial role is played by the travel distance from home to work (commuting distance). For reasons of expositional convenience, company businesses are supposed to be located in the center of the agglomeration (but this was relaxed in later versions of the classical models). In this case, all households would prefer to live in the center, if differences in land prices across the urban space were not yet taken into account (thereby minimizing their commuting costs). However, the excess demand of households for locations in the vicinity of the business center forces the prices for this scarcely available land up, because the households are willing to pay more for central locations. Now, a fundamental locational choice for households emerges in which they have to trade-off the conditions of living near the center (low commuting costs, but high costs for housing) with the countervailing features of living at some further distance of the center (high commuting costs, low housing costs). The difference in the costs for land (housing) will be determined—in the spirit of classical urban models—by an equilibrium state of the land market in which the household's well-being (or utility) is equalized over all possible locations within the urban space. The main economic principle of bidding for those (urban) locations that households consider to be attractive in some sense remains valid, when differences across households (e.g., size, income, preferences), the existence of urban employment subentries, governmental regulations of land and housing markets, and other locational variations or neighborhood characteristics (public and private facilities, environmental amenities, green areas, socioeconomic composition) are taken into account (see Straszheim 1986). This means that besides valuing shorter distances to the city (employment) center, households bid up housing prices in higher valued neighborhoods.

5. *Residential Relocation of Households: Search and Thou Shall Find*

People do frequently move to other locations to obtain better housing during the course of their expected lifetime. There are several reasons for this change of residence and most often the motives are job related (labor migrants) or housing related (size and facilities of the dwelling unit). The residential move could, of course, also be due to health, family moves, change in household composition (marriage or living together, childbirth), or improved transport facilities. Short-distance moves are usually associated with housing related reasons (such as a change in household income), whereas long-distance residential moves are likely to be triggered by job changes (see Clark and Van Lierop 1986). In general, people consider moving when some external shock makes the current location suboptimal, that is, the household becomes dissatisfied with the dwelling itself, the housing environment (social bonds with people living in the neighborhood, availability of parks, recreational facilities, playgrounds and schools), or the employment opportunities that are accessible from the current location through commuting. This shock may originate from the internal household circumstances (e.g., childbirth or a divorce), be related to market forces (rent, interest rate, commuting costs) or be due to externalities such as noise caused by new neighbors or, for example, pollution of the local environment (air, water, soil).

The propensity to move creates a search process in which households try to improve their current situation. At the heart of this search process, households face a lack of information on potential dwellings at alternative locations and are confronted with time and money costs to acquire such information. Moreover, in the search process the household has to decide on the spatial area of search. A residential move will then be made in case the expected gain is higher than the moving costs (this may also include nonmonetary costs related to the psychological value attached to the local social network of contacts).

Accordingly, it is well-known that residential moves are affected predominantly by age which represents the stage in the life cycle. Furthermore, households do not necessarily move in response to small changes in the environment due to transaction (moving) costs. From a methodological point of view, the search behavior of households on the housing market can be investigated appropriately by employing duration modeling techniques in which variations in residential duration are used to analyse housing market dynamics (preferably in a spatial context). Recent theoretical developments along the search-theoretical angle have

also stressed the simultaneity of the decision to move and to change jobs, thereby taking into account commuting costs (see Van Ommeren et al. 1996). One of the central recent issues in this respect is also whether people follow jobs (as outlined in the classical urban models) or jobs follow people (as argued in previous sections on industrial location). Empirical research has established evidence that firms tend to follow—but not to lead—workers to suburban areas (see White 1999).

Last but not least, it should be emphasized that in many Western societies the possibilities to realize the demand for particular locations are limited due to regulatory measures on the housing markets and restrictive spatial planning policies. In many western countries, both housing demand and supply are regulated extensively (by means of price regulation, allocation devices by local communities, etc.).

6. *Modern Residential Location Behavior in a Network Society: The Death of Distance*

Nowadays households live and work in an information society in which economies are characterized by networks and increasingly build on the input of knowledge (and less on the classical production factors capital, labor and land). This new paradigm for the world economy—in which Information and Commutation Technology (ICT) plays a decisive role (see Castells 1996)—has significant consequences for the spatial distribution of activities (at the macro level) and the location decisions of agents (at the individual level). The globalizing world creates footloose agents that are not tied to specific geographical places (either market- or input-related), but at the same time localization trends can be noticed with an increasing importance of local locational factors (such as favorable living conditions, the environmental quality of life and housing facilities).

So what are the main effects of ICT on household location and relocation decision-making? First, ICT greatly influences the search process for new dwellings (and alternative locations), since, search costs become virtually zero due to easy and full access to information (e.g., via the use of Internet). It may, however, be difficult to filter adequately information through these new media and also to obtain reliable information. Moreover, the actual moves still remain to be costly due to monetary and nonmonetary (psychological) moving costs. Second, the ICT-revolution, based on rapidly improving information transport, has initiated a process of internationalization and globalization, and the emergence of the service (network) economy. More specifically, technological progress leads to larger communication flows between firms and households in different regions and cities. In addition, the immaterial character of information removes physical barriers for households in their locational preferences. As a consequence, geographical distance becomes less and less important (due to the use of Internet, e-mail and fax); this seems to be the death of distance because of the enormous decrease in communication costs. At first sight, people may choose to work at any place they prefer, thereby enabling them to live where they want without taking into consideration the transportation (commuting) cost, as was highlighted in the classical view on household location behavior. However, it also appears that local networks of firms are vital to the exchange of so-called tacit knowledge (embodied in people) by means of face-to-face contacts. For example, headquarters of major companies often prefer to be located in large agglomerations with multimodal transport facilities (especially by air). This implies, then, that geographical proximity remains an important factor in the (re-) location decision of particular groups of households. Consequently, the basic trade-off for households between commuting costs and housing costs does not disappear in their locational choice process.

7. *Location of Public Facilities*

As has been argued in the previous sections on household locations, the proximity of private and public facilities will affect the locational decisions of households. From their perspective, the location of facilities is taken for granted. The suppliers of facilities do also have to consider the geographical location of their services (given the location of potential customers). In the real world, one observes that a wide range of services to local inhabitants is controlled by public authorities either at the local or at a regional/national level. The various types of public facilities can be classified as follows (see Johansson and Leonardi 1986).

Travel to facilities: consumers visit services offered such as schools, libraries, concert buildings, parks, hospitals, etc.

Insurance service facilities: consumers are protected against emergencies due to the existence of certain facilities as fire brigades, dikes, police force, army, etc.

Delivered from facilities: consumers obtain benefits (or costs) at the place of residence as a result of certain facilities such as broadcasting, pollution from airports, etc.

In case of the first two classes of facilities, consumers travel to the service concerned and the received benefits will be distance-dependent (due to transportation costs). For the third class, it holds that the consumer obtains the services at home.

In general, facilities are considered to be public if the services supplied by the public authorities also have a 'public good' nature. In short, consumption of a public facility does not hinder the consumption by other consumers of that same good (in technical terms, this means that public goods are nonexcludable,

non-rejectable and allow for joint consumption). Furthermore, the public authorities decide on the particular location of the public facilities. Therefore a major concern in this location decision is given to the distance of consumers to the service at hand. The distance dependence does, however, also imply that the public goods nature is not complete in the sense that some will have easier (cheaper) access to the service than others. To sum up, the authorities first have to select their set of public facilities (that is, they have to estimate the demand for public goods) and next, they have to choose how to locate these facilities, given the spatial distribution of potential consumers.

A well-known hypothesis on the allocation of public facilities across space originates from the early work of Tiebout (1956) who postulated that people reveal their preferences for local (municipal) services by 'voting with their feet.' By this 'feet-voting' behavior, Tiebout meant that households migrate to municipalities that offer the best combinations of preferred services and associated taxes. It also gives municipalities the scope to affect the supply of facilities. As a consequence, local communities can influence the size and composition of their inhabitants (through the in- and outmigration of households) as well as their local tax base to finance these facilities. Of course, households will differ in their spatial ('voting by feet') reactions to the provision of various types of facilities. For example, young households with children will probably be attracted by places of residence offering educational services, playgrounds, and recreational amenities, whereas older households are more likely to move to places with support and care services and social-cultural amenities. One of the most important implications of the concept of 'voting by feet' is that the allocation of goods takes place more efficiently than with majority voting. This conclusion does, however, presuppose that housing search and moving are costless, ideal places can be found for each household, and that local goods do not yield benefits to people living outside the community. This set of conditions is hard to meet in practice.

To conclude, the ultimate challenge to analyse jointly household location and public facility location would require an interactive modeling framework of spatial equilibrium in which household locational choices affect governmental decisions on public facility location and vice versa.

8. Concluding Remarks

Location theory is essentially the heart of economic geography and regional economics, but it is also linked increasingly to industrial organization and trade theory. In particular against the background of the current globalization process, location theory is positioned in a global force field. This force field leads to many rapid responses and behavioral adjustments of business firms, so that stable and robust locations are increasingly replaced by nomadic types of business behavior. The rapidly emerging technological changes (including ICT) encourage location theory to become a battlefield of industrial forces. Clearly, this dynamic evolution has both advantages and disadvantages, and much empirical work would be needed to find out the pros and cons of this dynamic change.

It also ought to be noted that from an economic perspective much attention is given to rational behavior of individual firms or households. In reality, we observe many behavioral responses which are instigated by derived factors, such as neighborhood effects, uncertainty analysis, intra-firm transaction strategies, outsourcing mechanisms, etc. This suggests that also the behavioral basis of location theory certainly needs to be reinforced.

Locational Conflict (NIMBY)

Locational conflict arises when individuals or groups believing themselves to be negatively affected express opposition to a locational or siting decision made by others. As an expression of protest or opposition within the public sphere, locational conflict represents a political manifestation of a geographical conflict over locational decision-making. Conflict may be initiated by the siting or locational designation of a facility, activity or land use believed by an affected party to be noxious, hazardous, undesirable, stigmatizing, or unwanted for any of myriad other reasons. Such targets of conflict have been dubbed locally unwanted land uses, or LULUs, by Popper (1985).

NIMBY, an acronym for Not In My Backyard, is a colloquial expression of locational conflict, articulating the sentiment that certain activities, facilities or land uses should be located elsewhere (not in my backyard) because of real or perceived negative effects of the sited activity on the surrounding area. NIMBYism, often referred to as the NIMBY syndrome, refers to the common or widespread opposition to change in one's surroundings associated with the introduction of an activity or land use thought to bring negative consequences. The term NIMBY is often used, by extension, to refer both to individuals or groups that habitually or expectedly oppose change in the local environment and to the unwanted land use or facility to be sited. In common usage, NIMBYism pejoratively connotes a reactionary parochialism based on self-interested, and thus possibly biased, perceptions. Locational conflict, in contrast, embraces a broader range of perspectives encompassing structural and systemic as well as perceptual causes and allowing for conflict to be liberating rather than simply reactionary in certain circumstances. This range of approaches, their conceptual origins, and means of conflict resolution are examined in this article, after describing the spatial and temporal dimensions of locational conflict.

1. *Spatial and Temporal Dimensions*

The relatively site-specific character of locational conflict differentiates it from relatively a-spatial forms of political expression such as social movements, protest movements, and even geopolitical territorial or jurisdictional conflicts. Individual sites of locational conflict, however, may seek coalitions with conflict participants in other locations to form aggregate social or protest movements covering wide geographic regions. Local advocacy groups in the USA and elsewhere, opposed to the siting of environmentally hazardous waste treatment facilities, for example, have become adept at forming broad-based coalitions seeking to alter regulatory provisions governing waste production, treatment, and disposal at regional and national scales.

Inherently geographic, locational conflict and NIMBYism are frequently manifested at the local scale of the immediate neighborhood or district in which deleterious effects of a proposed facility or activity are concentrated and experienced. If one conceptualizes the negative effects as an externality generated by the proposed facility (e.g., the smoke and particulates expelled through a factory's smokestack and falling on the surrounding neighborhood), then those effects can be mapped onto a spatial externality field defining the area of impact (Cox and Johnston 1982). Locational conflict is often relatively local in scale since such externality effects usually attenuate sharply with distance. Conflict also becomes manifest at larger spatial scales, often depending on geographical circumstances of adjacency or propinquity. A proposal to site a noxious facility near a municipal or regional border, for example, may generate locational conflict between the abutting jurisdictions. Proposals to site solid waste disposal facilities that will accept waste from multiple jurisdictions often generate opposition to the importation of waste from distant locations, expanding the conflict over a sizable area. Locational conflict has similarly emerged at the national scale over proposals to export hazardous waste from western industrialized nations to less-developed countries and over the migration of noxious effects, such as air or water pollution, across international boundaries. Concerns over the worldwide effects of climate change attributed to material practices in high-consumption nations can be understood as locational conflict at the global scale.

Locational conflict is not a uniquely recent phenomenon nor one exclusively associated with highly industrialized societies. Analysis of newspaper accounts of locational conflicts in nineteenth-century Worcester, Massachusetts (Meyer and Brown 1989) found that the frequency of reported conflicts on a per capita basis was essentially the same in Worcester in the 1870s as occurred in the 1970s in Vancouver, British Columbia (Ley and Mercer 1980), London, Ontario (Janelle 1977), and Columbus, Ohio (Cox and McCarthy 1980). The location of rendering plants, slaughter houses, and saloons generated protest in the nineteenth century, while waste incinerators, homeless shelters, and low-cost housing frequently motivated opposition in the late twentieth century. A vexing new problem for local officials is the location of cellular telephone towers, which are sometimes disguised inside church steeples or building cupolas to avoid protests over visual blight. In general, however, while the targets of conflict have changed to reflect changes in technology, economic activity, and society at large, the intensity of conflict was no less virulent a hundred years ago than it is today.

The perceptual basis of locational conflict exhibits both change and continuity over time. Newly industrializing cities of the nineteenth century provided a context in which proximity to the coal smoke and pollution emitted by mills and factories was perceived as beneficial, no doubt due to an association with steady employment and economic prosperity (Meyer and Brown 1989). In contrast, public awareness of the health hazards of industrial activity is one of the most frequent sources of locational conflict today. A common focus of protest in 1870s Worcester were the millponds which, despite their obvious economic importance, were thought to generate 'miasma,' believed to be a disease-bearing atmospheric poison produced by decaying organic matter (Meyer and Brown 1989). The parallel to today's conflicts over siting waste incinerators is striking. Both the millponds then and the incinerators now are considered necessary adjuncts to essential economic activity but both were and are also perceived to present risks to health and the environment. Both, consequently, are said to produce the NIMBY syndrome: yes, society needs the facility – but Not In My Backyard.

2. *Antecedents and Conceptual Approaches*

Formal analysis of locational conflict by American geographers began in the early 1970s as an extension of classical economic location theory. Classical theories of industrial and residential location presented a model of locational choice by autonomous units (firms or households) seeking to maximize individual utility functions within budget constraints. Political geographers such as Kevin Cox and his students at Ohio State University challenged the assumption of autonomous locational decision-making by recognizing that individual utilities are not independent of the externality effects produced by the locational decisions of others (Cox and McCarthy 1980). Conflict ensues when the utility of a locational choice is diminished by the negative externalities generated by the locational choices of others. This extension of traditional location theory shifted analysis away from individual locational choice towards a focus on the manipulation of the spatial distribution of externalities, that is, on attempts to exclude negative externalities and attract positive ones. While classical location theory addressed individual locational decision-making within a framework of economic rationality, locational conflict theory examines collective strategies for the protection and enhancement of neighborhood quality within a framework of collective political action. As a result, the focus of analysis moved from the economic to the political arena, from individual choice to collective action, and from locational decision-making to locational conflict as a politics of turf.

The view of locational conflict as turf politics, however, retains an axiomatic assumption of traditional location theory. The central assumption in this behavioral approach is that conflict arises when a locational decision perceived as beneficial by some is perceived negatively by others. While focus has shifted to collective action, the impetus for political engagement still resides in the individual's perception of positive or negative consequences associated with a proposed locational decision. The active agent is the autonomous individual whose behavior is guided by a unique calculus of perception, whether locational conflict is situated within an individual choice framework of conflicting utilities or in the pluralist politics of neighborhood change.

Situated at the level of conflicting perceptions, the behavioral approach to locational conflict rarely considers why changes occur in local areas such that conflict arises over their perceived positive or negative consequences. A structuralist approach views locational conflicts as symptomatic of fundamental contradictions situated within the basic structure of society. Locational conflicts, in this view, are merely surface manifestations of deep-seated conflicts inherent in the extant system of social organization (Cox and McCarthy 1980). Within a structural mode of explanation, negative externalities are not viewed simply as evidence of market imperfections subject to correction but rather are understood as necessary and inevitable consequences of class relations within the process of capital accumulation.

Identifying the particular structural contradictions that become manifest as locational conflict, however, is itself a subject of conflict and disagreement. In one view, the inherent contradiction between labor and capital generates contradictory orientations to neighborhoods, such that labor's attachment to place based on the neighborhood's use value conflicts with capi-

tal's investment interest based on the neighborhood's exchange value. Locational conflict, in this framework, arises from the fundamental antagonism between labor and capital with respect to neighborhood change. In another view, locational conflict is situated within the incessant competition between factions of capital, and results when the expansionary interests of mobile capital conflict with the exclusionary interests of capital already fixed in place (Plotkin 1987). For example, existing investors seeking to exclude potential new competitors may resist a shopping center developer's search for new investment sites. Bridging these two approaches is a third view in which labor's attachment to neighborhood erects a barrier to continued accumulation of capital. In response, capital encourages long-running societal processes—the homogenization of space, pervasive ideologies of materialism and consumerism, media manipulation and mass education, and increasing residential mobility, among other contributing factors—which succeed in transforming neighborhoods from communities into commodities and, consequently, transforming labor's attachment to community into an orientation based on protecting neighborhood exchange value (Cox 1981). Now locational conflict occurs when the exchange value interests of capital and labor fail to coincide as, for example, when a land developer's proposal for a shopping center generates traffic and pollution that threaten to reduce the resale value of surrounding homes.

More recently, a post-structuralist approach has emerged that situates locational conflict within the antagonistic discursive or representational strategies of contending groups vying for control over the use of space, where such control is an expression of political power. Rejecting the view of space as simply a container for action, this approach, influenced by the work of Lefebvre (1991) and others, considers the social and political process through which the meaning and use of space are constructed in particular instances. Now locational conflict is not primarily about the spatial distribution of activities or land uses nor is it simply about contrasting preferences for various activities in particular locations. Rather, locational conflict is symbolic conflict over the social distribution of power to assign meaning and uses to space (Mitchell 1992). Locational conflict symbolizes contention over whose values have standing within the political process and whose values, therefore, become expressed in the landscape. Recursively, control over the use of space symbolically constitutes the controlling group as a legitimate actor within the broader political process. Establishment of a squatter settlement within an affluent residential neighborhood despite the opposition of existing residents, for example, provides a site for housing impoverished families. Also, and perhaps more importantly, it discursively represents squatter families as legitimate occupants of space and, therefore, legitimate participants in the political process.

The evolution of locational conflict theory from classical to behavioral, to structural, and post-structural formulations parallels theoretical developments in the field of geography as a whole. Underlying each of these theoretical positions is a set of often incommensurate assumptions regarding the relative autonomy of individual actors, the primacy of market processes, the nature of the public interest, and the respective roles of structure and agency in creating geographic landscapes. In addition, the various theoretical understandings of locational conflict point to substantially different routes for its amelioration or resolution. A behavioral model of conflict based on contrasting perceptions suggests that resolution is attainable through public information and education designed to bring perceptions into agreement. A model of conflict based on the unequal spatial distribution of negative externalities suggests the use of compensation to equalize outcomes. Understanding conflict as symptomatic of deep underlying structural relations requires the elimination of structural contradictions. A focus on locational conflict as the symbolic expression of rights to create the meaning of space requires the deconstruction of opposing claims and their reconstruction in more equitable forms. Far from being merely an academic exercise, one's theoretical approach to locational conflict implicates significantly different avenues for its resolution, as discussed in the following section.

3. *Resolving Locational Conflict*

The contentious character of locational conflict has generated considerable debate over the intervention strategies conducive to its resolution. Approaches to intervention differ according to their proponents' understanding of the sources and dynamics of conflict, as described above, and according to their focus on the varying perspectives of conflict participants. Methods of resolving conflict distinguish between community-centered, user-centered, and state-centered approaches (Takahashi 1998 and DeVerteuil 2000).

3.1 *Community-centered Approaches*

Community-centered approaches focus on community opposition to a proposed facility siting. Depending on the characteristics of the community and, in part, on the perspective of the analyst, local opposition can be interpreted as exclusionary parochialism or as constitutionally protected freedom of speech and dissent (Takahashi 1998). Those taking the latter perspective point to instances in which poor or politically marginalized communities succeed in preventing the siting of an environmentally hazardous or otherwise noxious facility and consider that conflict has been resolved through defeat of the siting proposal (Heiman 1990).

More frequently, and especially when phrased in the NIMBY characterization, locational conflict is viewed as a shortsighted and parochial expression of self-interest that prevents achievement of the greater public good. Their proponents present the facilities whose siting generates locational conflict as both necessary and beneficial for society. A mobile society needs highways and airports. Consumers expect convenient access to shopping. Production of wastes is an inevitable by-product of a consumer society and requires safe and reliable disposal capacity. New prison construction keeps dangerous criminals off the streets and prevents prison overcrowding.

From this vantage point, conflict over siting proposals poses a barrier to attainment of the public good and requires a strategy to overcome, elude, or defuse opposition in order to allow the siting to go forward. Some professional associations of land and real estate developers offer guidelines and training to assist their members to negotiate the hazards of community opposition to proposed developments. Such strategies counsel facility proponents to anticipate opposition, solicit statements of support from potential allies, marshal expert testimony for public presentation, demonstrate the anticipated benefits of the proposed scheme, utilize formal appeals procedures, and the like.

Compensation of affected parties is a central premise within the community-centered approach. If locational conflict arises from the unequal spatial distribution of negative externalities created by the sited facility, then conflict can be resolved through compensation of those bearing a disproportionate share of costs. The theory of compensation assumes that costs are susceptible to translation into a single monetary metric and that a fair system can be devised for identifying affected parties and distributing payment. Such a system is difficult to devise in practice, however. It is difficult to distinguish between payment as compensation of costs and as inducement to accept costs, and communities often reject compensation as synonymous with a bribe. It is relatively easy to compensate for direct costs associated with a newly sited facility, such as additional emergency response equipment, but it is more difficult to assess a value for indirect costs such as stigmatization or economic growth foregone when potential investors avoid proximity to a noxious facility. There is disagreement as to whether costs should be compensated at an equal level in an impoverished and an affluent community. On purely economic grounds, the impoverished community can receive less compensation because poor people are satisfied at a relatively lower cost but this conclusion can easily be challenged on ethical grounds. Compensation as a means of resolving locational conflict is problematic for these and other reasons.

Some practitioners adopting the community-centered approach choose siting strategies based on equity considerations. Such strategies typically distinguish between the goals of procedural equity in decision-making and distributional equity in outcomes. Approaches based on distributive justice assume the necessity of the facilities in question and seek to achieve a fair distribution, where the primary criterion of fairness is to avoid neighborhood concentrations of unwanted facilities. One such method is to devise a point system for desirable and undesirable facilities (parks and libraries in the former category, for example, and waste incinerators and sewage treatment plants in the latter) and to equalize points across neighborhoods or political jurisdictions. Localities might be encouraged to opt for an undesirable facility so as to qualify for a desirable one under this system or might be disqualified from obtaining a beneficial facility due to insufficient points for hosting undesirable ones. The obvious difficulty in assigning points to facility types, however, has prevented this system from being implemented in practice. New York city's legislatively mandated fair share process for distributing unwanted city facilities across neighborhoods similarly has been abandoned in practice due to difficulties of implementation.

Community-centered approaches based on procedural justice argue that public opposition is mobilized not only by unwanted siting outcomes but also by perceived unfairness in the decision-making process. At a minimum, the procedural solution takes the form of a mandated hearing within a public review or permitting process. The public hearing has been criticized as a means of facilitating public participation, however, on the grounds that it is rarely more than advisory and that important decisions, such as the need for the facility, have usually been taken prior to the hearing. More detailed procedural approaches stress the importance of community consultation early in the siting process, inclusion of all stakeholders in negotiations, and the opportunity for sites to withdraw from consideration at any time. The most fully developed approach within this framework allows localities to volunteer themselves as sites for controversial facilities, subject to specified siting criteria and in return for generous compensation. This approach elides difficult ethical questions, however, if localities volunteer for controversial facilities not through choice but due to a lack of alternative means of economic survival.

3.2 User-centered Approaches

The user-centered approach usually applies to conflict over social service facility location. This approach moves beyond the perspectives of siting proponents and opponents and considers the perspective of facility users who often experience extreme poverty and/or physical, social, or mental disability as a barrier to access to needed services (Takahashi 1998). Omission of the users' perspective in community-centered

approaches both reflects and contributes to their stigmatization. While equity in community-centered approaches focuses on community participation in facility siting decisions, equity in the user-centered approach is concerned with facilitating access to needed facilities on the part of service-dependent clients. Residents and users of homeless shelters, drug or alcohol rehabilitation centers, domestic violence shelters, group homes, and similar facilities are often dependent on multiple services and benefit from service clustering that other community residents view as an undue concentration of unwanted facilities.

Social service providers choose from two divergent strategies in countering local opposition (Dear 1992). The collaborative approach seeks to establish a partnership between the service provider and the host community through public outreach and education aimed at improving awareness, tolerance, and acceptance. The autonomous approach considers access to needed services to be a civil right of facility users and relies on legislative and judicial protections to override community opposition.

3.3 State-centered Approaches

The state-centered approach to locational conflict reformulates the traditional question of locational conflict—'Why is the community opposed to this facility?'—and asks instead: 'Why is the state seeking to site this facility in this community?' (Lake and Disch 1992). This rephrased question problematizes the assumption, shared by community- and user-centered approaches, that facilities are needed by society. In the state-centered approach, controversial facilities are understood as needed by capital seeking to externalize costs as a competitive strategy and as an expedient solution for the state seeking to facilitate capital accumulation while maintaining legitimation of the capital-labor relationship (Lake 1993).

Facility siting in this context constitutes a particular problem-solving strategy that is instrumental for the state. By providing a locational solution to a problem of industrial production (waste production or homelessness, for example), facility siting allows production and capital accumulation to continue relatively unimpeded while concentrating costs on host communities. The decision to concentrate costs on communities rather than on capital reflects a political calculation that it is preferable for the state to confront localized political conflict than to risk a challenge to the capital-state relation. The siting strategy deflects political conflict away from a potentially daunting challenge to the capital-state relation and into a relatively benign debate over the merits of alternative facility locations (Lake and Disch 1992).

According to the state-centered approach, the root of locational conflict is situated not in the consequences of hosting a controversial facility but rather in a regulatory approach that inexorably leads to facility siting as a policy solution that concentrates costs on host communities. To the extent that this is the case, the resolution of conflict requires a restructuring of policy assumptions and policy solutions through political debate, redirecting costs from host communities back on to capital, and avoiding the emergence of conflict at its source rather than seeking to ameliorate its occurrence after the fact.

4. Future Directions: Ethical and Social Justice Issues

Recent locational conflict scholarship has increasingly intersected with the literature of environmental racism and environmental justice. This coalescence emerges from a common conceptual focus on equity and on the distinction between distributive and procedural equity, in particular. Influenced in part by development of the state-centered approach, locational conflict scholarship is increasingly shifting attention from siting outcomes to examine political and structural influences on the siting process. This shift closely parallels a redirection within environmental justice scholarship from a focus on distributional equity, concerned with the concentration of environmental burdens in disempowered communities, to a focus on procedural equity, concerned with democratic participation in the gamut of prior decisions affecting the production of burdens and benefits to be distributed (Lake 1996). Recent environmental justice literature explicitly seeks to relinquish its narrow focus on inequity in facility siting, emphasizing instead the pervasive inequity in the broad socio-spatial processes creating geographic landscapes (Pulido 2000). The challenge for these increasingly combined spheres of scholarship is to expand understanding of these processes and to inform the design of institutional structures that expand community participation in their operation.

R. W. Lake

Locke, John (1632–1704)

1. *Life and Writings*

Hegel perhaps excepted, John Locke is the most eminent philosopher of the Western world to have addressed himself to political and social issues. Indeed his standing as *the* great thinker amongst English speakers in the eighteenth and nineteenth centuries gave to his writings on such issues, the theories of politics, toleration, economics and education, a standing which they would not have commanded even when taken together. And yet the famous *Essay Concerning Human Understanding* (1975) scarcely provided a general intellectual framework for his theories on individual topics. The action of his mind was like that of the beam of a searchlight shining through the darkness on individual objects but with no linkage made between them or any reflection back from object to source.

John Locke the man can be taken as the archetype of the English country gentleman turned intellectual. He was the first born of the two sons of a lawyer who fought for the Parliament against King Charles I when John was a teenager. The family had a small landed estate in the county of Somerset and Locke was born on August 29 1632 in the village of Wrington, though the family seat was at Belluton some ten miles away. He inherited the family properties and his father's modest position within the community of gentry of the county. He was an absentee landlord, except for brief intervals, for most of his life. This was because his father designed him for a scholarly career, not all that unusual for the gentry but exceptional for an heir (Laslett 1948).

Locke's father set his sights high for his son, whose outstanding intelligence must have been evident from the beginning. In 1647 he sent him to Westminster School, the best in the country, and thereafter, in 1652, to the college of Christ Church in Oxford, where he went on to take office as a teacher between 1658 and 1684. Locke never married, and insisted that he would have liked to have lived his whole life there as a bachelor don. However, it proved otherwise, and within a decade he found himself for much of his time in London at the center of national politics, in the entourage of one of the great political magnates of the time, Anthony Ashley Cooper, Earl of Shaftesbury, who was then in high office but subsequently became leader of the movement of opposition to the succession to the throne of the Catholic James, brother of the childless Charles II, the Exclusion campaign, as it is called. The explanation for this transmogrification, which left his position at Christ Church unaffected, was that Locke had taken up medicine so that he could continue his academic career without becoming a priest. In 1666, on a visit to Oxford, the invalided Shaftesbury met Locke who performed upon his body one of the medical miracles of that age which saved his life. It was as a medical adviser of Shaftesbury, not as an academic, that Locke took up and pursued his career as a writer on the theory of knowledge, and on what we now recognize as social scientific subjects. *Two Treatises of Government*, also published in 1690, was composed while Locke acted as what a close friend called 'assistant pen' to Shaftesbury in the early 1680s during the Exclusion campaign. The Catholic James nevertheless became James II in 1685.

A now outmoded interpretation of *Two Treatises* perceives it as the subsequent rationalization of the so-called Glorious Revolution of 1688/9; it is now accepted that the author's intention was to justify a revolution yet to be brought about by Shaftesbury and

his party, but which did not take place. This makes it easier to understand its usefulness as a persuasive in favour of national revolutions for two hundred years and more after its publication. Without Shaftesbury, it has been said, Locke would not have been Locke at all. Indeed he had composed numbers of unpublished treatises before 1666, mainly of a theological type, though with a political admixture conservative in tone. But the younger Locke cannot be described as wholly backward looking, if only because of his association with Robert Boyle and others in the earliest advances in natural science in England, and in the establishment of the Royal Society, of which he became a fellow in 1668.

As his convictions changed in the liberal direction, Locke suffered for them, both at the hands of his Christ Church colleagues and of state authority. Getting further and further absorbed into Shaftesbury's affairs, taking a job in government, exercising responsibility for various commercial and colonizing undertakings, he undertook the writing out in 1668 of a political constitution of the colony that his master owned on the Atlantic seaboard of North America, the *Fundamental Constitutions of Carolina* (Locke 1794). This was the first written political constitution ever composed, and provided near-absolute toleration for nonconforming belief. Things like this, and failure to conform himself, were unacceptable to the regime and in 1684 Locke was expelled from Christ Church by Royal Order. Shaftesbury had died in exile in Holland, and the beleaguered Locke finally took up residence in that country, the haven of political progressives. He was there in 1689 when William and Mary sailed to England to bring about the Whig revolution. Locke returned with the joint monarchs, and was given minor political offices of a commercial kind. In the fifteen years left for him to live he twisted his fingers round the haft of English intellectual life and got it in so firm a grasp that it began to point in the direction of his choice. This is the period in which he published his books and addressed himself to posterity.

He spent this final, intellectually victorious, period at his London address, but also living as much as he could as a country gentleman once more, not on his own estate but as a lodger in the manor house of Oates in the country of Essex, much nearer his London activities. These activities made him into a founder of the British Empire, especially in relation to the North American colonies which were later to call on his doctrines when they came together as the United States (Laslett 1969). An intimate association grew up with the lady at the house at Oates, Dame Damaris Masham, a devout Christian and a theologian of the Lockeian description, along with her son and stepdaughter. When he died at the house on October 28 1704, he was buried in the churchyard of the nearest village, at High Laver. He should be remembered in this final dual role, as the sovereign of London intellectual society, and as the revered elderly gentleman seated in the garden at Oates—he himself was a passionate gardener—surrounded as often as possible by young people and children.

2. *Publications*

Included here are books he published on the social sciences which have affected his vast readership for three hundred years rather than the treatises left in manuscript, which have begun to influence scholars in recent years.

2.1 *Philosophy*

In *An Essay Concerning Human Understanding*, first published in 1690, Locke (1975) established himself as the first and most important empiricist thinker. The exclusive source of knowledge was experience gained from sensation. Apart from revelation, nothing else was given to the intelligence, and he was particularly insistent that no knowledge was innate. Everything to be known was printed on the blank sheet of the mind through its ideas, simple ideas elaborated systematically into a nexus of complex ideas. Locke went beyond his empirical assumptions and used rational arguments to underwrite his firm belief in a real world behind the ideas which he systematized, and in the existence of God. It is the inconsistency between his rationalism and empiricism which has been seen as his weakness, though by some as also a source of relevance and insight.

2.2 *Political Theory*

Two Treatises of Government (1960), lays it down that the sole source of political power is the consent of the citizens of the society concerned. The target throughout both treatises was the patriarchal theory of Sir Robert Filmer (died 1653) whose posthumous work *Patriarcha* (1680) provided theoretical justification for Shaftesbury's opponents. Filmer and his devotees, the Tories in the nascent English party system, believed that the source of all authority and property, political, social, and personal was fatherhood, on which God had conferred absolute divine right. Extreme, even ridiculous as it may seem, this had evident appeal to landowning gentry families, and it had strong scriptural and ecclesiastical authority behind it. Moreover Filmer displayed a needling effectiveness by exposing all alternative justifications of power and property as even more unrealistic and ridiculous.

This laid Locke's way open to fundamentals. Whatever may have been the patriarchal underpinnings of social and political relationships, governance could

only be exercised by those individuals specifically entrusted with it and elected representatively by citizens, mainly the propertied. Though property could be inherited, its basis was labor: you owned those natural objects on which you had done work, and this property was protected by the state set up in this way as its most important function. Government was in a sense divine, as an emanation of power, but no regime could conceivably rule by divine right, and once it lost the consent of the governed it could be, had to be, overthrown by the property-owning citizenry and replaced by one of their choosing. Both the pre-eminence of property in political society, and the intellectual origins of democratic revolution as a perpetual sanction on all political authority, are plain to see.

2.3 Toleration

Epistola de Tolerantia (1968). Locke flatly denied that any authority had a right to prescribe or proscribe religious belief, or to punish anyone for holding a religious opinion. All such matters were reserved to the Church, defined as 'a voluntary society of men.' The discipline within the Church was limited to exhortation with no other sanction than expulsion. Nevertheless, opinions contrary to civil peace had to be controlled, and atheists also, because they could not be bound by promises. A muted resistance to governmental intolerance was contemplated by Locke, in spite of what he says about civil peace.

2.4 Economics

Some Considerations of the Consequences of the Lowering Interest and Raising the Value of Money—Further Considerations (1991). Locke was the last and most influential mercantilist writer, preoccupied like all the others with the value of money, which was considered to be the spring, instrument, and channel of all economic activity. Money had a price which was determined to a considerable extent by the rate of interest. Maintaining the constancy of the value of money by regulating the coinage and manipulating interest rates was the object of this analysis and of the policy which he recommended. Particularly important were the regular supplements to the supply of money through foreign trade, a crucial activity in the Lockeian system.

2.5 Education

Some Thoughts Concerning Education (Locke 1988). The familiar phrase 'A sound mind in a sound body' are the opening words and the *leitmotiv* of this extraordinarily popular and influential treatise. A great deal of it is given up to habits conducive to health, especially exercise and diet. Strict discipline is needed but not through corporal punishment: the proper instrument is encouragement and strictly consistent practice. The mode of instruction should be as conversational as possible. In short, children should be treated not so much as little adults, but as adults in the making, learning by their own intellectual assent as their capacities developed.

3. Influence and Importance

The huge influence and great historical importance of Locke's political theory should be evident from the account already given. *Two Treatises of Government* was repeatedly printed as the eighteenth century went by; it was translated into French, the international language, in 1691, and was published more often in French than in English; editions also appeared in most of the other European languages (see Locke 1960).

As has been said, it repeatedly came to the fore in the history of nations when issues of despotic government arose, sometimes along with the *Epistola de Tolerantia*. The next most printed and cited work was that on *Education*, though *An Essay Concerning Human Understanding* ran it close. His economic theory had widespread influence up to the time of Adam Smith and has been regarded as the quintessential early expression of the capitalist spirit (MacPherson 1962). His educational doctrine has been continuously influential for at least two centuries and can be regarded as the origin both of companionate upbringing in the home, parents and children on a level, and of the teaching practice of Anglo-Saxon elite schools. In short, the social scientific works discussed here can be claimed to have ushered in empirical–rational social scientific enquiry in their respective areas. The *Essay Concerning Human Understanding* has been aptly called the first modern book, a title which would also sit well on all the treatises we have commented on. There is surely no need to go further to demonstrate Locke's outstanding influence and importance.

P. Laslett

Logic and Cognition, Psychology of

All about us, creatures seem more suited to their niches than we humans are: they are more fleet of foot and wing with more finely tuned sensorium. Yet, only humans are able to transcend restricted habitats, develop plans, adapt strategies, and remember not only who said what, but why. In sum, our greatest adaptation across the vicissitudes of time and place is our ability to reason. It has been said that *reasoning* is humans' central intellectual activity (Rips, 1986) that organizes language, culture, and our memories. It allows us to take events, assertions, suppositions, beliefs as input and draw conclusions and create new information. Reasoning allows us to go beyond the given in a situation and see the overall pattern; to find the theme; to see the plan or create one.

1. *Reasoning*

The pervasiveness of reasoning has captured the interests of cognitive psychologists who seek to understand universal principles of human cognition. Early in the twentieth century, psychologists were surprised at how poor people are in solving academic logic problems, yet how perfectly adequate the same people are in their reasoning with everyday materials—and without special training (Wilkins 1928). People tend to feel alienated from the prescriptive logic of the classroom, as well they might since from its very beginnings it had little to do with the rationality of the human mind and very much to do with creating a didactic device for educating students. Aristotle, in an effort to express to his students how to think clearly and how to draw conclusions from data, created a set of idealized conditions (called Figures) from which certain conclusions could be unequivocally drawn; and he contrasted these with conditions from which a conclusion could only be equivocally drawn. From these simple didactic beginnings, the field of philosophy of logic was born. Over the centuries, innovations in understanding human logical or rational abilities have continued to come from efforts at teaching: Euler, who invented the circles to represent sets, did so within the context of tutoring in logic (Euler 1775). Venn (1880), who expanded on the circle representation, introduced the notion of a universe of discourse and analyzed the overlapping of multiple sets/circles and did so within the context of trying to teach logic to his students at Cambridge University. Some of these didactic techniques have inspired modern cognitive psychologists to theorize about natural human inference. Erickson (1978) and Guyote and Sternberg (1981) borrowed Venn diagrams as an approximation to how students may interpret and mentally represent quantified sentences in their combinatorial theories of reasoning. One of the major cognitive accounts of the processes of human reasoning is called 'Mental Models'; it was developed by Johnson-Laird (1983) and had its origins in the efforts at the beginning of the twentieth century by Störring (1908) to teach his students how to reason by drawing pictures. Throughout the centuries, the impoverishment of didactic logic has been so daunting to students that they have argued they should not have to study it. After all, they say that 'we should only study things that are relevant to human life; syllogistic reasoning is not relevant, so we shouldn't be studying syllogisms.' This itself is a type of logical argument that could be rewritten in syllogistic form (the standard form for logic):

We should only study things that are relevant.
Syllogistic reasoning is not relevant.
Therefore: we should not study syllogistic reasoning.

Clearly this argument is self-refuting, but illustrates that even though we may wish to avoid the intricacies of prescriptive logic, some aspects may be descriptive of an underlying system of natural inference processing that becomes manifest even by people untutored in the philosophical tradition. Take a four-year-old, for example. We know that if you tell the child (in the form of a syllogism):

If you brush your teeth, I'll read you a story before bed and
The child brushes her teeth
You can be sure that the child will expect a story.

The structure of this argument is formally described as *If P, then Q*; *P therefore Q* and is termed *modus ponens* (positive mode) and is an argument that is accurately understood by children and adults, without any special instructions (e.g., Taplin et al. 1974). Just as Molière's *Bourgeois Gentilhomme* was surprised that he spoke prose all of his life, so too are the students of the psychology of logic surprised to find that people seem to be inherently rational (at least under specifiable circumstances) and follow a kind of *psycho-logic* which is illustrated below with three different forms of inference: linear, categorical, and conditional reasoning.

1.1 Linear Reasoning

One of the simplest forms of inference compares the extent of things and draws a conclusion about the item that has the most or least of the extent. For example:

Scott is taller than Paul.
Paul is taller than Nancy.
Who's tallest/shortest?

These kinds of syllogisms found their way on to the early measures of intelligence (e.g., Burt 1919) because reasoning skill with these problems seemed to increase with chronological age during adolescence (e.g., Hunter 1957). Interestingly, the pattern of difficulty shown on series problems by children is similar to that shown by adults (Huttenlocher 1968, Clark 1969) which suggests that linguistic processes (and the complexity of the terms: *older–younger*, *taller–shorter*, etc.) rather than inference *per se* contributes to the development of reasoning skill with age (Johnson-Laird and Steedman 1978).

These problems are called 'linear syllogisms' because one way to draw inferences from them is to imagine that the information is placed on a line or on an analogue scale (a continuously varying scale). When such a scale is used, it is possible for the reasoner simply to 'read-off' the mental image to find the answer. Consistent with this idea is students' expectation that the information will be presented in a linear form (left-to-right or right-to-left order), called the *canonical form*. When the information flow fits the canonical form, reasoning is fast and accurate and when it does not fit it, reasoning is labored and error prone (Hunter 1957). A similar effect has been observed for problems with more than just three terms in it. For example, Potts (1974) had students reason with relations among five items embedded in a passage (e.g., *A is greater than B, which is greater than C, which is greater than D, which is greater than E*) and discovered that terms that are further apart on the linear scale are easier for students to evaluate (e.g., *Is A greater than E?* was faster and more accurately judged than *Is A greater than B?*, even though the latter was actually presented in the narrative and the former inference was not). This effect of the way you mentally represent information has been termed the *semantic distance effect* (Holyoak and Mah 1981) and requires primarily that the information be coded on a uniform scale (such as size, intelligence, etc.).

1.2 Categorical Reasoning

Perhaps the simplest form of reasoning with categories is the categorical syllogism:

All men are mortal.
Socrates is a man.
Therefore: Socrates is mortal.

The ability to draw the appropriate inference is nearly universal, does not require knowledge of logical forms, or even to know the meaning of the term 'men' and 'mortal.' It requires only a basic willingness to cooperate to do the task. For example, Cole and Scribner (1974) showed that unschooled adults in Liberia will occasionally decline to draw an inference, but their explanation reveals basic inferential skills:

All men in Kpelle town are farmers.
Joe is a man in Kpelle town.
Therefore: Joe is a farmer.

'I cannot answer the question, because I only speak about people I know and I don't know this Joe.' In the canonical form, the man's explanation looks as follows:

I only speak of people I know.
I don't know Joe.
Therefore: I cannot speak of Joe.

So the justification for failing to do syllogistic reasoning takes the form of a perfectly phrased logical argument and is an example of the universality of this form of reasoning.

The critical factor in the willingness to solve syllogisms seems to be whether a person has had more than 2 years of basic schooling. When asked to solve categorical syllogisms, such educated people, while not necessarily tutored in logic, show the following profile. When they reason about everyday sorts of things, they are more accurate than when they reason about symbolic or abstract relations (Wilkins 1928). Reasoning on symbolic material can be enhanced by having a mental image of how many elements are contained in the sets—the sizes of the sets allows people to represent the relations more like concrete than like abstract materials (Revlin and Leirer 1978). When their beliefs about the world are consistent with the syllogism's conclusion, they are more accurate than when logic and belief are in conflict. When there is a definite unambiguous conclusion to be drawn, people are confident in the conclusion, but when no such conclusion is to be drawn, people are tentative and somewhat capricious in their answers. When reasoners are asked to draw inferences from a multitude of category relations as in the following narrative, they show a kind of semantic distance:

> All members of the Fundala Party are members of the Outcast Coalition. All members of the Outcast Coalition are members of the Hill People Union … members of the Peace Front.

The more distant the relation, the more accurate the judgment—just as with linear relations. A completely different pattern is seen when the categories do not readily fit in a common scale, as in the following (from Griggs 1978):

> All Fundala are Outcasts. All Outcasts are hill people. All hill people are farmers. All farmers are peace loving.

Reasoners view these relations as *divergent*, dealing in succession with a social group, geographic entities, occupational categories, and a political orientation. The very same people who performed optimally with the first passage are at near chance levels when asked to reason about this second narrative (Nguyen and Revlin 1993).

Reasoning with categories shows a developmental sequence somewhat akin to that shown for linear relations. The critical factor seems to be in the interpretation of the terms rather than possession of inferential processes. For example, when seven-year-olds are told that *all of the squares in a display are yellow*, they anticipate that the display will only contain yellow squares and no other kind of object. This is called an 'order-neutral interpretation.' Slightly older children interpret the quantified sentence as implying that all squares are yellow and that all of the yellow things will be squares. However, they are not surprised that there are nonsquares and these will have colors other than yellow. This is called a 'converted interpretation.' Finally, most adults (but not all of them) interpret such quantified sentences as true set-inclusion, that all squares are yellow, but some yellow things may not be squares (Bucci 1978). This ontogeny in the interpretation of quantifiers corresponds to the development of logical competence with categorical relations and suggests that the interpretative processing and not inferential ones may be what is developing.

1.3 Conditional Reasoning

Conditional syllogisms have as their central statement, a conditional expression of the form *If P is true*, *then Q is true*. Although conditional syllogisms are logically equivalent to categorical syllogisms, they have a communicative property that makes them especially interesting to psychologists in studying how people reason with them. The external marker *If* allows for an incredible range for conjecture: the reasoner can interpret it to mean *let's suppose that* … , or *someone believes that* … (e.g., *Paul believes that if P*, *then Q*, even though he may be wrong), or *to perform some action*, *there is a set of conditions that must be followed* (e.g., *If you're drinking alcohol*, *you must be the right age*), and so forth. That is, conditional syllogisms reveal the very property that makes human inference so dynamic: an ability to consider truth at many levels. When adults are presented with conditional syllogisms that have an unambiguous conclusion to be drawn, they are rapid and accurate:

If *P* then *Q*	If *P* then *Q*.
P is true	not *Q* is true.
Therefore: *Q*	Therefore not P.

These problems are called *modus ponens* and *modus tolens*, respectively. The former tends to be more accurately solved than the latter, but people demonstrate real skill in solving these problems without any special training. In cases where the conclusion is ambiguous, students take longer to reach a decision and tend to equivocate and generally draw an incorrect conclusion:

If P then Q	If P then Q.
Not P	Q.
Therefore: ?	Therefore: ?

Just as with other forms of inference, interpretation of the relational terms is critical to accurate judgment. A common error among adults is to assume that a kind of unique causal structure holds when they hear *If P then Q*. That *P* somehow causes *Q* and that it uniquely does this. This typically goes by the name *biconditional* interpretation: *If P is true then Q is true* and *if Q is true*, *so must P* (Taplin 1971). You will notice that this is similar to the 'converted interpretation' on categorical syllogisms. It has been argued that there is a developmental sequence in the ability to solve conditional syllogisms which is linked to the child's interpretation of the conditionals. Very young children treat conditionals as conjunctions, slightly older children treat them as biconditionals, and adolescents and adults are able to treat them as one-way conditionals. Just as with categorical reasoning, conditional inference is sensitive to the content of the material reasoned about. This is particularly striking when people have to test conditional rules (Cox and Griggs 1983). When the rules and situations match a *type* or *schema* (e.g., a permission rule: *If you meet the requirements*, *you can perform an action*), reasoning can be sharply more accurate than if the conditional rule is arbitrary (Cheng and Holyoak 1989, Cosmides and Tooby 1997). The ease and ubiquity of this kind of reasoning suggests it may actually be a part of the human cognitive apparatus, part of our biological heritage that permits us to engage in effective social interactions.

2. Where are the Rules?

These findings from cognitive research in three areas of logical reasoning show that people are far more

rational than is often assumed. Our inability to solve some impoverished symbolic problems does not mean that we are not rational. It does mean that if there is a logic within us—and we must be following some set of rules or procedures to allow us to be rational under normal circumstances—it is probably not the standard logic we are taught in schools. The logic of the head need not be the same as the philosopher's logic because human inference occurs in rich and varied contexts, with cognitive and social constraints operating all around us and directing our attention to critical assertions and providing us with just the right inference procedures to evaluate them. These pragmatic influences may at first sight seem impurities in the crystal clarity of inference, but we must be mindful that even logic rules *can* propagate errors. Rationality and the possession of general reasoning rules do not assure us that the premises are not false, or that situations are not misinterpreted, or that cognitive load will not contribute to erroneous processing. While natural logic may be the basis for rational judgments (Rips 1994, Braine and O'Brien 1998), this does not mean we cannot make errors and do irrational things. An error in the input can be propagated promiscuously throughout our knowledge. Without some pragmatic knowledge to direct our processing or the identification of degrees of truthfulness of propositions, our knowledge base would be completely suspect. To provide a kind of cognitive firewall (Cosmides and Tooby 2000), our inference system relies on the myriad of special representations of information that codes those things that are conjectures, possible truths, fantasies, and what other minds might know and how they may seek to influence us. These not only comprise the fabric of human inference, they are also domains of investigation of modern cognitive psychology. To understand human logical thought, we must also understand our system of knowledge and how it is able to represent the world as it is and as we imagine it to be.

Logic and Linguistics

Although the founding fathers of modern logic showed some interest in the analysis of meaning in natural language, solid links between the two disciplines of logic and linguistics had not been established before the middle of the twentieth century. In the late 1950s logical techniques were first applied to the analysis of grammars as theories of linguistic competence. These applications rapidly developed into the field of mathematical linguistics and later became a central part of theoretical computer science. They will be briefly addressed in the second part of this article. The tightest connections between logic and linguistics, however, grew out of the (re-) discovery of logical analysis as a tool of natural language semantics, starting with the advent of Montague Grammar in the early Seventies. The role of logic in the analysis of meaning forms the subject of the first part of this article.

1. *Logic and Natural Language Semantics*

The influence of logic on natural language semantics starts with the key notion of the field: meaning. Following the tradition of analytic philosophy (cf. Ammerman 1965), many linguists take a 'realistic' approach to meaning that makes abundant use of logical apparatus. The basic ideas of the logical analysis of meaning will be explained in Sect. 1.1. Sect.1.2 is concerned with some more specific relations between languages of formal logic and natural languages such as English. (See Barwise and Etchemendy 1990 and Gamut 1991 for introductions to modern logic from a semantic perspective.)

1.1 *The Logical Approach to Meaning*

A primary goal of semantic theory is to describe the *sense relations* that competent speakers perceive between expressions of a language (cf. Lyons 1968, Chap. 10; Larson and Segal 1995, Chap. 1). Thus, e.g., knowledge of the following facts about English phrases is part of native speakers' semantic competence: (a) *brown paper bag* is more specific than, or *hyponymous* to, *paper bag*; (b) *blonde eye-doctor* and *fair-haired ophthalmologist* are *synonymous* in that they necessarily apply to the same persons; (c) *Mary owns a dog* and *Nobody owns a dog* are *incompatible* with each other. Many sense relations can be expressed in terms of *entailments* between sentences: (a) holds because *This is a brown paper bag* entails *This is a paper bag*; (b) holds because *This is a blonde eye-doctor* and *This is a fair-haired ophthalmologist* entail each other; (c) holds because *Nobody owns a dog* entails *It is not the case that Mary owns a dog*. A theory that correctly predicts the entailment relations holding between the sentences of a particular language may therefore be expected to go a long way towards accurately describing its sense relations in general.

In modern logic, the notion of entailment has been successfully formalized by means of *truth conditions*: statement A entails statement B if, and only if, any way of making A true is also a way of making B true. Ways of making statements true are called *models*, which is why the enterprise of describing meaning in terms of truth-conditions is known as *model-theoretic semantics*. More specifically, a model consists of a set of objects, the model's *Universe*, plus an *Interpretation* assigning to every non-logical word a suitable denotation. For instance, the Universe of a specific model might be the set of all numbers, past US presidents, plants, or whatever—any set would do, as long as it is not empty. Similarly, the Interpretation could assign any individual to the name *Mary*—the number 20, Jimmy Carter, my little green cactus—as, long as that individual is in the model's Universe; and it could assign any set (even the empty set) to the noun *ophthalmologist*, as long as that set's members are all in the model's universe, and as long as it is the same set as that which the model assigns to *eye-doctor*. The idea is that any model in which the individual assigned to *Mary* happens to be a member of the set assigned to *ophthalmologist* makes the sentence *Mary is an ophthalmologist* true; and any model in which the set assigned to *ophthalmologist* happens to be empty, is one that makes the sentence *Nobody is an ophthalmologist* true.

In general, then, a model assigns each expression of the language a denotation, thereby deciding the truth and falsity of each (declarative) sentence. In fact, the denotation of a sentence is identified with its *truth value*: the number 1 if the sentence is true, and the number 0 otherwise. Using this numerical convention and writing $[\![X]\!]^{\mathscr{M}}$ for the denotation of an expression X according to a model $\mathscr{M}$, a statement A thus turns out to entail B just in case, for any model $\mathscr{M}$, $[\![A]\!]^{\mathscr{M}} \leqslant [\![B]\!]^{\mathscr{M}}$ whenever A's truth value $[\![A]\!]^{\mathscr{M}}$ according to any model $\mathscr{M}$ is 1, then so is B's truth value $[\![B]\!]^{\mathscr{M}}$ according to the same $\mathscr{M}$.

Traditionally, the statements made true by models are logical formulae. In linguistic semantics, there are two ways of adapting models to the interpretation of natural language: either natural language expressions are translated into logical notation (*indirect interpret-*

ation); or models directly assign denotations to them (*direct interpretation*). On either approach, complex expressions, i.e., anything longer than one word, are usually interpreted following the *Principle of Compositionality* (Janssen 1997): the translation or the denotation of a complex expression consisting of more than one word [like a sentence] is obtained by combining the translations or, respectively, the denotations of its immediate parts [like subject and predicate]. As a consequence, the denotations models assign to (the translations of) natural language expressions tend to be rather abstract. If, for instance, the denotation of the noun phrase *my car*, i.e., a concrete object, is to be obtained by combining the denotations of the noun *car*, which is a set of concrete objects, and that of the possessive *my*, the latter would have to be some 'selection mechanism' that picks out the unique object belonging to the speaker when combined with a set of objects. More abstract denotations turn out to be needed in a compositional treatment of determiners (like *every* and *most*), adverbs (like *quickly*) and prepositions (like *between*). This is one of the reasons why the most common systems of logic, propositional calculus and first-order logic, do not suffice as the basis of indirect interpretation.

The Principle of Compositionality has an important consequence, known as the *Substitution Principle*: if the denotation of a complex expression is completely determined by the denotations of its parts, then one may replace any part by something with the same denotation without thereby changing the denotation of the whole. A case in point is the sentence (*a*) *Mary is an ophthalmologist*. If Mary happens to be the speaker's neighbor, then the name *Mary* and the noun phrase *my neighbor* have the same denotation. Hence, if (*a*) is true and thus denotes the truth value 1, then, by the Substitution Principle, (*b*) *My neighbor is an ophthalmologist* has the same denotation as (*a*), i.e., it is also true. While the Substitution Principle appears to make the right prediction in this case, this is not always so. Together with the assumption that sentences denote truth values, the Substitution Principle immediately leads to what, in the philosophy of language, is known as *Frege's Problem* (Frege 1892): replacing any sentence by another one with the same truth value ought to preserve denotation, which it does not always do. For instance, the denotation, i.e., the truth value, of (*b*) *Nobody doubts that Mary is an ophthalmologist* ought to be preserved when (*a*) is replaced by a sentence with the same truth value. If Mary is an ophthalmologist, the truth value of (*a*) is 1 and hence the same as that of (*c*) *Paris is the capital of France*. However, (*b*) might well be false while (*b′*) *Nobody doubts that Paris is the capital of France is* true. Clausal embedding under so-called *attitude verbs* like *doubt*, *know*, or *tell*, thus turns out to be an *intensional construction*, i.e., one that defies the Substitution Principle.

Various solutions to Frege's Problem have been proposed. Practically all of them employ the idea that, at least in certain constructions, the contribution that a sentence makes to the denotations of larger expressions is not its truth value but something else. According to a widely accepted view (originating with Frege), it is its *informational content*: attitude verbs like *doubt* denote a relation between the individual denoted by the subject and the information conveyed by the embedded clause. A common way of modelling informational content is by means of *possible worlds*—whence the term *possible worlds semantics*. (See Barwise 1989 and Devlin 1991 for alternative approaches.) The basic idea is akin to that of measuring the expectance value of an event by the proportion between favorable and unfavorable cases. The cases become possible worlds, the event is the information (as expressed by a sentence) being correct and instead of the quantitative relation between the sets of cases expressed by a ratio, it is the qualitative difference that is emphasized, i.e., which worlds are favorable and which are not. Following this line of thought, the informational content of a sentence, then, can be represented by a function (in the mathematical sense) pairing worlds with truth values. For example, the informational content of (*a*) above becomes a function assigning to any possible world the truth value 1 if that world is such that, in it, Mary is an ophthalmologist; all other worlds will be assigned the truth value 0. Each possible world is thought of as representing a specific way the world could be, or might have been—to the last detail. So the informational content of a sentence will typically assign 1 to an infinity of possible worlds differing in all sorts of aspects that are irrelevant to the truth of that sentence; and it will typically assign 0 to innumerably many worlds differing in matters that do not affect the falsity of the sentence.

In order to give a full solution to Frege's Puzzle within possible worlds semantics, the informational content of each sentence must be systematically determined, which is again done compositionally, replacing denotations by *intensions*. The intensions of sentences are their informational contents, but the notion of intension is more general in that it applies to all kinds of expressions. The intension of any expression is its denotation (or *extension*) as it varies from world to world, i.e., a function (in the mathematical sense) assigning to each possible world the extension of the expression in that world. As a case in point, one may compare the descriptions (*d*) *the present capital of France* and (*e*) *the largest city in France*: in some worlds, including our actual reality, their extensions coincide, but given a different course of history, as represented by a possible world *w*, Reims, though smaller than Paris, would be the capital of France. So the intensions of (*d*) and (*e*) cannot be the same, because they disagree on *w* (and on many other worlds). In general, then, expressions with the same denotations may still differ in their intensions and hence, given compositionality, in the contribution

they make to the informational contents of the sentences in which they occur.

The method of extension and intension complements, rather than replaces, the model-theoretic approach to meaning. Instead of directly assigning arbitrary denotations to expressions, the models of possible worlds semantics couple each expression with an arbitrary intension, which then, being a function, uniquely determines an extension relative to a given world. Moreover, just like models come with their own Universes, in possible worlds semantics each model is also equipped with its own Logical Space of worlds. This construction originates from *modal logic* (see below) and offers an alternative to the model-theoretic reconstruction of entailment: a sentence *A strictly implies* a sentence *B* if *B* is true in all worlds in which *A* is true, i.e., if the intension of *B* yields the truth value 1 for any possible world for which the intension of *A* yields 1.

1.2 Logic and Language

The basic tools of logically based linguistic semantics—models and possible worlds—had originally been developed for artificial languages designed for specific purposes, like the analysis of mathematical proofs. These logical formulas can usually be paraphrased in colloquial language; the relation between formula and paraphrase is taught in introductory logic classes. Conversely, many constructions in natural language (passive, relative clauses, …) have long been known to be systematically expressible in languages of logic (cf. Quine 1960); *formalization*, i.e., the art of translating ordinary sentences into logical notation, is also something to be picked up in an introduction to logic. As a side-effect of the logical approach to natural language semantics, these relations between natural language grammar and logical notation can be explored in a more rigorous way. We will briefly go through some pertinent examples; more detailed case-studies can be looked up in any textbook or handbook on formal semantics (Dowty et al. 1981, Heim and Kratzer 1998, Gabbay and Guenthner 1984, Vol. 4, von Stechow and Wunderlich 1991, van Benthem and ter Meulen 1997).

The most obvious connections between logic and language concern the meaning of *logical words*, i.e., those lexical items that translate the basic inventory of logical formalism: the ('*Boolean*') *connectives* '¬,' '∧,' '∨,' … translated as *[it is] not [the case that]*, and, or, … and the *quantifiers* '∀' and '∃' corresponding to *everything* and *something*. The logicians' version of the former are combinations of truth-values. For example, just like a sentence of the form '*A and B*' is true just in case both *A* and *B* are, '∧' combines 1 and 1 into 1 and the other pairs of truth values into 0. Similarly, '¬' (glossed as *not*) turns truth (1) into falsity and vice versa; '∨' (∼ *or*) combines 0 and 0 into 0 and everything else into 1, etc. These combinations of truth values can thus be given by means of the *truth tables* in Table 1.

Table 1
Truth tables for Boolean connectives

A	B	¬A [negation; gloss: not *A*]	A ∧ B [conjunction; *A* and *B*]	A ∨ B [disjunction; *A* or *B*]
1	1	0	1	1
1	0	0	0	1
0	1	1	0	1
0	0	1	0	0

Even though truth tables work fine as first approximations to a semantic analysis of the words *not*, *and* and *or* as they are used in mathematical jargon, there is more to the meaning of these words. To begin with, *and* and *or* do not always stand between sentences but may be used to connect almost all kinds of expressions: *every book and a pen*; *see and/or hear*; *true or false*; etc. However, in many cases these non-sentential uses abbreviate coordinated sentences: *John owns every book and a pen* is short for *John owns every book and John owns a pen*, etc. In fact, non-sentential *and* and *or* can frequently be systematically reduced to the relevant truth tables by a *type shift*, a semantic rule that systematically generalizes combinations of truth values to combinations of other denotations (see Keenan and Faltz 1985, Hendriks 1993). However, even this generalization does not cover all non-sentential uses of these words. In particular, there is no obvious reduction of the group reading of *and*, as in *John and Mary are a married couple*, to the truth table of Boolean conjunction. Neither does there seem to be a straightforward reduction of alternative *or*, as in questions like *Shall we leave or do you want us to stay?*, to Boolean disjunction. Certain other semantic aspects that the truth table analysis seems to miss may be captured by pragmatic principles governing efficient use, as opposed to literal meaning (Grice 1989, Levinson 1983). As a case in point, the difference between *John lit a cigarette and Mary left the room* and *Mary left the room and John lit a cigarette* may be explained by a general principle of discourse organization, according to which the order of sentences should match the order of the events they describe. More involved pragmatic reasonings have been given to account for the exclusive sense of *or*, according to which *John missed the train*, *or he decided to sleep late* implies that John did not both miss the train and decide to sleep late.

In addition to the Boolean connectives, standard formal languages of logic contain both a *universal* and an *existential quantifier*, usually translated as *everything* and *something* and expressing properties of predicates: being universal, i.e., true of everything, and being non-empty, i.e., applying to something. Natural

language statements are only expressible in standard ('first-order') logic if they can be rephrased by combinations of Boolean connectives and the two quantifiers. A case in point is the sentence (*N*) *Every boy loves a girl* that can be paraphrased by (*L*) *For everything it holds that either it is not a boy, or for something it holds that it is a girl and the former loves the latter*—which translates into predicate logic as (*F*) $(\forall x)\ [\neg\ B(x) \vee (\exists y)\ [G(y) \wedge L(x,y)]]$. As the logician's paraphrase (*L*) indicates, the internal structure of quantified statements in natural language is quite different from that in logic. In particular, it usually involves *determiners* like *every* and *a* instead of the natural language quantifiers *everything* and *something*. The difference is that a determiner relates *two* sets, whereas a quantifier makes a statement about *one* set. Thus, in (*N*), *every* relates the set of boys with the set of girl-lovers, whereas the quantifier *everything* in (*L*) as well as the universal quantifier '$\forall$' in (*F*) attribute universality to the set of individuals that love girls if they are boys, i.e., the set of those that are either not boys or else love a girl.

Another means of expressing quantification in natural language is by way of certain *adverbs*. In particular, in so-called *donkey sentences* like *If a farmer owns a donkey*, *he never beats it*, the adverb *never* (on one reading) expresses that the set of donkey-owning farmers that beat their donkeys is empty. The very form of this *adverbial quantification* is rather remote from the usual logical formalization; it is not even clear whether in this case, as is usually assumed (see above), the indefinites *a farmer* and *a donkey* correspond to existential quantifiers. Recent work in natural language semantics has developed special logical systems to give a more adequate logical account of indefinites in donkey sentences and related constructions. (See Kamp and Reyle 1993, Chierchia 1995.)

Apart from these structural differences in the formulation of quantified statements, there are also differences in expressive power. In particular, not all natural language determiners can be paraphrased by combining Boolean connectives and logical quantifiers. For instance, it can be shown that a statement like *Most boys are asleep* cannot be expressed in first-order logic (Barwise and Cooper 1981). Adequate formalizations of such sentences, and hence of natural language in general, again call for more powerful and complex languages of logic. (See *Quantifiers, in Linguistics* for more about quantification in natural language and its relation to logic.)

Logicians have devised various extensions of classical propositional and predicate logic as tools of formalizing reasoning involving specific locutions (cf. Gabbay and Guenthner 1984, Vol. 2). For instance, in addition to Boolean connectives, languages of (propositional) *modal logic* (Chellas 1993, Bull and Segerberg 1984) contain a *necessity* operator, usually written as '$\Box$'; a formula '$\Box\varphi$' [read: it is necessarily so that φ] is true *in a world w* of a given model if the formula φ itself is true in all worlds that are possible for (or, technically: *accessible* from) *w*. Combining negation and necessity, it is also possible to express a corresponding notion of possibility as '$\neg\ \Box\ \neg$.' Models of modal logic thus contain domains of possible worlds organized by an accessibility relation. Depending on the precise structure of the latter, modal logic can be used to formalize various uses of modal verbs as in *Someone must have been here* (*epistemic* must) or *You may now leave the room* (*deontic* may). However, detailed studies of modality have revealed that these formalizations are at best approximations of the meanings of modal verbs in natural language (cf. Kratzer 1991). A similar relation is that between *tense logic* (Burgess 1984) and the tenses and other means of reference to time in natural language (see *Tense, Aspect, and Mood, Linguistics of*).

Various phenomena have led semanticists to explore alternatives to classical logic with its model-theoretic interpretation assigning one of two truth values to each formula or sentence (cf. Gabbay and Guenthner 1984, Vol. 3). A sentence like (*1*) *John knows that there will be a party tonight* seems to imply (*P*) *There will be a party tonight*; on the other hand, so does its negation (*2*) *John doesn't know that there will be a party tonight*. But if (*1*) and (*2*) both implied (*P*) in the sense of classical model-theory, then (*P*) would be true throughout the models in which (*1*) is true—as well as in those models in which (*2*) is true, i.e., the ones in which (*1*) is false. But then (*3*) would have to be a *tautology*, i.e., a statement that is true in all models; for any model would have to make (*1*) true or false. Giving up this last assumption, one enters the realm of (certain) *non-classical logics*, the simplest among which are *three-valued logics* with an additional truth value *U* (read: *undefined*) which models assign to sentences like (*1*) if their *presupposition* (*P*) is not true in them. (See *Linguistic Presupposition* for more on this.)

2. The Logic of Grammar

As theories of language structure, grammars themselves have been the objects of logical analysis. The earliest such investigations mark the beginning of generative grammar and were directed to shedding a light on the complexity of human language (see Sect. 2.1). Later approaches focused on the role of grammatical rules in the activity of parsing, which bears some resemblance to the process of deduction in logic; and more recently, grammatical reasoning has been seen as a non-monotonic process, thus reaching beyond the limits of classical logic (see Sect. 2.2).

2.1 Syntactic Complexity

A syntactic theory of a particular language may be seen as a body of theoretical statements describing the

structure of grammatically correct phrases. Formal reconstruction reveals that these theories come in different formats and complexities. For instance, a *context-free* description of a language only contains grammatical rules of the form: 'If a phrase of category B is immediately followed by a phrase of category C, the result will be a phrase of category A.' The standard notation for a rule of this form is: '$A \rightarrow B + C$'. Thus the following rule of English grammar is context-free: *if a preposition* (like *about*) *is followed by a noun phrase* (like *corrupt politicians*), *they form a prepositional phrase* (*about corrupt politicians*). In standard notation, this rule reads: '$PP \rightarrow Prep + NP$.' On the other hand, the following would-be rule is *not* context-free: *after a ditransitive verb* (like *give*), *two noun phrases* (like *every kid* and *a penny*) *form an object-phrase* (*a kid a penny*). Rather, the rule comes under the more complex scheme: 'If a phrase of category B is immediately followed by a phrase of category C, the result will be a phrase of category A, provided that it follows a phrase of category D'; one just has to put A = *object-phrase*, $B = C =$ *noun phrase*, and $D =$ *ditransitive verb*. Rules of this form are called *context-sensitive*. Using standard notation, they are written as: '$A \rightarrow B + C/D__$.'

The distinction between context-free and context-sensitive rules—and similar distinctions between other kinds of grammatical rules—can be used to define an abstract complexity ranking between languages, the *Chomsky Hierarchy* (after Chomsky 1957, 1959). A language is context-free (or, as the case may be, context-sensitive) if it can in principle be described by a body of context-free (or, respectively, context-sensitive) rules. Languages in the sense of this definition are arbitrary sets of sentences, which themselves are arbitrary strings of words. It turns out that, in this abstract mathematical setting (known as *mathematical linguistics* or *formal language theory*), though all context-free languages are trivially context-sensitive, the converse is not the case: one can construct languages that are context-sensitive without being describable by any body of context-free rules whatsoever. A famous example is the 'language' $a^n b^n c^n$ whose 'sentences' consist of arbitrarily many occurrences of the 'word' a followed as many bs, which are again followed by the same number of cs. (A proof and further examples can be found in Martin 1997, Chap. 8.)

In applying these abstract concepts, one must identify a language like English with the set of its grammatical sentences and individuate the latter by their words only—and not, say, by their internal grammatical structure. Given this identification, it is natural to ask for the exact location of human languages in the Chomsky Hierarchy. It may seem that an answer to this question requires complete knowledge of the grammatical sentences of any given language—something that current linguistic research has not attained. However, at least some of these complexity issues can be settled on the basis of partial information about the languages under investigation. In particular, it has been shown that, given the intricate structure of its verb complexes, the Swiss German dialect spoken in Zurich cannot be captured by context-free means (Shieber 1985); a similar result concerning word formation has been obtained for the African language Bambara spoken in Mali (Culy 1985), thus proving that natural languages in general are not context-free.

2.2 Further Issues

The fact that ordinary syntactic notation looks rather different from logical symbolism should not distract from the close connections between the two. For instance, as indicated above, a context-free rule only abbreviates a lengthy statement about the internal structure of phrases; and this statement can be easily (though somewhat clumsily) expressed in standard logical symbolism (= first-order predicate logic). This fact becomes particularly important when it comes to the task of *parsing* phrases of a given language according to a given grammar. As a case in point, parsing the prepositional phrase *about Mary* on the basis of the above context-free rule boils down to making a connection between the following three pieces of information: (*I*) *about* is a preposition; (*II*) *Mary* is a noun phrase; and (*III*) if x is a preposition and y is a noun phrase, then $x\ y$ (i.e., x followed by y) is a prepositional phrase. (*I*) and (*II*) are basic facts about English words to be recorded in a *lexicon* (which may be thought of as part of a syntactic description); (*III*) is just a paraphrase of the above context-free rule: '$PP \rightarrow Prep + NP$.' (*I*)–(*III*) obviously entail that *about Mary* is a prepositional phrase, and this is precisely the kind of entailment that can be formalized by means of elementary logic. Hence it should not come as a surprise that there are close relations between parsing strategies and procedures for verifying logical entailments. This connection has been studied in computational linguistics and in categorical grammar under the heading *Parsing as Deduction* (see Johnson 1991).

The role of logical deduction in grammatical theory is more complex than can be indicated in an article of this length. In particular, certain phenomena like the markedness of grammatical features or the interaction of phonological constraints, seem to call for non-classical logics that violate the *Law of Monotonicity*, according to which a conclusion once drawn remains correct when more premises are added.

Logical Positivism and Logical Empiricism

The philosophy of the Vienna Circle, which revolved around the work of Moritz Schlick, Rudolf Carnap, and Otto Neurath in Vienna in the 1920s and 1930s, was strongly influenced by Ludwig Wittgenstein, Bertrand Russell, Ernst Mach, and Henri Poincaré. It was one of the most important parts of twentieth century analytic philosophy. Together with related tendencies in Poland and Berlin it shaped nearly all serious philosophy of science in the twentieth century, gave rise to many more or less sympathetic developments of its main claims, and to a great deal of opposition, for example the philosophy of science of Karl Popper.

The logical positivism of the Vienna Circle, which came also to be called 'logical empiricism,' contained a number of claims about the nature of empirical science, in particular a strong rejection of the view that the subject-matter, methods, and logic of the natural sciences differ from those of the social and human sciences (the 'unified science' program). Three surveys of the philosophy of logical positivism are Kraft (1968), Barone (1986), and Haller (1993); a very thorough history of the movement and of its influence is provided in Stadler (1997); Ayer (1959) is a representative anthology of work by the logical positivists and associated philosophers.

One remarkable sociological feature of the writings of philosophers belonging to or associated with the Vienna Circle is the militant, polemical tone of the criticisms of alternative accounts of the nature of the nonnatural sciences. Zilsel (1941, p. 131) identified the Circle's philosophical enemies as belonging to the 'anticausal rebellion' in philosophy after 1890 and mentions in this connexion Windelband, Rickert, Dilthey, Weber, Troeltsch, neovitalism, and phenomenology. This polemical attitude went hand in hand with great self-consciousness about the historical, social, and sociological position of the movement. Neurath's ([1936], 1981) monograph, first published in French as 'Le développement du Cercle de Vienne et

l'avenir de l'Empirisme logique' (The development of the Vienna Circle and the future of logical empiricism), which stresses the Austrian context of logical empiricism (Bolzano, Brentano, the near absence of Kantianism in Austria) is exemplary in this connexion (see also Zilsel 1992 and, on Neurath, Hegelsmann 1979).

Among the more important early studies of the foundations of the human and social sciences are Neurath's ([1931], 1981) monograph 'Empirische Soziologie. Der wissenschaftliche Gehalt der Geschichte und Nationalökonomie' (Empirical sociology. The scientific content of history and of political economy), his *Foundations of the Social Sciences* (1944) and two books by Felix Kaufmann (1936, 1944) on the methodology of the social sciences. In addition to their work on the nature of science, members of the Circle such as Edgar Zilsel wrote on the history and sociology of science.

Surprisingly, one of the most important philosophical works to emerge from the Circle, Carnap's ([1928], 1968). *Der logische Aufbau der Welt* (*The Logical Structure of the World*) contains the claim that *geistige* (spiritual, intellectual) objects, i.e., cultural, historical, and sociological objects, must be distinguished from both physical and psychological objects; the autonomy of this class of objects has, Carnap says, too often been overlooked; recent philosophy of history after Dilthey is credited with the discovery of this autonomy. Carnap distinguishes between episodic physical and psychological manifestations of spiritual objects and the enduring physical objects which are documentations of spiritual entities—the buildings that document an artistic style ([1928], 1968, sections 23–4). He explains that he is able to provide only hints as to how cultural objects are to be constructed since 'the psychology (phenomenology) of cultural knowledge' is much less developed than that of perception (Carnap [1928], 1968, Sects. 150–1).

But thanks to Neurath the logical positivists came to reject the view that physical, psychological, and cultural entities all deserve different cages in the philosopher's zoo. The doctrine of physicalism, as expounded in Neurath's ([1931], 1959) paper 'Soziologie im Physikalismus' (Sociology in physicalism) and in his ([1931], 1981) monograph, 'Empirische Soziologie', is the view that:

> every scientific proposition is a proposition about a law-like ordering of empirical facts. All scientific propositions can be connected with one another and form a unified domain, which embraces only propositions about observable facts. For this domain the name Unified Science is suggested. If one wants to emphasise that in this way everything turns out to be physics, one may speak of physicalism. (Neurath [1931], 1981, p. 424)

Since 'observable' means observable by different people (intersubjectivity) psychological entities must be physical; since the facts in question are the spatiotemporal entities of physics, 'propositions about sociological facts' must be about such entities. Psychology, history, and political economy deal only in gestures, words, ways of acting, but not in motives, subjects, personalities, if these cannot be described as spatiotemporal entities (Neurath [1931], 1981, pp. 425, 431). The language of Unified Science is 'derivable by and large from modifications of the language of everyday life' once all 'pre-physicalistic' components have been eliminated (Neurath [1931], 1981, p. 537). Sociology is no *Geisteswissenschaft* but 'social behaviorism' (Neurath [1931], 1981, sections 3–4). Marxism, he thinks, comes closer than any other present-day sociological theory to being a genuinely empirical sociology (Sect. 7).

Whereas interest in the status of sociology looms large in Neurath's formulation of physicalism, it is psychology that is considered at length in Carnap's turn towards physicalism in his paper, 'Die physikalische Sprache als Universalsprache der Wissenschaft' (Physical language as the universal language of science, Carnap 1931, cf. also Carnap 1932/3). But Carnap also claims that:

> if our thesis concerning the translatability of psychological propositions into the physical language is correct, the corresponding thesis for the propositions of (empirical) sociology is readily grasped ... all historical, cultural, economic processes belong here. But we have in mind only the genuinely scientific, logically acceptable propositions of this domain. In the so-called 'Geisteswisenschaften' or 'sciences of culture', as they are at present, logical analysis often reveals pseudo-concepts, concepts which have no correct definition, concepts therefore for which no empirical criteria have been laid down ... (Examples: 'objective Geist (spirit)', 'meaning of history') ... sociology deals with nothing other than states, processes, ways of behaving of groups or individual subjects (humans or other animals), reciprocal reactions, and reactions to environmental processes (Carnap 1931, p. 451)

Carnap rejects all alternatives to observation such as *Verstehen* (understanding), empathy, and feeling one's way into historical products and events in order to grasp their essence or sense (p. 434).

Kaufmann was a regular participant in the meetings of the Vienna Circle, rather than a member of it, and was heavily influenced by phenomenology. But it is his work on a finitistic philosophy of mathematics rather than on the foundations of the social sciences which is phenomenological. In his philosophy of science he argues for a distinction between two sorts of laws: empirical, synthetic propositions, on the one hand, and scientific rules of procedure (theoretical laws) in terms of which 'warranted predictions' are defined, on the other hand. The distinction is applied so as to yield a unified account of scientific methodology or of the logic of scientific procedure, to criticize physicalism and to bring out differences between the subject matters of the natural and the nonnatural sciences. Of particular interest are Kaufmann's analyses of the

conceptual foundations of a number of different social and human sciences, in particular his discussion of what some claim has to be considered as the most important research program in the social sciences in Vienna at the time, Austrian marginal utility theory, in the course of which he rejects the apriorism of Ludwig von Mises (Kaufmann 1936, pp. 255–90, Kaufmann 1944 Chap. XVI).

Although it was the positivists' work on the logical structure of scientific theories that attracted most attention, they also wrote extensively on the history and sociology of science and on the sociology of knowledge. This is particularly true of Neurath, in the publications already mentioned, and of Edgar Zilsel—both heavily influenced by Marx. Neurath's holism and sociological approach to science lead to a view which anticipates some aspects of the views later developed by T. S. Kuhn (see Haller 1986, pp. 130ff.). Zilsel (1942, 1976) investigated in detail the role of craftsmen as pioneers of causal thinking in the period before 1600 and made many contributions to a program he formulated as follows:

> The rise of science is usually studied by historians who are primarily interested in the temporal succession of the scientific discoveries. Yet the genesis of science can be studied also as a sociological phenomenon. The occupations of the scientific authors and of their predecessors can be ascertained. The sociological function of these occupations and their professional ideals can be analyzed. The temporal succession can be interrupted and relevant sociological groups can be compared to analogous groups in other periods.... It is strange how rarely investigations of this kind are made.... there is no reason why the most important and interesting intellectual phenomena should not be investigated sociologically and causally. (Zilsel 1942, p. 560)

Perhaps the most thorough confrontation of views like those of the logical positivists with the views of such founders of the sociology of knowledge as Scheler and Mannheim is given by Kaufmann (1944, ch. XIV).

Logical positivism shaped subsequent philosophy of science. Such classic investigations of the nature of scientific laws and explanation as Ernest Nagel's *The Structure of Science* (1961) and Carl Hempel's (1965) collection of papers *Aspects of Scientific Explanation* emerged from the discussions of the Viennese logical positivists and of related groups in Berlin and Poland.

Logics for Knowledge Representation

Knowledge representation and reasoning play a central role in Artificial Intelligence (AI). Research in AI started off by trying to identify the general mechanisms responsible for intelligent behavior. However, it quickly became obvious that general and powerful methods are not enough to get the desired result, namely, intelligent behavior. Almost all tasks a human can perform which are considered to require intelligence are also based on a huge amount of knowledge. For instance, understanding and producing natural language relies heavily on knowledge about the language, about the structure of the world, about social relationships, etc.

One way to address the problem of representing knowledge and reasoning about it is to use some form of logic. While this seems to be a natural choice, it took a while before this 'logical point of view' became the prevalent approach in the area of knowledge representation. This article describes how the field of knowledge representation evolved and what kind of logical methods have been used. In particular, it argues that the important point about using formal logic is the logical method.

1. *Logic-based Knowledge Representation: A Historical Account*

McCarthy (1968) stated very early on that mathematical, formal logic appears to be a promising tool for achieving human-level intelligence on computers. In fact, this is still McCarthy's (2000) vision, which he shares with many researchers in AI. However, in the early days of AI, there were also a number of researchers with a completely different opinion. Minsky (1975), for example, argued that knowledge representation formalisms should be flexible and informal. Moreover, he argued that the logical notions of correctness and completeness are inappropriate in a knowledge representation context.

While in those days heated arguments of the suitability of logic were exchanged, by the end of the eighties, the logical perspective seemed to have gained the upper hand (Brachman 1990). During the nineties almost all research in the area of knowledge representation and reasoning was based on formal, logical methods as demonstrated by the papers published in the biannual international conference on *Principles of Knowledge Representation and Reasoning*, which started in 1989.

It should be noted, however, that two perspectives on logic are possible. The first perspective, taken by McCarthy (1968), is that logic should be used to represent knowledge. That is, we use logic as the representational and reasoning tool inside the computer. Newell (1982), on the other hand, proposed in his seminal paper on the knowledge level to use logic as a formal tool to analyze knowledge. Of course, these two views are not incompatible. Furthermore, once we accept that formal logic should be used as a tool for analyzing knowledge, it is a natural consequence to use logic for representing knowledge and for reasoning about it as well.

2. *Knowledge Representation Formalisms and Their Semantics*

Saying that logic is used as the main formal tool does not say which kind of logic is used. In fact, a large variety of logics (Gabbay et al. 1995) have been employed or developed in order to solve knowledge representation and reasoning problems. Often, one started with a vaguely specified problem, developed some kind of knowledge representation formalism without a formal semantics, and only later started to provide a formal semantics. Using this semantics, one could then analyze the complexity of the reasoning problems and develop sound and complete reasoning algorithms. This will be called the logical method, which proved to be very fruitful in the past and has a lot of potential for the future.

2.1 *Description Logics*

One good example for the evolution of knowledge representation formalisms is the development of description logics, which have their roots in so-called structured inheritance networks formalisms such as KL-ONE (Brachman 1979). These networks originally were developed in order to represent word meanings. A concept node connects to other concept nodes using roles. Moreover, the roles could be structured as well. These networks permit, for example, the definition of the concept of a bachelor.

Later on, these structured inheritance networks were formalized as so-called concept languages, terminological logics, or description logics. Concepts were interpreted as unary predicates, roles as binary relations, and the connections between nodes as so-called value restrictions. This leads for most such description logics to a particular fragment of first-order predicate logic, namely, the fragment L_2. In this fragment only two different variable symbols are used. As it turns out, this is a decidable fragment of first-order logic.

However, some of the more involved description logics go beyond L_2. They contain, for example, relational composition or transitive closure. As it turns out, such description logics can be understood as variants of multi-modal logics (Schild 1991), and

decidability and complexity results from these multimodal logics carry over to the description logics. Furthermore, description logics are very close to feature logics as they are used in unification-based grammars. In fact, description logics and feature logics can be viewed as members of the same family of representation formalisms (Nebel and Smolka 1990).

All these insights, that is, determination of decidability and complexity as well as the design of decision algorithms (e.g., Donini et al. 1991), are based on the rigorous formalization of the initial ideas. In particular, it is not just one logic that it is used to derive these results, but it is the logical method that led to the success. One starts with a specification of how expressions of the language or formalism have to be interpreted in formal terms. Based on that one can specify when a set of formulae logically implies a formula. Then one can start to find similar formalisms (e.g., modal logics) and prove equivalences and/or one can specify a method to derive logically entailed sentences and prove them to be correct and complete.

2.2 Nonmonotonic Logics

Another interesting area where the logical method has been applied is the development of the so-called nonmonotonic logics. These are based on the intuition that sometimes a logical consequence should be retracted if new evidence becomes known. For example, we may assume that our car will not be moved by somebody else after we have parked it. However, if new information becomes known, such as the fact that the car is not at the place where we have parked it, we are ready to drop the assumption that our car has not been moved.

This general reasoning pattern was used quite regularly in early AI systems, but it took a while before it was analyzed from a logical point of view. In 1980, a special issue of the *Artificial Intelligence* journal appeared, presenting different approaches to nonmonotonic reasoning, in particular Reiter's (1980) default logic and McCarthy's (1980) circumscription approach.

A disappointing fact about nonmonotonic logics appears to be that it is very difficult to formalize a domain such that one gets the intended conclusions. In particular, in the area of reasoning about actions, McDermott (1987) has demonstrated that the straightforward formalization of an easy temporal projection problem (the 'Yale shooting problem') does not lead to the desired consequences. However, it is possible to get around this problem. Once all underlying assumptions are spelled out, this and other problems can be solved (Sandewall 1994).

It took more than a decade before people started to analyze the computational complexity (of the propositional versions) of these logics. As it turned out, these logics are usually somewhat more difficult than ordinary propositional logic (Gottlob 1992). This, however, seems tolerable since we get much more conclusions than in standard propositional logic.

Right at the same time, the tight connection between nonmonotonic logic and belief revision (Gärdenfors 1988) was noticed. Belief revision—modeling the evolution of beliefs over time—is just one way to describe how the set of nonmonotonic consequences evolve over time, which leads to a very tight connection on the formal level for these two forms of nonmonotonicity (Nebel 1991). Again, all these results and insights are mainly based on the logical method to knowledge representation.

3. Outlook

The above description of the use of logics for knowledge representation is necessarily incomplete. For instance, the area of qualitative temporal and spatial reasoning has been left out completely. Nevertheless, one should have got an idea of how logics are used in the area of knowledge representation. As mentioned, it is the idea of providing knowledge representation formalisms with formal (logical) semantics that enables us to communicate their meaning, to analyze their formal properties, to determine their computational complexity, and to devise reasoning algorithms.

While the research area of knowledge representation is dominated by the logical approach, this does not mean that all approaches to knowledge representation must be based on logic. Probabilistic (Pearl 1988) and decision theoretic approaches, for instance, have become very popular lately. Nowadays a number of approaches aim at unifying decision theoretic and logical accounts by introducing a qualitative version of decision theoretic concepts (Benferhat et al. 2000). Other approaches (Boutilier et al. 2000) aim at tightly integrating decision theoretic concepts such as Markov decision processes with logical approaches, for instance. Although this is not pure logic, the two latter approaches demonstrate the generality of the logical method: specify the formal meaning and analyze!

Lone Mothers in Affluent Nations

Lone mother families are formed by death, divorce, or by a woman having a child outside marriage. Indeed, until the 1970s, there was no single term to describe these families. 'Lone mother' is now the most common term used in English to refer to them, although 'single mother' is still often used. However, this carries specific connotations in respect of marital status, referring as it does only to unmarried mothers, and thus strictly speaking does not cover all types of lone mother family. Much of the international data refers to 'one-parent' or 'lone-parent' families, but only a relatively small percentage (usually below 10 percent) of lone-parent families are headed by men. Countries also define lone mother families differently, for example, in regard to the age under which a child is considered to be dependent, and this makes cross-national comparisons of data difficult.

Lone motherhood is not, of course, new. For example, the UK experienced a sharp increase in unmarried motherhood during the 1840s, at the beginning of the industrial revolution, and at the beginning of the twentieth century, as many families were broken by death as were broken by divorce in the early 1970s. However, widowhood as a pathway into lone motherhood has declined whereas divorce and unmarried motherhood have increased. As lone mother families have become both more numerous and more visible in western countries, so they have also become an issue for public policy (McLanahan and Sandefur 1994), although only in the English-speaking countries have they come to be regarded as something of a social threat as well as a social problem.

1. *The Changing Demography of Lone Motherhood*

There is only a limited amount of statistical information on the proportions of families with dependent children that are lone-parent families. Table 1 shows the position of 12 member states of the European Union at the beginning of the 1980s and the 1990s, together with data for the US. Even within Western Europe there is a good deal of variation, with high proportions of lone parents in Denmark and the UK, intermediate levels in the continental European coun-

tries, and low levels in Southern Europe with the exception of Portugal.

Tables 2 and 3 show that this pattern of differences within Europe holds good for both divorce and extramarital birth rates. Divorce climbed steadily in most countries from the late 1960s. In the 1990s, it remains high, but the rate has leveled off. Some countries, such as Ireland, have only permitted divorce relatively recently, but the level of informal separation, which is impossible to measure, has probably been quite high. In most European countries the chances of divorce stand at about one in three, with Sweden, Denmark, and the UK leading the league table at around two out of five. However, the chances of divorce in the USA (and the former USSR) are one in two.

Births outside marriage have shown the largest increase in the US and Northern Europe (including the UK). With few exceptions the rise of extramarital childbearing is directly associated with the rise of cohabitation (Prinz 1995), and it is the breakdown of cohabiting unions that has contributed to the recent increase in never-married lone motherhood. This is because a separated cohabitant will be classified *de jure* as single, however there may in practice be little to distinguish the way these women feel from divorcees. There are further differences between countries, which aggregate statistics such as these do not reveal and which may be important from the point of view of policy making. For example, the English-speaking countries have a disproportionately high proportion of young unmarried mothers. The teenage pregnancy rate in the UK is, in the late 1990s, six times that of The Netherlands.

Finally, it should be pointed out that there may well have been some 're-labeling' in respect of the pathways into lone motherhood (Kiernan et al. 1998). In the 1960s, with the advent of the pill and the sexual revolution, sex was increasingly separated from marriage. Large numbers of unmarried women became premaritally pregnant, but the majority married before the baby was born in what were popularly known in English as 'shot-gun marriages.' From what is known about the characteristics of the divorcing population, it is reasonable to suppose that many of these marriages ended in divorce. At the end of the century, pregnant, unmarried women are more likely to have their babies outside marriage and probably to cohabit, which has increased the numbers of unmarried mothers. In addition, cohabitations are more likely than marriages to breakdown. Lone motherhood is the result of many different demographic 'events,' and over time the relative importance of the pathways into it have changed.

Table 3

2. *Causes of the Increase in Lone Motherhood*

The causes of the increase in lone motherhood are hotly disputed and in any case differ over time (Laslett 1977). They can only be understood in relation to wider changes in the marriage system. In the case of the rise in the extramarital birth rate in the UK in the 1840s, Shorter (1975) argued that the main reason lay in women's increased independence due to the new possibilities of wage-work in factories. However, others have argued convincingly that women in the traditional occupation of domestic service were particularly vulnerable to extramarital pregnancy. Intercourse seems not to have taken place until marriage was promised, and unmarried motherhood happened when the marriage failed to take place, often because of employment difficulties on the intended husband's part. Thus in this interpretation, traditional practices fell foul of new economic mobility and uncertainty, just as the rise in unmarried motherhood during the Second World War may in large part be attributed to war-time disruption and thwarted marriage.

Debates about the causes of lone motherhood today continue to revolve around the degree to which they can be attributed to women's increased autonomy, in terms of both the exercise of control over fertility and increased economic independence. Both demographers and economists have tended to pay most attention to this variable.

In the postwar period women have acquired the capacity to live alone with a child. This is a very recent phenomenon; until the last quarter of the twentieth century the majority of unmarried mothers found refuge with kin and in countries with little by way of welfare benefits or employment for women they must continue to resort to kin or to charity. A majority of social scientists agree that in western countries the growth in women's employment is more important than the increased availability of state welfare benefits in providing lone mothers with the income that in large measure explains the growth in their numbers. Only in the US has a vigorous case for welfare benefits as the cause been made (especially by Murray 1984), although the 'welfare dependency' of lone mothers has also been deplored in the UK from the late 1980s.

The importance attached to women's earning capacity as an explanatory variable is reinforced by influential economic theories of marriage. The new

'home economics' Becker (1981) and other neoclassical economists has argued that marriage should be understood in terms of the way in which it permits each partner to maximise their welfare. In this view, for biological and social reasons, women are deemed to be better at rearing children than are men. Marriage is seen as involving an efficient specialization of roles, with men acting as breadwinners and women as housewives and carers. But rising female employment and an increase in women's wages means that the parts played by men and women in marriage are less specialized and that there is less incentive for people to be married. While there are many academics who do not subscribe to such a theory of marriage and the family, the idea that women's economic independence has an effect on marital behavior is widespread, possibly because people with very different politics can buy into it.

However, any monocausal explanation of what is an extremely complex phenomenon is unlikely to be satisfactory. The nature of the choices and constraints faced by women who become lone mothers is complicated and involve the position of men. In the first place, it is significant that men's capacity to act as the main earner has been conspicuously eroded. Wilson (1987) was among the first to suggest that more attention should be paid to the deteriorating economic position of black men in the United States. In addition, in the UK the proportion of income contributed to married couple families by men has fallen sharply, eroding their historical position as breadwinners (Harkness et al. 1966). Studies of young unmarried mothers have shown that the putative fathers are all too often unemployed and that there are few economic reasons for the women to marry them. In the case of women seeking divorce, research has shown that women who have suffered violent treatment in their marriage (which some estimate to be the case in 20–25 percent of divorces) are also likely to have been mistreated economically. In Western Europe, these women may find that they are better off living on state benefits.

Men have also been charged with behaving irresponsibly in no longer being prepared to marry the women they get pregnant, and opportunistically in being willing to divorce their wives in favour of—typically—a younger woman. However, for some the increase in female economic autonomy remains the most important cause, because it permits men to behave irresponsibly (Fukuyama 1999). Others stress not so much male irresponsibility but inflexibility. Thus, Hochschild (1989) has documented the tension that results from men's failure to increase their contribution to household work in face of their wives' increased participation in the labor market. This points not to the fact of women's increased employment *per se* as a cause of divorce, but rather to the difficulties couples have in negotiating their domestic roles and, in particular, the problems men have in responding to and coping with change. Burns and Scott (1994) have referred to the increasing 'decomplementarity' between men and women, preferring to ground their explanations in changing structures rather than in individual decision-making, selfish or otherwise. Male inflexibility has undoubtedly exacerbated tensions in modern marriages and may be an important contributing factor to the high rate of divorce.

Research has shown more appreciation of the importance of cultural variables. Mason and Jensen (1995) have pointed out that the microtheory of the neoclassical economists does not recognize or allow for collectively generated or agreed upon norms and sanctions. Yet the meaning that is attached by the majority to marriage may well have changed. For example, women's increased labor market participation may lead the more successful among them to prioritise sexual satisfaction and emotional companionship over men's capacity to provide, and to a greater readiness to divorce if these expectations are not met.

At the broadest level, sociologists have grappled with the changing meaning of personal relationships, identifying a shift towards autonomy and individualism. Giddens (1992) has argued that we have seen the emergence of the 'pure relationship,' a social relationship entered into for its own sake and for what can be derived by each person from it in terms of material, but more usually, emotional exchange. Love has thus become contingent rather than 'forever,' and cohabitation rather than marriage is the logical concomitant. Beck and Beck-Gernsheim (1995) have also pointed out that it is no longer possible to say what family, marriage, parenthood, sexuality, and love mean. All vary from individual to individual and from relationship to relationship. The twin prescriptive norms derived from the male breadwinner model on the one hand, and from an externally imposed moral code (enforced through legislation such as fault-based divorce) on the other have both been eroded. In the vacuum that is left people are left to negotiate their own solutions, which does not necessarily mean that they do so selfishly or without due regard for moral responsibility, but the result will inevitably be more diversity in terms of family structures.

3. *The Problem of Lone Motherhood for Policy*

Lone motherhood has always tended to be defined as a social problem. This is because social policies have worked historically on the assumption that families will broadly adhere to a 'male breadwinner model,' whereby men earn and women care for children (and other dependent adults). The male breadwinner model family is an ideal type. It has never actually existed for all families in any state. Women have always been economically active to different degrees in different

countries and in different socioeconomic classes; however, their earnings are still substantially less than men's because they work fewer hours, and often in female ghetto occupations which pay low wages. Thus, the majority of women are still economically dependent even though their earnings are increasingly crucial to the operation of the family economy. In the context of assumptions regarding the traditional two parent family, the problem of lone mothers becomes essentially that of women-with-children-and -without-men. In the absence of a male breadwinner, the state has to decide to what extent and under what conditions it will step in to fill the place of the missing husband; how far it will exert pressure on an able-bodied absent father to support his child and possibly its mother; and how far it will expect the lone mother to support the child by herself becoming a breadwinner.

In other words, the social problem of lone motherhood has been defined primarily in terms of the costs of financial support. But the solutions favored have changed over time. In early nineteenth-century Britain, the state was unwilling to countenance any claim by an unmarried mother for financial support from a putative father, believing that it would only encourage female immorality. This policy did not last long, but expectations regarding the maintenance of women and children by men remained low until the last decade of the twentieth century in Britain. In contrast, the Swedish authorities made strenuous efforts to enforce the father's obligation to maintain from 1917.

Attitudes towards the behavior expected of lone mothers themselves have undergone more changes still. There have been pendulum swings in their treatment. Broadly speaking in the nineteenth century it was assumed that they should be in employment, working to support as many children (usually one or two) as possible. Where a poor law system operated, as in the UK and in some American states, public relief might be offered in respect of the other children. In other words, in the absence of a male breadwinner, the mother should herself become a worker. By the mid-twentieth century, the policy assumption was rather that she should be a mother and stay at home with her dependent children, drawing a cash benefit from the state. However, the length of time she was deemed to be a mother varied considerably. In the postwar period in The Netherlands and the UK lone mothers were not required to register for work so long as they had a child under age 16. In France, the same rule applied only to mothers with children under age 3. At the end of the twentieth century the pendulum swung again. In the mid-1990s governments in the USA, The Netherlands, and the UK all decided that lone mothers should obtain a greater proportion of their income from earnings, although only the US took the decision also to phase out state benefits (Lewis 1997).

Policy makers have been reluctant to treat all lone mothers the same. Following the logic of the male breadwinner model, widows have long been regarded as inherently more 'deserving' than either separated/deserted or divorced wives, or unmarried mothers. In countries with social insurance provision for those of working age, widows usually have qualified for insurance-based benefits by virtue of their position as wives. The treatment of separated or divorced women historically has been harsher, although once fault-based divorce legislation was abandoned, which happened in the vast majority of western countries during the late 1960s and early 1970s, it became impossible to distinguish between 'guilty' and 'innocent' wives in the settlements made by private law. As lone motherhood, whether by divorce or extramarital childbirth became more common in the late twentieth century, so the stigma attaching to it diminished, and lone mothers became much more ready to claim the social assistance benefits that were available to them in most western countries. This was the case even in the USA, which until 1996 provided for lone mother families via the 'aid to families with dependent children' program (Gordon 1994).

Lone motherhood has served as a focus for all sorts of social concerns. In the US, it seems to have wrapped up fears about the socialization of children, in terms of low levels of educational attainment and rising levels of criminality; anxieties about the role of women, particularly in terms of whether the mothers of young children should go out to work and suspicion of greater female sexual autonomy; concern about the role of men, who appear to be unwilling to shoulder financial responsibility for their children; and anxieties about race. All except the last have also been powerfully expressed in Britain.

However, in other European countries, where the proportion of lone mother families is as high or higher, lone mothers have not become problematized in the same way. The difference is that the difficulties experienced by lone mothers and their children have not been attributed to their status. Thus in Denmark and Sweden, for example, debate has centered on the position of one-earner as opposed to two-earner families. These countries drew virtually all adult women into the labor force from the 1970s onwards, such that the female labor participation rate is almost the same as that of men. Thus, in these countries a choice has not had to be made between defining lone mothers as mothers or workers. All adults share a common worker/citizen status. In this context, one-earner families, whether headed by a lone mother or a male breadwinner (of which there are very few) are recognized as likely to have financial problems. Furthermore, it is recognized that the vast majority of adult women face difficulties in reconciling family and employment responsibilities, but that the problems of lone mothers will be especially acute. The adult worker/citizen model is thus supported by the extensive collective provision of childcare, which is absent in the English-speaking countries, even now

that the pendulum has swung once more towards treating lone mothers as workers. Continental European governments have not subscribed to the view that reconciling paid work and the unpaid work of care is a private responsibility (Hantrais and Letablier 1996). In addition, they provide more generous financial support to all families with children, which is reflected in the much lower poverty rates among lone mothers in these countries than in the US, where they are the highest in the western world.

4. Future Prospects

One of the most striking aspects of the growth in inequalities in the English-speaking countries has been the increase in child poverty. In the UK the number of children living in households with below 50 percent average income trebled between 1979 and 1990. Given that patterns of family change are unlikely to be reversed, the challenge for policy is clear.

Lone Mothers in Nations of the South

As in the Northern Hemisphere, women in the poor regions of the 'South' (comprising Africa, Asia, Latin America, and the Caribbean) become lone mothers in various ways, notably through widowhood, divorce, separation, and out-of-wedlock birth (see *Lone Mothers in Affluent Nations*). Aside from this diversity of routes into lone motherhood, it is difficult to draw generalizations about the phenomenon across an area of the world containing myriad cultures and around four-fifths of the global population. Women's identities and circumstances as lone mothers are variegated not only on account of their insertion in different kinship systems, as well as religious, political, and economic contexts, but by individual factors such as age and dependency of children, marital status, and residential organization. Indeed, in several countries of the South, the issue of whether women regard themselves, or are regarded by others, as lone mothers is contingent upon whether or not they head their own households.

Although both 'household' and 'headship' are problematic, contested, and far from universal constructs (Bruce and Lloyd 1992), most official and international statistical sources define households as female-headed when the senior woman in a dwelling and/or consumption unit lacks a co-resident legal or common-law husband. In some cases this also extends to include the physical presence of another adult male such as a father, brother, or grown-up son (United Nations [UN] 1991). Although the senior woman in question is often a lone mother, she may also be childless, or at a stage where her children have left home. Recognizing that female household headship is

a generic category in which lone mothers are only one group, it is also important to note that not all lone mothers head their own households but may live in the homes of others (see below).

Acknowledging these distinctions, households headed by women in general, and lone mothers in particular, may be severely disadvantaged on three main counts. First, they often have higher children to adult ratios than their male-headed counterparts. Second, women routinely face gender discrimination in the labor market and earn less than men. Third, female heads are time- and resource-constrained by their triple burden of employment, housework, and childcare. Notwithstanding that some money may enter female-headed units through remittances from migrant offspring, relatives, and so on, transfer income from other sources may be limited. In most Southern nations there is only weak provision for, and enforcement of, child maintenance payments from absent fathers (especially in cases of nonformalized unions). Added to this, there is little support for lone mothers in the form of social welfare or other state assistance. As such, it is not surprising that 'female household headship' has received more attention than lone motherhood *per se* in the academic and policy literature on the South, not to mention in official statistics.

1. Data on Lone Motherhood and Female Household Headship

Data on lone motherhood in nations of the South are rarely available in their own right and have to be picked up 'by proxy' from data on female household headship. This is problematic because, as noted above, female household headship and lone motherhood are not necessarily synonymous. Moreover, even if figures on female-headed households disclose the marital and fertility status of women, thereby indicating the proportion represented by lone mothers, they do not generally reveal lone mothers who constitute 'embedded units' within larger (often male-headed) households. Young unmarried mothers and their children in the Philippines, for example, frequently form subunits in the households of their parents or senior kin as a means of securing financial support or to make their socially disapproved status less visible (Chant and McIlwaine 1995). This type of 'nesting' arrangement also occurs in countries such as Bangladesh, where widowhood is the predominant route into lone motherhood. Here older women and their younger children are often absorbed into the households of adult sons because they have no independent means of survival and/or because headship of households is culturally and symbolically equated with men (Lewis 1993). In Chile too, one in every five households is estimated to contain a 'sub-family,' and over half of these comprise single mothers with children (Buvinic and Gupta 1997).

In addition to the underestimation arising from 'invisibility,' the difficulties of using data on female household headship to ascertain numbers of lone mothers are compounded by the fact that definitions of female headship are often vague or inexplicit, that they vary across countries, and that they are frequently inaccurate (Chant 1997). Further problems arise from the fact that some female-headed households may be formed through the migration of partners/fathers who, while technically absent from the household, provide support for spouses and children through remittances (see below).

2. Routes to Lone Motherhood

Although it is difficult to generalize about routes into lone motherhood at a national, let alone regional, scale, in areas of the South where there is strong social emphasis on formal marriage, such as in Asia, the Middle East, and North Africa, levels of lone motherhood are low. Here the majority of women enter this state through widowhood, although desertion by men has become more common in places such as southern India and Bangladesh as rates of international male labor migration have risen (Baden and Milward 1995). In the Caribbean, by contrast, where consanguineal links among women, children, and female kin have historically been stronger than marital bonds, out-of-wedlock birth is the principal pathway to lone motherhood. Unmarried motherhood also occurs in Latin America, although separation and divorce are usually more significant. In both these latter regions, lone motherhood is more frequent.

In many instances, high levels of lone motherhood are reflected in high levels of female household headship. This relates not only to the larger pool of potential female heads in the population, but also to the fact that where there are fewer restrictions on women's sexual activity outside marriage, it may be more socially acceptable for women to reside alone with their children. Having said this, it cannot be assumed that lone mothers will necessarily constitute the primary subgroup of female household heads. In many countries of sub-Saharan Africa, for instance, relatively high levels of female household headship are associated not with large numbers of lone mothers, but with male-selective labor migration and/or war, and civil conflict.

Data for the 1980s suggest that female-headed households constitute the highest proportion of households in the Caribbean (17.7 percent), followed by Latin America (14.5 percent), with sub-Saharan Africa intermediate (13.6 percent), and South Asia lowest (5.7 percent) (Folbre 1991). Table 1 shows levels of female headship for selected countries within

the regions of the South in the 1990s, indicating that there is often as much intra- as inter-regional diversity.

3. *Reasons for the Growing Incidence of Lone Motherhood and Female Household Headship*

As in Europe and North America, lone motherhood is by no means a new phenomenon in developing regions. Nonetheless, it is generally agreed that levels have risen throughout the South from the mid-twentieth century onwards. Again, this has tended to be read

Table 2
Recent trends in female household headship, selected developing countries

Notes: Countries listed in descending order of score on UNDP's Human Development Index (HDI). Countries included for which data are available for 1980 and 1990

from figures on female-headed households, which, as noted earlier, are problematic. Additional complexities when considering long-term trends are that census bureaus in many developing societies have only recently begun to register gender breakdowns of household headship, and have often been inconsistent in respect of terminology and definitional criteria. Notwithstanding these caveats, for the few countries where national records extend back to the 1960s and 1970s, there appear to have been appreciable increases over past decades. In Ghana, for example, women-headed households grew from 22 to 32.2 percent of the household population between 1960 and 1990, and in Brazil the corresponding proportions were 5.2 percent and 20.1 percent. Even in countries such as the Philippines, where the incidence of female household headship is low, the percentage rose from 9.8 to 11.3 over the same period. More recent data for a variety of countries point to a general maintenance of upward trends between 1980 and 1990 (see Table 2).

Specific reasons for increases in female household headship in the South in the last 30 to 40 years vary in accordance with the particular histories of individual countries, although there are some factors of general significance. One is the way in which processes of postwar capitalist development and 'modernization' have undermined traditional economic and kinship structures, most of which were patriarchal and allowed women limited access to income and resources in their own right. Coupled with the growing demand for female labor brought about by economic globalization and the spread of multinational factories specializing

in the assembly of garments, electronics, and other light industrial goods, waged work for women has been seen as a central factor in women's mounting propensity to head households (Safa 1999). This trend has been exacerbated by declining employment opportunities for men, especially those at the lower end of the occupational hierarchy. Inability to fulfill social expectations to be family breadwinners appears to be making men in some countries less likely to marry, and is also associated with rising rates of conjugal breakdown (González de la Rocha 1995, Moore 1994). Other aspects of economic change linked with female headship include the effects of structural adjustment packages (SAPs) implemented in a range of countries in the South in the 1980s and 1990s at the behest of the International Monetary Fund and the World Bank. Although SAPs aim to restore financial equilibrium in countries with heavy debt burdens, and to promote renewed economic growth, in the short run they have been associated with extreme hardship, especially for poorer groups in society. Typical elements of these programs have included cutbacks in public services, the reduction or removal of government subsidies on basic foodstuffs, and wage freezes. These have tended to increase poverty, which, in turn, has placed greater strain on family relationships, as well as diminishing the prospects for women's (re)incorporation in the households of parents and male relatives following widowhood, divorce, or abandonment. Demographic factors associated with rising female household headship include increased geographical mobility and gender-selective migration. In sub-Saharan Africa, for example, men predominate in most rural–urban migration flows leaving women heading households in the countryside. Declining fertility is another demographic trend with implications for rising rates of female headship. On the one hand, it reduces the child care burdens of lone mothers, thereby increasing their ability to take up paid work. On the other hand, reduced numbers of children mean less likelihood that older lone women will be taken into the households of their offspring in later life.

Last but not least, increases in women's rights in the spheres of sexual and reproductive freedom, access to divorce, and custody of children have also increased female headship. These factors, coupled with changing labor-market trends and poverty, are the most relevant when considering rises in lone motherhood *per se*. Marriage in many societies is not the prerequisite for childbirth that it once was, and divorce rates have increased as the grounds for divorce have widened, as women have become freer to petition for divorce in their own right, and as their entitlements to conjugal property, maintenance payments, and child support have risen. In Costa Rica the number of divorces rose from two per 100 marriages in 1975 to 15.3 in 1991, and in Thailand, a 50 percent rise in divorce during the 1980s meant that by the early 1990s, nearly 25 percent of marriages were ending in divorce (Chant 1997).

4. *Stereotypes and Challenges of Lone Motherhood*

In South and North alike, the married two-parent family is a widespread normative ideal for raising children. Despite the fact that this arrangement provides no guarantee of financial or emotional support, let alone shared parenting (Baylies 1996), most other alternatives are regarded as undesirable. Lone motherhood is wont to be viewed as especially symptomatic of 'family breakdown,' and, as a result, is often marginalized and stigmatized.

The extent to which lone mothers in the South encounter social opprobrium depends on many factors. One is the degree to which women are controlled and/or subordinated in different societies. In strongly patriarchal cultures with marked gender divisions of labor, in which marriage is the major route to social legitimacy and economic survival for women, lone mothers are often shunned in their communities and condemned within political and religious doctrines. Although the most marked disapproval seems to accrue to women who enter lone motherhood through nonmarriage, in some countries, divorced and separated lone mothers are attributed a disproportionate share of the blame for conjugal breakdown. This seems to be particularly the case in South Asia, where even women who have been bereaved can find themselves socially outcast. Symbolically, widows have defied male authority by outliving their husbands, and anxiety surrounds their status as sexually experienced women lacking male guardianship (Buitelaar 1995). By contrast, least stigma seems to attach to lone mothers in areas such as the Caribbean, where historical legacies of slavery and plantation agriculture are argued to have laid the basis for more flexible, informal unions, and substantial social and economic autonomy among women (Ellis 1986). Mothers in the region have also been observed to rely more on their natal kin than on the fathers of their children (Safa 1999). Yet even where there is more societal tolerance of lone mothers, women raising their children alone are commonly regarded in a negative light. One prominent conventional wisdom in government, academic, and media discussions is that rising levels of lone motherhood (and female household headship) are linked with a worldwide 'feminization of poverty,' i.e., that lone-mother households are disproportionately concentrated among low-income and indigent groups, and suffer greater extremes of poverty than male-headed two-parent households (Moghadam 1997). A second and related belief is that lone motherhood gives rise to an 'intergenerational transmission of disadvantage.' Aside from material privation, the life chances of children in one-parent homes are deemed to be severely prejudiced by the psychological problems emanating from 'father absence,' lack of maternal attention, limited parental discipline, and social stigmatization. Influenced by

frameworks such as the 'Culture of Poverty' thesis of the US anthropologist Oscar Lewis, dating from the 1960s, lone motherhood is also regarded as perpetuating a long-term 'vicious circle' of downward mobility and family instability. Children are assumed to have high rates of juvenile delinquency and school drop out, early entry into unskilled segments of the labor market, and premature and fragile sexual unions, which in turn lead to further cohorts of lone-mother families who have few capabilities of breaking out of impoverishment.

Although poverty and intergenerational disadvantage clearly do apply to some lone- mother households in the South, it is also true that these patterns are found in other types of household unit. Moreover, stereotypes about lone motherhood have been criticized as overly crude, generalized, and lacking in substantiation. Feminist analyses in particular have suggested that there is insufficient empirical evidence and that there are too many weaknesses in existing methodologies (for the tracking of family influences on child and youth development, for example) to warrant unilaterally negative conclusions. They also point out that disparaging stereotypical portrayals of lone mothers can be construed as ideologically and politically harmful. To represent a group who is routinely scapegoated for a wide range of social ills as marginal, deviant, and problematic can be even more damaging to the women's public image and self-esteem, and reinforce existing prejudices against them.

A crucial element in calls to arrest the overwhelmingly pathological treatment of lone mothers is the need to recognize their considerable diversity (Baylies 1996). Lone-mother households vary not only in respect of how they come into being, but on several other grounds, such as age and relative dependency of offspring, household composition, socioeconomic status, and access to resources from beyond the household unit (from absent fathers, kinship networks, state assistance, and the like). A common finding from a range of countries, for instance, is that the average age of female heads of household is greater than that of female spouses in male-headed units. As a consequence, they often have children of working age who are able to help out financially or with the care of younger siblings. This may be complemented by incorporating relatives into the home, with lone-mother households showing higher levels of extended composition than their male-headed counterparts. In low-income neighborhoods in urban Mexico, for example, more than one-half of female-headed households are extended, compared with just over one-quarter of male-headed units (Chant 1997).

Detailed comparative research on the economic characteristics of male- and female-headed households has frequently indicated that through the twin strategies of household extension and multiple earning, female-headed units may actually have lower dependency ratios and higher per capita incomes than their male-headed counterparts. Moreover, expenditure within female-headed households is often dedicated to the basic needs of children and is less skewed toward personal consumption by adults. Whereas in two-parent units, considerable portions of the household budget may be spent by male heads on 'nonmerit' goods such as tobacco and alcohol, in lone-mother households, more resources are usually allocated to food and education (particularly that of daughters) (Engle 1995, Hoddinott and Haddad 1991). Contrary to prevailing conventional wisdom, levels of nutrition and educational attainment may thus be higher among children in female-headed units (Chant 1997). Aside from the importance of these issues in deconstructing blanket stereotypes, it is also acknowledged that, in situations where families are affected by male violence or financial neglect, lone motherhood and/or female headship may be important survival strategies in their own right, as well as increasing women's personal power and autonomy (Jackson 1996).

5. *Social Policy and Lone Motherhood*

Comparatively speaking, lone motherhood has not occupied the place in social policy discussions in the South that it has in the North (see *Lone Mothers in Affluent Nations*). This is partly because long-term subsidized programs of social assistance for health, housing, unemployment, and so on are few and far between in Third World countries. Moreover, poverty exists on such a large scale, and public resources have been cut back so severely through debt crises and recession, that the prospects for establishing any comprehensive system of social welfare remains remote. Having said this, a larger share of the spotlight has fallen on female-headed households in the last two decades, as countries undergoing neoliberal economic adjustment have been forced to develop more streamlined programs of poverty alleviation. In the interests of cost savings and 'efficiency,' efforts have been made to reduce public expenditure on universal social programs which benefit all groups in society (albeit with an emphasis on those with lower incomes) in favor of redirecting smaller amounts of resources to target groups of the population. Whether poor households headed by lone mothers should receive priority has become a key question, even if only a handful of countries to date (Chile, Colombia, Bangladesh, India, Honduras, Puerto Rico, and Costa Rica, for example) have actually implemented programs specifically oriented toward female-headed households.

Recognizing the empirical limitations of few test-case evaluations, Mayra Buvinic and Geeta Rao Gupta (1997) have mounted an ambitious review of the potential benefits and drawbacks of targeted assistance. One of their major arguments in favor of targeting is that in societies where there may be

unreliable data on poverty, isolating households headed by women is likely to capture a significant share of the population in need of assistance, especially where there are substantial gaps in male and female earnings, and where subsidized child-care facilities are limited. Another persuasive argument is that targeting assistance to lone mothers may be a very effective means of improving child welfare, given widespread empirical evidence that children fare better where women have resources at their own disposal. Other potential benefits include greater equitability of development resource allocation among men and women (Buvinic and Gupta 1997).

Arguments against targeting include the difficulties inherent in screening processes whereby some female-headed households may not be classified as such due to cultural norms of naming men as heads of household, even if they are largely or permanently absent, or make little contribution to family life and welfare. Many women may not want to be identified as lone mothers given the stigma attached to the status. They may also feel that taking public money will increase antagonism against them. By the same token, female-headed households may become male-headed over time through remarriage or cohabitation, thereby resulting in a leakage of benefits to male-headed households. Another potential slippage of benefits to nonpoor households arises from the fact that not all female-headed households have low incomes, and some may receive support, albeit periodically, from men. Tactics for determining which types of female heads are most in need of help may also be problematic. In Honduras, for example, a food coupon program targeted at primary-school children from female-headed households attempted to ascertain the financial status of mothers through questioning children and neighbors in the community. Aside from the invasive nature of this approach, it did not prevent a number of arbitrary and inappropriate decisions being made (Grosh 1994).

Buvinic and Gupta (1997) also draw attention to the fact that targeting can alienate male-headed households, and thus have high political costs. This is especially likely to be the case when women heads are targeted with interventions that are not perceived as female-specific, such as housing subsidies, food coupons, and so on. Less conflict, alternatively, is likely to occur when female heads receive benefits that are perceived as female-specific, such as skills training for 'female' jobs, or child and maternal health interventions.

Finally, targeting may also produce so-called 'perverse incentives' insofar as programs of support for female household heads may lead to more households adopting this form, which no government in the South (not to mention elsewhere in the world) seems to want. In Costa Rica, for example, the Social Welfare Ministry established its first program for female household heads in 1997. While this offered a relatively minimal temporary stipend for women to enable them to take courses in assertiveness- and skills-training, specific mention was made in the supporting documentation that the government had no intention of encouraging increases in lone motherhood (Chant 1998). Similarly, subsequent programs oriented to adolescent mothers in the country have concentrated not only on helping this group complete their studies, but also on raising awareness among young people generally about the need to prevent early pregnancy and lone motherhood.

An additional consideration in the field of policy is that specialized programs of support might not be necessary where there is substantial public assistance for women and mothers in general. Cuba is a case in point, where although Fidel Castro's revolutionary government has resisted providing special welfare benefits to female heads, policies favoring greater gender equality, higher levels of female labor-force participation, and the provision of support services such as daycare have all made it easier for women to raise children on their own (Safa 1995). A useful counterpoint is presented by Chile, which piloted a Program for Female Heads of Household in 1992–3 that was later extended nationally. Although the program aimed to increase women's access to employment through labor training, access to child care, and so on, success was tempered by the government's failure to address the social and cultural structures underlying gender segregation in the labor market and the perpetuation of poverty among women (Badia 1999).

6. *Lone Motherhood and the Future of 'the Family'*

Given limited programs of state support for mothers in general, and lone mothers in particular, it is unlikely that social policy will play a major role in fuelling increases in lone motherhood in the South in the twenty-first century. However, if recent trends in economic globalization and its accompanying social and demographic corollaries persist, it is entirely conceivable that the widespread ongoing decline in patriarchal family units based on marriage and a 'male breadwinner/female housewife' model will be counterposed by further rises in female-centered arrangements (see also *Lone Mothers in Affluent Nations*). Given the entrenchment of poverty and gender discrimination in many countries of the South, it is also probable that a substantial number of lone-mother households will continue to have to rely on strategies of co-residence and/or cooperation with relatives in order to compensate for the absence of male partners.

Longevity, Genetics of

Virtually every aspect of a person's life and well being and, in turn, their survival and longevity is influenced by genes—early development and maturation, metabolic rate and body regulation, resistance and vulnerability to disease, and personality and behavior. Inasmuch as the influence of genes is inextricably intertwined with longevity, it is virtually impossible to consider the broad determinants of longevity without a basic understanding of the underlying genetics. Many of the questions asked by lay persons concerned with longevity are inherently genetic: do long-lived parents have long-lived children? Will it ever be possible to genetically alter the rate of aging? How do genes influence disease susceptibility?

1. Conceptual Framework

1.1 Genetics

The influence of genes on the life span of organisms can be explained at several biological levels including: (a) a phylogenetic level where genes generate growth and form and thus determine the basic body plan, metabolic framework, and the broad details of a species' life history. Thus from a phylogenetic perspective, insects are generally shorter lived than mammals, rodents are usually shorter lived than primates, and chimpanzees are generally shorter lived than humans, *ceteris paribus*; (b) a mechanistic level where genes regulate the basic mechanisms affecting the rate of aging and life span. For example, genes will

influence the life span of individuals through their effects on oxidative damage or replicative senescence in cells; and (c) a disease vulnerability where genes determine the susceptibility of individuals to specific diseases. For example, an individual's risk of contracting breast cancer or Huntington's disease is linked to his or her genes.

1.2 Demographic

Longevity is a shorthand term for a number of different actuarial constructs, the two most common of which are *life expectancy* which is an empirical concept referring to the average age of death in a cohort and *life span* (or *maximum life span*) which is a theoretical concept referring to the highest age attainable by any member of a population. Longevity is the actuarial outcome of individuals subject to the risk of death at each age expressed as *age-specific mortality rate*—the probability that an individual currently alive will die in the next time period (e.g., one year). Longevity can be altered by changing mortality in one of three ways, all of which are under genetic control: (a) shifting the age of maturity—this is one of the most common ways in which fruit fly longevity is increased in population genetics selection experiments; (b) reducing mortality over part of the life course—this can occur through disease prevention or cure and reductions in accidental deaths; and (c) reducing the actuarial rate of aging—this effectively reduces the rate of change (slope) of mortality with age.

2. Genetics of Longevity in Model Systems

Genetic mechanisms that determine longevity and the rate of aging can be grouped into two categories: (a) private—those mechanisms that are idiosyncratic of certain lineages, populations, or species. Most mechanisms of aging associated with mutation accumulation are private mechanisms since the fate of these alleles is largely determined by genetic drift; and (b) public—mechanisms that are generally operational over a large diversity of organisms. By studying aging in different systems it is possible to begin to identify genes that appear in multiple species and thus likely control aging at the most fundamental level. In contrast, those genes that enhance longevity only in the species being studied may point toward genes that are less conserved and affect the mortality of smaller groups of related species.

2.1 Polygenic Approaches

The three main animal models used to study the polygenic (many genes) effects on longevity include:

(a) *Mice*. Studies on mouse strains congenic for the H-2 locus showed significant differences in longevity, that certain H-2 alleles were associated with increased life span, and that genes at the H-2 locus may affect the age of onset of reproductive cyclicity. Quantitative analysis suggests that immune responsiveness can be selected for in mice and that the mode of inheritance is polygenetic with 3–7 independent loci being involved in the response. The genetics of aging has also been studied through the use of senescence-accelerated mice which represents a polygenic progeroid model.

(b) *Drosophila*. Selection studies are polygenic by design—any number of genes which favor long life are retained in laboratory populations subjected to conditions favoring longevity such as allowing only the oldest individuals to breed. Selection studies on *Drosophila* have produced strains whose life spans differ by twofold. Associated with these life span differences include increased resistance to starvation, desiccation, and other environmental stresses and reduced ovary weight early in life.

(c) *Nematodes*. The primary approach for studying polygenic aspects of aging in the free-living soil nematode *Caenorhabditis elegans* has been quantitative trait loci (QTL) mapping. This technique is based on the concept that if one has a dense array of detectable genetic markers spread across each of the chromosomes, it is possible to make appropriate genetic crosses between nematode lines and determine which sets of markers are preferentially associated with the phenotype (i.e., longevity) of interest. The longevity genes thus lie somewhere between and are linked to the known markers. Nematode studies on crosses between two wild-type strains have identified QTLs that are responsible for increased life span located on chromosomes 2, 4, and the X. Estimates suggest that approximately seven QTLs are involved in determining life span of *C. elegans*.

2.2 Mutants

Inasmuch as mutations modify the life span of animals through mechanisms that may be shared by common effects on metabolism and gene expression, the analysis of mutations is the most effective means of identifying genes involved in a biological process because the physiological activity between the mutant and the wild type can be compared. However, one of the problems with this approach in aging research is that it is sometimes difficult to identify mutant strains with altered aging processes.

(a) *Yeast* (*Saccharomyces cerevisiae*). Mutation analysis of aging in yeast has yielded a number of candidate genes including *LAG1* that determines both mean and maximum life span, *LAC1*, a virtual copy of *LAG1* on a different chromosome, and *RAS1* and *RAS2* which have life shortening and life extending

effects, respectively. One of the major distinctions between aging in yeast and aging in other model organisms is that in yeast the scale on which aging is measured in yeast is reproduction (i.e., budding) but in other organisms aging is measured in chronological time.

(b) *Nematodes* (*C. elegans*). Mutational analysis in nematodes has yielded much physiological information on aging and has identified regions of the genome that contain longevity genes including *daf* genes which control a program that results in the formation of a dispersal form, the dauer larva—an alternative waiting stage that worms may enter in response to unfavorable periods (e.g., insufficient food), the gene *age-1* which has been assigned to the *daf* pathway for adult longevity but which increases the resistance to stresses, and *clk-1* which appears to control metabolic adjustments, particularly in response to temperature. Virtually all of the increases in longevity in mutant strains of nematodes have occurred at the post-reproductive ages.

(c) *Drosophila*. The effects of single genes in *Drosophila* that extend longevity have been difficult to find perhaps because of the lack of a waiting stage similar to the nematode dauer or yeast spore stages. However, flies which carry the 'Methuselah gene,' *mth*, displayed a 35 percent increase in life span and exhibited enhanced resistance to stress.

2.3 Transgenics

Transgenics refers to the transfer of genes from one organism to another which, in the context of aging, means transferring into a model organism a gene that extends longevity in another organism. If this so-called 'transgenic' organism then lives longer than the wild type, this then provides the ultimate demonstration that the gene affects the aging process either directly or indirectly. The best example of the use of this concept in aging research is in *Drosophila* using transgenic strains that overexpress several different enzymes and exhibit greater longevity and lower mortality than the wild type. Transgenic strains of both *C. elegans* and mice have been produced but have not yet produced definitive results.

2.4 Gene Expression and Regulation

Although the DNA in all somatic cells is the same and thus contains the same information, each cell expresses only a distinct subset of its genes at any one time. Which genes are expressed differs between cell types and also differs slightly as organisms age. For example, blood cells only expresses the genes needed to produce hemoglobin and other proteins associated with blood; genes capable of producing hair are not expressed in tongue cells. Altered gene expression has been suggested as a central mechanism for causing aging and senescence in which regulatory elements act like on (up-regulated), off (down-regulated), and dimmer switches. Experimental manipulations of life span in both flies and rodents have been shown to cause changes in gene activity including: (a) during temperature-induced shifts in fruit fly life spans, the age schedule for decreased expression of genes in the adult antenna and muscle is shifted in proportion to life span over a threefold range; (b) the potential influence of physiological factors in rat brain aging is demonstrated by the impact of food restriction which slows the age-related increases in transcription; and (c) gene expression is altered in bakers' yeast (*Saccharomyces cerevisiae*) through under- or overexpression of some wild-type genes, a gene that is homologous to the human gene for Werner progeria, and of genes causing a redistribution of telomeric silencing proteins.

2.5 Mitotic Clock

The majority of cell types grown in laboratory cultures have a finite ability to proliferate. After a number of population doublings the cell cultures enter the terminally nondividing state referred to as replicative senescence (so-called Hayflick limit). Many investigations have established a link between aging *in vivo* (live animals) and the proliferative potential of cells in culture. For example, cell cultures derived from one of the longest-lived species of animals, the Galapagos tortoise, doubled up to 130 times, whereas cultures derived from mice with maximum life spans of three years were capable of doubling only 10 or fewer times.

One of the most compelling theories for explaining replicative senescence is that incomplete replication of specialized structures at the ends of chromosomes called telomeres account for the gradual loss of proliferation potential. Telomeres are essential for proper chromosome structure and function including complete replication of the genome—if organisms could not overcome the 'end-replication' problem, they would fail to pass their complete genetic complement from generation to generation. The simplest theory accounting for the Hayflick limit is one in which permanent cell-cycle arrest is due to a checkpoint mechanism that interprets a critically short telomere length as damaged DNA and causes cells to exit the cell cycle. This telomere hypothesis of aging provides a molecular mechanism for counting cell divisions in the normal somatic cell. According to the telomere shortening model of cell senescence, to avoid telomere loss and eventual cell cycle arrest it is necessary for cells to synthesize telomeric DNA by expressing the enzyme telomerase. Therefore, a prediction of this model and one that is borne out in recent

studies is that telomerase activity will be absent in normal somatic cells but present in germline cells and carcinoma cells.

3. *Genetics of Human Longevity*

3.1 *Gerontogenes in Humans*

The term *gerontogenes* is used to describe genes that are involved in aging and usually involves genes whose normal function shortens rather than lengthens life. One of the approaches that researchers use in an attempt to identify genes that influence aging in humans is to study the prevalence of different genes in centenarians relative to younger people (e.g., 20–60 years). One of the most studied genetic polymorphisms involved in human longevity is the apolopoprotein E (APO-E) gene which encodes a protein that is synthesized in the liver, brain, spleen, kidneys, and macrophages and in human populations exists as three common alleles—E2, E3, and E4. Frequencies of these three alleles in centenarians and in noncentenarians revealed that: (a) there was a shortage of the APO-E4 allele among centenarians (5.2 percent) compared to controls (11.2 percent) which suggests a negative effect of this allele on longevity. In fact, individuals who carry the APO-E4 allele are strongly predisposed to developing late-onset Alzheimer's disease; and (b) an excess of APO-E2 allele among centenarians (12.8 percent) relative to the normal controls (6.8 percent) which suggests a positive effect of this allele on longevity.

3.2 *Age-related Genetic Diseases*

3.2.1 Progeroid mutations. Progeroid mutations refer to one of several human genetic syndromes that accelerate some aspects of aging. Although all of the progeroid-like diseases are rare, their effects on aging in young persons are so striking that they have received considerable attention in gerontology and medicine. In this section two of the best known progeroid diseases—Hutchinson–Gilford syndrome and Werner's syndrome—will be described. The outward signs of premature aging are similar in both of these diseases but they differ in their ages of onset and ultimately in the ages at which patients succumb to the disease.

Hutchinson–Gilford (*HG*) *syndrome* is one of the rarest genetic syndromes in humans with only 17 cases reported in the world by 1990. It is caused by a *de novo* gene mutation that is expressed in a dominant manner. At birth HG patients appear normal, but by about one year severe growth retardation is seen followed by rapid loss of subcutaneous fat and hair resulting in a prominent display of the scalp veins. Median age of death in HG patients is 12 years. The most prevalent progeriod disease is *Werner's syndrome* which is an autosomal (i.e., all chromosomes except sex chromosome) recessive disease that is first manifested as a failure to undergo the usual adolescent growth spurt. By the early twenties persons with this disease suffer substantial hair loss, graying of hair, atrophy of the skin, and cataracts as well as an increase in the likelihood of diabetes and cancers. Cytogenetic and molecular genetic studies have suggested that Werner's syndrome is due to a loss in the maintenance of genomic stability due to an unusually high frequency of reciprocal chromosome translocation and of single-gene mutations referred to as a mutator phenotype.

3.2.2 Adult-onset diseases. This section contains a description of three of the best-known adult-onset genetic diseases. The first is *Lou Gehrig's disease* which is formally referred to in the medical literature as amyotrophic lateral sclerosis (ALS). It is a progressive paralytic disorder that strikes middle-aged adults and is usually fatal within five years after diagnosis. Paralysis is due to degeneration of the large motor neurons of the brain and spinal cord. Approximately 10 percent of the ALS cases are inherited as an autosomal dominant disorder while the remaining 90 percent are sporadic. The second of the adult-onset genetic diseases is *Huntington's disease* (HD) which is due to an autosomal dominant gene that typically causes degeneration of the nervous system. HD disease causes memory loss and dementia as well as wrinkled skin, weight loss, and uncontrollable jerky movements. It differs from Alzheimer's disease inasmuch as the average age of onset for this disease occurs at 35–42 years with death occurring within about 15 years after diagnosis. The third and most extensively studied age-related genetic disease in humans is *Alzheimer's disease* (AD). Approximately 2–6 percent of people over 65 show symptoms of AD with the prevalence of symptoms increasing with age—as many as 40 percent of persons over 65 show symptoms of AD. Although the majority of cases of AD appear to be sporadic, several hundred families have been identified in which AD is inherited as an autosomal dominant mode of transmission. Analysis of the familial AD (FAD) has allowed the localization of three distinct genes that are involved in the specification, including: (a) rare mutations in the genes encoding the precursor protein of Alzheimer-associated amyloid on chromosome 21 (2–3 percent); (b) genes on chromosome 14 account for late-onset forms of AD (after age 65); and (c) genes on chromosome 19 are responsible for early-onset forms of AD. One of the major complications of studies of the disease is determining the degree to which FAD is genetic—estimates range from 10 to 100 percent. Individuals homozygous for APOE-ε4 have an al-

most eightfold increase in the probability of getting AD at almost any age when compared with people carrying other alleles of APOE.

3.3 Genealogical Studies

Despite studies demonstrating that genetics account for only 25–35 percent of the total variance in longevity, one of the most enduring and widespread notions in gerontology is the longevity resemblance of kin, particularly between parents and offspring and among siblings. The findings on kinship resemblance of longevity can be grouped into three categories.

(a) *Parent–offspring (familial) resemblance*. Although a modest familial component has also been established in several studies, they are generally plagued by the problem of conflation of shared genetics and environments and so cannot provide conclusive evidence for a genetic component of longevity.

(b) *Twin registries*. This use of twin registries has allowed more quantitative analyses of familial resemblance. Comparing the correlations between monozygotic (genetically identical) twins, fraternal twins, and nontwin siblings begins to disentangle the effects of shared genes from those of shared family environments. Investigations of the relationship between age of death between like-sex fraternal (dizygotic) twins and between identical (monozygotic) twins both reared together and reared apart reveal that longevity is moderately heritable. One twin study of longevity reported that the average absolute difference in age at death between two members of a monozygotic twin pair, two members of a dizygotic twin pair, and two randomly selected same-sex individuals was 14.1, 18.5, and 19.2 years, respectively.

(c) *Comparative ancestry of centenarians and shorter-lived groups*. This comparative approach can elucidate the familial resemblance in extreme longevity. Siblings of centenarians in one study had a four times greater chance of surviving to their early nineties than siblings of a comparison group that died at age 73. Twenty-four percent (13/55) of the immediate ancestors of the oldest person on record, Jeanne Calment from France (died at 122 years 164 days) longer than 80 years, vs. 2 percent in a reference family (1/50). Her immediate ancestors lived an average of 68.2 years vs. 57.7 years for controls in the reference family. An implication of the twin and centenarian ancestry studies is that whereas life span in general is under moderate genetic control, genes play a somewhat larger role for persons attaining the more extreme ages.

4. Evolutionary Biology of Aging

4.1 Theoretical Foundation

Whereas gerontology is concerned with questions concerning the mechanisms of aging, evolutionary biology is concerned with questions in a different biological domain concerned with how senescence evolved. Evolutionary theory of aging postulates that the force of natural selection will always decrease with age with either replacement-level or positive population growth. This provides the conceptual foundation for two population genetic hypotheses of aging. The first is termed *negative pleiotropy* and is based on the concept that alleles that have beneficial effects on one set of components of fitness also have deleterious effects on other components of fitness. The underlying concept is one of tradeoffs—a beneficial effect at young ages may have a deleterious effect at older ages. The declining force of natural selection leads to a tendency for selection to fix alleles that have early beneficial effects, but later deleterious effects. This biases evolution toward the production of vigorous young organisms and decrepit old organisms. Although antagonistic pleiotropy is an important possible mechanism for the evolution of aging, it probably plays a limited role in explaining the persistence of genetic variation in fitness components. The second population genetic hypothesis concerning the evolution of senescence is *mutation accumulation* which arises when the force of natural selection has declined

Table 1
Results of genetic testing in a hypothetical patient in 2010 (from Collins 1999)

Condition	Genes involved[a]	Relative risk	Lifetime risk
Reduced risk			
Prostate cancer	HPC1, HPC2, HPC3	0.4	7
Alzheimer's disease	APOE, FAD3, XAD	0.3	10
Elevated risk			
Coronary artery disease	APOB, CETP	2.5	70
Colon cancer	FCC4, APC	4	23
Lung cancer	NAT2	6	40

a HPC1, HPC2, and HPC3 are genes for hereditary prostate cancer; APOE is gene for apolipoprotein E; FAD3 and XAD are hypothetical genes for familial Alzheimer's dementia; APOB is gene for apolipoprotein B; CETP is gene for choleseryl ester transfer protein; FCC4 is the hypothetical gene for familial colon cancer; APC is the gene for adenomatous polyposis coli; NAT2 is gene for *N*-acetyltransferase 2.

to a point where it has little impact on recurrent deleterious mutations with effects confined to late life.

4.2 Empirical Foundation

A number of empirical studies concerned with understanding the extent to which genes control longevity have been conducted on *Drosophila* in which the ages of reproduction are carefully controlled. A typical design involves the young–old dichotomy of fly strains. Specifically, 'young' lines are created by allowing females to lay eggs at two weeks of age and rearing their offspring whose eggs, in turn, are collected at 14 days. This is repeated for a number of generations. The 'old' lines of flies are created using the same concept except that eggs are collected only from the females who have survived to much older ages. The results of these types of selection studies have revealed that the mean and maximum life spans of cultures selected for early reproduction are lower than those for cultures selected for later reproduction.

5. Longevity Implications of Molecular Medicine

One of the most profound changes in biological research including biomedical and gerontological studies has been the emergence of molecular biology and genomics. These two disciplines are leading to the creation of a universal periodic table of life that will reflect common genetic properties and patterns of ancestral and functional affinities among the genes of both plants and animals. Comparison of related organisms will reveal regulatory regions and key architectural features of proteins that can be used as Rosetta stones for translating and understanding informational pathways and for deciphering biological complexity.

In the very near future, molecular biology and genomics research will have a profound impact on the quantity and quality of human life through disease prevention. One of the best examples of how this emerging science and technology might be applied in the future is provided by the hypothetical example given in a paper by Francis Collins—the Director of the Human Genome Project. The human genome project will provide a baseline of an individual's genome to shed light on the person's risk profile and thus point to prevention strategies if available. The example uses a 23-year-old male college graduate who has smoked for six years and has a strong paternal history of heart disease. This individual agrees to undergo 15 genetic tests that provide risk information (both relative and absolute) for illnesses for which preventive strategies are available. The results of the genetic testing in this hypothetical patient are given in Table 1. The good news is that his risks of contracting prostate cancer and Alzheimer's disease are reduced because he carries low-risk variants of the several genes that contribute to the illnesses. The bad news is the genetic evidence of his increased risks of contracting coronary artery disease, colon cancer, and lung cancer. Confronted with this information, the patient arrives at that 'teachable moment' when a lifelong change in health-related behavior is possible by focusing on reducing specific risks including quitting smoking, reducing his cholesterol level, and having annual colonoscopies starting at age 45.

Longitudinal Data

Longitudinal data analysis is a subspecialty of statistics in which individual histories—interpreted as sample paths, or realizations, of a stochastic process—are the primary focus of interest. A wide variety of scientific questions can only be addressed by utilizing longitudinal data together with statistical methods that facilitate the detection and characterization of regularities across multiple individual histories. Despite the stated focus on individual histories, most of the analytical strategies either invoke strong assumptions about stochastic dependencies across time and/or use variable-centered methods to study the influence of multiple covariates on process dynamics and its relationship to diverse outcomes. An exception to this pattern is the literature on growth curve analysis, where the full individual histories are modeled and frequently aggregated into categories of similar histories. This set of techniques, as currently constituted, has severe limitations when a study objective is to understand the interrelationships between multiple dimensions of a multivariate time series. Problems arise due to the utilization of interaction terms, as in regression analyses, which represent the imposition of a variable-centered idea in an inherently person-centered question.

The purpose of this entry is to describe some person-centered methods that respond to the challenge of characterizing life histories, ascertained with longitudinal data, placing emphasis on the effective utilization of both cross-time and multiple-life-domain information. We motivate the methods and illustrate their use in the context of explaining how a variety of health outcomes occur. However, the methodological issues are generic and transfer to a wide range of problems in the behavioral and social sciences.

1. *Motivation*

Extensive empirical evidence documents associations between early and mid-life risk factors and later-life chronic disease and disability (Barker and Osmond 1986, Wadsworth and Kuh 1997). These findings generate considerable interest in understanding the subtle nuances of life histories that might explain how such outcomes occur. Broad-gauged interest in successful aging (Rowe and Kahn 1998), with particular emphasis on how some individuals manage to adjudicate effectively multiple difficult challenges, also suggests in-depth comparative studies of life histories. Detailed accounts of whole lives have previously been studied primarily as individual cases, with evidence presented in forms ranging from rich ethnographies to focused interviews and, in a medical context, from open-ended responses to structured inquiries by clinicians.

Complementing such narrative accounts of life histories are structured longitudinal surveys that contain—for each individual—hundreds, or even thousands, of responses to questions about experiences over time and across multiple life domains (Hauser et al. 1993, Power et al. 1991, Wadsworth and Kuh 1997). In principle, those interested in the impact of multiple facets of life histories on a given outcome(s) should be able to construct representations of whole lives from the survey responses. Despite considerable interest in this task across multiple disciplines (Elder 1974, Vaillant 1983), there has been a dearth of analytic strategies for producing representations of whole lives and for aggregating them into meaningful taxonomies that facilitate understanding of how given outcomes occur.

With these observations at hand, our primary objective is to describe top-down and bottom-up methods for constructing taxonomies of life history representations and use them as the basis for explaining how given outcomes occur. We will also emphasize the construction of narratives from numerical survey responses and their utilization as part of an analytical strategy to understand 'whole lives.' We illustrate the ideas and methods in the context of health outcomes. However, the methodological issues are quite general and by no means restricted to this class of outcomes.

2. *Classes of Methods*

The techniques discussed in this entry are called person-centered in the sense that the individual life history is the unit of analysis. Within this broad class of methods are two categories of techniques called 'bottom-up' and 'top-down.' The bottom-up strategies begin with highly idiosyncratic individual histories, and the analytical steps then identify important commonalities and differences across lives, leading to aggregation of histories into relatively homogeneous groups. Optimal matching (Abbott and Hrycak 1990), p-technique integrated with dynamic factor analysis (Shifren et al. 1997), and the integrated qualitative–quantitative aggregation strategy of Singer et al. (1998) are examples of bottom-up strategies.

Top-down techniques sequentially partition a heterogeneous population into progressively more homogeneous sub-groups. Recursive partitioning (Zhang and Singer 1999), Grade-of-Membership models (Berkman et al. 1989), and the clustering methods of Bergman (1998) are generic examples of these methods.

3. *A Bottom-up Example: Understanding Psychological Resilience*

3.1 *The Problem*

Among those who experience major episodes of depression in adult life, or earlier, some manage to

subsequently regain high levels of well-being—that is, they demonstrate resilience. We ask whether those who show recovery have particular features that distinguish them from those who continue to suffer depression. An affirmative answer could suggest prevention strategies which, if applied early in life, might serve to bypass episodes of depression, or minimize their severity and facilitate recovery from them.

3.2 Longitudinal Data

The Wisconsin Longitudinal Study (WLS) began with a random sample of 10,317 men and women who graduated from Wisconsin high schools in 1957. Survey data were collected from the original respondents in 1957, 1975, and 1992/93. Telephone interviews were conducted in 1992/93 with 8,020 of the 1975 respondents, 6,535 of whom also responded to a mail survey. Data have been collected on respondents' family background, starting resources, academic abilities, youthful aspirations, social support, social comparisons, and the timing and sequencing of adult educational and occupational achievements, work events and conditions, family events, and physical and mental health. We focus on a subset of the 5,009 primary respondents who participated in all three waves of the WLS and who responded to questions assessing affective disorder and well-being in the most recent survey. The affective questions were administered to a randomly selected 80 percent of respondents. For each individual, there were responses on over one thousand variables covering all three waves of the survey and information across the multiple life domains indicated above.

The resilience criteria (see Singer et al. 1998) were satisfied by 168 women. There were 59 women who satisfied the depressed/unwell criteria. The analytical task is the development of a taxonomy of life histories for each group such that the characterization of any history is sufficiently nuanced to capture the richness of individual experience, but not so detailed as to represent only very few women. For a more broad-based discussion of resilience, using both narrative and numerical data on individual histories to the study of racial and ethnic inequalities in health, see Singer and Ryff (1997).

3.3 A Person-centered Strategy

Construction of an empirical taxonomy of life histories requires a set of organizing principles—based on prior literature—that constrain the distillation of over one thousand responses for each individual into composite variables. Such composites are the basis for the ultimate representations of categories of histories. The following five principles were used to specify combinations of individual characteristics essential to explain how the outcomes come about.

(a) Adversity and its cumulation over time has negative mental health consequences.

(b) Advantage and its cumulation over time has positive mental health consequences.

(c) Reactions to adversity or advantage influence the impact of life experiences.

(d) Position in social hierarchies has consequences for mental health.

(e) Social relationships influence the impact of life experiences.

These propositions are not new to the social sciences, mental health, or aging fields. What is new is the integration of them into an analytical strategy to guide life-history analysis. The methodology is usefully decomposed into five principle steps:

(1) guided by the organizing principles, life history narratives are constructed for a sub-sample of cases from each outcome group (i.e., resilient and depressed/unwell);

(2) abstracted chronological charts, each one representing the synthesis of several narratives, were constructed;

(3) reduced response vectors, **b**, consisting of composite variables suggested by the chronological charts and individual variables whose rationale derives from the organizing principles are specified;

(4) aggregates (categories) of histories, in terms of response vectors judged to be close to one another, are specified; and

(5) tests of distinguishability are conducted.

Step (5) reduces to ascertaining whether or not the categories of histories characterizing the resilient women occur with low frequency in the depressed/unwell group and, conversely, whether histories characterizing the depressed/unwell women occur with low frequency among the resilient women. If the taxonomies of histories are to be a basis for explanation of the mental health outcomes, there should be distinguishability of categories of histories between the two groups.

3.4 Narratives

A small random sample ($\sim$ 10 cases) is selected from each outcome group, and a narrative biographical story is written about each individual. We adopt Stone's (1979) conception of narrative, defined as 'the organization of material in a chronological sequential order and the focusing of the content into a single coherent story, albeit with subplots.' Our rationale for writing narratives based on survey data (with over one thousand responses per individual) is that the human mind has difficulty processing enormous amounts of information in parallel (i.e., long lists of responses representing a single life), although it is well suited to process a coherent story (i.e., a written narrative about a life) (Turner 1996). The use of narratives here is qualitatively different from their role when they are part of the raw data. Specifically, the construction of

narratives—by the analyst and starting with numerical response data—is part of an analytical strategy. The narratives do not represent empirical data derived from focused interviews, recorded conversations, or text written by the respondents, but stories written by investigators to describe 'whole lives through time.' In generating the narratives, responses selected for inclusion were those expected to impact mental health, based on prior theoretical and empirical literature. The goal is to tell a life story in such a way that omitted information would make little or no difference for understanding the relevant life experiences preceding and predicting midlife mental health outcomes.

3.5 Abstract Chronological Charts

Two life histories can be aggregated and called similar, or even approximately indistinguishable, when the response vectors representing them are similar. At the level of individual cases, represented by raw response data on more than one thousand variables or by narratives, there is so much idiosyncratic detail that meaningful aggregation seems almost hopeless. However, via the organizing principles, it is possible to start with three or four narratives and begin specifying composite variables that ultimately lead to the specification of response vectors, some of which are sufficiently similar that they can be aggregated into a common category.

The composite variables are the initial basis for revised response vectors for all individuals that need to satisfy two criteria. First, the revised response vector for a given individual should provide for a nuanced summary of the person's life history as it relates to mental health outcomes. Second, the response vector should not be too idiosyncratic. The latter condition is essential if we are to aggregate life histories—represented as reduced response vectors—so that individuals with 'similar' response vectors can be grouped into common categories of histories.

3.6 Reduced Response Vectors

Guided by the abstract chronological charts, we specify a provisional reduced vector of variables, whose values for a single individual define the person's reduced response vector. The provisional reduced vector of variables will, clearly, represent all persons for whom we have constructed narratives. However, this is only a small sub-sample of a much larger population. We augment this group with 10–15 new cases for whom we do not have narratives. Their provisional reduced response vectors augmented by responses on additional variables that are clearly linked to the organizing principles are displayed. Visual examination of these augmented response vectors for the new cases AND those for which there are narratives serves to suggest new composite variables and revisions of those specified for the provisional reduced vector of variables. The result of this visual inspection and judgment is a new second-stage reduced vector of variables. We continue bringing in blocks of 10–15 new cases at a time, repeating the above step, and thereby iteratively refining the reduced vector of response variables until all cases for a given mental health outcome group have been examined. The final reduced vector of response variables, **b**, is the basis for initiating the formal specification of a taxonomy of histories.

3.7 Aggregation of Reduced Response Vectors: Pathway Specification

All variables are identified by binary codes in **b**. Next, we identify the longest AND statement common to at least 20 individuals. This identifies a set of response vectors—equivalently, a set of life histories—that exactly match one another on the components of the AND statement. If the components of the AND statement are distributed across the whole lives and they are interpretable as meaningful pathways to a given mental health outcome, then we have succeeded in aggregating a set of life histories into a well-defined group. For the resilient women in WLS, the binary coded version of **b** had 17 components, and the longest AND statement common to at least 20 individuals had seven components.

With an initial aggregate of histories at hand, we eliminate this group from further consideration and identify the longest possible AND statement characterizing at least 20—and hopefully more—of the remaining men. In the WLS resilient women, this did not lead to a long enough AND statement that was sufficiently nuanced to characterize possible routes into episodes of depression, as well as the cumulation of advantage that would promote recovery. This led to specification of more complex Boolean statements that were both consistent with our organizing principles and represented the life histories of a substantial number of women. At least two strategies can be used for this specification. First, visual inspection of the 17-component response vectors revealed a group of 48 women, all of whom grew up in a household with at least one alcoholic parent AND who had a diversity of different forms of compensating advantage in adulthood (represented by logical OR statements). For a narrative description of the resulting Boolean statements, see Singer et al. (1998).

A more formally mechanized approach to this step—using, for example, Ragin's QCA software (1987)—would be to minimize the Boolean expression representing all women who are not in the first group identified via the 'longest possible AND statement criterion.' The resulting minimal Boolean expression would, hopefully, have clearly interpretable components that would represent distinct pathways—

hence, additional members of the desired taxonomy of life histories—to given mental health outcomes. Although the analysis in Singer et al. (1998) proceeded beyond the first specification of an initial group by inspection and judgment, linked to organizing principals, we recommend application of both strategies en route to a final taxonomy. Indeed, as illustrated in Ragin (1987), minimal Boolean expressions that are not readily interpretable on a first pass through reduced response vectors often suggest recoding and construction of alternative composite variables that ultimately lead to a useful taxonomy.

3.8 Tests of Distinguishability

Having constructed a taxonomy of pathways for each outcome category—resilient and depressed/unwell in the present example—it is necessary to demonstrate that the routes to any one outcome differ in important ways from the set of routes to a different outcome. To this end, we first ask whether the aggregate pathways for the resilient women differ from the pathways for the depressed/unwell population. In particular, we tabulate the frequency with which the resilient pathways occur in the depressed/unwell population. Conversely, we take the aggregate pathways representing the depressed/unwell women and tabulate the frequency with which those pathways actually occur among the resilient women. We expect to find that the resilient pathways are rare in the depressed/unwell population and also that the depressed/unwell pathways are rare in the resilient population. For example, 16 percent of the resilient women are on the pathway indicated above by the seven-component logical AND statement. Only 8 percent of the depressed/unwell have the same pathway ($p < .10$). Twenty percent of the resilient women are on the pathway where at least one parent is a chronic alcoholic AND there is a diversity of compensating positive experiences in adulthood. This pathway only occurs for 5 percent of the depressed/unwell population ($p < .05$). There are persistently negative-experience pathways in the depressed/unwell population that have no counterpart in the resilient group. Sharper discrimination occurs depending upon the particular application (see e.g., Zhao et al. 2000). The central point, however, is that assessment of distinguishability is important for making the case that there are, as hypothesized, qualitatively different routes to distinct mental health outcomes.

4. An Alternative Bottom-up Strategy

An analytical strategy that might serve as an alternative to what is put forth in the above example is optimal matching (Abbott and Hrycak 1990, Abbott and Barman 1997). Optimal matching derives from the literature on comparison of DNA sequences. It takes univariate time series for individuals and groups them together into sets of what are regarded as equivalent histories. The grouping requires the availability of a metric on the space of possible sequences (histories); and two sequences are defined to be members of the same group if their distance apart—in terms of the metric—is sufficiently small. To apply the automated optimal matching technique requires that input data be in the form of what we have called 'reduced response vectors.' The analogue of steps leading from more complex longitudinal data to this stage, as we have described above, must still be carried out for univariate time series prior to carrying out the formal aggregation step (Abbott and Hrycak 1990). Although optimal matching is a natural way to proceed in the construction of a taxonomy of histories, the problem with its implementation on cross-time, multi-life-domain data is that there is no obvious metric yet developed that is suited to the complex multidimensional time series corresponding to individual histories, as discussed in the above example. Furthermore, a single measure of distance between two multidimensional histories seems too coarse for decisions about what constitute equivalent histories. The strategy for aggregation of reduced response vectors—in the above example—uses information about multiple features of life histories. This suggests that any automated aggregation technique, analogous to optimal matching, should be based on a multidimensional measure on the space of histories.

5. Top-down Methods

There is a considerable diversity of top-down, person-centered analytical strategies. A valuable review of both concepts and methods is contained in Cairns et al. (1998). One common strategy focuses on clustering techniques, where a critical input to the algorithms is a metric on the space of histories. Not surprisingly, applications of these techniques, which partition a heterogeneous population into relatively homogeneous clusters, have been restricted to low-dimensional data and rather simple summaries of histories. To reach the level of nuance and multi-domain representation of the kind we have discussed above requires a quite different set of measures of similarity of histories to be constructed than heretofore. This is an important research topic for the future.

Recursive partitioning (RP) classification (Breiman et al. 1984, Zhang and Singer 1999) is an automated procedure that fits trees to multi-dimensional longitudinal data such that pathways down the tree to a given outcome (terminal node) identify homogeneous sub-populations with common histories. Trees are

constructed with the objective of maximizing ability to predict membership in the outcome categories. Each pathway down the tree ending in a given terminal node (identified, for example, with a health outcome) corresponds to a logical AND statement incorporating information across multiple life domains. Two or more pathways into the same terminal node are identified with a logical OR statement describing how that particular outcome occurred. The judgment of the investigator is required to determine whether all pathways to the nodes identified with a given outcome should be summarized by a single complex Boolean expression, or partitioned into two or more sets of pathways defining qualitatively different kinds of histories. Recursive partitioning (RP) algorithms could accept either the original raw response vectors or reduced response vectors, as described in the above example.

From our perspective, a limitation of RP for generating a taxonomy of life histories is the fact that the performance criteria and the splitting rules for tree construction are not constrained by substantive knowledge from any field of scientific inquiry (e.g., a set of organizing principles). Thus, pathways down the best predictive tree are not always interpretable within the knowledge of a given field. This disjunction between statistical performance criteria, based solely on numerical goodness-of-fit, and constraints on tree structure and splitting rules derived from extant scientific knowledge have proven problematic in past applications of RP (Levy et al. 1981, 1985), for example, applied RP to neurological assessments of comatose patients to predict which patients were likely to recover with moderate disabilities as opposed to remaining vegetative or dying within one year of hospital admission. The numerically best predictive trees were virtually never neurologically interpretable. Rather, inspection of 20+ nearly optimal trees led to selection, based on scientific judgment, of a prognostic tree that had interpretable pathways. For a start at more interactive—i.e., allowing the investigator to modify trees during the construction process on the basis of organizing principles—and flexible strategies based on RP technology, the reader should consult Zhang and Singer (1999).

6. *Conclusions*

We have described a variety of person-centered methods for the analysis of longitudinal data. Particular emphasis has been given to a relatively new strategy—the bottom-up example—that takes a full complex individual history as the unit of analysis. The principal and novel features of this strategy are:

(a) It includes the writing of narratives at the beginning and terminal stages of the analysis of survey data.

(b) It is person- not variable-centered.

(c) It produces pathways that represent aggregates of individual life histories.

(d) It works simultaneously across multiple life domains.

(e) It is capable of identifying multiple pathways to a given outcome.

(f) It systematizes the decision making en route to delineation of the pathways.

(g) It tests hypotheses about whole lives that are the integration of what is typically studied as separate pieces.

Point (a) underscores the importance of examining whole lives in story form as a means of comprehending the volume of detail that necessarily comprises human lives. Although point (b) is a clear objective in much of the life-history literature (e.g., Elder 1974, Magnusson and Bergman 1990), the lack of person-centered methodological tools has prevented investigators from proceeding to point (c). Attempts to get at aggregates have typically involved the use of variable-centered techniques, since these were available. However, the investigators mentioned above and many others were well aware that the lack of preservation of individuals as units of analysis severely limited the inferences they could draw about the dynamics of individual (or aggregates of individuals) change. Point (d) is conventionally dealt with, if at all, by variable-centered techniques. The bottom-up example strategy is, to the best of our knowledge, the first incorporation of multiple life domain information in a process of aggregation of whole life representations. Many investigators (e.g., Harris et al. 1990, Magnusson and Bergman 1990) have struggled with point (e); however, the absence of tools for aggregating whole life representations has prevented their delineating full pathways. Harris et al. (1990) set forth a template of several pathways to depression, and Magnusson and Bergman (1990) looked for 'patterns' connecting childhood problems with adult maladjustment. Nevertheless, their variable-centered empirical analyses (using logistic regression with interaction terms in the former, and cluster analysis in the latter) did not achieve the desired objective. What was needed was a person-centered methodology. Point (f) emphasizes the critical role of scientific judgment embedded in the progression of methodological steps, something that is an essential part of any data analysis, but is infrequently reported. Finally, point (g) carries hypothesis testing into the uncharted territory of whole lives.

Recommended reading for more detail on the person-centered methods emphasized in this entry and on the integration of numbers and narratives to study whole lives, including narratives as data, see Singer et al. (1998), Singer and Ryff, (2001), and Sampson and Laub (1993). An in-depth exposition of recursive partitioning, including online software, is contained in Zhang and Singer (1999). An instructive example of formal modeling of multiple-episode event history

data is given in Heckman and Walker (1998) and a useful illustration of modeling of multivariate event history data, with both observed and unobserved covariates, is contained in Manton et al. (1987).

Longitudinal Data: Event–History Analysis in Discrete Time

The practical motivation for considering discrete-time models of event histories (Allison 1982, Thompson 1977) comes from the fact that such longitudinal data

are often recorded and presented in a discrete-time form (see *Longitudinal Data*). Thus, for example, it is common to collect information on the values of considered individual status variables at regularly spaced time points and to report such measurements directly as the data. A time unit is then fixed, typically to be a day, a week, a month, or a year, thus creating a regular time lattice. A slightly different but related reason why event-history data often appear in a discrete-time form is that the event times themselves are reported in a rounded form. Then the events which happened inside a time interval of unit length are somewhat arbitrarily assigned to either of its end points or, in so-called *actuarial methods*, to the middle. As a consequence, the reported event times are often *tied*, with several individuals sharing the same value. As an example, one can consider the changes of a person's employment status during the work history, typically consisting of spells of employment and unemployment, and finally ending with a permanent transition to outside of the work force. In order to be completely accurate, the reporting might have to done day-by-day. More realistically in practice, it can only be done monthly, and then a number of different alternatives exist.

For example, one could directly report the employment status on the last day of the month. A drawback of such reporting would be that, if the status can undergo frequent changes, the status at the end of the month might be purely accidental and not represent the entire month in an adequate way. An alternative would be to set a threshold x and ask whether the person has been employed for at least x days during the month. Such a solution may not be completely satisfactory either, as a low value of x does not distinguish between people who were employed only briefly from those who were employed during the entire month, with a similar but opposite problem arising for a high value of x. Such problems are of less concern if changes in the status variable are less frequent (such as marital status), or even irreversible.

1. Discrete-time Hazards

The main advantages from linking a statistical model directly with such data are that model construction becomes relatively straightforward, and that no special methods are required for dealing with the ties. For an illustration, suppose for simplicity that there are only two states for each individual, say *alive* and *dead*, and that the chosen time unit is one month. Then the lifetime T of an individual, in a discretized time scale, can be thought of as being determined by a sequence of Bernoulli trials, resulting in a sequence of 'zeros' as long as the individual is alive and ending with a 'one' for the month during which the individual dies. The basic element for setting up a corresponding statistical model is the conditional probability of recording 'one' in a unit interval given that all preceding intervals resulted in 'zeros', that is, the probability of death during the tth month for a person still alive after $t-1$ months (see *Survival Analysis: Overview*). Because of the discrete-time lattice used, such *discrete-time hazards* can be simply expressed as conditional probabilities:

$$h(t) = Pr(T = t | T \geqslant t) \tag{1}$$

By applying the chain multiplication rule of conditional probabilities progressively for increasing values of t, one finds readily that the unconditional probability for the survival is given by the product

$$Pr(T > t) = \Pi^{t}_{s=0}[1 - h(s)] \tag{2}$$

Note that moreover

$$Pr(T = t) = Pr(T > t-1)h(t) \tag{3}$$

These are discrete-time analogues of the well known *exponential formulas* for the survival probability and density, respectively, which are valid in continuous time and express a lifetime distribution in terms of the corresponding *hazard rate* (see, e.g., Andersen et al. 1993, Kalbfleisch and Prentice 1980). In fact, the exponential formulas can be obtained as limits when the time lattice used in the discretization becomes more and more dense, thereby making the discrete-time hazards $h(t)$ numerically small.

2. Regression Models and Likelihood Inference

When considering data consisting of lifetimes of several individuals, the number of such Bernoulli trials equals the total number of person-months at risk, and under natural independence conditions across individuals, a statistical model for the entire data can be formulated in terms of equally many Bernoulli trials, with the corresponding discrete-time hazards depending on age. This gives rise to a simple likelihood expression of a product form, without that tied lifetimes in the data would be a problem. The structure of the likelihood remains essentially unchanged if the discrete-time hazards of the considered individuals depend on covariates, as long as the covariates are fixed in time. One is then dealing with a regression problem, in which the observed development of the response variables (lifetimes) is explained in terms of the corresponding realized covariate values in the data (see *Survival Analysis: Overview*). A convenient framework for considering such regression models, including the possibility of using standard software, is offered by *generalized linear models* (for a general account and references, see Fahrmeir and Tutz (1994), and for asymptotic properties of the estimators, see, e.g., Arjas and Haara (1987)). In the important special

case of a *logistic link* function, if the considered time unit is short enough to make the discrete-time hazards $h(t)$ small and the intercept of the linear expression is allowed to depend on the interval, the model corresponds closely to the proportional hazards model of Cox (1972). If the covariates can themselves change in time, the same logic and structure of the likelihood can be used as long as the covariates are *external* (Kalbfleisch and Prentice 1980) in the sense that their development can be thought of as being exogenous from the point of view of the studied event-history data of individuals.

This is because there is then no need for an explicit modeling of the process governing the covariate process, as the resulting contributions to the likelihood expression do not depend on the actual parameters of interest and can therefore be coalesced into a proportionality constant. The same logic applies if the individual event histories are right censored and the censoring mechanism is assumed to be noninformative. If the model also involves time-dependent *internal* covariates, special care is needed in modeling and inference to make sure that their development in time does not *confound* the regression problem and the corresponding conclusions, which are often given a causal form. The issue of confounding, in the case of sequential designed experiments, has been considered in a series of papers by Robins (e.g., Robins 1997). Sometimes, in order to give useful causal interpretations, it becomes necessary to build the regression model in two or more levels representing, for example, group level and individual level effects. For a recent contribution in this direction, see Barber et al. (2000). The same general ideas apply also in situations in which the considered status or response variables are no longer just binary. For example, the status of an individual could assume more than two possible values, and the same status could repeat itself many times during the follow-up. For example, as noted above, a person's employment status could first alternate several times between the states *employed* and *unemployed*, until it finally reaches the absorbing state *outside of work force* because of retirement. What is needed, however, is a convenient form of conditioning, which carries information about an individual's earlier history and present status and thereby influences the assessment of the discrete-time hazards associated with the future development, always by one time unit ahead. For an interesting case study, applying a variety of inferential techniques, see Fahrmeir and Wagenpfeil (1996).

3. *Structure of the Likelihood*

Let us now make this idea more explicit. Indexing the individuals in the data by $i \in I$ and denoting the value of the corresponding status or response variable at time t by $X_t(i)$, we are led to consider conditional probabilities for a transition from a state $X_t(i)$ at time t to a state $X_{t+1}(i)$ at a later time $t+1$. Denoting by $H_t(i)$ the pre-t-history of individual i, which contains all observations made on i up to and including time t, including the past values of $X_s(i)$ $(s \leqslant t)$ and of possible covariates considered in the analysis, the first task is to specify the conditional probabilities $\Pr[X_{t+1}(i)|H_t(i)]$.

The following natural conditional independence assumptions will then often be valid:

(a) The variables $X_{t+1}(i)$, $i \in I$, are conditionally mutually independent given the collective pre-t-past $\{H_t(i), i \in I\}$ in the data.

(b) Knowledge of the individual's own pre-t-history $H_t(i)$ is sufficient for predicting $X_{t+1}(i)$ in the sense that

$$Pr(X_{t+1}(i)|H_t(j), j \in I) = Pr[X_{t+1}(i)|H_t(i)] \qquad (4)$$

Under conditions (a) and (b), the likelihood expression arising from discrete-time event history data becomes a product of terms of the form $\Pr[X_{t+1}(i)|H_t(i)]$, where the product is taken over all individuals i and all times t. (A tacit assumption here has been that if the covariates registered in $H_t(i)$ are themselves time dependent, they are either exogenous or their evolution is modeled in a way which does not involve the actual parameter of interest.) This makes the statistical inference of the model parameters in principle a straightforward problem, for example, by applying maximum likelihood. If, moreover, the condition

(c) Knowledge of the current state $X_t(i)$ is sufficient in the sense that

$$Pr[X_{t+1}(i)|H_t(i)] = Pr[X_{t+1}(i)|X_t(i)] \qquad (5)$$

holds, the model can be formulated in terms of a discrete-time *Markov chain* (see, e.g., Cinlar 1975, and *Markov Models and Social Analysis*). Information contained in the observed past history $H_t(i)$ can then be stored into a covariate vector of a fixed length, and the likelihood becomes a product of transition probabilities $\Pr[X_{t+1}(i)|X_t(i)]$, again taken over both i and t.

In spite of the seemingly general applicability of such a discrete-time approach to likelihood inference, the following two conventions, both usually involving an approximation, seem necessary in interpreting such models. First, censoring and possible other forms of controlling the number of individuals at risk are always thought to happen at times which are integer multiples of the chosen time unit. Second, if the model involves time-dependent covariates which are used as regressors of the observed status or response variable, their measured values need to be interpreted as 'prevailing (constant) conditions for exposure' during each considered time interval of unit length (see Sandefur and Tuma 1987). In particular, if the response variable can feed back and influence the

values of the covariates, in order to save a causal interpretation of the regression model, the covariate values must be determined already at the beginning of each time interval, thus avoiding the potential problem of conditioning on variables which are intermediate between a contemplated cause and the effect.

4. Embedding into Continuous-time Models

Another, and perhaps a more serious, drawback from a modeling perspective concerns the interpretation of the discrete-time parameter. In almost any conceivable applied context, and corresponding the common human perception, time is viewed as being continuous. Based on this perception, and even in situations in which the data are in a discrete-time form, a more natural alternative for statistical modeling of event histories starts from the idea that there is a true underlying status process in continuous time, and that the recorded event-history (panel) data consist then of a series of measurements from this underlying process taken at a number of typically prescheduled time points. The term *current status data* is sometimes used to emphasize this aspect. The development of a person's true employment status, marital status, support of political parties, or presence or absence of a chronic disease, as functions of time, would be natural examples. Indeed, such individual status histories would be the focus of a statistical analysis if they only could be observed, while discrete-time event history data consist merely of incomplete information, typically drawn from a sequence of cross-sections of such histories. As a consequence of such imprecision, individual event histories in continuous time are generally unidentifiable from discrete-time data. In particular, the exact times of occurrence are then not recorded, and if the status of a person has changed back and forth within a unit interval, this possibility may not even become explicit in the data (see, e.g., Stasny 1986). Nevertheless, it may be possible to embed the data successfully into a larger statistical model in continuous time. The fact that the individual underlying continuous-time developments cannot generally be determined uniquely from the data can often be compensated with some form of *data augmentation*. In other words, we can then consider an entire collection, or distribution, of sample paths which are consistent with the data. The practical solution may involve some form of simulation (multiple imputations), while a theoretical motivation to such techniques comes from Bayesian statistical inference. Exact numerical computations become quickly infeasible in practice, however. This leads to an application of sampling-based *Markov chain Monte Carlo* methods, in which the possible realizations of the individual processes are drawn by simulation (see *Monte Carlo Methods and Bayesian Computation: Overview*). Such data augmentation methods have been applied to data describing recurrent bacterial infections by Auranen et al. (2000), but the same approach applies more generally to problems in which it is natural to relate discrete-event history data to underlying individual developments in continuous time.

5. Conclusion

Depending on the context, modeling of event-history data may emphasize more the *event times* at which some particular events of interest occurred, or the *states* in which some studied process happened to be at the times at which it was measured. To stress the former aspect, one often speaks of survival or duration data. The second aspect is similarly stressed by talking about repeated measurements or longitudinal data. When the time variable in the data and in the model is discrete, it may sometimes be difficult to make a clear distinction between these two basic forms. On the other hand, the likelihood expressions will be of the same canonical product form in both cases, so that likelihood inference will remain the same. Recommended reading on these and closely related issues include Allison (1982), Barber et al. (2000), Diggle et al. (1994), Kalbfleisch and Prentice (1980) and Sandefur and Tuma (1987).

Longitudinal Research: Panel Retention

1. Introduction

Panel studies involve the collection of data over time from a baseline sample of respondents. Unlike other forms of longitudinal studies, panels allow for the study of individual behavior change over time. However, because the same individuals are followed over time, there is considerable respondent burden and eventual attrition from waves of interviewing. Since the value of panel surveys is dependent upon the ability to study the same respondents at different points in time, reducing attrition is of major concern. Loss of respondents raises the possibility of bias if those who are lost to follow-up differ from those who remain in the panel on key dependent variables. Therefore panel attrition can affect both the internal and external validity of the study (Cook and Campbell 1979. In this paper, we review the recommended strategies for minimizing panel attrition with general populations. Some of the strategies depend on institutions like the Post Office whose functions vary from country to country. The information provided here is about the USA, but we judge that much of it will transfer to other countries or can be adapted to their particular circumstances. The recommendations discussed here for minimizing panel attrition apply mainly to population-based samples. Panel surveys with more hard-to-locate or high-risk populations (such as the homeless, drug users, or runaway youths will require more specific, tailored strategies (Cottler et al. 1996, Walton et al. 1998, Wright et al. 1995) (see Cottler et al. 1996, Walton et al. 1998, Wright et al. 1995).

2. Factors Associated with Panel Retention

Retaining panel respondents is generally believed to depend on three factors. First is the respondent's willingness to participate in the study at future waves. Even when respondents are located for follow-up, keeping them interested and engaged in participation is a challenge. Second, the respondent's continued availability to participate depends on factors like illness or death. The third, and most important factor in panel maintenance, is the ability to locate respondents for interview at later waves.

Failure to find a respondent at later waves is predominantly due to residential mobility. Based on data from the 1998 Current Population Survey, during which respondents were asked whether they had lived at the same residence one year before the interview, it was estimated that 42.5 million Americans moved (Faber 2000). The majority (64 percent) moved within the same county, 19 percent moved to a different county in the same state, and 16 percent moved to a different state. Age is correlated with moving; the highest rates of residential mobility are found among those aged 20–29 and they decline as age increases. Rates of residential mobility also vary with race and ethnicity and by region of the country. They are lowest for non-Hispanic whites (14.5 percent), higher for Blacks and Asians (18.9 percent) and highest among Hispanics (21.2 percent). People who rent their homes are more likely to relocate than those who own their residences are. Nearly one-third of people living in rental units reported having moved in the previous year compared with less than 10 percent of homeowners. Rates of residential relocation vary by region as well. They are highest in the West (19.4 percent), lower in the South (17.2 percent), Midwest (14.7 percent) and Northeast (11.5 percent), respectively. Understanding these correlates of residential relocation will help investigators plan for the level of tracking they will need to do during follow-up interviews. For example, a panel of Hispanics in California would be likely to have higher attrition than a panel of white householders in Maine. Hence more resources would be required for respondent retention in the California sample than in the Maine sample. Including these variables as indicators at the baseline wave of data collection is important for postsurvey attrition assessment and weighting to adjust for it.

3. Study Design Features to Minimize Panel Bias

There are three main factors that affect attrition: recruiting the respondent to the study, locating the respondent for subsequent interviews, and maintaining the respondent's commitment to the panel.

3.1 Recruiting Respondents to the Panel

Plans for recruitment and retention should be developed at the time the study is designed. They are as important as any other feature of the study design, but often do not get the serious attention (or budget

allocation) they deserve. Later, we discuss the specific recruitment and relocation strategies that might be built into these plans.

3.1.1 Preplanning. Preplanning will ensure not only that there are sufficient resources to successfully recruit and retain the respondents, but also that the information needed to track respondents is collected during the baseline interview. It will also guide the selection of the sample size since this must allow for attrition if locating respondents is anticipated to be a serious problem. It may also affect decisions about the mode of interview because certain segments of the population may not be available by telephone or computer. For example, telephone coverage is related to socioeconomic status and to ethnicity (Belinfante 2000), and computer access is even more strongly so.

3.1.2 Study logo. Part of recruitment and retention is creating a recognizable identity for the study. A study logo and identifiable study title that is used in all correspondence (written and oral) and that appears on self-administered questionnaires, where applicable, have also been suggested as a way to create an identifiable image of the study for the respondent (Given et al. 1990).

3.1.3 Advance letters. Depending on the sample frame (list, random-digit dial generated, or block-listed sample), an advance letter should be sent to respondents at baseline that explains the purpose of the study, and where they can go for further information (a phone number or study web site, depending on the population). Advance letters are most commonly used in studies where the mode of interview administration is face-to-face. Advance letters have also been used in dual frame telephone surveys where telephone interviewing is combined with face-to-face or mail on the theory that they will increase response rates, although the evidence is mixed (Parsons et al. 1999, Traugott et al. 1987). Clearly, however, advance letters require that the investigator have a current address for the respondent. Even if addresses are not possible at the baseline interview wave, they should still be obtained at the baseline interview for follow-up purposes.

3.1.4 Response rates. The most important aspect of recruitment is the baseline survey where respondents have their initial contact with the study. Obtaining an acceptable rate of cooperation to the interview will affect the overall data quality. If the baseline survey is biased due to nonresponse, then the internal and external validity of the panel will always be problematic. Four methods are typically used for ensuring high contact and recruitment rates (Groves and Couper 1998): (a) budget for additional contact attempts with those sample units that cannot be immediately contacted; (b) schedule these contact attempts (whether by telephone or face-to-face) at various time of the day, evenings, and weekends to maximize the opportunity to reach someone at home; (c) plan for lengthier data collection during the follow-up waves to allow for respondent vacations and for locating hard-to-find respondents; and (d) allow interviewers to use local sources, such as neighbors, for information on the respondent or household. These techniques are standard in cross-sectional surveys but are especially important for panel studies to improve response rates.

3.2 Locating and Tracking Respondents for Follow-up Waves

Once respondents are recruited into the panel, several methods can be used to increase the likelihood of contact at designated follow-up waves.

3.2.1 Advance letters. Regardless of whether advance letters were used to recruit subjects, at every subsequent data collection wave, advance letters should be sent before interviewing begins. These letters notify the respondent of the upcoming visit or call and alert the investigator to a possible address change. The 'address correction requested' service available through the post office should be used with each letter.

3.2.2 Secondary sources. During the baseline interview, information should be obtained that will help locate respondents later. One invaluable resource is the secondary contact source. Secondary sources are usually one or two persons, not residing with the respondent, who will know how to contact the respondent at any point in time. At a minimum the relationship of the secondary source to the respondent and that person's telephone number should be collected.

In addition, during the baseline interview all respondents should be asked to provide their dates of birth, social security numbers (for use with credit-based tracking programs), and the names under which the respondents' telephones are listed. Depending on the population, respondents' e-mail addresses should also be collected as they can be used as an inexpensive means of tracking respondents.

3.2.3 In-person location strategies. Even the most conscientiously designed study will not prevent respondents from being lost to follow-up. If all secondary source information does not lead to the whereabouts of the respondent, there are several sophisticated tracking devices that can be used. At the very least, attempts at locating the respondent should persist until a final disposition of the case can be ascertained for the purposes of calculating response rates.

In face-to-face studies, an excellent source of information about respondents comes from people who are connected in some way with the respondent. Roommates, neighbors, property managers, mail carriers, family, and friends might be available to assist in searching for, and contacting, a hard-to-find study participant. When finding the respondent through direct contact does not lead to complete or solid information, personal informants can sometimes provide essential information about how to reach the respondent, what kind of schedules they keep, and whether they have moved.

3.2.4 Mail location strategies. In addition to 'address correction requested' stamped on advance letter envelopes, a number of other useful services are available through the US Postal Service (USPS) to improve mailing addresses and locate respondents who have moved (United States Postal Service 1999). Through the Address List Correction Service, business and resident mailing lists can be submitted for correction. Services provided include cross-listing of names to which mail cannot be delivered or forwarded; correcting ZIP codes, house numbers, rural, or post office box numbers, street names, and suffixes; furnishing new addresses for customers who have moved; and adding building, apartment, suite or room numbers when known. There is a minimum charge for correcting each submitted list, which can be arranged through local post office branches. In addition, the USPS National Change of Address (NCOA) program processes change of address data nationwide. The NCOA service is provided by private sector companies, certified and licensed by the USPS, who charge a fee for the service. These companies receive updated, computerized COA information on a regular basis. To search for lost or unlocatable study respondents, a file of names and addresses is submitted to one of the NCOA vendors, who search for matches in the NCOA. New addresses are provided when an exact match is found. Most other countries will have systems with many of these attributes.

3.2.5 Haines criss-cross directories. In the USA, the Haines Directory alphabetically cross-lists every street in a given community with the associated names, address, and (officially listed) telephone numbers of the people who live on these streets. A second section of the directory lists all published telephone numbers in sequence and cross-references them with the corresponding address and names of the residents. Haines directories can thus be used when only the telephone number or only the address is available. They can be found in local public libraries, which also house the directories for several years in the past.

3.2.6 Credit bureaus and vital statistics agencies. Another source for tracking panel respondents is credit bureau records. Software packages can be purchased from credit bureaus that allow investigators to search the credit bureau databases directly (for updated name and address information). By entering the last known address of the respondent, the file will provide data on whether the respondent has moved and, if so, the new address will be provided. These systems are a valuable investment if you are able to obtain the respondents social security numbers, as credit records are tied to that identifier. However, the social security number is not useful for locating all populations in the USA. For example, low-income or homeless respondents will be unlikely have a credit history that can be referenced or tracked. There are also a variety of Internet search sites that can be used for tracking. While they are free of charge, they are also not very comprehensive or up-to-date. They are often linked to the respondents' e-mail address and if the respondent does not use the Internet, they may not be found via this source.

In other situations, accessing public records is necessary for obtaining missing information about respondents. Public records contain data on births, deaths, marriages, criminal activity, military service, motor vehicle registration, and employment. Of particular use in panel studies that span a long period of time is the National Death Index, maintained by the National Center for Health Statistics. For a fee, the index will match respondents with their file of deceased persons using the name and date of birth. The likelihood of a match increases if the social security number or middle initial is available. In some states it is possible to search a web site from the department of corrections to ascertain if any study participants have been incarcerated. (For searching public records in the USA, see Gunderson 1996, Hoyer and McCann 1988, and Parco 1994.)

3.3 Retaining Respondents Between Interview Waves

Being a member of a panel is burdensome for the respondent. Thus, it is critical to the successful

maintenance of the sample that the relationship be reinforced between contacts.

3.3.1 The importance of contact. Regardless of the duration of time between data collection waves, it is advisable to maintain contact with respondents every 3–6 months as resources allow (Hunt and White 1998). Regular contact keeps the respondents engaged and reminds them of the value placed by the investigator on their participation. It also helps the investigator keep track of the respondent. The extent of the contact need not be more than the advance letter or a thank you note. Besides a friendly greeting and an expression of thanks for the respondents' participation, the content should include a reminder of the time of the next follow-up survey and a request for new contact information if the respondent has moved or will be moving. Investigators can also personalize the contact between interviewing waves by using birthday cards, holiday greetings, or other forms of written correspondence (Walton et al. 1998). These formats reinforce that the study staff is interested in and cares about the participants.

3.3.2 Incentives. Incentives are also critical to effective panel maintenance. Overall, the literature favors the use of incentives to increase response rates. Not only do they represent a concrete expression of appreciation to the respondent, but they also have the effect of keeping the respondent interested and involved. Anecdotal evidence also suggests that respondents are more likely to notify investigators of new addresses when they have moved if they expect an incentive.

Incentives typically take the form of money (cash or checks) or something with cash value (such as gift certificates or gifts), and can be presented to the respondent in advance of the interview, at the time the interview is conducted, or postinterview. The benefits of incentives have been empirically demonstrated in a meta-analysis of their effects on response to mail surveys (Church 1993). This analysis demonstrated that prepaid incentives yielded higher response rates than when the incentive was promised upon return of the survey form, and that cash was more successful than gifts in increasing response rates. Similarly, Singer et al. (1999) reported the results of their study of the effects of incentives in telephone and face-to-face studies and concluded that monetary incentives have a demonstrable effect on response rates. As did Church, they also found that cash incentives are more effective than gifts or tokens. Moreover, the authors found incentives to be effective regardless of the degree of burden on the respondent (e.g., 20 minutes vs. an hour interview).

The work reported by Singer et al. (1999) is also applicable to panel respondents. It suggests that informing the respondent at the start of the study that they will be offered an incentive for participation increases cooperation at later waves. Thus, at the conclusion of each interview, and before collecting the data that will help track the respondent at subsequent waves, it is useful to inform respondents that they will be paid an incentive for their future participation. However, it is important to emphasize that the respondent is not being paid for the data just provided. Rather, the incentive is a token of appreciation for having provided something that is invaluable and therefore cannot be purchased.

4. Summary

Panel retention is an under-appreciated but very important part of longitudinal studies that involve re-interviewing a cohort of respondents over time. While participation in a panel is a burden for the respondent, maintaining an unbiased panel is a challenge for the investigator. Thus, before such a project is undertaken planning is critical and the level of effort and associated costs need to be considered from the outset.

A key aspect of a successful panel is the study design. The sample, questionnaire, and associated budget must all accommodate the need to recruit an unbiased panel and maintain their participation over a lengthy period of time. Recruitment involves attracting individual respondents to agree to participate in the baseline and to be followed for some period of time afterwards. Locating respondents is critical to ensuring the continued quality of the panel data. Finally, recruiting and maintaining the panel will be facilitated if respondents develop a commitment to it. Ensuring that the panel is an unbiased sample of the population of interest requires effort to not only convince individuals to participate but to provide sufficient information to enable the panel to continue.

Achieving a high level of cooperation to the baseline is critical and obtaining cooperation must be done in a manner that does not alienate the respondent. It must also be recognized that overall trends in survey research response rates indicate that collecting any survey data collection is going to become increasingly difficult. In the USA, there has been sufficient decline in response rates to social surveys since the 1990s that the leading statistical agencies and professional associations that rely on survey data convened a special conference devoted to the topic (the International Conference on Survey Nonresponse in Portland, Oregon, October 1999).

In sum, plans for follow-up must be established at the onset of the study so that all the relevant information is collected from the respondents as necessary resources are allocated. Without sufficient data on respondents, when they change residence or

telephone, they are likely to be lost to follow-up, introducing bias into the data. Convincing respondents that they are important to the success of the panel and that the investigator values their participation ultimately helps reduce the cost of locating and following the respondents. Overall, participation in research is a process of exchange. Thus, it is important to show respect and consideration for the sources of the data.

Long-term Depression (Cerebellum)

While long-term depression (LTD) occurs under various conditions and plays various roles (*Long-term Potentiation and Depression (Cortex)*; *Long-term Depression (Hippocampus)*), the cerebellar LTD examined in this article is characterized by its association with a unique structure in the cerebellum, Purkinje cells and climbing fibers, and by its distinct role played in cerebellar function.

1. Neuronal Elements Involved in LTD

Mossy fibers arising from various precerebellar nuclei in the brain stem and spinal cord enter the granular layer of the cerebellar cortex and form synaptic contact with granule cells there. Axons of granule cells ascend through the Purkinje cell layer to the molecular layer and bifurcate to parallel fibers, which extend 2–3 mm to each side of the bifurcation point through the extensive dendritic arbor of Purkinje cells. Estimates of the number of synapses that each Purkinje cell receives from parallel fibers vary from 60,000 to 175,000 (Ecles et al 1967, Palay and Chan-Palay 1974, Ito 2001). While parallel fibers make up the majority of granule cell inputs to Purkinje cells, the ascending axons of granule cells also contribute about 20 percent of the total granule cell inputs, preferentially on the smallest diameter distal regions of the Purkinje cell dendrites.

Another input to Purkinje cells, a climbing fiber, originates from the inferior olive in the medulla oblongata. In contrast to the convergence of numerous granule cell axons to a Purkinje cell, only one climbing fiber comes into contact with each Purkinje cell and forms numerous discrete synaptic junctions on stubby dendritic spines of the Purkinje cell. The number of junctions formed between a climbing fiber and a Purkinje cell has previously been estimated to be approximately 300 in the frog cerebellum. However, in rats, a much larger number (26,000) is suggested because a 100 μm length of PC dendrite contacts 11.45 granule cell axons and 1.7 climbing fibers on the average (Ito 2001).

2. Electrical Signals Involved in LTD

Impulses of granule cell axons evoke fast excitatory postsynaptic potentials (EPSPs) in Purkinje cells as mediated by AMPA receptor. These EPSPs, when sufficiently large, evoke Na^+ spikes in the somatic region, which passively spread into the dendrites. During extracellular recording, these spikes are observed as 'simple spikes,' which are spontaneously discharged *in vivo* at a rate of 50–100 Hz. Impulses in climbing fibers evoke responses composed of large EPSPs and Ca^{2+} spikes evoked by the EPSPs in Purkinje cell dendrites. During extracellular recording, climbing fiber responses take the form of short bursts of spikes, called 'complex spikes,' which are discharged *in vivo* at irregular, low rates around 1 Hz.

During *in vivo* extracellular recording, LTD is represented by the persistent reduction in the probability (firing index) of a Purkinje cell to generate simple spikes in response to the stimulation of granule cell axons. Under slice or tissue culture conditions, LTD is observed as a persistent reduction in the granule cell axon-evoked AMPA-mediated EPSPs or excitatory postsynaptic currents (EPSCs) (see Eccles et al. 1967, Ito 2000).

3. Conditions for Induction of LTD

LTD is optimally induced by conjunctive stimulation of climbing fibers and granule cell axons at 1–4 Hz by 100–300 pulses. LTD can also be induced by a more natural stimulus paradigm such as a series of eight pulses (80 msec, 100 Hz) to granule cell axons and immediately thereafter three pulses to climbing fibers (Ito 2000). LTD is input-specific; it occurs only in those granule cell–Purkinje cell synapses conjunctively stimulated by climbing fibers. However, spread of LTD to synapses in the close neighborhood has recently been reported (Reynolds and Hartell 2000, Wang et al 2000).

Various reduced forms of LTD have been generated by replacing either granule cell axon stimulation or climbing fiber stimulation, or both, with chemical stimuli or electrical currents directly applied to Purkinje cells. In cerebellar slices, climbing fiber stimulation can be replaced by the application of depolarizing pulses, which bring about the entry of Ca^{2+} ions into Purkinje cells through voltage-gated channels. The simplest procedure for inducing LTD is to apply quisqualate or to increase the extracellular K^+ concentration. In cultured Purkinje cells devoid of both granule cells and climbing fibers, a reduced form of LTD is induced by a combination of glutamate (or quisqualate) pulses and membrane depolarization. The LTD is detected as a reduced sensitivity of PCs to glutamate or AMPA. This form of LTD occurs in very simple preparations devoid of dendritic spines, indicating that LTD induction does not require such morphological specialization.

4. Duration of LTD

The observation time for LTD is usually limited to one half to one hour, and occasionally for two to three hours, but in certain special cases, it has been extended to one to two days (Ito 2000). LTD induced in the amplitude of mEPSCs in cultured PCs by conjunctive application of 50 mM K^+ and 100 μM glutamate was observed to last for 36 hours and return to the original level after 48 hours. When the rabbit cerebellum was sliced 24 hours after the rabbit had been trained for eyeblink conditioning (*Eyelid Classical Conditioning*), sequentially applied granule cell axon and climbing fiber stimuli failed to induce LTD, which occurred in slices dissected from control rabbits. This suggests that LTD underlying the eyeblink conditioning persists for at least 24 hours and precludes eliciting another LTD.

5. Signal Transduction for LTD

Diverse chemical reactions have been found to underlie LTD induction (Levenes et al. 1998, Ito 2000). They can be roughly classified into the following seven major pathways:

(a) The glutamate released from granule cell axons reacts with AMPA receptors in Purkinje cells, which open associated cation channels for Na^+ and K^+ ions to generate AMPA-EPSPs. These EPSPs act to open voltage-dependent Ca^{2+} channels.

(b) Granule cell-derived glutamate also reacts with mGluR1s, which in turn activate phospholipase C through G protein (Gαq). Phospholipase C produces diacylglycerol (DAG) which activates protein kinase C (PKC), as well as inositol trisphosphate (IP_3), which acts upon IP_3 receptors to release Ca^{2+} ions from intracellular stores.

(c) mGluR1s activated by granule cell-derived glutamate also stimulate phospholipase A2 via G proteins, eventually producing unsaturated free fatty acids including arachidonic acid and oleic acid.

(d) Granule cell-released NO diffuses into Purkinje cells and activates guanylyl cyclase which produces cyclic GMP (cGMP). cGMP in turn activates protein kinase G (PKG), which, following phosphorylation, converts a protein, G-substrate, into a potent inhibitor of protein phosphatase.

(e) A climbing fiber-derived amino acid transmitter (most likely glutamate, yet unidentified) reacts with receptors and opens associated channels for Na^+ and K^+ ions to evoke a large EPSP, which in turn causes Ca^{2+} influx through voltage-dependent Ca^{2+} channels.

(f) A climbing fiber-derived corticotropin-releasing factor (CRF) reacts with type-1 CRF receptors and associated G proteins, and then yields an as yet unidentified second messenger, which interacts with PKC.

(g) A climbing fiber-derived type-1 insulin-like growth factor (IGF-1) may facilitate internalization of receptors by endocytosis.

There is cross-talk between these pathways. Protein tyrosine kinases (PTKs), mitogen-associated protein kinases (MAPKs), glial fibrillary acid protein (GFAP), an as yet unidentified rapidly turned-over protein(s) and immediate early gene, *Jun*-B, are also implicated in LTD induction. A recent hypothesis is that these complex chemical reactions eventually lead to removal of AMPA receptors by internalization (Wang and Linden 2000, Matsuda et al. 2000).

6. *Error Representation by Climbing Fiber Signals*

What information do climbing fibers convey to induce LTD? In simple situations such as reflexes, climbing fibers convey sensory signals such as pain or loud sounds. These sensory signals suggest a harmful consequence of an inadequately executed movement. In various types of ocular movements, climbing fiber signals are known to represent retinal slips, which reflect a deviation of a realized eye movement from a desired one, that is, an error in controlling eye movement. These observations support the view that, during the repeated exercise of a movement, error-driven LTD reshapes the neuronal circuit of the cerebellum in the direction which minimizes errors consequent to the movement (Ito 1984, 2001).

During locomotion, climbing fiber signals are evoked by a sudden descent of a stepped-on rung at the beginning, but not at the cessation, of the fall of a paw. These signals appear to reflect the discrepancy between command signals descending from the brain stem center to the spinal cord and the signals that the command signals evoke in the spinal cord neuronal circuit. During hand/arm movements, climbing fiber signals arise in three phases of movement: at the beginning, before the end, and after. Climbing fiber signals therefore encode not only the consequence errors detected through sensory systems, but also other types of errors arising from the internal mechanisms of the motor systems.

7. *Involvement of LTD in Motor Learning*

Recent data that the inhibition of LTD following pharmacological or genetic manipulation impairs various types of motor learning supports the view that error-driven LTD is the basis of motor learning (Ito 2001).

(a) Adaptation of the vestibuloocular reflex (233) has been shown to be blocked by superfusing the cerebellum in rabbits and monkeys with a NO scavenger, hemoglobin, or by injection of an inhibitor of NO synthase (NOS) into the goldfish cerebellum. Transgenic mice that selectively express the pseudo-substrate PKC inhibitor in Purkinje cells lacked the vestibuloocular reflex adaptation consistent with the loss of LTD induction in cerebellar slices obtained from these mice. Neural NOS (nNOS)-deficient mice lacked adaptation of the optokinetic eye movement response, which normally occurs under continued rotation of the visual field around a stationary animal. Subdural applications of NO scavenger or NOS inhibitor to the paraflocculus-flocculus depressed the adaptation of smooth pursuit in monkeys.

(b) Rabbits administered a NO synthase inhibitor exhibited learning deficits in the conditioned eyeblink response. GFAP-deficient mutant mice exhibited a loss of LTD and also impaired eyeblink conditioning. Injection of an IGF-1 antisense oligonucleotide in the inferior olive, which reduces IGF-1 levels in the cerebellum, blocked conditioned eyeblink learning in rats.

(c) Postural compensation after unilabyrinthectomy was delayed in rats after intracerebroventricular application of PKC inhibitors. When a decerebrate cat walking on a treadmill experienced a sudden increase in the speed of only the running belt under the left forelimb, regular stable locomotion was restored in 50–100 steps. Injection of a NOS inhibitor into the cerebellum blocked this adaptation. mGluR1-deficient mice walking on a treadmill exhibited abnormally dispersed locomotor cycles of two limbs and did not adapt to an increase in the belt velocity. This sign of impaired interlimb coordination in locomotion diminished when the mGluR1-deficiency was rescued in the cerebellum.

(d) Motor coordination is evaluated by measuring the duration that an animal can remain on a horizontally placed rotating rod. In five types of gene-manipulated mice showing significant reduction in staying time, three types (mGluR1-, GluRδ2-, and Gαq-deficient) lacked LTD. However, the other two (PKCγ- and mGluR4-deficient) retained LTD, and their motor discoordination is explained by the persistent multiple innervations of Purkinje cells by climbing fibers, abnormal transmission in granule cell–Purkinje cell synapses. GFAP-deficient mice and PKC-inhibitor-transfected mice were reported to exhibit motor coordination indistinguishable from wild-type mice in spite of the lack of LTD. These observations are inconsistent with the hypothesis of motor learning. The reasons for this discrepancy need to be investigated.

8. *Comments*

How is LTD eventually converted to permanent memory? One possibility is that LTD as a functional depression is consolidated as a structural change in synaptic contacts and spines. How can the error-

driven LTD-based learning mechanism be expanded to apply beyond motor learning to implicit learning in mental functions such as cognition, language, and thought? This expansion has been achieved at experimental and conceptual levels, but in the future it should be made at computational levels as well.

Long-term Depression (Hippocampus)

Hippocampal LTD is a form of activity-dependent synaptic plasticity where the cumulative activation of inputs to specific neural pathways in the hippocampus produces a decrease in the excitability of the activated neurons. Several forms of hippocampal LTD have been identified, and much research has examined the mechanisms by which LTD is expressed in the hippocampus. In this article, a characterization of hippocampal LTD and its possible involvement for memory storage in the mammalian brain will be examined.

1. Synaptic Plasticity in the Hippocampus

Synaptic plasticity is a term used to describe several forms of long-lasting, activity-dependent changes in synaptic strength. The importance of synaptic plasticity is due to the presumption that information, or memories, are stored in the brain as complex spatial-temporal patterns of neuronal activity that occur in large ensembles of neurons (see *Memory: Synaptic Mechanisms*; *Neural Plasticity*). Learning, defined as any type of experience-dependent change in sensory processing or experience-dependent change in behavior, is thought to involve the storage of new information via a process that involves long-lasting changes in synaptic strength in the circuits that were activated during the learning process (see *Learning and Memory, Neural Basis of*). Synaptic plasticity is also important for the development of neural circuitry, because an initial activity-independent phase occurs during which axons grow into their target regions and produce an overabundance of synaptic contacts followed by an activity-dependent phase during which some of the synapses are strengthened and consolidated, while other synapses are weakened and pruned away (see *Synapse Formation*).

During the early 1970s, the discovery of long-term potentiation (LTP), a long-lasting enhancement of synaptic activity that follows a brief, high-frequency electrical stimulation, provided strong experimental evidence for a model of synaptic plasticity associated with a number of important functions of the nervous system, including learning and memory (see *Long-term Potentiation (Hippocampus)*). When LTP was first identified, it was most reliably and robustly elicited in the hippocampus, an integral component of the medial-temporal lobe system that mediates a number of very important forms of declarative memory (Squire 1987). LTP can be reliably elicited in intact *in vivo* preparations, as well as in reduced *in vitro* preparations, making it amenable to detailed experimental manipulation and analysis.

If synapses in the hippocampus simply continued to increase in strength as a result of LTP, all synapses would eventually reach some level of maximum efficacy. At this point, it would be difficult or impossible, at least in principle, to encode new information. Moreover, active synapses would be so plentiful that even a small stimulus would excite many cells, resulting in pathologies like epilepsy. To make synaptic strengthening a useful mechanism for encoding information, other processes must selectively

weaken specific sets of synapses. LTD in the hippocampus may be an example of just such a process.

2. Hippocampal Anatomy and Circuitry

The hippocampus provides a useful model system for the study of synaptic plasticity on both anatomical and electrophysiological grounds. The hippocampus is divided into two major subpopulations of neurons: the hippocampus proper, composed primarily of pyramidal cells (subdivided into four subfields: CA1–CA4), and the dentate gyrus, composed primarily of granule cells (see *Hippocampus and Related Structures*).

A series of discrete, anatomical units called lamellae oriented along the transverse axis of the structure compose the hippocampus (Andersen et al. 1971). It is this lamellar organization that allows for the precision in identification of known stimulation and recording sites within the hippocampal trisynaptic circuit. Stimulation of perforant path fibers of the entorhinal cortex, which provides the main input into the lamellae of the hippocampus, results in the activation of granule cells of the dentate gyrus. Stimulation of the granule cells, in turn, activates the pyramidal cells of the CA3 region through the mossy fiber system. The axons of the CA3 pyramidal cells bifurcate, sending an efferent stimulus through their main branch out through the fimbria to the fornix, and a collateral branch (Schaffer collaterals) sweeping upward to synapse on the apical dendrites of CA1 pyramids. The sequential activation of this trisynaptic circuit has been verified both anatomically and electrophysiologically (Swanson et al. 1982).

The Schaffer collateral-CA1 pyramidal cell synapse is one of the best understood synapses in the mammalian brain, and many of the currently known phenomena of synaptic plasticity, including short-term potentiation, LTP, paired pulse facilitation, and LTD, have been found to occur at this synapse.

3. Two Forms of Hippocampal LTD

Two basic forms of hippocampal LTD have been distinguished. Homosynaptic LTD occurs only when the strengths of active synapses are depressed, e.g., homosynaptic LTD can occur at synapses that are given low-frequency electrical stimulation. Heterosynaptic LTD occurs only when the strengths of inactive synapses are depressed, e.g., heterosynaptic LTD can occur at synapses that are inactive during high-frequency stimulation of a converging synaptic input. Heterosynaptic LTD was discovered in the dentate gyrus *in vivo* in 1979, with evidence for homosynaptic LTD in area CA1 reported in 1992. In this article, hippocampal LTD will be described by first focusing on homosynaptic LTD in area CA1, followed by a discussion of heterosynaptic LTD in the dentate gyrus.

3.1 Homosynaptic LTD in area CA1

Homosynaptic LTD has been studied *in vitro* in the excitatory monosynaptic pathway running from the Schaffer collaterals (afferents) to area CA1 cells (see *In Vitro Neurophysiology*; *Perception and Cognition, Single-/Multi-neuronal Recording Studies of*). In the paradigm most often used to induce homosynaptic LTD, the delivery of several hundred electrical stimuli to the Schaffer collaterals at low frequencies produces a sustained depression of modest but significant magnitude in area CA1 cells. The key properties of homosynaptic LTD produced by low- frequency stimulation are summarized below (see Bear and Abraham 1996, Dudek and Bear 1992, Mulkey and Malenka 1992):

(a) Low frequency stimulation-induced LTD is input specific. Only synapses receiving low-frequency conditioning stimulation show LTD; other synaptic inputs converging onto the same population of postsynaptic neurons are unaffected (hence the term homosynaptic LTD).

(b) Low-frequency stimulation-induced LTD is frequency dependent. LTD depends on the frequency of conditioning stimulation. LTD usually results from 0.5–3 Hz stimulation, but the same number of pulses at higher frequencies can produce LTP instead.

(c) Low-frequency stimulation-induced LTD is saturable and reversible. Repeated episodes of low-frequency stimulation in CA1 saturate LTD. Furthermore, synapses that are depressed can be potentiated, and vice versa, indicating that LTD is not a result of lasting damage to the stimulated synapses.

(d) Low-frequency stimulation-induced LTD usually requires *N*-methyl-D-aspartate (NMDA) receptor activation. Under most circumstances, NMDA receptor antagonists reversibly block homosynaptic LTD.

3.2 Heterosynaptic LTD in Dentate Gyrus

Heterosynaptic LTD has been studied *in vivo* in the excitatory monosynaptic pathway running from layer II cells of the entorhinal cortex via the perforant path to the granule cells of the dentate gyrus; it has not yet been observed *in vitro*. Like LTP in the hippocampus, heterosynaptic LTD is saturable and reversible, and, depending on stimulation parameters, can last for days or weeks. In most experiments, the induction of heterosynaptic LTD in one pathway is accompanied by LTP of the path that was tetanized. This fact, plus the failure to observe this form of LTD *in vitro*, has

Figure 1
Long-term synaptic depression in the hippocampus (reproduced by permission of Sinauer Associates, Inc. from *Neuroscience*, 1997). In this experiment, two stimulating and one extracellular recording electrode are used. Low-frequency stimulation (1 per second) is applied to the test pathway (stimulus electrode 1). After 15 minutes, the size and slope of the extracellular population response are depressed by about 50 percent (upper panel), while the control pathway (which was stimulated once every 10 seconds) remains unchanged (lower panel). The depression persists for the duration of the experiment

restricted investigations of the mechanisms specifically underlying heterosynaptic LTD.

4. *Mechanisms of Hippocampal LTD Induction*

In most cases, hippocampal LTD requires activation of glutamate receptors and postsynaptic calcium (Ca^{2+}) ion influx at the site of synaptic contact in the dendritic spine (see *Ion Channels and Molecular Events in Neuronal Activity*; *Synaptic Transmission*). Biochemically, hippocampal LTD also appears to require activation of protein phosphatases, which may be preferentially activated by Ca^{2+} influx. Interestingly, the magnitude of synaptically-evoked changes in postsynaptic Ca^{2+} concentration appears to dictate whether LTP or LTD is elicited.

4.1 *Receptor Activation*

Synaptically-released glutamate can activate several types of glutamate receptors, presumably co-localized at individual synaptic contacts at individual dendritic spines (see *Neurotransmitters (Glutamate)*). One of these is the NMDA receptor; another is the α-amino-3-hydroxy-5-methyl-4-isoxazoleproprianate (AMPA) receptor. During basal synaptic transmission, the current that generates hippocampal synaptic responses is due to activation of the AMPA receptor, which is associated with sodium-potassium channels. The channels open briefly, sodium ions rush in, and the excitatory postsynaptic potential develops. This glutamate-AMPA transmitter-receptor is the prototypic fast excitatory synapse in the brain.

Figure 2
A model for the induction of LTP and LTD (reproduced by permission of Sinauer Associates, Inc. from *Biological Psychology*, 1996). During afferent activity, Ca^{2+} enters dendritic spines through NMDA receptors. High-frequency stimulation causes phosphorylation (via protein kinase) of a synapse protein, and low-frequency stimulation causes dephosphorylation (via protein phosphatase) of the same synaptic protein. The state of phosphorylation of this protein helps to control synaptic strength

Although the NMDA receptor is a glutamate receptor, it is not activated by weak synaptic actions like that of the AMPA receptor, and therefore contributes very little to changes in the membrane potential during basal synaptic transmission. However, when the cell is depolarized by various patterns of synaptic activation, magnesium ions leave the channels, and glutamate activation of the NMDA receptors opens the channels allowing Ca^{2+} to rush into the neuron because unlike AMPA receptors, NMDA receptors are highly permeable to Ca^{2+}. There is strong evidence that the NMDA receptor-mediated change in Ca^{2+} is a necessary, and perhaps sufficient trigger for both LTP and LTD. Hippocampal homosynaptic LTD is reversibly blocked by the NMDA receptor antagonist DL-2-amino-5-phosphonovaleric acid, and is also blocked by strong hyperpolarization during the hyperpolarization protocol or buffering postsynaptic Ca^{2+} (Bear and Malenka 1994, Kemp and Bashir 1997, Mulkey and Malenka 1992). This evidence suggests that NMDA receptor-dependent changes in Ca^{2+} might be the primary mechanism by which hippocampal LTD is mediated.

While much has been learned about the mechanisms of NMDA-dependent hippocampal LTD, there is some additional evidence that another type of glutamate receptor, the metabotropic glutamate receptor (mGluR), might also play a key role in establishing LTD, particularly during early postnatal life (Bolshakov and Siegelbaum 1994). This receptor would be classed as having a slow or modulatory action: it does not directly control ion channels, but controls a second-messenger system via a G protein that acts on the intracellular biochemical machinery of the cell. One of the primary functions of mGluRs in synaptic transmission is to provide activity-dependent autoinhibition through presynaptic suppression of transmitter release (Glaum and Miller 1994). Activation of mGluRs results in reversible depression in the strength of synaptic input to principal neurons in the trisynaptic hippocampal circuitry, and in the presence of mGluR antagonists, LTD is inhibited, as well as mRNA translation, which suggests that protein synthesis, triggered by synaptic activation of mGluR, can modify synaptic transmission (Huber et al. 2000).

4.2 Biochemical Activation

Activity-dependent modulation of synaptic strength in area CA1 pyramidal cells is at least partially controlled by the balance between the activities of critical protein kinases and phosphatases in the postsynaptic cell, with the synaptic glutamate receptor being a potential substrate for this biochemical competition. In one model for the induction of LTP and LTD, during efferent activity, Ca^{2+} enters dendritic spines through NMDA receptors. High-frequency stimulation allows Ca^{2+} to reach high levels, which preferentially activates a protein kinase. Low-frequency stimulation allows Ca^{2+} to reach low levels, which preferentially activates a protein phosphatase. It is then argued that both the protein kinase and phosphatase act on a common synaptic phosphoprotein, the phosphorylation state of which controls synaptic strength (Bear and Malenka 1994).

Long-term Potentiation and Depression (Cortex)

Long-term potentiation (LTP) is a long-lasting increase in postsynaptic response seen at glutamate synapses following afferent activation. In the laboratory, LTP typically is induced by a brief tetanus to afferents and results in a larger postsynaptic response to a constant input that lasts for an hour or more. Long-term depression (LTD) is a long-lasting decrease in the postsynaptic response seen at the same synapses. LTD is induced by a low-frequency tetanus leading to a postsynaptic response depression lasting for an hour or more. Both LTP and LTD are alterations in synaptic gain that display an induction threshold, are specific to the synapses activated, are induced by Ca^{2+} entering the postsynaptic cell, and display associativity—such that the pairing of a strong and weak (unable to induce change alone) stimulus will induce gain change in both inputs. Both forms of synaptic plasticity are thought to be central to the formation of neural networks underlying information storage. The commonly accepted model of the storage of experiential information (e.g., memory) involves the establishment of networks of neurons interconnected in such a way to encode the salient aspects of the experience. These networks—which may be quite extensive and involve thousands of neurons—are themselves the neural representation of experience. LTP and LTD are found in brain regions and at developmental times that suggest that they may encode far more than ongoing experience, perhaps being generic synaptic mechanisms involved in the establishment of fundamental cortical sensory and motor representation, among other things. Cortical LTP is most pronounced during early development coinciding with the critical period for environmentally-induced synaptic plasticity, suggesting that the same mechanism may underlie both phenomena.

1. Cortical Distribution

LTP/LTD are found throughout the neocortex at glutamatergic synapses of pyramidal cells and interneurons. One or both of these forms of synaptic plasticity have been reported in primary sensory areas, primary motor areas, and 'association' cortex of rodent, cat, and primate brain, as well as cortical projections to subcortical structures (thalamus, striatum). While there are some differences between cortical areas, generally both LTP and LTD are seen at all locations, as in hippocampus (but unlike cerebellar Pyrkinje cell synapses where LTD predominates). As opposed to the hippocampus, where most studies of synaptic plasticity are performed, the complex anatomy of cortex makes it difficult to stimulate monosynaptic, homogeneous afferent pathways. Most studies, either *in vitro* or *in vivo*, tetanize the white matter afferents and record the postsynaptic effects in corresponding cortical column, or stimulate and record intracortically within the column (layer IV/V to II/III or layer II to V). In both cases, stimulation activates a heterogeneous population of afferents and antidromically activates efferents traversing the region, making interpretation of the synapses involved

problematic. Similarly, the postsynaptic responses are often combinations of orthodromic mono- and polysynaptic responses and antidromic responses.

2. Mechanisms of nmdaLTP

There are two different forms of cortical LTP: one mediated by activation of the NMDA glutamate receptor subtype, the other mediated by activation of Voltage Dependent Calcium Channels (VDCCs). Both cortical forms appear to have the same characteristics as LTP found in hippocampus, namely: glutamate receptor subtype or VDCC involvement, input specificity, associativity, activation threshold and Ca^{2+} dependency. The induction of the form of LTP mediated by the NMDA receptor (nmdaLTP) requires afferent activity associated with postsynaptic depolarization via the AMPA receptor (a ligand-gated glutamate receptor gating Na^{+}/K^{+}) sufficient to activate the ligand and voltage sensitive NMDA receptor (NMDAR). The active NMDAR gates Ca^{2+} into the postsynaptic cell where it activates several serine–threonine kinases (PKA, PKC, CaMKII) leading to the phosphorylation of the AMPAR—resulting in larger EPSPs, and the activation of incompletely understood signal transduction cascades (involving the CREB and Ras-MAPK cascades) ultimately leading to an alteration in gene expression/protein synthesis. Most of the studies investigating the signaling pathways in LTP have been done in hippocampal neurons using both enzyme inhibitors, and developmental or targeted/inducible genetic knock-out animals. The relatively few neocortical studies indicate that the same mechanisms are present. The activated kinases, some of which are autophosphorylated as a result of their activation (thus ensuring their continued activity in the absence of the calcium transient), serve to phosphorylate their substrates. Many of the receptors, channels, and enzymes present postsynaptically have phosphorylation sites which, when activated, result in increases in postsynaptic responsivity. The expression of LTP immediately following a tetanus is primarily due to phosphorylation of the AMPAR. As will be seen later, some phosphorylation sites on the AMPAR and other substrates are reversible and can be dephosphorylated through the action of phosphatases associated with LTD. It is thought that the persistence of LTP involves synthesis of synaptic proteins, as enzyme inhibitors and protein synthesis inhibitors limit the duration of LTP expression (in hippocampus).

3. Mechanisms of vdccLTP

The form of LTP mediated by VDCCs (vdccLTP) is initiated by depolarizing the postsynaptic cell beyond that required for nmdaLTP—to activate L-type VDCCs and allow an influx of Ca^{2+} into the postsynaptic cell. This means that either the degree of afferent activity must lead to a higher level of postsynaptic depolarization or that other elements must assist in the establishment of appropriate levels of depolarization to induce this form of LTP. There are two known means by which cellular processes contribute to the induction of vdccLTP. The first is through the simultaneous induction of nmdaLTP which contributes depolarization to the postsynaptic cell and thus helps to achieve the conditions for the activation of VDCCs. The second is by reducing the inhibitory drive onto the postsynaptic cell to facilitate the induction vdccLTP. As compared to hippocampus, neocortical LTP appears to be regulated to a greater extent by enhanced inhibitory tone, as GABAa blockers are often required to elicit either form of cortical LTP *in vitro*. The cellular targets of Ca^{2+} gated through VDCCs appears to be different from Ca^{2+} gated through NMDAR channels, in that enzyme inhibitors of serine/threonine kinases that block nmdaLTP have no affect on the induction or expression of vdccLTP. vdccLTP depends upon the activation of tyrosine kinases, and involves the participation of tyrosine receptor kinases (*trk*)—the receptors for neurotrophins. In visual cortex of young rats, the application of the neurotrophin BDNF facilitates the induction of synaptic plasticity to a weak tetanus. As opposed to nmdaLTP which can be reversed

Table 1
Comparison of the features of the three forms of synaptic plasticity observed at neocortical glutamatergic synapses. *Depolarization* and *Calcium levels* refer to approximate values achieved during the initiating tetanus

	nmdaLTD	*nmdaLTP*	*vdccLTP*
Induction tetanus	1–5 Hz	> 25 Hz	> 50 Hz
Depolarization	~ 4 mV	~ 10 mV	~ 18 mV
Calcium levels	~ 6 nM	~ 13 nM	~ 20 nM
Duration	hours	days–weeks	?
Reversability	by LTP	by LTD	no
Signaling	Serine–threonine phosphatases	Serine–threonine kinases	Tyrosine kinases

(depotentiated) by LTD induction, vdccLTP appears to be irreversible. Since both forms of LTP are induced by afferent activity leading to postsynaptic depolarization, sufficient activity will lead to the expression of both forms simultaneously.

The two forms of LTP have somewhat different cortical distribution, with nmdaLTP found at intracortical synapses and associated with white matter activation early in development. In adult cortex, NMDARs decline in number and nmdaLTP seen to white matter stimulation is reduced or absent, leaving vdccLTP dominant. A similar, but less pronounced, effect is seen in hippocampus as well.

4. *Long-term Depression*

LTD is the decremental counterpart of LTP whose mechanism of action also utilizes Ca^{2+} gated through NMDARs. The evidence from Ca^{2+} imaging studies suggests that the amount of Ca^{2+} entering the postsynaptic cell is critical in determining which form of synaptic plasticity will be expressed. LTP induction seen following high frequency afferent activity is associated with greater postsynaptic cytosolic Ca^{2+} levels than that seen following prolonged low frequency activation leading to LTD. These low levels of calcium in the postsynaptic cell bind to high-affinity Ca^{2+} binding sites on protein phosphotases, whose action is to dephosphorylate the substrates of serine/threonine kinases. Thus, LTD acts to dephosphorylate sites that have been phosphorylated by the action of protein kinases (the removal of nmdaLTP by LTD induction is termed depotentiation). Thus, nmdaLTP and LTD (or phosphorylation and dephosphorylation) exist in a opposing regulatory relationship.

5. *Properties of Plastic Cortical Synapses*

Studies in hippocampus have revealed several other forms of synaptic plasticity that have not been reported for neocortex. These include a presynaptic form of LTP at hippocampal CA3 synapses and a form of LTP utilizing opiate transmitters. Given the relative paucity of mechanistic studies of LTP in neocortex, it is unclear if these forms are absent or undiscovered. Two additional aspects of LTP seen in hippocampus are present in at least some regions of neocortex: the influence of the metabotropic glutamate receptor (mGluR) and the presence of the retrograde messenger NO. The mGluRs are a family of G-protein linked glutamate receptors whose different effects are mediated by PKC activation and IP3-mediated release of Ca^{2+} from postsynaptic endoplasmic reticuluum stores. Various mGluR antagonists and knock-outs have demonstrated the requirement for mGlu involvement in LTP in both hippocampus and neocortex, although it's precise role remains elusive. There may be regional cortical differences however, as some mGluR antagonists are ineffective in blocking PI hydrolysis and synaptic plasticity in visual cortex. As in hippocampal pyramidal cell synapses, there is evidence for the involvement of the retrograde messenger NO in neocortical synapses, as inactivation of its synthetic enzyme blocks LTP in auditory and somatosensory cortex.

As changes in synaptic gain are initiated by incremental increases in postsynaptic depolarization (with increasing depolarization, nmdaLTD, then nmdaLTP, then vdccLTP are induced), modulatory synaptic influences onto cortical pyramidal cells can be expected to influence the form and degree of synaptic plasticity induced by glutamatergic activity. Studies primarily in visual cortex have demonstrated: the inhibiting effect of mACh antagonists on LTP, the inhibiting effect of 5-HT1A agonists on visual cortex LTP, and the dopamine facilitation of intracortical prefrontal cortex LTD. As different cortical regions have differential neuromodulatory inputs, it might be expected that they will influence synaptic plasticity in different directions. More detailed studies in hippocampus have revealed that no two synapse types share identical properties. While they are outwardly similar, they differ mechanistically. The same may be found across neocortical synapses.

In sum, neocortical synaptic plasticity is phenomenologically and mechanistically similar to that seen in the better studied archicortex (hippocampal formation). Differences are seen primarily in the regional distribution of forms of LTP between cortical areas and within cortical laminae and the relative dominance of the VDCC form of LTP, particularly its prevalence with maturity. LTP/LTD remain the best candidates for processes that alter the synaptic gain at nodes in neural networks encoding information—and thus defining the architecture of the network. If the forms of synaptic plasticity seen in neocortex underlie information storage, it must be demonstrated that they are specific and necessary to the process they govern. Beyond this, consideration must be given to the nature of the information that is stored, how it is reaccessed, and how it integrates with other brain functions.

T. J. Teyler

Long-term Potentiation (Hippocampus)

Since Ramon y Cajal, neurobiologists have been looking for activity-dependent modifications of synaptic efficacy as a potential mechanism for learning and memory. When Bliss went to Per Andersen's laboratory in 1968, he probably did not know he was going to discover a phenomenon that would become one of the most popular, controversial, and debated one in Neuroscience until the end of the twentieth century. The first publication (Bliss and Lomo 1973), reporting the existence of long-term potentiation (LTP) in rabbit brain, was noticed by only a small number of laboratories. Even the demonstration that LTP could be elicited in the *in vitro* hippocampal slice preparation (Lynch et al. 1977, Andersen et al. 1977) remained somewhat of a curiosity until the end of the 1970s. It was not until the mid-1980s and the identification of the unique properties of the N-Methyl-D-Aspartate (NMDA) receptors and of the links between LTP and learning and memory (Morris et al. 1986) that LTP began to attract very large numbers of investigators. This review covers the major advances that have taken place since the 1960s, and gives the reader a sense for what is well understood, what remains speculative, and what remains to be understood.

1. *The NMDA Receptor and LTP Induction*

The cellular events that are necessary and sufficient to produce LTP are now well understood (Malenka and Nicoll 1999). What is required is sufficient postsynaptic depolarization (i.e., the high frequency bursts of stimulation) to relieve the NMDA receptor/channel from a voltage-dependent magnesium blockade and to produce a postsynaptic influx of calcium at the right place and of the right amplitude. The NMDA receptor thus functions as an AND gate (presynaptic release of neurotransmitter and postsynaptic depolarization) and accounts for most features of LTP, such as associativity, calcium dependency, regulation by the degree of inhibition, etc. It should be noted however, that some forms of LTP do not require NMDA receptor activation, and thus there may be multiple forms of LTP as well as multiple ways of triggering the biochemical cascades leading to LTP.

2. *The Pre- vs. Post-synaptic Debate*

It was clear from the outset that LTP could be due to changes in either the release characteristics of the presynaptic terminals or the postsynaptic responsiveness to the neurotransmitter or some combination of both factors. As some reports suggested that glutamate release is enhanced following LTP induction (Bliss 1990), the postsynaptic localization of NMDA receptors imposed the existence of some retrograde signals that could link LTP induction to LTP expression mechanisms. Several such signals were proposed such as arachidonic acid, nitric oxide (NO), or carbon monoxide (CO) (O'Dell et al. 1991). On the other hand, many reports have also indicated several postsynaptic modifications including changes in the properties of another type of glutamate receptors, the α-amino-3-hydroxy-5-methylisoxazole propionic acid (AMPA) receptors, and in the morphology and number of dendritic spines (Maren et al. 1993; Lee et al. 1980). There is now some general agreement that LTP expression is due to several modifications of the distribution of AMPA receptors and the structure of synaptic contacts (Malenka and Nicoll 1999).

3. *The Biochemical Confusion*

Since the 1980s, a very large number of biochemical events have been proposed to participate in one way or another in LTP induction or expression (Sanes and Lichtman 1999). Among these, several calcium-dependent processes have been identified. Activation of the calcium-dependent protease, calpain, results in modifications of the structure of several cytoskeletal proteins and cell adhesion molecules and therefore is ideally suited to promote modifications in the structure of synaptic contacts (Baudry 1991). Activation of several protein kinases, and in particular, calcium/calmodulin kinase type II (CamKII), is also a key process to phosphorylate key proteins in synaptic contacts, including glutamate receptors (Kennedy 1989). Autophosphorylation of CamKII might also provide for a form of short-term plasticity that exceeds the duration of the LTP-inducing stimulus. Finally, activation of phospholipases provides for both the synthesis of lipid breakdown products with various signaling properties as well as for the breakdown of membrane lipids, an essential element for structural

modifications (Massicotte and Baudry 1991). It is interesting to point out that most of these cell biological processes are not unique to neurons but are present in many cell types where they participate in regulation of structure and function.

4. *Gene Expression and LTP Stabilization*

A much-debated issue in the LTP literature concerns the role of gene expression and protein synthesis and the mechanisms linking LTP induction to the protein synthesis machinery of neurons. Numerous studies have attempted to identify genes activated as a result of LTP induction (Abraham et al. 1993, Thomas et al. 1994). In most cases, several transcription factors are induced as a result of trains of electrical activity producing LTP. However, it has been quite difficult to further establish the relationship between gene induction with mechanisms underlying LTP expression and maintenance.

Advances in molecular biology techniques, and in particular, the possibility of knocking out or knocking in specific genes have produced a large number of mutant mice with various 'learning and memory' impairments, in addition to problems with LTP induction or maintenance (Silva et al. 1997). In addition, the mutations that have been generated often affect enzymes, receptor/channels, or other cellular elements, which participate in 'normal' cellular functions, and are likely to modify, even in a subtle way, various aspects of brain structure and function. The limitation on the role of gene expression in synaptic plasticity resulting from the cell-wide modifications it generally produces would be seriously eliminated if there were mechanisms coupling gene expression and local translation of the corresponding mRNAs. For local protein synthesis to take place requires the dendritic targeting of mRNA and there are now a number of examples of such mRNAs. Furthermore, there is also experimental evidence for links between synaptic transmission and regulation of local protein synthesis as activation of glutamate metabotropic receptors in synaptoneurosomes has been shown to rapidly stimulate protein synthesis (Weiler and Greenough 1993). There are therefore two types of mechanisms by which synaptic activity can produce localized modifications of synaptic properties restricted to activated synapses. In the first one, a small population of mRNAs is constitutively present in dendrites, and in response to an appropriate signal, these mRNAs are locally translated, and the newly synthesized proteins are incorporated into the activated synapses. Note that this process is rapid and does not require gene expression, as it only depends on constitutively present mRNAs. In the second one, some locally generated signals are transmitted to the cell nucleus, trigger gene transcription, and the synthesis of mRNAs. These mRNAs are targeted to the dendrites and locally translated at the appropriate site. Note that this requires the existence of a signal or signals that remain present at activated synapses for quite some time as the transcription of genes, and their targeting to the dendrites necessitate a significant period of time. This mechanism is somewhat related to the synaptic tagging described by Frey and Morris (1998). In their model, these authors propose that LTP induction is accompanied by the activation of signals they call 'synaptic tags,' which interact with plasticity-related newly synthesized proteins and stabilize the formation of long-term potentiation. Clearly, much more work is needed to clarify the exact mechanisms involved in this type of regulation, and to determine the types of mRNAs present in the dendrites, the mechanisms involved in targeting them to dendrites and the signals responsible for tagging activated synapses. Finally, the types of proteins involved and their roles in regulating synaptic structure and function need to be further investigated.

It has only recently been recognized that the extracellular matrix plays an equally important role in regulating synaptic morphology and properties. Antibodies to N-CAM and peptide inhibitors of integrin receptors inhibit the formation of stable long-term potentiation (LTP) (Luthi et al. 1994, Lynch 1998). In several current models of LTP, stabilization of the modifications triggered during the induction phase of LTP is accomplished first by the disruption of the adhesive properties of synaptic contacts, possibly mediated through the proteolysis of CAM molecules, followed by the activation of integrins. In this way, synaptic contacts undergo a cycle of destabilization resulting from intracellular as well as extracellular proteolysis of proteins contributing to the morphology of synaptic contacts, followed by restabilization of a new synaptic structure implicating integrin activation and extracellular matrix components (Lynch 1998).

5. *LTP and Learning and Memory*

LTP is the most widely proposed mechanism of memory storage in the hippocampus and neocortex. Although this issue is still debated, evidence supporting this hypothesis comes from a variety of experimental data and theoretical models (Baudry and Davis 1996). LTP is prevalent in hippocampal and cortical networks and exhibits many properties required for a large capacity information storage device: rapid induction, associativity, long duration, links with brain rhythms (in particular, the theta rhythm). Pharmacological manipulations or gene mutations interfering with LTP also interfere with various forms of learning and memory, while pharmacological agents facilitating LTP formation also facilitate learning. Finally, incorporating LTP-based rules in biologically realistic neuronal networks produces large capacity storage devices.

6. Conclusions

Much progress has been made on our understanding of the mechanisms and functions of LTP since its discovery in 1968. At the beginning of the twenty-first century there might still be a few unanswered questions, but there is little doubt that (a) these questions will receive definite answers rapidly and (b) the knowledge gained from the study of this phenomenon will be instrumental in designing new tools to study and improve various forms of learning impairments.

M. Baudry

Lorenz, Konrad (1903–89)

1. Biography

1.1 Family

Konrad Zacharias Lorenz (born November 7, 1903 in Vienna, Austria) grew up within the upper crust of pre-World War I Vienna: his mother Emma (née Lecher) from a family of writers and scientists; his father, Adolf Lorenz, world-renowned orthopedic surgeon, Nobel prize nominee (A. Lorenz 1936). Konrad spent his formative years in Vienna and at his family's country estate in Altenberg on the banks of the Danube. At that time the river was still lined by large tracts of virgin riverine forest, and his inquisitive mind became fascinated by nature. He became a passionate observer and skilled caretaker of any swimming, crawling, or flying creature. These interests did not interfere, however, with his early socialization into the network of learned relatives and their friends (e.g., Karl Popper; see *Popper, Karl Raimund (1902–94)*).

1.2 Education

After visiting a 'progressive' elementary school, he was sent to the esteemed *Schotten-Gymnasium*, where his biology teacher, an enthusiastic Darwinist, introduced

him to evolutionary reasoning. At his father's suggestion, he began to study medicine at Columbia University, New York in 1922. Homesick, especially for his wife-to-be, he continued his studies in Vienna, receiving his Dr.med. degree in 1928. During his first appointment as *Demonstrator* (~ assistant professor) at the department of anatomy at the University of Vienna, he studied zoology (J. Versluys), paleontology (O. Abel), and psychology (K. Bühler, his assistant E. Brunswik); he received his Dr. phil. degree in 1933.

1.3 Scientific Career

Lorenz's meager salary as *Demonstrator* and his wife's (Margarethe née Gebhardt) income as physician at a local hospital provided just enough to raise their family. Lorenz was always short of funds for the private research facility he had established in Altenberg. His negotiations with the (German) Kaiser-Wilhelm-Gesellschaft for funds to create a special institute for behavioral studies date back to 1937, but at the outbreak of World War II this project was shelved. In 1940 E. Baumgarten (a nephew of Max Weber (see *Weber, Max (1864–1920)*) and a pupil of J. Dewey (see *Dewey, John (1859–1952)*) and, hence, a representative of the pragmatist school of philosophy) accepted the famed chair of philosophy at Königsberg University, once occupied by Immanuel Kant (see *Kant, Immanuel (1724–1804)*), and looked for a biologically oriented psychologist who, at the same time, was interested in theory of knowledge, to share with him the prestigious appointment. E. von Holst became the match-maker, and Lorenz was chosen (Lorenz 1974, Leyhausen 2000).

One year later, however, Lorenz was drafted into the German Army as a motorcycle rifleman (in his papers he had not mentioned his medical training because of his limited experience with patients, and stressed only his proficiency in motorcycle racing and repair). When the authorities discovered that he held a medical degree and was a professor of psychology, he was assigned to a unit of the *Heerespsychologie* (Army Psychology) in Posen. Two months later, however, this unit was dissolved, and he was transferred to the Posen Army field hospital for neurology and psychiatry, where he worked as *Unterarzt* (medical noncommissioned officer) in a unit of 285 beds with patients suffering from war injuries, psychoses, and psychosomatic disorders. During a field assignment on the Russian front in 1944 he was captured by the Red Army. After that, he served in various POW camps as field surgeon until his release in 1948.

In post-World War II Austria career prospects for a biologist were worse than ever, while in Britain Lorenz's colleagues became especially interested in the Darwinian approach to behavioral studies. Niko Tinbergen became reader at Oxford University and, in 1950, Lorenz received a similar offer from the University of Bristol. German colleagues, notably E. von Holst and G. Kramer, both meanwhile directors at the newly founded Max Planck Institute for Marine Biology (Wilhelmshaven), were able to revive the old project of an institute for behavioral studies. A matching offer was made, and Lorenz accepted the appointment as head of a small behavior research unit in Buldern, Westfalia, founded in spring of 1951 as precursor to a special Max Planck Institute for Behavioral Physiology. Construction started in Seewiesen, Bavaria in 1955, and the institute opened in 1958: Lorenz was Director of his own division there until he retired in 1973.

1.4 Retirement

Upon retirement, Lorenz returned to his home in Altenberg, Austria. Shortly thereafter, he was awarded, together with Niko Tinbergen and Karl von Frisch, the 1973 *Nobel Prize for Medicine*. During retirement, he tidied up his work on evolutionary epistemology, on the social behavior of greylag geese and reef fishes, and became an eloquent spokesman for environmental conservation (Schleidt 1988). Lorenz died in Vienna on February 27, 1989 at the age of 85 and was buried near Altenberg at St. Andrä-Wördern cemetery (Wuketits 1990).

2. Contribution to Knowledge

Lorenz, cofounding with Niko Tinberger the science of Ethology as 'the study of the biology of organismic behavior', ranks among the most important stewards of Darwin's (see *Darwin, Charles Robert (1809–82)*) heritage of the twentieth century. In the 1930s and 1940s, most psychologists, sociologists, and biologists tried to understand behavior within the framework of Aristotelian (see *Aristotle (384–322 BC)*) philosophy, theology, Marxism (see *Marx, Karl (1818–89)*), or Behaviorism. Lorenz, on the other hand, viewed behavior as playing a central role in the process of evolution, and shaped primarily by 'natural selection', rather than by learning. By applying the methods of comparative morphology and paleontology to the study of 'species specific' behavior, he created a scientific approach which rapidly provided a wealth of data and new insights (Lorenz 1931, 1932, 1950a, 1965b, 1978). Contrary to the claim of his critics, Lorenz ignored neither the conventional schools of thought nor their observations, but was cautious in accepting their theories and conclusions. For example, he never denied the importance of environmental factors in learning, but he challenged the behaviorists' claim that innate behavior was restricted to only a few basic vital reflexes. In fact, he emphasized especially

the interlocking of modular innate and learned behavioral (e.g., as in 'imprinting,' Lorenz 1935, and in his analysis of the channels through which information can enter a living system, Lorenz 1961, 1965b).

2.1 Observation as Research Tool

Fundamental to Lorenz's approach to behavior is his rigorous adherence to the doctrine of *induktive Naturwissenschaft* (inductive natural science; Lorenz 1942, 1959, 1978), i.e., first establish a solid base with meticulous observations, supported by objective records (photos, film), tainted as little as possible by theories, and—only after a solid data base (*Induktions-Basis*) has been established—let patterns emerge from the data.

2.2 Behavioral Modules

Lorenz considered behavior to be composed of basic modules: e.g., classical reflexes, species specific *Instinktbewegung* 'Fixed Action Pattern' (FAP), in later years *Erbkoordination*, *erbkoordinierte Bewegung* (1978) (in English: 'fixed motor pattern'), specific circuits for the environmental control of reflexes and FAPs: 'Innate Releasing Mechanisms' (IRM, *angeborener Auslösemechanismus*), 'appetites and aversions' (*Stimmungen*), etc. Such modules provide each organism with basic behavioral skills to navigate within its environment, detect necessary resources, avoid danger, and interact with conspecifics. Learning can enter in various ways at the level of each of these modules, e.g., in the case of a reflex as 'conditioned reflex.'

This FAP/IRM diad is basically an extension of the classical Stimulus/Response concept, enhanced by several new features: the classical reflex, activated only by a specific external stimulus, cannot account for the observation that 'a healthy animal is up and doing' (as W. McDougall so aptly remarked). Consequently, the spontaneous nature of behavior, in general, and especially in many typical FAPs (locomotion, courtship behavior, certain types of bird song, etc.) became a topic of special interest (FActionP). FAPs constitute much more complex patterns than any of the classical reflexes (FAPatterns) and particular spatiotemporal parameters of FAPs are highly stereotyped within any one species (FixedAP), but different between species. Lorenz exemplified the complex interaction between internal and external variables in his 'psychohydraulic' model (1950a, 1978), and applied this reasoning to explain the control of aggression in animals and humans (1963).

It was basically for this work on behavior modules, which are central to ethology, that Lorenz, Niko Tinbergen, and Karl von Frisch shared the distinction of winning the 1973 Nobel Prize for Medicine 'for their discoveries concerning the organization and elicitation of individual and social behavior patterns.'

2.3 Ethograms

Given the existence of species specific behavior, a behavioral study of individuals of any given species starts with an assessment of the modules of its behavioral repertoire, working towards the open-ended task of a complete 'ethogram' of that species. Lorenz had already touched on this in his first publication (1931), and a decade later published an exemplary comparative study of the courtship modules of ducks (1941). He delayed publishing of his ethogram of the graylag goose until 1988 … as a sort of swan-song.

2.4 The Innate Forms of Possible Experience

This heading is a translation of *Die angeborenen Formen möglicher Erfahrung*, the title of Lorenz's 1943 seminal paper dealing with the evolution of cognition, as a new paradigm. The results of many years of research into 'learning'—from the classical curves of learning and forgetting by I. Pavlov and E. L. Thorndike (see *Thorndike, Edward Lee (1874–1949)*)—indicate that it is a slow process. If an animal's survival depended solely on learning, it would be dead long before it had completed its first set of learning trials. Thus, it should not be surprising that an animal, entering into its world, is equipped with (a) certain 'innate' skills, behavior patterns to satisfy vital needs and escape danger, and (b) '*a priori* knowledge' to detect essential features of resources and danger —innate in the sense that particular patterns of behavior or relevance of particular environmental features are available prior to individual experience. In other words: a reflex, FAP, or IRM not only enables survival enhancing action, but it also constitutes organismic 'knowledge' about the environment and its contingencies, to which that individual's ancestors had been exposed in the evolutionary process (Lorenz 1941, 1943, 1953, 1965b, 1973, 1978).

2.5 Imprinting

This peculiar process of forming an irreversible association between a behavior pattern and a 'stimulus' (object), without any reward other than the presence of that object, has been used for ages in animal breeding, and noted in the literature, but Lorenz was the first to recognized imprinting's far-reaching theoretical significance (1935, 1965b, 1978).

2.6 Nature–Nurture

Much ink has been spilled on this duality, not much because of any intellectual challenge posed by these two concepts, but because of deeply rooted beliefs, religious or political, touching upon free will, accountability, and fate. Lorenz was attacked early on for his use of 'innate' as though he had excluded the possibility of learning, while all he suggested was that innate behavior was essential for the survival of individual organisms. Early on, he pointed to the intertwining of innate and learned behaviors (e.g., *Trieb-Dressur-Verschränkung*, drive-training-interlacing 1935), and with imprinting, provided a splendid example of such a process, which was ignored by the ruling psychologists of his time. He was attacked relentlessly for defending the concept of innateness, despite numerous attempts to respond to his critics (1961, 1965b, 1978, etc.).

2.7 Epistemology

'Philosophy is the academic abuse of those human potentials which have evolved by natural selection for the individual's survival in his struggle with the daily contingencies of his world.' This definition, attributed to Lorenz's mentor O. Heinroth, encapsulates the insight that human ability to acquire knowledge is not merely a matter of the reasoning individual *Homo sapiens* within a literate society, but is based on a long, evolutionary process, preceding the emergence of humanity by millions of years. Lorenz, having been elevated to Immanuel Kant's former chair in Königsberg in 1940, and facing the challenges by contemporary philosophy, and specifically by resident neo-Kantians, took a radically new approach to Kant's concept of *a priori* (Lorenz 1941, 1943), pioneering what is now called Evolutionary Epistemology (Popper 1972, Vollmer 1980). The most detailed discussion of this is contained in his posthumously published *Russian Manuscript* 1944–48 (1992), written with the fresh memories of his encounter with Kant's Königsberg in mind, while a more concise discussion can be found in the English edition of his textbook (1978/81).

2.8 Moral Analogous Behavior, Human Morality, and Environmental Awareness

Lorenz, throughout his life, struggled with his belief that morality could well have an evolutionary basis (as he had shown convincingly for the evolutionary basis of cognition in his evolutionary epistemology). He coined the term 'moral-analoguous behaviour' (moral-analoges Verhalten): special behavior that channels the individual's selfish struggle for its individual existence and reproductive success into an altruistic contribution for the good of its community. Based on his observations of a variety of highly social animals, Lorenz noticed that domesticated forms had lost certain elements of their moral-analoguous social behaviors which their wild ancestors had evolved as essential part of their sociality. Lorenz concluded, by analogy, that human evolution in general, and especially our own modern civilization, has led to comparable domestication effects ('self-domestication'), which have become a mixed blessings. Modern humans have freed themselves from the firm guide of instincts and consequently have more freedom to learn, and to make their own choices, but they also have lost some of their instinctive inhibitions to inflict damage to, and even kill conspecifics to an extent not known in any other species (1940, 1943, 1963, 1983).

In his early papers Lorenz proposed to counter these dangers to humanity with eugenic measures (before the attrocities of Hitler's Germany a widely respected field, especially in England and the USA), especially by encouraging ethically guided (not ethnically, as often misread) mate choice (1940, 1943). Starting in the mid-1950s, Lorenz's proposal of an evolutionary basis of human moral were attacked for various reasons or dismissed as unfounded. As competing hypotheses—especially those claiming sole environmental control of ethical behavior—have failed so far to resist falsification, these issues are, on the scientific level, far from resolved.

Lorenz's concern about human evolution running awry and leading us to extinction by our destruction of the environment was not merely a consequence of the atrocities of World War I, World War II, and of the nuclear demise scenarios of the Cold War, but had been deeply rooted in both his trust in science and in his allegiance to the Hippocratic oath. Thus, when by the vagaries of political and economic interests a nuclear power plant was built near his home in Altenberg, at a location that had been flawed by previously undisclosed risks, he opposed completion of its construction violently. Soon he found himself the revered leader in this fight that ultimately prevented the key ready nuclear power plant from going into service. A few years later, Lorenz was equally successful in a fight to save the last stretch of wetlands along the Danube.

3. Relevance

Lorenz's impact on behavioral and social science is linked closely to his collaboration and friendship with Niko Tinbergen, and it is difficult to measure each one's individual contribution. Both were curious naturalists endowed with outstanding skills: in observing, in detecting regularities—patterns of nature—and in formulating testable hypotheses; and, both were outstanding teachers (e.g., Lorenz 1949, 1950b).

While Tinbergen was more inclined toward an experimental approach, as exemplified in their joint paper (Lorenz and Tinbergen 1938), Lorenz's imprint on ethology is obvious in matters of pure observation, inductive reasoning, and formulating a comprehensive theory: the modular concept of action patterns and releasing mechanisms, these modules being shaped by evolution as well as by learning, and imprinting as a special type of learning.

3.1 Selected Topics

Lorenz achieved his scientific breakthrough in 1936. At an invited lecture before the German scientific elite of the Kaiser-Wilhelm-Gesellschaft in Berlin he proposed to stop arguing about how many drives and instincts one can define and instead start describing and analyzing behavior patterns as though they were anatomical features. In a discussion following the lecture, Max Hartmann, doyen of German biology, remarked that 'Konrad Lorenz's approach opens up to causal analysis a field that was previously just a playground for fruitless philosophical speculation' (Lorenz 1992).

World War II severely restricted research and exchange. But soon after the war had ended, Tinbergen traveled in the UK and the USA, presenting the new, ethological approach to behavioral studies, his effort culminating in his book *The Study on Instinct* (1951). Lorenz, who, up to then, had established an international reputation only among ornithologists, argued the case for a biological approach to the study of behavior and soon became the leading theoretician in the new science of ethology.

The high esteem for ethological research resulted in generous support by the Max Planck Gesellschaft, and subsequently by various national funding agencies, notably National Institutes of Health in the USA. Small informal meetings soon turned into international affairs. The biennial *International Ethological Conferences*, dominated by the Lorenz–Tinbergen School and 'converts' from a variety of related fields, became the central event for discussing new results and theories. The German journal *Zeitschrift für Tierpsychologie*, founded in 1937 with Lorenz as one of its editors, the first journal to favor ethological publications, soon got an English language companion in the Dutch journal *Behaviour*. A few years later *Animal Behaviour* was introduced, as the official organ of Animal Behavio(u)r Societies, founded in the US and UK, as publications in the new science steadily increased. While *animal psychology* and *comparative psychology* had been little known specialties, dealing mainly with the learning abilities of rats, the Lorenz–Tinbergen-inspired new *animal behavior* became a hot topic for lectures in academic departments both in biology and psychology, resulting in a demand for teachers and textbooks (e.g., Eibl-Eibesfeldt 1967/99), and spawning new opportunities and funding for behavioral research.

Since Lorenz, Tinbergen' and their colleagues were not only qualified biologists, but equally well-established in neighboring fields, the popularity of ethology soon led to fruitful cooperation, notably with sensory physiology, brain sciences, and psychiatry (e.g., Lorenz 1953). This process had considerable impact on the emergence of neurobiology, psychobiology, and evolutionary psychiatry, emphasizing a naturalistic, Darwinian approach at a time when the general trend in biology was toward molecular biology and biochemistry.

Subjects of ethological research at first were mainly vertebrates—birds, mammals, and fishes—and insects. The new approach was tested succesfully and applied to all kinds of species, including our own. Even though the magnitude and difficulties of a task like establishing a human ethogram may appear mind-boggling, 'human ethology' becomes workable as a special case of primate ethology (e.g., Eibl-Eibesfeld 1997). A healthy human newborn faces similar tasks as any other primate baby and behaves very similarly.

By applying ethological methods within the framework of natural science and evolutionary reasoning, similarities and differences between human and non-human animals are no longer a matter of poetic license, but causal analysis—not, however, without drawing heavy critique from the old religious and political establishment. *On Aggression* and *The Waning of Humaneness* (Lorenz 1963, 1983) are examples of an ethological approach to the moral strongholds of the humanities.

Human Ethology has become a domain of its own, of broad overlap not only with primatology, but anthropology (physical and cultural), psychology, and sociology, leading toward a new synthesis of knowledge which proves that the old distinction between hard sciences and humanities has become obsolete.

3.2 Politics

Fame has its price. Especially since having been awarded the Nobel Prize, Lorenz has been branded a racist and an anti-Semite and alleged to have provided a pseudoscientific justification for the Holocaust (e.g., Klopfer 1999).

In regard to these allegations, we must consider first that Lorenz grew up within a part of the Viennese society that was enmeshed intimately by friendship, marriage, and professional ties with the wealthy Jewish elite. He maintained these connections throughout his life by hosting many guests and being a guest on many in his frequent travels of old and new friends especially in England and the USA, and was certainly more pro-Semitic than average, and far less racist, especially

than some of those who are now raising their voice. Thus, the charge that he advocated racist and anti-Semitic genocide is unfounded.

With respect to the allegation that Lorenz provided a pseudoscientific justification for the Holocaust, it must be considered that there is a long chain of inferences necessary to connect between his—always controversial—writings on the potentially dangerous effects of human self-domestication on the biological basis or ethical (not, and never ethnical!) behavior or Lorenz's proposed use of eugenics to combat the rise of unethical behavior, and the atrocities of the Third Reich. And, there is no indication—inspite of many inquiries and searches (summarized in Klopfer 1999) that prior to the end of World War II anybody in power was aware of such a link. Lorenz being called to the army early in World War II, his first assignment as a rifleman and later as medical NCO (never promoted to a higher rank) give ample evidence that he lacked political pull (Schleidt 2000).

Lorenz became active in politics only after his retirement. Given all the academic and public honors he had received, people listened when he spoke—as he proudly proclaimed—and he spoke loudly and clearly for environmental preservation and moral responsibility.

4. Concluding Remarks

When in the mid-1970s sociobiology made the headlines and behavioral ecology started riding the new wave of environmental awareness, the glamor of ethology began to fade. In 1999, the crown jewel of ethology, the Max Planck Institute for Behavioral Physiology at Seewiesen, was downgraded to an ornithological research station. However, the ideas conceived and publicized by Lorenz, Tinbergen, and their contemporaries as the foundations of ethology have become so much public property that their original sources are now rarely cited. This may be the best indicator of the importance of the work of Konrad Lorenz, and of ethology.

W. M. Schleidt

Lotka, Alfred James (1880–1949)

When A. J. Lotka died on December 5, 1949 his obituary in the *Journal of the American Statistical Association* began 'A brilliant chapter in modern demography came to a close with the death of Alfred James Lotka.' David Smith, translator of his major work in the field (Lotka 1939), calls him 'the father of mathematical demography.' And these were understatements of his contribution, for demography was only a part of Lotka's scientific interests—he was also described as chemist, physicist, biologist, and actuary, everywhere seeking better understanding through the use of mathematics.

Lotka was born on March 2, 1880 in Lemberg (Lvov), a Polish town of the Austro-Hungarian Empire, of American parents who were traveling Moravian missionaries; he died in Red Bank, New Jersey. His training was international: a boyhood mostly in France; a degree at the University of Birmingham (B.Sc. 1901, D.Sc. some 10 years later); graduate work in physics at Leipzig. Coming to the USA in 1902, he worked for the General Chemical Company, briefly for the US Patent Office as a patent examiner, and for the National Bureau of Standards as a physicist. He was editor of the *Scientific American Supplement* (1911–14), finally settling in the Statistical Bureau of the Metropolitan Life Insurance Company (1924–47). He was for long a bachelor, somewhat shy, described as quiet, learned, modest, and gently humorous. In 1935 he married Romola Beattie; they had no children. He was elected President of the Population Association of America (1938–9) and of the American Statistical Association (1942).

In his terminal year of graduate school, at Cornell in 1908–9, he began work with Professor F. R. Sharpe that led to the famous renewal equation—a mathematical description of the replacement of the generations:

$$B(t) = \int_{\alpha}^{\beta} B(t-a)p(a)m(a)da \qquad (1)$$

In the simplest case, rates of birth and death are constant over time, there is no migration to or from the defined area and the female sex only is considered. These conditions make possible a strict accounting of the relation between two generations. For on the right side is $B(t-a)$ the number of births a years earlier ($\alpha \leqslant a \leqslant \beta$ where α is the youngest age of childbearing and β the oldest); $p(a)$, the probability that a child born a years ago survives to time t; $m(a)$ is the birth rate for women aged a; integrating gives current births and so should be comparable to the births $B(t)$ on the left side. The unknown quantity that should make the two sides equal is the trajectory of births, to be provided in terms of the known functions $p(a)$ and $m(a)$. If the trajectory of $B(t)$ in Eqn. (1) is simplified down to a curve of geometric increase, as Lotka initially assumed, then the question posed by the renewal equation is what rate of increase of births would equate the two sides of Eqn. (1). If that rate is r, taken either arbitrarily or from past data, then the age distribution of the population would stabilize over time to numbers proportional to $\exp(-ra)p(a)$ at the several ages a.

In finite intervals of time and age, Eqn. (1) can be expressed naturally as a recurrent series and this was done by Lotka himself late in his career. P. H. Leslie formulated it in matrix terms. To these can be added a fourth version in partial differential equations (Keyfitz and Keyfitz 1997), that also shows and compares the three other formulations.

Like most other discoveries, this one had predecessors who in part anticipated, as well as followers who marginally improved on, Lotka's work. Leonhard Euler (1760) came close on the theory; Edwin Cannan (1895) in the nineteeth century published an arithmetic calculation projecting the population of England and Wales that forecast the (then surprising) fall in births. R. Kuczynski (1931) and Richard Böckh of the Berlin Statistical Office were important predecessors working with the ratio of change per generation, the Net Reproduction Rate (NRR), $R_0 = \int p(a)m(a)da$. Willy Feller (1941), Princeton mathematician, noted that the solution to the renewal equation fell out simply and rigorously if each of the functions involved is translated into its unique Laplace Transform. Golubitsky et al. (1975) published an even more compact and more general solution.

Lotka went on to other demographic questions. He was curious to know why old populations have so few surnames and found the answer in a pure probability accounting for the extinction of family lines (1931a). He ascertained the frequency of orphanhood as a

function of birth and death rates (1931b) and calculated the money loss to dependents and to society when a person dies prematurely (Lotka and Dublin 1946). In an early paper he went beyond human populations on the mode of growth of self-renewing aggregates; then on industrial replacement—for instance in a fleet of trucks of varied ages—he showed how the mathematics fits trucks as well as people.

Lotka's *Elements of Physical Biology* (1925), composed between 1922 and 1924 under a fellowship arranged by Raymond Pearl at Johns Hopkins University, is sharply distinguished from his earlier work—it looks at the whole of the living world from a physicochemical perspective. A first chapter on definition rejects a concept of life that sets it up behind an impassable boundary, such that living matter can never emerge through physical and chemical mechanisms. But it must have so emerged at least once in the history of the planet, and that emergence was of interest to Lotka.

Lotka anticipated modern ecology in his continual search for cyclical processes. One of many examples is the circulation of sulfur, that may be summarized from the *Elements of Physical Biology* as follows.

Sulfur occurs in abundance in inorganic nature in the form of the sulphates of the alkalies and the alkaline earths. Plants assimilate these compounds directly and then form proteins containing from 0.3 to 2 percent of sulfur. In this form it is assimilated by animals, who excrete the element chiefly in the form of sulfates. These, returned to the soil, complete the cycle.

And in the same way, Lotka portrays the cycles of water, iron, chlorine, and other components of the earth's crust. He took the science of these cycles from Swedish chemist Arrhenius and others, but he gets credit for being among the very first to see how crucial these cycles are to life and how they fit into and sometimes exacerbate one another. The number of people in the world more than doubled since his time, and production per person far more than doubled, so we are now forced to attend to such cycles as those of fresh water and carbon, and they enjoy considerable attention in legislative bodies and space in late twentieth-century newspapers and magazines. But all that is a development of the late twentieth century, so we have to remind ourselves that these issues were a preoccupation of Lotka from early in the century when there were very few far-sighted enough to think they might have practical consequences.

Lotka refers to the Swedish chemist Arrhenius who first saw from theoretical considerations the possibility of man-made carbon dioxide leading to global warming, and he cites Arrhenius' finding that the air is becoming richer in CO_2. Moreover plants, especially trees, withdraw CO_2, and the cutting of trees releases CO_2; the oceans could offset the tree-cutting by increasing their absorption of the gas. These are only three of the determinants of free CO_2 in the air and no one has yet shown a way to isolate the man-made CO_2 released by the burning of fossil fuels and cutting of forests from changes in the capacity of the oceans to hold carbon. Seventy-five years ago Lotka had a realistic view of the complexities of global equilibrium and the difficulties of forecasting what forces would dominate within it. The earth is a vast and complex physico-chemical-biological engine in constant motion, and if this is now a commonplace, Lotka was in the forefront of those who made it so.

The Lotka–Volterra equations are much referenced. Vito Volterra, an Italian mathematician, was asked by his biologist son-in-law Humberto D'Ancona whether he could explain the cycles of fish population in the Adriatic Sea. Lotka, also in the first half of the 1920s, wanted to see whether the relation of predator and prey could be assimilated to the autocatalytic processes of chemistry he had studied earlier. A pair that comes to mind as a model for both Lotka and Volterra are foxes ($F(t)$) and rabbits ($R(t)$), in which a carnivorous species is dependent on a grass-eating species. The flow of energy is *sun* → *grass* → *rabbits* → *foxes*. Lotka (1925) and Volterra (1927) seem independently to have noted and explained the same features of predation, especially the cycles it generates. The simplest form of the Lotka–Volterra equations is

$$F'(t) = -\alpha F(t) + \gamma R(t) \tag{2}$$

$$R'(t) = \beta R(t) - \delta F(t) \tag{3}$$

Primed symbols are derivatives, and the four positive numbers $\alpha, \beta, \gamma, \delta$ are fixed parameters. The $-\alpha$ in the first equation tells us that in the absence of the prey (i.e., if $R(t)$ is zero) then the predator declines in numbers, to ultimate extinction. The second equation shows the prey increasing indefinitely in the absence of the predator. That γ has a plus sign in the first equation allows for the fact that with more abundant prey the predator grows faster. With other configurations of signs the same equations can represent competition, symbiosis, etc. They can incorporate limits on the amount of grass and can be extended to three or more species.

Lotka's indifference to what he considered mathematical niceties was matched by a quality found in many other original minds, great sensitivity on priorities. He engaged in a long and indecisive controversy with R. R. Kuczynski. The history of science is pockmarked with such disputes. What puts this one in a special class is that Paul Samuelson undertook a uniquely thorough investigation (1977) to sort out the issues, and credits Lotka, Böckh, and Kuczynski, among others. With access to the Princeton archives where Lotka's private papers, as well as his publications, are deposited, he demonstrates with the help of pages of solid algebra that Lotka's predecessors turned up a good part of the renewal story, but their work was

incomplete. Lotka had both the theoretical interest and the command of data, plus the drive to follow through.

So, Samuelson concludes on this issue, the brighter light has drowned out the earlier light. But now that the dust has died down, it looks as though Lotka's place in history, which is a secure one, is based less on the priorities he claimed so vigorously in controversy than on his anticipation and objective treatment of a complex of problems revolving around population and environment, problems barely suspected when he lived, that we now realize will be with us for a long time. A half-century after his death he is very much alive through his books and papers, and in the demographic profession we can still say, with Frank Notestein (see *Notestein, Frank Wallace (1902–83)*), that 'his is the greatest name.'

Love and Intimacy, Psychology of

When people talk about the things that matter most in their lives, they usually place close relationships at or near the top of the list. And when researchers examine the processes that make close relationships satisfying, love and intimacy are usually among the most influential factors. The apparent importance of love and intimacy to human well-being has fueled longstanding interest by lay persons and scholars alike in these fundamental properties of close relationships, yet empirically minded researchers are relatively new to the pursuit, perhaps because of the challenges inherent in studying such subjective concepts (see *Social Relationships in Adulthood*). The sizable literature that has materialized since the 1970s suggests, however, that empirical research into the nature and consequences of love and intimacy can be profitable. Moreover, recent research in this area has been invigorated by methodological advances (e.g., in studying interdependent dyads and in psychophysiological assessment), as well as by increased appreciation of the importance of love and intimacy during human evolution, as noted below.

Although research on love and intimacy evolved as largely independent traditions, a basic connection is now clear. Early on, Berscheid and Walster (1969) distinguished between two types of love. Passionate love refers to a state of intense arousal, characterized by strong emotions, deep longing for the other, and mental preoccupation with that person. In contrast, companionate love, 'the affection we feel for those with whom our lives are deeply intertwined' (1969, p. 9), involves trust, caring, respect, and mutual responsiveness, processes that also characterize intimacy. Both forms of love may arise in any close relationship, although passionate love generally is studied only in regard to romantic relationships. Passionate and companionate love are considered widely to be independent processes, each with its own antecedents, consequences, time course, and underlying mechanisms, although they may co-occur in a given relationship. To be sure, the many variations with which people experience love—maternal love, love for one's fellow humans, courtly love, and so on—suggest that love is a complex and multifaceted phenomenon not easily reduced to common elements. Nevertheless, formal approaches to differentiating its many varieties generally have identified these two factors, labeled as

passion and intimacy, as a first-order distinction (as well as a third factor, commitment; e.g., Sternberg 1986). One such example is Aron and Westbay's (1996) analysis of cognitions, feelings, and behaviors associated with the various experiences of love.

1. *Passionate Love*

Substantial research has investigated the nature and dynamics of passionate love, especially its behavioral and cognitive manifestations. For example, passionate love tends to be associated with high levels of physiological arousal (attributed to the neurotransmitters dopamine, norepinephrine, and serotonin); longing for connection, both physical and emotional, with the loved one; strong, often idealized, positive feelings about the other; mental preoccupation with the loved person, often intrusively so; and emotional sensitivity to the other, such that emotional states may swing from euphoria to despair depending on perceptions of the loved person's response (see Fisher 1998 for a more extensive review). As these and the many other phenomena characteristic of passionate love indicate, but as has not always been recognized, passionate love is properly regarded as one of the emotions (see *Emotions, Psychological Structure of*).

Scholars also have attempted to understand passionate love by considering its functional consequences. Self-theorists see passion arising when relationships, be they imagined, incipient, or ongoing, are perceived to present new or expanded opportunities for meeting the self's most important needs (i.e., for fulfilling personal ideals; for self-enhancement; for mating). In this view, passionate feelings reflect the process of personal growth experienced in the individual's real and/or anticipated involvement with the other. To evolutionarily oriented theorists, in contrast, passionate love serves to redirect the individual's attention and behavior away from routine ongoing activities and instead toward the existence of a potential mating partner, thereby facilitating the initiation and development of mating relationships. This latter approach can help explain one of the more intriguing findings in the literature: that levels of passionate love tend to be a poor predictor of long-term marital satisfaction and longevity. It is thought that this is because passionate love tends to diminish in the early years of marriage, once the function of attracting reproductive partners to each other has been fulfilled (see *Sexual Attitudes and Behavior*).

Intimacy, on the other hand, tends to be better associated with the long-term success of marital and other types of close relationships. It is believed widely that intimacy is essential to human well-being and that its absence can cause significant emotional distress; for example, many studies have demonstrated that the existence of intimate ties and social interactions is associated with higher levels of social and psychological development, and with better mental and physical health. Indeed, to some theorists, 'the capacity to make intimate emotional bonds with other individuals … is regarded as a principal feature of effective personality functioning and mental health' (Bowlby 1983, p. 121). Accounts of laypersons interpersonal experiences, expectations, and goals likewise show a similar appreciation for the qualities that intimate relationships provide, beginning in early adolescence and continuing throughout the lifespan (see *Friendship: Development in Childhood and Adolescence*).

2. *Intimacy*

Diverse phenomena have been investigated under the general heading of intimacy: for example, the concept of intimacy has been used to describe the process of revealing private thoughts and feelings to others; to identify a relatively intense form of nonverbal engagement (e.g., through eye contact, touch, or physical proximity); to refer to the existence of an affectionate, supportive relationship; or to characterize the stage of life in which the primary developmental task is to establish an emotionally close, trusting, and sexual relationship with another person. The variability inherent in these usages, when considered along with yet further everyday-language meanings of the word 'intimate,' that is, as a synonym for closeness, sexuality, privacy, or marriage, has sometimes fostered conceptual ambiguity, making it difficult to compare and integrate different theoretical perspectives and different research traditions. However, this diversity has also provided an extensively documented, multifaceted depiction of a complex phenomenon.

Research on self-disclosure has played a particularly influential role in the development of knowledge about intimacy. Spurred by the pioneering studies of Altman and Taylor (1973), who defined intimacy in terms of the depth and breadth of one person's revelation of nominally private facts and feelings to another person, this work has supported two general conclusions: that self-disclosure moves from superficial to intimate topics as partners become acquainted; and that partners tend to reciprocate levels of self-disclosure. (In other words, too little or too much disclosure, in comparison to personal standards, situational norms, or a partner's behavior, tends to hamper relationship development.) More recent and more sophisticated models have sought to broaden this conceptualization, predicated on the recognition that spoken messages represent only one method of communicating intimacy. Nonverbal communication also contributes to intimacy, in either of two ways: by indicating current affective states, including partners' responses to each other (e.g., facial expressions of sympathy or scorn), and by regulating existing levels

of interpersonal engagement (e.g., behaviors that enhance or diminish immediacy; see *Nonverbal Communication, Social Psychology of*). Intimacy may also be established through behavior (e.g., coming to know another through observation and shared experience and supportive acts that express care and concern for the other).

Other theorists have emphasized the interpersonal process components of intimacy. One such theory stresses the partner's perceived response in the context of self-disclosure (Reis and Shaver 1988, Reis and Patrick 1996). In this approach, intimacy refers to the experience of a partner's response to core (often emotion-laden) aspects of the self as understanding, validating, and caring. This and similar models are helpful in focusing attention on the fundamentally interactive nature of intimacy. Many relationship theorists, in fact, share the perspective of conceptualizing intimacy as a complex process that cuts across two levels of analysis: the psychology of the individual self, and the psychology of interaction and relationships. Intimacy in this sense possesses in common certain features with other intrinsically interdependent processes such as social support, commitment, trust, conflict, cooperation, and shared experience.

2.1 *Individual Differences in Love and Intimacy*

Although it is apparent that passion and intimacy are at their core relationship-specific—for the most part, people feel love for a particular person, not for people in general—considerable research has examined individual differences in love and intimacy, if for no other reason than the fact that people tend to exhibit modest levels of consistency in their responses to various others. For example, people vary in the extent to which they are motivated to pursue intimate relations with others; these tendencies influence their behavior in appropriate social contexts (although situational factors may moderate the extent to which behavior reflects dispositions in particular circumstances). Individual differences reflect both personality (including genetically determined and learned qualities) and past experiences in close relationships. The study of relationship cognition is concerned with how these experiences are represented in the various mental structures that embody knowledge about significant others and relationships (e.g., expectations, beliefs, self- and other-schemas), and how these beliefs influence subsequent relationship-relevant behavior. These effects can be profound. For example, research on attachment theory indicates that early experiences with caregivers may have substantial impact on an individual's feelings of security in adult relationships, as well as a wide variety of behaviors in such relationships (see *Adult Psychological Development: Attachment*).

3. *Future Directions*

Research on love and intimacy seems likely to profit from several recent trends in psychological research. One such trend concerns the recognition that many important constructs are better investigated from an interdependent than from an individual perspective, that is, as noted above, although individual-level variables may contribute meaningfully to love and intimacy, properties such as love and intimacy are most fully illuminated when they are examined within the relationship context in which they emerge and operate (see Reis et al. 2000).

Another important trend concerns the integration of biological and psychological approaches. Thus, recent advances in brain imaging may help researchers better understand the essential nature of love and intimacy, and their broad impact, both behaviorally and physiologically, on the human organism. Also, the rapid growth in evolutionary theorizing holds considerable promise for addressing many as yet unanswered questions about love and intimacy. Although the intrinsic importance of these subjective feelings for human well-being is incontrovertible, recognition of the role played by relationships, and especially close relationships, during human evolution suggests even broader implications. That is, if small groups and nuclear families provided the primary context for human evolution, as is widely believed, then love and intimacy, the processes that attract individuals to mating partners and promote the longterm viability of the relationships that ensue, must be acknowledged as significant contributors to natural selection and sexual selection.

In short, it seems likely that the relevance of these two cardinal processes to a broad understanding of human well-being and functioning will, if anything, expand in future investigation.

Luce's Choice Axiom

1. Context and Notation

Luce's Choice Axiom (hereafter LCA) is a quantitative hypothesis about choice behavior first proposed and analysed by Luce (1959). It envisions a setting in which an individual makes repeated choices from a set A containing N alternatives: $A = (a_1, a_2, \ldots, a_N)$ (e.g., N restaurants). Sometimes all N alternatives are available for selection (all the restaurants are open); on other occasions only subsets of A are available (some restaurants are closed). On each occasion exactly one alternative is chosen. Choice is assumed to be probabilistic: faced with the same set of alternatives on different occasions, the individual may make different choices. $P(i; S)$ denotes the probability that a_i is chosen when the set of available alternatives is S; e.g., $P(1; A)$ is the probability that a_1 is chosen when all N alternatives are available, and if $S = \{a_1, a_2, a_3\}$, $P(1; S)$ is the probability that a_1 is chosen when only a_1, a_2, and a_3 are available. The special case of 2-alternative choice (known as 'paired comparison') arises often and has its own notation: $P(i, j)$ is the probability of choosing a_i when the available set is $\{a_i, a_j\}$.

In this context it is natural to wonder about relationships between choice probabilities for different sets of available alternatives. For example, suppose the full-set probabilities $P(i; A)$ are known for all $i = 1, \ldots, N$. Can those probabilities be used to predict the paired comparison probabilities $P(i, j)$? Alternatively, can the paired comparison probabilities be used to predict the full-set probabilities? LCA allows one to do both things and more—provided, of course, it is empirically valid for the situation under investigation.

2. The Axiom

LCA has two parts. Part 1 is the heart of the matter: it relates the choice probabilities for subsets of A to those for A itself. Part 2 is a housekeeping assumption whose effect is to make all the relevant choice probabilities nonzero. ('$P(S; A)$' below is the probability that when the whole set A is available, the alternative chosen belongs to subset S, i.e., $P(S; A) = \sum_{a_i \in S} P(i; A)$. '$S \backslash \{a_i\}$' is the set S with a_i deleted from it.)

(a) Part 1. If $P(i, j) \neq 0$ for all $a_i, a_j \in A$, $i \neq j$, then for all $S \subseteq A$ and every $a_j \in S$

$$P(i; A) = P(i; S)P(S; A) \tag{1}$$

(b) Part 2. If $P(i, j) = 0$ for some pair a_i, a_j in A, then for all $S \subset A$

$$P(S; A) = P(S \setminus \{a_i\}; A \setminus \{a_i\}) \tag{2}$$

Note that $S = \{a_i\}$ in Eqn. (2) implies $P(i; A) = 0$. The intuition here is that if restaurant i is never chosen in a paired comparison with restaurant j, it will remain unchosen when more restaurants are added to the available set. In Part 1, the assumption $P(i, j) > 0$, combined with Eqn. 1, implies $P(i; A) > 0$ for all i. Consequently $P(S; A)$ is nonzero, so Eqn. (1) can be rewritten as

$$P(i; S) = \frac{P(i; A)}{P(S; A)} \tag{3}$$

The right side of Eqn. (3) is the conditional probability that a_i is chosen from A, given that the choice from A is some member of S. Thus, Part 1 asserts that when the choice alternatives are restricted to any subset S, the probability of choosing a_i from S equals the conditional probability that a_i is chosen when the full set A is available, given that the choice from A belongs to S. Note that this is an empirical hypothesis, not a theorem of probability theory.

3. Implications

First and foremost, LCA implies that there is a function v (a 'scale') mapping the N alternatives in A on to N non-negative real numbers $v(a_1), \ldots, v(a_N)$, with the following useful property: for all $a_i \in S \subseteq A$

$$P(i; S) = \frac{v(a_i)}{\sum_{a_j \in S} v(a_j)} \tag{4}$$

Clearly, from Eqn. (3), $v(a_i) = P(i; A)$ guarantees one such scale, but infinitely many more can be created by multiplying the $P(i; A)$ values by any positive constant (i.e., Eqn. (4) remains true if one substitutes $v'(a_i) = cv(a_i)$ for any $c > 0$). Thus v is a ratio scale: its values for a given set of alternatives are unique only up to multiplication by a positive constant.

From Eqn. (4) it follows that for all a_i, a_j

$$\frac{P(i; S)}{P(j; S)} = \frac{v(a_i)}{v(a_j)} = \frac{P(i; A)}{P(j; A)} \tag{5}$$

(This is called the 'constant ratio rule'.) In particular

$$\frac{P(i, j)}{P(j, i)} = \frac{P(i; A)}{P(j; A)} \tag{6}$$

Thus, when LCA holds, the paired comparison probabilities $P(i, j)$ can be predicted from the full set probabilities $P(i;A)$. Moreover $P(i;A)$ from Eqns. (4) and (6)

$$P(i; A) = \frac{1}{\sum_{a_j \in A} v(a_j)/v(a_i)} = \frac{1}{\sum_{a_j \in A} P(j, i)/P(i, j)} \tag{7}$$

so the full-set choice probabilities can be predicted from the paired comparison probabilities.

Finally, for any triple of indices i, j, k

$$\frac{P(i, k)}{P(k, i)} = \frac{v(a_j)}{v(a_k)} = \frac{v(a_i)}{v(a_j)}\frac{v(a_j)}{v(a_k)} = \frac{P(i, j)}{P(j, i)}\frac{P(j, k)}{P(k, j)} \tag{8}$$

Thus, if any two paired comparison probabilities $P(i, j)$, $P(j, k)$ are known, $P(i, k)$ can be predicted. (This is known as the 'product rule'.) Eqns (6), (7), and (8) all provide ways to test LCA experimentally.

4. Validity

LCA has been tested in both real experiments and thought experiments (Luce 1977). A famous early thought experiment (Debreu 1960) shows that LCA is certainly not universally valid. Consider a choice set consisting of a red mug of coffee (RC), a blue mug of the same coffee (BC), and a green mug of tea (GT). One can readily imagine a person who is equally fond of coffee and tea, and indifferent as to color. In this case we expect that in pairwise choices $P(\text{RC, BC}) = P(\text{RC, GT}) = P(\text{BC, GT}) = 1/2$. Then LCA implies $v(\text{RC}) = v(\text{BC}) = v(\text{GT})$, so in a choice with all three alternatives available, each alternative should be chosen with probability 1/3. But intuitively it is much more plausible that the probability of choosing GT will be 1/2, or very near, on the grounds that the fundamental decision is whether to have coffee or tea, and mug color is irrelevant.

Debreu's thought experiment makes it easy to design real experiments in which LCA will fail, and investigators have done so. However, it is pointless to carry out many such exercises. LCA is arguably the simplest possible relationship between choice probabilities for subsets of a master set of alternatives, and when it is empirically valid, it is extremely useful. The real issue is not its universal validity, but whether there are nontrivial contexts where LCA is valid for practical purposes. And indeed there are; Luce's (1977) review describes several. (In testing whether LCA holds empirically it is important to be aware that because of potential individual differences in v-scale values, every member of a group can satisfy LCA individually and the axiom may still appear to fail when tested against group-average data; Luce 1959.)

5. Relationship to Thurstone's Theory and the Double Exponential Probability Distribution

L. L. Thurstone's (1994) 'Law of Comparative Judgment' is an important early theory of choice behavior covering the same ground as LCA. Here, the alternatives are thought of as having numerical values ('utilities') that vary randomly from one choice occasion to another. If the utilities of alternatives $a_1, \ldots, a_N$ are the random variables $U_1, \ldots, U_N$, the probability of choosing a_i from any set S is the probability that U_i is currently the largest of the random variables $\{U_j: a_j \in S\}$. (Theories of this sort are known as random utility models; see *Decision and Choice*: *Random Utility Models of Choice and Response Time*.) Thurstone assumed that utilities are normally distributed, and applications have generally assumed that these normal U_is are independent and identically distributed except for their means. Then U_i can be written as $u_i + X_i$, where u_i is a real constant (the expected utility of a_i), and X_i is a normal random variable with mean zero and variance one; X_i and X_j are independent for all $i \neq j$. The empirical validity of this theory can be compared to that of LCA using its predictions for paired comparisons vs. those implied by LCA's product rule (Eqn. (8)). When that is done the predictions of the two theories prove to be numerically nearly

identical. This near-identity is explained by E. Holman and A. J. Marley's discovery (cited in Luce and Suppes 1965) that LCA is equivalent to (makes exactly the same predictions as) a Thurstone model in which the independent normal random variables X_i are replaced by independent random variables that have a double exponential probability distribution:

$$P(X_i \leqslant x) = \exp(-\exp(-x)) \quad \text{for } -\infty < x < \infty \tag{9}$$

For paired comparisons, the choice probabilities of any independent Thurstone model depend entirely on the probability distribution of the difference random variables $X_i - X_j$ $(i \neq j)$. For Thurstone's normal model those differences are normally distributed, while for LCA (i.e., the double exponential Thurstone model) they have a logistic distribution:

$$P(X_i - X_j \leqslant x) = 1/(1 + exp\,(-x)).$$

That distribution is numerically very nearly normal, so the pair comparison predictions of LCA and Thurstone's model are understandably nearly identical.

A general family of independent Thurstone models can be formed by allowing the X_i random variables to have various distributions besides the normal and double exponential. It can be shown that within this family, only the double exponential model is equivalent to LCA for choice sets with $N \geqslant 3$ (Yellott 1977, McFadden 1974). That distribution is distinguished in probability theory as one of three forms that can be limit distributions of the maxima (suitably normalized) of sequences of independent random variables (Gumbel 1958). That property in turn can be used to show that LCA is unique in an interesting way. Consider a thought experiment in which there are three basic alternatives—say, the beverages coffee, tea, and milk. On each choice occasion the set of available alternatives consists of n identical cups of coffee, n cups of tea, and n glasses of milk. Intuition suggests that the probability of choosing coffee (i.e., any one of the n identical cups) should be independent of n for all n, no matter how large. Within the family of independent Thurstone models, only the double exponential model has that property (Yellott 1977).

6. *Relationship to Tversky's Theory of 'Choice by Elimination'*

This theory (Tversky 1972) was designed to handle Debreu's counterexample and others like it, doing so in the spirit of LCA (to which it reduces in special cases). Here, the choice alternatives are regarded as sets of attributes or 'aspects.' For example, in Debreu's counterexample, RC has the aspects 'coffee' and 'red,' GT has aspects 'tea' and 'green,' etc. Each aspect has a weight w—a nonnegative real number, e.g., $w(\text{red}) = 1$, $w(\text{tea}) = 0.5$, etc. Choice involves a series of stages. At each stage the individual selects one aspect from the set of all aspects belonging to the available alternatives (ignoring aspects shared by every alternative), and eliminates from further consideration every alternative that does not possess that aspect. The probability of selecting a given aspect is equal to its weight divided by the sum of the weights of all the aspects present in the alternatives still available, omitting aspects that are shared by every alternative. (Thus aspect selection obeys LCA, with the weights as v-scale values. If the alternatives have no aspects in common, choice is a one-stage process that obeys LCA exactly.) The process of aspect selection and elimination continues until only one alternative remains.

To apply this model to Debreu's counterexample, let $w(r)$, $w(b)$, $w(g)$ be the weights of the colors, and $w(c)$, $w(t)$ the weights of coffee and tea. Assuming $w(r) = w(b) = w(g)$, and $w(c) = w(t)$, one easily derives $P(\text{RC, BC}) = P(\text{RC, GT}) = P(\text{BC, GT}) = 1/2$, and

$$P(\text{GT};\{\text{RC, BC, GT}\}) = \frac{1}{2 + \dfrac{w(g)/w(t)}{1 + w(g)/w(t)}} \tag{10}$$

Then Debreu's prediction that $P(\text{GT}; \{\text{RC, BC, GT}\})$ should be near 1/2 can be obtained by making the color weights much smaller than the beverage weights, i.e., $w(g)/w(t) \approx 0$.

7. *LCA in Economics*

Applications of LCA in econometrics (where it is known as the Multinomial Logit model) were pioneered by McFadden (1974), who developed a widely applied extension of LCA called the Generalized Extreme Value model (McFadden 1981).

8. *LCA and Ranking*

An individual's preferences among a set of alternatives can be expressed by rank-ordering them instead of choosing a single one (see also *Ranking Models, Mathematics of*). Rankings can be made in a forward direction ('best,' 'next best,' etc.) or a backward direction ('worst,''next worst' ...). Luce (1959) suggested extending LCA to ranking via a model in which ranking is accomplished by a sequence of covert choices. In forward-ranking the most preferred alternative in the available set is chosen and ranked first,

then a second choice is made from the remaining alternatives (with choice probabilities that obey LCA) and ranked second, and so on until all the alternatives have been rank-ordered. In backward-ranking a least-preferred alternative is selected first and ranked worst, then a second-worst choice is made from the remaining alternatives, etc., again with the choice probabilities obeying LCA. Intuitively this model seems quite plausible, but surprisingly it proves to be mathematically incompatible with the equally plausible idea that when a person ranks the same alternatives from best to worst, and also from worst to best, rankings expressing the same preference ordering should occur with the same probability (Luce 1959). From a Thurstone model perspective, this unexpected incompatibility stems from the asymmetry of the double exponential probability density function. Other (though not all) independent Thurstone models based on asymmetric densities share the same property (Yellott 1997).

Luhmann, Niklas (1927–98)

Niklas Luhmann was born on December 8, 1927, in Lüneburg as the son of a brewer. His mother came from a family related to the Swiss hotel industry. At the end of World War II Luhmann was conscripted to the air defense for a short time. After the war he studied law at Freiburg (1946–9), became an assistant to a local lawyer, and from 1952 to 1962 worked as a public servant in the regional administration of Niedersachsen. In these years Luhmann was an official who after his office hours read lyrics and theory, especially Edmund Husserl and Talcott Parsons. There are two early publications of his in the journal *Verwaltungsarchiv* from 1958 and 1960, but a break in his career came with Luhmann gaining a leave in 1960/61 to study at Harvard with Talcott Parsons. After Harvard Luhmann changed, now as a researcher, to the *Verwaltungshochschule Speyer*, an institution for the continuing education of administrators. Luhmann's early writings were noted by the then very influential German sociologist Helmuth Schelsky at Münster who persuaded Luhmann, who had no academic degrees, to acquire a doctoral degree and a *Habilitation* at Münster in 1966. He became head of a new division Sociological Theory and Sociology of Law at the *Sozialforschungsstelle Dortmund*, affiliated with Münster, from 1966 to 1968. In 1968 he became the first professor of the newly established University of Bielefeld. He stayed there until his retirement in 1993 and continued this relationship until his death on November 6, 1998, in Oerlinghausen.

1. Theory of Social Systems

From its beginnings in the early 1960s Luhmann called his contribution to sociological theory systems theory (Luhmann 1970). Another early self-designation was functional-structural theory, an obvious opposition to Talcott Parsons's structural-functionalism by which Luhmann intended to say that in his writings the concept of function takes a more strategic role than in Parsons. Social reality is thought to consist in problem solutions; the identification of the problem a specific

structure solves is what functionalism is about; and having identified the function of a specific structure one may look for functional equivalents, that is, alternative institutional solutions for the same problem. Methodologically this points to the essentially comparative character of Luhmann's theory; he was always looking at reality as problem solving and compared the solutions identified to institutional alternatives.

What is systems theory? First of all this self-designation establishes system/environment as the guiding distinction for processes of theory building. One possibility is to conceive systems theory as a theory of open systems which implies a focus on exchange processes connecting a system and its environments. In Luhmann's case we have to do with a cybernetic systems theory in which a system is described by the selectivity of its relations to its environments. For this Luhmann invented the formula which made him famous: reduction of complexity. Environments are seen as overly complex and systems constitute themselves by a selective reconstruction of this complexity.

Luhmann primarily was interested in social systems and therefore had to establish their specificity. He did this by a theory of meaning (Habermas and Luhmann 1971, pp. 25–100). Whereas all types of systems produce a surplus of possibilities and then generate selection mechanisms reducing this surplus, social systems are constituted by a specific mode of dealing with reductions. In social systems the possibilities not chosen are not eliminated. They are instead maintained as possibilities to which one can recur at a later point in time.

There exists one other system type which operates on the basis of meaning: psychic systems. As it already was the case in Parsons, social and psychic systems are conceived as two different types, separate from one another but coupled via media such as meaning and language. Luhmann's thesis that human beings (as psychic systems) belong to the environment of social systems was always one of the most controversial aspects of his work. But how does a strict separation of social and psychic systems come about if both operate in the medium of meaning? Luhmann proposes to distinguish the elementary constituents from which both types of systems are built. In the case of psychic systems Luhmann favors a theory related to Husserl (Luhmann 1995a, Chaps. 1–4). Thoughts are elementary constituents in psychic systems which are described as systems of consciousness. Occasionally he experiments with more inclusive concepts of consciousness—including feelings, perceptions, acts of will—and points to intentional acts as a more general element of consciousness.

Which is the constituent element of social systems? In a first approximation one would think of social actions as elements (as unit acts in a Parsonian sense). One finds this understanding in the early Luhmann. He even then complicated the understanding of action by introducing a distinction between action and experience for which there were no antecedents in the sociological tradition. Social systems are conceived as processing selections which are either attributed to one of the systems involved which means they are social actions or to objective circumstances of the world which implies that one only experiences these selective events and can influence them in the present situation. This distinction of action and experience depends on attributions, that is, it is a processual result of social systems themselves.

This already points to the fact that social actions can't function as the constituent elements of social systems. Luhmann opted for communications instead, thereby becoming the first major social theorist to base the understanding of society on communications theory (Luhmann 1984, Chap. 4). This implies a switch in sociological theorizing from focussing on the exchange of resources to accentuating information transfer in social processes. Luhmann's communications theory, closely related to Bühler (Bühler 1934), does not conceive of communication as a single selective event. Instead any communicative event is based on interrelating three selections. (a) An informative event which—in the Batesonian understanding (Bateson 1973)—is a 'difference which makes a difference' to an observing system, but which is not a complete communication in itself. (b) An utterance which means that there exists a system conveying the information in question. (c) An understanding which implies that a second system is involved which projects the difference of information and utterance on the first system and understands thereby. A communication is a unity consisting from these three components. The acceptance or rejection of a communication can be identified as the fourth component of a communicative event, but it already belongs to the next communication, thereby securing the sequential unity of a communication system.

But how are communications elements of social systems? Do they possess the internal stability one should demand of an element? Luhmann theorizes this in terms of the temporality of the elements of social systems. In an essay from 1979 (Luhmann 1981a, pp. 101–25) he proposed that the elements of social systems—be it actions or communications—are events. They are of vanishing duration. Just having begun they are already gone, and new events must arise for the system not coming to an end. The reproduction of events is the most important structural imperative of social systems, and reproduction does not mean invariant reproduction which is inexistent in social systems. Reproduction means that new events connect to previous events and are limited by this. Such reproductive events Luhmann calls operations, and this substitution of the concept of operation for the concept of element is accompanied by further fundamental changes in systems theory.

First among them is a slide toward concepts of self-reference. This is already to be seen in Luhmann's early self-presentation as a proponent of cybernetic systems theory which means that selectivity in the relations of the system to its environment is always related to the self-identity of the system. Self-reference is articulated more strongly in the theory of autopoiesis which Luhmann adapted in the eighties from the Chilean neurobiologists Maturana and Varela (Maturana and Varela 1980, Luhmann 1984). Autopoiesis means that anything which functions as unity in a system—element, operation, structure, boundary—results from the production processes of the system itself. There are no imports to the system, no inputs and outputs. The system is closed operationally and structurally, but it is informationally open which means that from observed differences it projects to its environment the system derives internal differences which influence system processes. Systems which are closed structurally toward one another can be structurally coupled, that is, there exist two sets of structures in two systems which evolve under the pressure of irritations resulting from operations of the other system.

A last conceptual change regards the concept of operation. The theory of meaning and information theory point to the understanding that operations always are controlled by differences. Operations choose a specific option and they exclude another alternative option, that is, one can infer an underlying distinction. In social and psychic systems the other side of the distinction, the possibility not chosen, is often included representationally. If this is the case Luhmann calls the operation an observation (cf. Luhmann 1990b, Chap. 2). Agreeing with numerous social theorists from Garfinkel to Giddens who call this reflexivity, Luhmann postulates that observations and self-observations are basic to modern social systems. Second order observation (von Foerster 1984) is the type of observation characteristic of function systems in modern society. In function systems most observations are reflexively oriented to observations by other observers and only indirectly refer to reality.

Luhmann complements this by a calculus of observations invented by the British logician Spencer Brown (Spencer Brown 1972). Regarding the logical structure of observations Spencer Brown postulates a unity of distinction and indication. In distinguishing the two sides of an observation one always has to indicate one of these two sides and one has to do this in the same moment one uses the distinction. This demonstrates that one can not at the same time observe the observation one just makes use of. One can only do it later by applying another distinction to it. Therefore, insight (by using a distinction) and blindness (by being unable to observe the distinction one uses) always go hand in hand in social systems. Reentries are one strategy of dealing with this. A distinction can enter into the domain which is distinguished by it. A system can observe itself via the distinction of system and environment by which it was demarcated in the first place. Luhmann tried to conceive a theory of reentries as the modern version of a theory of rationality (Luhmann 1984, Chap. XI, 1997, Chap. 1, XI).

2. *Theory of Society*

For Luhmann modern social theory always consisted from two main undertakings. First, the theory of social systems; second, among social systems he identified one which encompasses all other social systems: society. His two main theoretical treatises were, therefore, devoted to the theory of social systems and to the theory of society (Luhmann 1984, 1997).

Luhmann postulates three levels of the formation of social systems: Interaction, Organization, and Society. Interaction is an analogue to what Goffman called encounter or interaction order (Luhmann 1975b, pp. 9–38, Goffman 1965). Interaction systems presuppose the copresence of the participants and their reciprocal perception. If these conditions are fulfilled, a social system will arise because then it is impossible not to communicate as Watzlawick demonstrated (Watzlawick 1967). Interaction systems are limited in their capacity: they can process only one topic at a time. When the participants leave the interaction system comes to an end.

Organizations constitute an intermediary level of system formation being based on membership (Luhmann 1964). Organizational members are bound by rules. Organizations as autopoietic systems consist from decisions which are binding for organizational members as long as they do not conflict with the organizational rules. Society is the encompassing social system including interactions and organizations. Luhmann defines society via communicative attainability and from this he concludes that in the present world there is only one societal system. Therefore, one should speak of World Society (Luhmann 1975, pp. 71–91) which is a stronger claim than what is postulated in globalization theories.

The theory of society is developed in Luhmann's writings in four parallel complexes. The most recent of them arose with the intensified interest in self-reference. Even society as the encompassing macro order is a self-referential system and cultivates this in self-observations and self-descriptions. Luhmann pursued these questions mainly in studies on the historical semantics of modern society (Luhmann 1980, 1981b, 1982, 1989, 1995b, 1997, Chap. 5).

The other three complexes are related to Luhmann's theory of meaning. Luhmann distinguishes a social, a temporal, and a material dimension of meaning and these three terms are connected to his theory of communications media, his theory of evolution, and

his differentiation theory as the core elements of his theory of society. These theories give an answer to the question how social, temporal, and material differences are dealt with in society.

Regarding the social dimension of meaning Luhmann's theory asks: how is it possible to mediate differences of conception and interest among participants in social processes? Language is one medium of communication effective in doing this, and since classical antiquity this function was supported by the art of rhetoric which always concentrated on persuasive effects. In modern society this function was taken over by symbolically generalized communication media such as power, money, love, and truth (Luhmann 1975b, 1988, 1982, 1990b, Chap. 4). This theory is related closely to the theory of generalized exchange media which Parsons invented (Parsons 1969). But whereas in Parsons media are specializing on mediating exchange processes between functional sectors such as the economy and the polity, in Luhmann they operate entirely internal to the function systems. All function systems, such as the economy and polity and science, are in Luhmann conceptualized as communication systems, and communication media are specialized in securing acceptability for communications internal to these systems. Luhmann postulated that in a highly differentiated society the acceptance of communicative suggestions becomes improbable and communication media realize symbolically effective ways of organizing persuasion. Money is one example of this. Why should I accept that someone becomes an owner of goods which I would like to have myself (Luhmann 1988, Chaps. 6–7)? Luhmann explains this by the symbolical effects of money. Money symbolizes the liberty to acquire something if I need to, and therefore makes it acceptable to me that some other one now buys desirable goods. He has to spend money and therefore the liberty of acquiring goods circulates in the economy in a direction opposite to the circulation of goods. Luhmann isolates comparable motivational structures for other communication media, and he formulates a complex technical apparatus for explicating internal structures of communication media and for comparing them. Binary codes (truth/falsity, legal/illegal), inflationary and deflationary phenomena (analogous to money), interrelations with bodily infrastructures of communication (sexuality, perception).

The second complex in Luhmann's theory of society regards structural changes in time. Already in his writings from the 1970s Luhmann did neither opt for modernization or development but instead for a neodarwinist theory of sociocultural evolution, closely related to the writings of Campbell (Luhmann 1990b, Chap. 8, 1993, Chap. 6, 1995c, Chap. 6, 1997, Chap. 3, Campbell 1988). There are two main motives in Luhmann's evolutionary theorizing. First, he was fascinated by the possibility of structure formation in social systems brought about by chance events. For him this was the conceptual core of evolutionary theory. Second, for Luhmann evolutionary theory was a theory of the interplay of evolutionary mechanisms such as variation, selection, and selective retention. Chance, therefore, meant the interruption of interdependencies between evolutionary mechanisms.

In conceptualizing the evolution of society Luhmann identified the variation mechanism in the possibility of saying no. Selection is effected by the binary codes of communication media distinguishing among new meaning components generated by negations. The patterns of meaning arising this way have to be stabilized by building social systems around them. Differentiated and more clearly articulated patterns of meaning enhance the probability of new negations arising, thereby demonstrating the circular interrelatedness of evolutionary processes (Weick 1979). This three-term structure of evolutionary theory mirrors the three-term-structure of Luhmann's theory of society: there is one mechanism which makes plausible how to operate on the base of chance events (temporality); a second mechanism enhances the probability of acceptance for new meaning components (social dimension); and a third which via differentiation orders the material complexity of the world (material dimension).

The third complex is differentiation theory, near to the core of the sociological tradition. The change Luhmann proposes is to interpret differentiation theory as a theory of system formation. Differentiation means that inside of systems new system/environment differences arise (Luhmann 1997, Chap. 4). There is no AGIL logic behind differentiation. New systems are inductive solutions for local or global problems. But Luhmann postulates that there is a limited repertoire of forms of system differentiation. First of all there exists segmentary differentiation. Segments such as kinship units in tribal societies are characterized by equality of status and similarity of internal structure. A second differentiation form Luhmann introduces is center/periphery. Center/periphery distinctions such as town/country always mean institutionalized and systematic differences in the control of resources and information. The third differentiation form is hierarchical differentiation or stratification. Hierarchical differentiation divides society into social systems (estates, castes, strata) which are distinguished by inequality of status. For the persons belonging to these systems they define a total context of life. Modern society, finally, is characterized by functional differentiation. By this is postulated that today it is dominated by macrosystems such as law, science, mass media, the polity, and the economy which are worldwide macrosystems and which are related toward one another by extreme material diversity. No stratification or status order among these macrosystems can be observed. Functional differentiation is the central empirical hypothesis of Luhmann's theory of society. It may be predicted that the future influence of systems

theory on sociology will to a considerable amount depend on the success of functional differentiation as a diagnosis.

3. Profile of Theory Building—Relevance for Contemporary Social Sciences

One of the most conspicuous features of the writings of Niklas Luhmann is a strong belief in the validity and cognitive strength of theoretical thinking. Theory for him primarily meant conceptual work, and in this he had close affinities to the cognitive style of Roman law and of philosophy. Luhmann never would have considered himself a philosopher but for him the philosophical tradition was a treasure trove of conceptual resources which sociology only could neglect at considerable cost. One example is his transformation of the blunt Parsonian concept of contingency which simply meant dependence into the scholastic concept which was defined by the double negation of chance and necessity. This way he created a more flexible conceptual instrument.

Interdisciplinarity was in Luhmann's case a logical corollary of his stance toward the philosophical tradition. In the development of Luhmann's theories he imported concepts continuously from disciplines as heterogeneous as social psychology, cybernetics, linguistics, biology, and logic. And the conceptual structures and theories which he imported were then sociologized completely. A remarkable case in point is autopoiesis, a biological concept well adapted to circular production processes of biological macromolecules in the living cell, which Luhmann transferred to the communication-based function systems of modern society. This is a controversial operation but on one point there can't be any dispute: there are not even traces of materialism or biologism in the sociological theory resulting from the transfer. Marxism was an important context in the development of Luhmann's theories. When Luhmann's scientific work became visible in the late 1960s the intellectual scenery in Germany was dominated by the student movement and its intellectual accompaniments. Luhmann became famous in 1971 when he published a book with Habermas, the main representative of the Frankfurt school (Habermas and Luhmann 1971). In the following years the career of systems theory in Germany was coupled with the demise of Marxism. After the mundane and middle-range sociology of the 1950s and1960s, the intellectual opposition of the late 1960s had re-established the expectation that sociology should deliver complex theories of society. When Marxism and political economy failed, systems theory was the only alternative remaining. Luhmann had no sympathy for the intellectual and political claims of Marxism but systems theory was adapted perfectly to an expectation structure looking for macrotheories of society and their universalizing claims. The structural functionalism of Talcott Parsons is the theory Luhmann started from. From the beginning this was an unusual intellectual relation. On the one hand Luhmann reconstructed point to point, often taking up minor theoretical distinctions hidden in the appendices of the essays on generalized media of exchange. On the other hand, the theory Luhmann built via this reconstructive effort is very different from the Parsonian undertaking: an open, inductive list of function systems supplanting the deductive logic of AGIL; World Society supersedes the solidarity-based national communities Parsons postulates; neo-Darwinist evolutionary theory pushes away the Parsonian thinking in developmental trends; a loose, heterarchical arrangement of different theories is substituted for the hierarchical structure of the Parsonian paradigm. When today systems theory is one of the few elaborated and universalistic paradigms of sociological thinking which will probably have an influence far into the twenty-first century, this is due to the theory-building and theory-reconstructing venture undertaken single-handedly in the writings and teachings of Luhmann.

R. Stichweh

Luria, Aleksander Romanovich (1902–77)

Aleksander Luria was born in Kazan, an old Russian University town east of Moscow on July 16, 1902. He entered Kazan University in 1918 at the unusually early age of 16 owing to the social disorganization (and associated opportunities) associated with the Russian revolution. He obtained his bachelor's degree in 1921 at the age of 19. In 1923 he moved to Moscow where he remained for the ensuing 54 years (with the exception of a period between 1942 and 1945 when he directed a clinic for rehabilitation of soldiers who had suffered brain injuries). During this long career he taught and conducted research at a variety of important institutions including the Institute of Psychology, the Department of Psychology at Moscow State University, the Institute of Defectology, and the Bourdenko Institute of Neurosurgery. He died in Moscow on August 14, 1977.

While an undergraduate student, he established the Kazan Psychoanalytic Association and planned on a career in psychology. His earliest research sought to establish objective methods for assessing Freudian ideas about abnormalities of thought and emotion, as well as the effects of fatigue on mental processes. His dream was to create a unified psychology that would encompass both the intimate personal thoughts and emotions of individuals, as well as the biological and social conditions that supported such processes (Luria 1979). As he summarized his notions about psychoanalysis:

> Here, I thought, was a scientific approach that combined a strongly deterministic explanation of concrete, individual behavior with an explanation of the origins of complex human needs in terms of natural science. Perhaps psychoanalysis could serve as the basis for a scientific *reale Psichologie*, one that could overcome the nomothetic-idiographic distinction (Luria 1979).

In emulation of the psychoanalytical writers, he conducted clinical research on free associations, but he mistrusted the results of such efforts, feeling that any conclusions he tried to reach about the flow of his subjects' thoughts were insufficiently grounded. As he wrote in his autobiography, 'While I was able to fill notebooks with (a patient's) free associations, I was in no position to carry out my plan to use such data to capture the concrete reality of the flow of ideas' (Luria 1979).

In response to this dissatisfaction he created a methodology designed to embody a psychodynamic theory of mind in an objective set of laboratory procedures. The centerpiece of this methodology was an experimental technique that he called the combined motor method, which, he hoped, would provide a way of rendering Freud's clinical methods accessible to experimental treatment.

The fullest existing description of this work is contained in a monograph published in English under the title *The Nature of Human Conflicts: Or Emotion, Conflict and Will* (Luria 1932). Luria explicitly rejected mechanical determinism in psychological analysis, declaring that 'The structure of the organism presupposes not an accidental mosaic, but a complex organization of separate systems…(that) unite as very definite parts into an integrated functional structure' (Luria 1932).

This approach required Luria to solve the following problem. Since this structure is the consequence of a long complicated development, both ontogenetically and cultural-historically, and because the parts are integrated into a whole functional system, how can it be possible to isolate elements in this system for purposes of psychological analysis? Phrased differently, since no two people are constructed alike, how could one possibly obtain valid evidence about the thought processes of another person?

The answer that Luria provided was that other people's thoughts can only be revealed indirectly in so far as they can be reflected in a publicly displayable, voluntary behavior. He phrased his strategy as follows:

> We should on the one hand, produce the central process of the disorganization of behavior; on the other hand, we should try to reflect this process in some [other] system accessible and suitable for examination. The motor function is such a systematic, objectively reflected structure of the neurodynamic processes concealed from immediate examination. And there lies before us the use of the motor function as a system of reflected structure of hidden psychological processes. Thus we proceed along the path we call the combined motor method (Luria 1932).

The first phase in his technique was to induce a well-coordinated, publicly available behavior as the medium of coordination necessary for the psychological analysis to be accurate. He used various devices for this purpose. Often the subject was requested to hold the left hand steady in a device that could record its movements, while simultaneously being asked to press a button or squeeze a bulb in response to verbal stimuli

presented by the experimenter. Once this behavior became stable, the analyst sought to disrupt it selectively in line with his hypothesis about particular internal psychological states.

The combined motor method was applied to psychodiagnosis in a wide variety of real-life circumstances consistent with Luria's goal of demonstrating the possibility of a methodology powerful enough to reach beyond the laboratory to engage the kinds of long-term emotions that typically organize human behavior. For example, it became the basis for early lie detector tests and later for studies of the role of speech in the development of normal and mentally retarded children as well as adults suffering various neuroses and brain damage. It also served as the foundation for a great deal of his subsequent research on the relation of culture and human thought. As Luria (1932) expressed this relationship at the end of *The Nature of Human Conflicts*, 'The analysis of complex cultural mechanisms is the key to the understanding of the simple neurodynamical processes.'

In 1924 Luria had met Lev Vygotsky, a developmental psychologist whose influence was decisive in shaping Luria's future career. Together with Vygotsky and Alexei Leontiev, Luria sought to establish an approach to psychology that would enable psychologists to 'discover the way natural processes such as physical maturation and sensory mechanisms become intertwined with culturally determined processes to produce the psychological functions of adults' (Luria 1979). Vygotsky and his colleagues referred to this new approach variably as 'cultural,' 'historical,' and 'instrumental' psychology. These three labels all index the centrality of cultural mediation in the constitution of specifically human psychological processes, the role of the social environment in structuring the processes by which children appropriate the cultural tools of their society in the process of ontogeny, and the need to study processes of change over time. An especially heavy emphasis was placed on the role of language, the 'tool of tools' in this process: the acquisition of language in early childhood was seen as the pivotal moment in ontogeny when phylogeny and cultural history are merged to form specifically human forms of thought, feeling, and action. From the late 1920s until his death, Luria sought to elaborate this synthetic, cultural-historical psychology in different content areas of the discipline.

During the 1930s he conducted two lines of research aimed at elucidating the relationship between phylogeny and cultural history in children's development (this topic is often referred to as the 'nature–nurture question'). The first project falls within the scope of what is now referred to as 'cross-cultural psychology.' It seeks to hold phylogeny constant while studying the effect of rapid cultural change.

In one implementation of this strategy, Luria led two expeditions to Central Asia where he investigated changes in psychological functioning brought about by changes in economic activity, social organization, and literacy that were then taking place (this work was only published after a long delay resulting from its ideological implications). In this research he presented psychological tasks believed to tap such areas as perception, reasoning, problem solving, and self concept to groups of adults who had, or had not, been incorporated into the Soviet system of collectivized farming or formal system of schooling. He found a marked difference in tested performance as a function of these variations in life experience. The thinking of those people who remained isolated from modern forms of agricultural work or schooling appeared to be dominated by immediate practical concerns bound to particular situations while those who had undergone the modernizing changes sponsored by the state appeared to think in more general and abstract ways that could be applied across a wide variety of situations.

A second line of work on the nature–nurture issue focused on comparisons between identical and fraternal twins exposed to different regimes of deliberate instruction. This work was organized at the Institute of Medical Genetics where hundreds of twins attended a specially organized boarding school. One set of studies involved the performance of identical and fraternal twins of different ages on tasks designed to vary in the extent to which they depended upon cultural knowledge. Luria's basic finding in this work was that the correlation between the performances of identical twins were higher than those of fraternal twins when the tasks they were presented required relatively little specialized cultural knowledge. But the more the tasks required such knowledge, and the older the children were, the closer the correlations between fraternal twins approached the correlations among identical twins. He concluded that as children grow older and acquire more cultural knowledge, the influence of phylogeny over development gives way to the influence of cultural history.

He also conducted a special case study of a pair of identical twins who had developed what appeared to be their own private language before entering the boarding school as young children. For several months one of the twins was provided specialized training in the use of language to guide thinking about a variety of intellectual tasks while the other was not. The twin who received specialized training showed markedly more rapid intellectual development than the untrained twin, although the untrained twin's development rebounded once he, too, was provided specialized training. This result provided converging evidence on the role of culturally organized experience, especially language, on cognitive development (Luria and Yudovich 1959).

In the late 1930s, largely to remove himself from public view owing to the period of political purges initiated by Joseph Stalin, Luria entered medical school where he specialized in the study of aphasia, retaining his focus on the relation between language,

thought, and self-regulation, but now in the context of the politically neutral arena of medical practice. The onset of World War II made his specialized knowledge of crucial importance to the Soviet war effort, and the tragic widespread availability of people with various forms of traumatic brain injury provided him with voluminous materials for developing his theories of brain function and methods for the remediation of focal brain lesions. It was during this period that he developed the systematic approach to brain and cognition that has come to be known as the discipline of neuropsychology.

Several ideas were central to Luria's approach to brain-behavior relationships. First, he conceived of the brain as consisting of three, global 'blocks' which underpin and control three associated kinds of brain processes. The first block, sometimes referred to as the 'primary sensory areas,' controls perceptual and motor integration. The second block, which includes the prefrontal and frontal areas, undergirds programming and executive control of thought and action. The third block, which includes the brain stem and paleocortex, controls the level of arousal and activation of the cortex as a whole. In addition to considering the workings of each of these blocks, he was particularly interested in the ways in which the 'arousal-activation' block interacts with the other two.

Within this general framework, Luria sought to overcome a classical dichotomy between those who believed in the strict localization of brain functions and those who emphasized the 'equipotentiality' of different parts of the brain in subserving various psychological functions. While he accepted the idea that elementary functions such as the registration of sensations from the retina could be localized in particular groups of cells, he insisted that the systemic structure of complex forms of mental activity characteristic of adults humans represent complex functional systems involving the coordinated action of many anatomical locales. These brain systems are themselves mediated by the culturally organized environment, especially its systems of signs. As a consequence, he argued, 'to understand the brain foundations for psychological activity, one must be prepared to study both the brain and the system of activity' (Luria 1979). This insistence on linking brain structure and function to the proximal, culturally organized, environment provides the thread of continuity between the early and later parts of Luria's career. Third, he combined clinical practice with basic research on brain function, taking his ability to create systems of remediation as crucial evidence concerning the adequacy of his theories.

Following the war Luria sought to continue his work in neuropsychology. However, his plans were interrupted for several years in 1948 when he was removed from the Institute of Neurosurgery during a period of particularly virulent antisemitic repression. For the next several years he pursued his scientific interests through a series of studies of the development of language and thought among mentally retarded children at the Institute of Defectology. This work used a variation on the combined motor method to explore how the development of self-control is linked to the development of language, and provided a theoretical basis for the development of special curricula for the mentally handicapped.

In the late 1950s Luria was permitted to return to the study of neuropsychology, which he pursued until his death of heart failure on August 14, 1977. During this period he continued developing the idea of the brain as composed of functional systems closely linked to the conditions of the proximal environment, producing a number of important monographs on the brain bases of language, memory, and cognition. As this work became known outside of Russia, it gave rise to the development of standardized diagnostic tests (often referred to as the Luria Neuropsychological Battery) which are still widely used in clinical work. However, with the advent of highly sophisticated neuroimaging methods the diagnostic function of these tests has decreased in importance. What has remained internationally influential are the basic theoretical principles concerning the organization of higher psychological functions into complex functional systems mediated by sign systems and the use of these principles to guide the development of remedial procedures for brain damaged patients.

In the years just prior to his death, Luria returned to his early dream of constructing a unified psychology that overcame the centuries-old split between natural and cultural science approaches to psychology. He proposed to do this by showing how theoretical principles arrived at through the experimental study of groups of people ('nomothetic' knowledge) could be made relevant to understanding and coping with the concrete life circumstances of an individual human being (idiographic knowledge). He called the approach combining the two psychologies 'romantic science.' He contrasted romantic science with what he called classical science:

> Classical scholars are those who look upon events in terms of their constituent parts. Step by step they single out important units and elements until they can formulate abstract, general laws.... Romantic scholars' traits, attitudes, and strategies are just the opposite. They do not follow the path of reductionism, which is the leading philosophy of the classical group. Romantics in science want neither to split living reality into its elementary components nor to represent the wealth of life's concrete events as abstract models that lose the properties of the phenomena themselves.

He illustrated his concept of Romantic Science in two longitudinal case studies involving people for whom ordinary ways of mediating action in the world is impossible (Luria 1968, 1972). One was a man with a superb, but unusually organized memory. The other was a man who had suffered unusual disorganization

of memory owing to massive destruction of the right-posterior part of his brain. In each case Luria combined information from experimental studies of large groups of subjects with the peculiarities of the individual case. His ideas about how the two kinds of processes combine was evaluated by the therapeutic regimes he prescribed.

These two case studies illustrate in dramatic detail his blend of classical, experimental approaches with clinical and remediational approach, a synthesis that stands as a model for psychological research and theory to the present day.

Land Information System

1. History

The concept of the Land Information System was first developed during the 1980s, but its roots go far back to ancient times. Its present-day evolution is a direct result of two simultaneously occurring phenomena of the closing decades of the twentieth century, one being the rapid growth of the world's human population and the pressure that this growth has had and is having on the planet's dwindling land resources. The other continues to be the prodigious progress in the field of computer-based information systems. Before reviewing what a Land Information System could look like today, let us briefly look back at its origins and appreciate that many of the principles maintained at present have come to us from many centuries ago.

There can be little doubt that humans have always in one way or another classified and arranged their immediate and surrounding territorial space. This endeavor is a necessity even for an individual acting alone, and more so for groups or clans working in unison. We can very well imagine prehistoric cave dwellers designating areas for such purposes as cooking, sleeping, storing, and gathering—together within the confines of their individual and shared living space. Over time, as societies grew in numbers and in complexity, accompanied by the conscious setting aside of spaces or units of land within which to perform specific activities or functions, the task of preparing an accounting system designed to establish formally and govern these activities or functions became an inescapable necessity.

A detailed history of the evolution of land recording is not readily available. What we do have is evidence that as a formal activity land accounting or inventorying is several thousand years old. For example, there is proof in the form of a Chaldean tablet prepared some six thousand years ago. The same may possibly represent some form of agricultural inventory, describing the production of different crops within distinct areal units, for a particular harvest period. This singular type of registry, performed over time, could have undoubtedly given the ancient Babylonians a detailed view of their food production in the Tigris Euphrates river valley, which in turn allowed this form of wealth to be planned for and dealt with accordingly.

There is also evidence that the ancient Egyptians, Greeks, Romans, and in America the Incas and the Aztecs, maintained elaborate land records. As for Asia, the Chinese have a millenary tradition in the establishment of formal accounting and controls for the administration of land. The Romans, for example, were particularly active in the preparation of 'cadastral' records. Not only would they prepare and maintain land registers in outlying provincial cities and towns but also copies were remitted to Rome to be consigned to a central registrar. During the reign of Roman emperor Diocletian (AD 284–305) the *jugum*, a tax on a unit of cultivable land, was imposed. Besides requiring extensive surveying to be undertaken and periodic assessments, it established a linkage between the levying of taxes and the ownership and productivity of land. As empires and kingdoms grew in size and complexity, the inventory of land, and thus the capability of exercising controls over this most important source of wealth and power, was indispensable to their survival. But it was not until the end of the eighteenth century and the beginning of the nineteenth that what can be qualified as a 'modern cadastre' began to be implemented, particularly in continental Europe. The driving force behind its development and implementation was the taxation of land and its component buildings, and thus its name 'tax cadastre.'

The modern cadastral survey, with its concomitant cadastral record, is the mainstay of any land information system of the present or near future. What must be kept in mind is that no single cadastral system is suitable for all cases due to the enormous disparities that presently exist between national cultures, jurisprudence, and available material and human resources. It is clear that a cadastral survey must be 'tailored' to particular circumstances, but maintaining universally recognized methodology and content. In short, it is an ongoing process that over time can acquire the additional elements that will eventually result in a modern system with all its inherent advantages.

2. The Cadastral Survey

The term cadastre is believed to have derived from the combination of two late Greek words, *katá* (according to) and *stíchon* (line). At the present time, most land recording activity is undertaken by local or municipal public authorities under the guise of the cadastral survey, performed by the 'cadastral office.' Its primary purpose has been for the most part that of establishing the foundation for the implementation and collection of the property tax, predominantly at the urban level.

The cadastre is a parcel-based system, with the gathered information referenced to unique and well-defined units of land. A land parcel is defined to be 'a continuous area of land (and its components) in which unique and homogenous interests are recognized.' Each parcel is assigned an exclusive parcel number or identifier, generally by means of a geocodification system, and all are graphically described by means of a large-scale cadastral map.

The data collected for each unique parcel, and linked directly to the cadastral map via the parcel number, generally come under four headings: (1) Location attributes; (2) Physical attributes; (3) Economic attributes; and (4) Legal attributes.

2.1 Location Attributes

The location attributes fix the land unit's position on the cadastral map, be it at a small scale (1:20,000) such as a metropolitan area, or with a large scale (1:500) of a city block or the basic unit, the parcel. There are three basic ways of locating a parcel, all of which should, if at all possible, be simultaneously present in the parcel's cadastral record. These are the tangential location, the coordinate location, and the areal location. Each one merits a brief individual description.

Most if not all nations utilize the tangential location for the positioning of individual properties. This age old system is simply the commonplace 'street number or address,' or some other similar locating element or counterpart. The premise is that the parcel's location is a function of the means or method of physically accessing it. Be it for example a street, avenue, or alleyway, along with an additional component, usually a number, it is possible to identify the parcel's singular location. For even greater reference, accompanying political administrative elements are included to give the parcel a global position, example: 1900 Pennsylvania Avenue, Washington, District of Columbia, United States of America, the address of the White House.

Modern cartography has always been dependent on astronomy and the use of geographic coordinate systems. But in spite of being available in one form or another for hundreds of years, the use of coordinate location as a component of the cadastral survey is actually a twentieth century occurrence. Its inclusion must be considered an important advancement in the steady progress and modernization of any cadastre system. The confusion often present in the exclusive use of tangential location, especially in rural areas or regions of difficult access, can most often be satisfactorily resolved by means of coordinate location. Its presence in the cadastral survey can be of two forms, one being a single coordinate reference point within the boundaries of the parcel. The other presence is generally referred to the cadastral map, where the coordinates of each of the existing vertices, or corners of the closed polygon, are clearly labeled.

Areal location refers to the linkage between the total space of the parcel with a technically established identifier or geographic code. The advances in the development of geocodification have occurred simultaneously with the progress in the field of computer technology. Assigning a unique numeric code to each parcel not only enormously facilitates the organization of the data files but also provides for rapid access to both graphic and alpha numeric information, and allows for the cross-referencing of information of a particular parcel from various sources. There is no single unique way of designing what can be called a cadastral location code, but they generally fall into two categories: the technical cadastral code and the simplified cadastral code. The former is based on the use of quadrants of equal size, using as the starting point, for example, maps based on the UTM coordinate system. The advantage of this method is that extensive geographical areas can be associated with a common cartographic reference. The disadvantage is that its complexity renders its use difficult, except to those especially trained. The latter, the simplified cadastral code, has as its main advantage in that it utilizes commonplace geographic elements in establishing the boundaries of the different levels of spatial aggregation, thus making it easy to understand and use. Its disadvantage is that the commonplace is vulnerable to change. Regardless of the method to be chosen, a numeric code of no less than 10 digits can easily link land data with its corresponding location on the cadastral map.

2.2 Physical Attributes

A single universally accepted cadastral register, or dossier, useful for all necessities and circumstances, does not exist. Each governmental authority must select the type and amount of information that it deems necessary and desirable. In order to avoid unnecessary costs and complications, the volume of information should be kept at the necessary minimum. Nevertheless, the design of the register should be modular and flexible so as to allow for adjustments over time, the implementation of positive changes that will not negatively affect the integrity, and usefulness of the existing database.

With respect to the physical attributes of each parcel, the following information should be included:

- Basic characteristics of the land such as size, shape, occupied or vacant, topography, and availability of public services.
- Basic characteristics of existing buildings such as type of occupancy (by owner, rented, unoccupied), type of building (single family home, apartment complex, commercial establishment), use, conservation, and basic structural characteristics.

If possible, it is recommended to include one or more photographs of all parcels and constructions, but especially so of the building if it is of some historical and/or architectural value. In some jurisdictions, the planning office or engineering department stores copies of the building's blueprints. If so, a reference to the location of these instruments should also be included.

2.3 Economic Attributes

For most of its existence, the cadastral survey had as its central and most important function the calculation and collection of the property tax. This tribute represents the primary source of income for many local governments, and therefore the focus of the cadastral undertaking has been very often narrowly confined to this end. But it is now clear that besides being an indispensable instrument for the levying of the property tax, the economic attributes reflected in the cadastral survey can be of significant assistance in the formulation of a multifaceted economic policy, embracing not only the traditional financial aspects but also as an instrument for the planning of growth and development. Examples of the latter include the use of tax incentives and disincentives in order to direct development as a reliable reference for the correct execution of eminent domain, and as a complimentary tool for the calculation of value added to property as a result of investments in public infrastructure.

The financial health of many local governments may very well depend upon an effective implementation of a dynamic, efficient, and fair property tax code. To accomplish this end, the cadastral office must establish a working methodology that will enable it to continuously adjust values to reflect changes in the land market (the inflation and depression in the price of real property), effectively charge and collect the corresponding tax from each property holder, and finally, to ensure that the amount collected is reasonable and in accordance with the law. It is clear that this enormous and complex task cannot be adequately accomplished without automating the land data base.

The initial problem in obtaining the economic attributes of the parcel is in defining the concept of value. There exists no single accepted formula for accomplishing this end, but regardless of the one adopted, it must be flexible enough so as to make adjustments for the purpose of perfecting it over time. Once defined, a value is then assigned for each parcel (individually to the land, and if present, in combination with the building components), and it is then possible to calculate the appropriate tax. Generally, the manner of assigning value to each individual parcel is accomplished by means of a two-tiered process, beginning with a massive appraisal to be followed by an individual appraisal.

Whenever there exists a general backlog in the cadastral record, which may very well be the case in most of the world's municipalities, the recourse to the massive appraisal is unavoidable. Its principal advantage is that it permits an initial calculation of value and the assigning of a tax duty to a large number of properties in the short term. Its main disadvantage is that to ensure fairness to the taxpayer, the massive appraisal should lean towards minimum values so as not to incur the injustice of overtaxing. This in turn represents a lower tax income than would be the case if the survey were reasonably up to date. Consequently, the median-term goal should be to undertake systematic individual appraisals so as to insure that higher valued properties are appraised first, and that eventually each contributor's property tax be in correspondence to the market value of their holdings.

2.4 Legal Attributes

It is often the case that the cadastral record refers legal ownership of each individual parcel to the prevailing jurisprudence governing the Land Registration System. Nonetheless, the cadastral record should include the following basic information concerning tenure and use:

- The name, address, and phone number of the property's presumed owner, and if applicable, the same data as to its administrator. The owner in turn can be of several categories, including private individual, government agency (national, state or provincial, local), community, corporate, condominium, and mixed (national and local government ownership for example).
- The nature of the occupancy of the parcel, for example, whether the same is unoccupied, occupied by owner, rented, entrusted, or squatted.
- The present use given to the property in accordance to an established system of classification of land use activities. These uses in urban areas generally include the following: vacant, residential, commercial, industrial, governmental, religious, transportation, and cultural-recreational. In non-urban or rural areas, uses such as agricultural, mining, and forestry are classified. The legal importance of determining existing use is related directly to the established zoning ordinance and/or approved land use plan, and thus whether or not the use in question is in compliance, as well as the effect the prescribed zoning has on its tax bracket.

2.5 Multipurpose Cadastre

Around the 1930s and 1940s, the term 'multipurpose cadastre' first appeared. The expression 'modern cadastre' could just as easily be used in its place. Regardless of whichever term is employed, they both illustrate the progress the cadastral survey has experienced in the twentieth century. An important aspect of this progress has undoubtedly been the enormous advances in the automating of both the mapping, and the data collection and maintenance, the 'how' aspect. But equally important, if not more so, have been the advances made with respect to 'for what end' the cadastral survey is undertaken. The systematic inclusion of information such as land use,

soil assessment, public services, and historical conditions allow for the cadastral record to be of singular usefulness in the implementation of land management strategies and the preparation of urban and regional plans. The purpose is no longer just fiscal, but managerial and planning as well.

One must not confuse Multipurpose Cadastre with Land Information System. Whereas the cadastre is generally a public sector endeavor, with laws and ordinances governing its purpose and execution, a Land Information System is the outcome of an understanding attained by numerous participants from both the public and the private sector. Of these participants, there can be no doubt that foremost from the public sector is the role played by the cadastral office. But to establish a Land Information System effectively, the presence of another public sector undertaking is required, the one performed by the entity responsible for maintaining the Land Registration System.

3. *Land Registration*

Land Registration is concerned with land tenure, which is 'the nature of the legal estate in land,' or simply stated, the rights by which an individual or groups lay claim to landed property. Internationally, there exist innumerable ways of conceptualizing the character and manner of existing rights over land, but generally they are an expression of a particular combination of 'customary law' and of 'formal law.' In most States, this expression is manifested by means of one of two acknowledged systems of Land Registration, the Land Deed and the Land Title.

A Land Deed is a 'writing or document executed under seal and delivered to effect a conveyance,' with conveyance signifying the transfer of property from one entity (person or party) to another. This in turn can result in the establishment of a Deed Registration System, which 'means that the deed itself, being a document describing an isolated transaction, is registered. This deed is evidence that a particular transaction took place, but it is in principle not in itself proof of the legal rights of the parties to conduct that transaction.' Thus in order to strengthen or guarantee the purchaser's rights of ownership, it is recommendable to trace backwards the property's 'root title.' This can generally be accomplished when a close relationship is established and maintained between a systematic deed registration archive and a functioning cadastral record.

A Land Title entails the registration of the consequence of a transaction, that is, the 'title' or the acquired right in and of itself. It is by means of a publicly accepted registration that the acquired right is produced. The registration of property (land title) is a public institution 'for the purpose of registering the possession of title and the conditions of dominion over a particular landed property, for the exercising of the contractual obligations over the same and as a guarantee for the contracting parties, not only with respect to the property in and of itself, but also to the personal circumstances of the proprietor.' From a juridical point of view, some argue that the relation between deed registration and title registration is comparable to the relation between legal facts and legal consequences.

To be effective, all land registration systems should abide by the following three principles: (1) The Mirror Principle—the land register is the true reflection of the legal status of the property; (2) The Curtain Principle—no further investigation into the root title of the property is required; and (3) The Insurance Principle—the State guarantees to all parties the validity of the information thus subscribed, and is liable to honor any valid disclaimer presented unto the register. In order to best insure the upholding of these three principles, there must be cooperation and coordination of the activities performed by the surveyor, the notary, and the registrar. Each of these parties should have a clear understanding of the role played by the other two if the land recording process is to be effective and reliable.

Almost all land registration systems are exclusively descriptive and legalistic. In order to strengthen the important relation between the 'legal object' (parcel) with its location and physical attributes, modern legislation should require a direct relationship between the register and the cadastral office. Some would argue that the most recommendable direction should be toward an eventual fusing of these two activities. Although the advantages of doing so appear to be obvious, the benefits of having them separate should not be overlooked. Land registration worldwide is fraught with abuse and fraud, due in great measure to the absence of oversight and checks-and-balances between the different actors in the process. Rather than fusing, which would concentrate the decision-making process and thus facilitate possible arbitrariness and corruption on the part of public officials, improved coordination and integration between the register and the cadastral record should improve the detection of irregularities and incongruities when and wherever these may arise. The more open a Land Registration System is to public inspection and scrutiny, the less vulnerable the information it contains.

4. *Public, Private, and Mixed Land Recording Systems*

In Brazil it is called *logradouro*, and it means 'public way, street, public square or garden.' When these spaces, or any nonparcel areal unit is officially surveyed and recorded, it is called *cadastro de logradouro* (public way cadastre). As the management

of urban space has become more and more complex, the importance of having and maintaining information of these and other shared spaces is paramount. But to do so the participation of both the public and private sector, or a combination of the two (mixed), is essential.

The public park or square is incorporated into the cadastral record generally in the form of the 'city block.' Not so the highway, street, or alleyway. Although viewed as a separate entity, these 'spaces of movement' are clearly an important part of the urban landscape. So much so that some studies of major cities in the United States have calculated that streets occupy between 20% and 40% of the land surface of the Central Business Districts. By no means should this significant portion of urban space be excluded from the land recording process.

The preparation of a public way cadastre requires the participation of numerous parties, most of which are involved with the provision of public services. Basic street infrastructure (sewer, water, drainage, pavement, sidewalks, and sidewalk furniture) is generally the responsibility of the public sector. On the other hand, services such as electricity, telephone, and television cable, all of which utilize the public way, are very often provided by private sector companies. But either way, all of them are subjected to some form of public regulation, mostly with respect to the manner the particular service is physically established. Until recent years little importance was given to 'centralizing' the information of these various service providers, a step that would have set the stage for improved planning, coordination, and control over the public way. And even if regulations were in place to create a unified public way cadastre, unless all parties involved agreed to a common geocodification base, the goal of establishing and maintaining a public way cadastre would be seriously hampered.

In the early 1970s, J. Brian McLoughlin addressed the importance of establishing a single cartographic reference base when he stated the following: 'What we wish to reiterate is the need to bring all data to a common system of areal units; unless this is done its utility is very considerably reduced, indeed it may be valueless. This is because of our cardinal need to understand activities within spaces from which it follows that information on all aspects of activity (e.g., the familiar conventional measures of population, employment, land value, ownership, etc.) as well as the spaces which support them must be coincident and congruent; this principle must be maintained strictly.' At the present time this principle of commonality is absent in most societies. National government agencies, local authorities, universities, public service providers, and private land management agencies more often than not design their very own particular geocodification system, with little or no agreement with one another. This veritable Tower of Babel approach to land-related information gathering inevitably results in diseconomies and high opportunity costs when approved land policies lack an up-to-date and integrated Land Information System.

In the case of rural areas the same principle applies. There can be no doubt that the particular attributes of nonurban spaces require a different approach with respect to the type of information to be gathered and the manner in which this is accomplished. Nevertheless the convenience, economy, and usefulness of common areal units for the preparation of 'ecological inventories' (term utilized by Ian McHarg in his landmark work *Design with Nature*) that 'would include human artifacts as well as natural processes,' should not be ignored. It is not uncommon to see government agencies, as for example those responsible for the protection of the environment and for the preparation and implementation of agriculture policy, work in almost complete isolation from one another. The absence of a common land database not only results in important diseconomies when there is duplicity present in the information gathering process, but more importantly, the lack of coordination and information sharing can oftentimes result in the formulation of policies by the different parties that are in direct conflict with one another.

Governments should waste no time in working towards establishing a unified geocodification system, the design of which should include the active participation of all the nonpublic actors involved. But should for some reason or another the creation of a common system of areal units be unattainable, efforts should be made so as to enable the translation, or transformation, of information from all relevant information systems to one another. Clearly, all efforts toward achieving commonality by every agent involved in gathering land information would contribute positively towards the effective implementation of a Land Information System.

5. *Land Information System*

Unfortunately today very few countries have a working Land Information System as has been defined. The required steps that lead towards achieving this goal involve significant economic investments and a determined political will on the part of the society and government. Many would argue, and with some reason, that the larger and more unified an information system is the greater the dangers to individual privacy and liberty will become. But the world we live in today cannot afford to be without well-designed land recording systems and to continue as it has with inadequate land management strategies. With the proper measures in place, it is possible to realize an acceptable balance between individual rights and the public good. Without a working Land Information System, nations individually and collectively will be

ill-adapted to manage future population growth with its ever-increasing demands on the planet's limited land and natural resources. The first quarter of the twenty-first century will be crucial to this end, and should be a period of human history in which governments give land recording systems high priority in order to be better prepared to face the challenges of growth and development in the years ahead.

What does the future hold for Land Information Systems? This question must be addressed under two headings, technological advancements and scope. In the short term, the next 15–25 years will continue to experience advances in computer sciences and their applications in the development of extremely large data base systems. With respect to mapping, which will inevitably become more digitilized and automated, the mission of Space Shuttle Endevour of February 11, 2000 is a harbinger of things to come. Titled *Shuttle Radar Topography Mission*, in a period of eleven days, close to one trillion measurements of the Earth's topography were performed from an orbit of 126 miles. Approximately 80% of the planet's land mass will benefit by the availability of 'unrivaled 3-D images of the Earth's surface.' This information will contribute significantly to improved urban and regional planning, as well as the development of environmentally sound policies.

With respect to scope, the very distant future can very well resemble something like what Isaac Asimov described in one of his novels 50 years ago: 'Biron leafed through the *Standard Galactic Ephemeris* with something like despair. Tens of thousands of stars were listed in detail, with their positions crammed into three figures. There were hundreds of pages of these figures, symbolized by the Greek letters ρ (rho), θ (theta) and ϕ (phi)... .ρ was the distance from the Galactic Center in parsecs; θ, the angular separation, along the plane of the Galactic Lens from the Standard Galactic Baseline (the line, that is, which connects the Galactic Center and the sun of the planet Earth); ϕ, the angular separation from the Baseline in the plane perpendicular to that of the Galactic Lens, the latter measurements being expressed in radians. Given those three figures, one could locate any star accurately in all the vast immensity of space.' No person can foresee how humanity will one day manage the information on the scale of the vastness of the Milky Way Galaxy, but what is clear from Asimov's speculations about the very distant future is that the need to classify and arrange the space in which the human race moves has been, is, and will always be a necessity.

Before we can even seriously speculate on the remote future, it is possible to imagine that over the next century Land Information Systems will most probably evolve in a manner so as to include the whole of the biosphere, with special attention given to the inclusion of detailed data concerning the ocean floor. As land resources continue to dwindle, the oceans will become more important as a source of materials required by human progress. The sound management of the exploitation of the resources under the surface of the oceans will require a well-designed information system, integrated necessarily to all the existing information of the land mass. Once accomplished, this new scope will probably result in the Land Information System, along with the Ocean and possibly Atmosphere Information systems, becoming not the end product of today, but instead a component of a larger information system. This future inventory could very well be titled Biospheric Information System.

Law, Diffusion of

1. *Definitional Issues*

The definitional issues adumbrated by the concept of 'Diffusion of Law' need preliminary clarification. So diffuse a concept overlaps with other titles of this chapter; also, particular definitions of the concept may contradict each other, implicitly if not explicitly. 'Diffusion' suggests definitional issues of motivation, of processes, and of outcomes. Especially with respect to the last issue, 'diffusion' also suggests an affinity with a concept much in use recently; namely, 'the convergence of law and of legal systems.' This concept, while in play for over a century, today is principally associated with the globalization or regionalization of national economies, and secondarily with the acceptance of a common standard of international human rights potentially binding the state. Because of these contextual associations, a focus on the 'Convergence of Law' aspect of 'Diffusion of Law' helps clarify the definitional morass inherent in the latter term.

First, this focus serves to differentiate some otherwise overlapping and contradictory neighboring concepts, in particular, those relating to the unification of law and the harmonization of law. The latter are intentional practices, consciously articulated and consciously engaged in (Wiener 1999, 189ff). In the second place, 'Convergence' as a more operational concept of 'Diffusion' highlights that the latter term too broadly suggests both a process or tendency and a result. Convergence focuses more on the latter point, since directly or indirectly it may be the more or less successful outcome—however measured—of the more conscious efforts suggested by 'unification' and 'harmonization.'

At the same time, however, it in turn suggests two other features of particular importance in recent times. First, 'Convergence' captures the underlying polar elements of inevitability and contingency that accompany, facilitate, or hinder those conscious efforts at Unification and Harmonization. Second, it widens our focus beyond the narrow range of formal law-making organs to include the broader range of actors engaged in law production, ranging from individuals through institutions to systems, who or which express the process and shape its outcome. 'Diffusion' of necessity is of a preexisting 'other' law into a host system. To understand it as 'Convergence' more openly and instrumentally faces that reality, while simultaneously accepting the reality that two systems interact in this process, that these may if they do not necessarily influence each other, and that the process may result in a synthesis that differs from each system's starting point.

All of the foregoing facets of gaining an understanding of the concept of 'Diffusion' are displayed in the two principal forms of diffusion of law in the early stages of the modern era, stages that will not be separately discussed herein, though their influences still may be noted in the contemporary era, which is the subject of this entry. The first is the diffusion of law that accompanied the dissolution of the shadow Holy Roman Empire and the arrival of the Napoleonic Period on the European continent at the turn of the nineteenth century. Coing (1989, 56f) describes the situation succinctly:

> The loss of a transnational law [at this time] was viewed as an unnecessary constriction [of legal life]. The way out of this situation, since a ius commune no longer existed, was the study of foreign law. A new discipline, the comparison of laws, emerged.

The motives for the diffusion of law inherent in this new discipline may have differed between the two principal state actors—France and the states of the later Germany. In the former, the instrumental interest in other systems' solution of new problems may have predominated, and in the latter, the need to find a common approach to the search for the applicable law. What was common to both, however, and what therefore is relevant to this discussion, was the outcome: the reciprocal diffusion of law, in the sense of bringing into consciousness the possibility of the convergence of previously disparate law (Buxbaum 1996, 206f).

The second principal form of diffusion in early modern times was that accompanying colonialism. The more or (at later stages) less unreflective introduction of the English common law to lands as varied as Australia, India, and West Africa was an inherent feature of colonial expansion itself, and the same may be said to varying degree of the colonial powers on the Civilian side of the families of law (Zweigert and Kötz 1998, p. 218). Late examples of this wholesale approach, though now marked by more sensitivity to local conditions, would include the (invited and well-considered) introduction of major parts of the Swiss and German code systems in Atatürk's Turkey (Watson 2001, 14ff) and the (invited) French introduction of entire Codes to Ethiopia in the late 1950s (David, 1982).

The principal focus of this entry is on the diffusion of law in the contemporary era. Even to that study, however, a brief overview of some central issues concerning the political and economic substrata of law, including some enduring theoretical issues, is necessary. These issues may have been brought to the fore during the Colonial and Imperial Era one and a half centuries ago, but their currently attenuated forms remain relevant to this era of globalization.

2. *Value Issues*

Law may be seen as an expression of other, more basic forces. The first modern argument in favor of Laws derivation from the cultural seedbed of a linguistically unified nation-state is that of Montesquieu in 1748: 'The political and civil laws of each nation should be adapted in such a manner to the people for whom they are made, as to render it very unlikely for those of one nation to be proper for another ['…doivent tellement propre au peuple pour lequel elles sont faites, que c'est un grand hasard si celles d'une nation peuvent convenir à une autre]' (Montesquieu 1748, p. I/3). And soon after the French Revolution, arguing against law as social engineering, Savigny, in his polemic against Thibaut, restated this view with a power that only he, in his later capacity as Prussian Minister of Justice (and thus of legislation), was able to resist (Savigny 1814, pp. 30, 137):

> The sum, therefore, of this theory is, that all law is originally formed…by custom and popular faith, next by jurisprudence, – everywhere, therefore, by internal silently-operating powers, not by the arbitrary will of a law-giver….[The object of the historical method of jurisprudence] is to trace every established [legal] system to its root, and thus discover an organic principle….

On the other hand, the nineteenth century also saw a considerable amount of conscious shaping of the legal framework of the burgeoning national economies, as these burst the household confines of the classical *oikos*, leading a contemporary scholar to suggest that '[t]he process of economic, social, [and] cultural assimilation or integration…has been accompanied by a process of political differentiation. It is this dual development of cultural and social assimilation and political differentiation which compels us to shift the emphasis of Montesquieu's test in order to find some workable criterion that can be used to determine how far a legal institution is transplantable….'(Kahn-Freund 1974).

These quotations' juxtaposition of Culture and Politics suggests an affinity to the phenomenological juxtaposition of *Lebenswelt* and System, particularly as applied to Law by Habermas (1973/75, 1981/87). The same juxtaposition also suggests an affinity to the tenets of classical Marxism: Law as much as Culture would be superstructural elements, with Economy, recast in Marxist terms more narrowly as control of the means of production, serving as the juxtaposed Basis. To these two approaches, however, Law presents a problem of contradictions. To the former theory, Law not only is the handmaiden of System, legitimating Money and Power. Rather, it may also contain inherent, dare one say essential, attributes (often if inadequately identified as 'procedural regularity') that restrain those expressions of System. Further, if it arose from and depends on Culture/Lebenswelt in Montesquieu's terms, it may carry some of the resistance of Lebenswelt towards System. In later Marxist theory, too, Law is seen to harbor apparent if only partially autonomous power to influence Basis (Renner 1949).

Within Legal Theory's own discourse of recent vintage, autonomously innocent or disparaging of this debate between Social Theories, arguments about the capacity of Law to rise above the vagaries of national cultures—arguments central to the issue of Convergence—have been conducted both at the general level of historical and economic theories, and at the specific level of case studies. In a modern return to the famous Savigny–Thibaut debate that accompanied the Napoleonic era's codification venture, Watson (1974) and Grossfeld (1990, 1986) have pressed their respective claims of Law's autonomy over or embeddedness within Culture largely on the basis of historical evidence. And in the contentious discussions over the inevitability of legal convergence in consequence of economic globalization, some of the Marxist framing of Basis and Superstructure has been reproduced by the Economic-Determinism camp in its own framing of Efficiency as an evolutionary inevitability (Gilson 2001), while the Path-Dependency deniers of necessary convergence (Roe 1994, Coffee 1999) in their turn reproduce both the older Cultural and the newer Habermasian/Lebenswelt arguments.

Preceding and underlying these issues lies the question of whether the very concept of globalization, in its cultural and societal as much as in its economic aspects, is consciously produced or not. While this debate is not directly at issue in the description of Convergence, it influences the perception of that process as undesirable or desirable, resistible or irresistible. The former, or Wallersteinian formulation (Wallerstein 1979), is well expressed by Santos (1995, 250f):

> In view of the hierarchical nature of the world system, it becomes crucial to identify the groups, classes, interests and states that define partial cultures as global cultures, thereby setting the agenda for political domination under the guise of cultural globalization.

The latter formulation finds typical expression in Slaughter, who welcomes Convergence on the assumption that the Thibaut/Watson view of Law's autonomy can be reconciled both with the Montesquieu/Savigny Organicist position and with Habermas' assertion of Law's capacity to tame System (Slaughter 2000, p. 1124):

> Constitutional courts—or any courts concerned with constitutional issues—will be forging a deeply pluralist and contextualized understanding of human rights law as it spans countries, cultures, and national and international institutions.… All this activity…requires recognition of participation in a common judicial enterprise, independent of the

content and constraints of specific national and international legal systems. It requires that judges see one another not only as servants or even representatives of a particular government or polity, but as fellow professionals in a profession that transcends national borders.

A third view of the underlying values and forces supporting the Convergence phenomenon contends that to the extent any conscious will drives it, it is that of the less-favored members of the international community of states and societies—members who see in the end result of Convergence a shortcut to a larger share of aggregate wealth and respect than they enjoy now. This is a theme well expressed by Teubner, who concludes a review of this argument with the assertion that '[g]lobal law will grow mainly from the social peripheries, not from the political centres of nation-states and international institutions' (Teubner 1997; p. 3). Within any of these 'peripheral' states, however, it may—and not paradoxically—be the social forces/classes standing to gain the most from that increase, which in turn drive this effort. As Schneiderman (2000; p. 757) puts it, '[t]his inchoate global law is being developed by economic subsystems ''in relative insulation from politics'' outside the usual centers of gravity of legal development.'

The substantive content of the law that is being diffused or is converging of course is as varied as the substantive content of law as such. Nevertheless, put in substantive and extreme terms, we can identify two principal societal forces converging on Convergence, and each is hinted at in the preceding citations: those involved in the evolution toward a new international order of Human Rights and those involved in the evolution toward a new international order of economic activity (Delmas-Marty 1998). While the drives toward these respective orders share some common features, they also evidence one essential distinction. The movement toward a new Human Rights Order is driven mainly by conscious social forces, often already successful in achieving the embodiment of their values in the formal legal orders of their home states and as a result deriving some of their own power from the political and economic power of those states. The movement toward a new Global Economic Order is driven in the main 'from below,' by market forces that generate the demand for their legal facilitation within those very market processes. This is not to deny that, especially at later stages in the evolution toward transnational markets, these forces evidence conscious use of state power to achieve that result; the role of TRIPS within the post-Uruguay international trade structure of the World Trade Organization alone is ample evidence thereof. And in some cases, of course, the two movements may themselves converge both as to the level of their conscious introduction into legal discourse and in their intended or unintended outcomes: whether the drive to ban the industrial-level fishing that catches dolphins in tuna nets is an issue of ecology or of protectionism may depend on the perspective of the observer.

3. *Diffusion as Osmosis*

3.1 *The Hegemonic Imposition of Law Upon Formal Equals*

The experience of Germany and Japan after World War II is a paradigmatic example of this phenomenon. Two elements mark these legal 'transfers:' their emphasis upon the more political and public branches of the law, especially of constitutional and administrative law; and the degree to which their success depended upon their relatively negotiated as against relatively coerced transplantation. Especially in Germany, but to an extent also in Japan, the vanquished nation's government no longer existed, and the occupation authorities, standing in for these governments, could be said to have negotiated with themselves. In fact, however, these countries' legal experts from the beginning were in essential discourse with those authorities, and their increasingly autonomous negotiation capacity quickly became evident and influential (Symposium 2000, p.1). As a result, one can trace a successful diffusion of these components of public law to that process, as especially the history of the Basic Law of the Federal Republic of Germany attests.

3.2 *The Liberal Economy As the Political Initiator of the Diffusion Process*

The experience, especially of Central European states after 1989, exemplifies this form of diffusion. Their political transformation, once they were out of the shadow of the Soviet Union, was an internal and not an imposed process, nor has the process been either uniform or completed (Mádl 2000). The diffusion of the legal superstructure of a liberal economy into their legal systems, however, has been driven largely if not totally by the purported requirements of the Western European and American economic actors whom these states have invited or been pressured by Western political actors to invite as participants (the title of a major US legislative initiative for the CIS states makes the point: 'The Freedom for Russia and Eurasian Economies and Open Market Support Act of 1992'). In the first stage of this diffusion process, a relatively uncontested acceptance of major legislative packages occurred; as the specifics of national needs became more apparent and the timing of economic liberalization within the larger context of democratization and resource redistribution became more contested, a second stage of partial rejection of these transplants and of more nuanced adaptation came

into being. At this time, it is too early to predict any eventual and in any event temporary equilibrium.

The difference between a diffusion process that is part of a clearly marked larger political transformation, as in the above examples, and one that is part of an incremental change of national markets toward more global units is one of degree as much as it is of kind. A principal differentiation between the two, however, lies in the intermediation, in the latter case, of global or at least supranational legal regimes in this diffusion process. The paradigmatic example of this situation is that of the evolution of the General Agreement on Tariffs and Trade into the World Trade Organization, and especially in the latter's increased scope of substantive coverage from trade through technology transfer (partly correlated with trade in services) to investment.

From the beginning of the postwar (II) period, efforts of goods-, services-, and capital-exporting states to encourage the creation of legal regimes in the importing states facilitative of these processes have been marked by this internationalization of the diffusion process. The first efforts were those of UN-supported agencies such as the abortive International Trade Organization proposed by the Havana Charter, but because of internal conflicts between these exporting states (and the reluctance of the United States to enter an international organization governing trade regimes (Diebold 1952), this ambitious effort was cut back in substance and in institutional power to the GATT regime (Jackson 1969, Jackson et al. 1984). As the subject matter of these efforts suggests, the regimes they produced within municipal legal orders were largely specific elements of public law requiring the reduction of state distortion of a global liberal regime supporting the trade in goods (and later, since the Uruguay Round, in services).

On the investment side, this effort was first internationalized at the private-sector level through the Investment-Code proposals of the OECD and then formalized at the supranational governmental level by the World Bank through its sponsorship of the treaty regime institutionalized in the International Conference on the Settlement of Investment Disputes (ICSID). Here, too, what was introduced into municipal legal regimes were largely specific public-law prohibitions; in this case, of expropriation measures without adequate compensation. In recent years, this international process has doubled back into national venues, with the introduction of networks of so-called Bilateral Investment Treaty regimes. These extend the obligation to provide national and most-favored-nation treatment of incoming direct investment to the point, at least in some of them (Vandevelde 1992), of forcing 'open-door' investment-entry regimes upon the signatory capital-importing countries (Dolzer 1995).

On the other hand, international organizations also play a role in the recent transformative experiences of countries of the former Socialist camp. This is evident in the trade sector (where the desire of these countries to gain the benefits of membership in the WTO in turn requires them to adopt the domestic liberal economic policies and their legal dress that constitute the *acquis mondiale* attributes of membership). It is most pronounced, and in this differs from the immediate post-WWII situation, in the sector of public finance, in which IMF and World Bank assistance is premised on liberal and to some degree politically controversial fiscal and monetary policy regimes.

All of these revolutions or evolutions have in common the relatively unilateral push of prepackaged legal goods onto these host states for relatively nonnegotiated and often nonnegotiable acceptance. This version of diffusion of law may be characterized pejoratively in neo-colonial terms, or it may be characterized as representing and meeting the wish of the recipient nations to gain the benefits of the existing international trade and investment regimes, however legitimated a wish internally along the spectrum of more or less democratic processes in formal and functional terms. In terms of the diffusion of law, however described, it is a unidirectional diffusion. The effort of developing countries in the 1960s and 1970s to negotiate a New International Economic Order, with its implication of a different outcome in the substance of what was diffused, did not succeed at that time.

3.3 The Competition Among the Providers of the Law Being Diffused

While all more or less committed to liberal economic regimes, the states providing the legal goods, in retail or wholesale packages, are not a monolithic legal block; indeed, in their variety they illustrate both Montesquieu's and Kahn-Freund's analyses. Whose offer is accepted, or whose wares are preferred, may depend on preexisting (including in colonial times) affinities of the respective legal systems; may depend upon tying agreements that lead the state proffering desired resources to condition those offers on the condition of acceptance of specific legal regimes; or may depend 'on chance and prestige' (Ajani 1995, 1998).

This competition has had the effect of recreating a degree of bargaining power for the law-importing states, both directly, as a consequence of gaining from this competition, and indirectly, as a consequence of the increase in knowledge of the specific wares and in the sophistication of the tests of their adaptability to the host system (Ajani 1998). This has been helped and to a degree encouraged by the acceptance by the World Bank and the International Monetary Fund of the relevance of appropriate specific legal regimes to the success of their own

primary missions. The policy implications of the IMF's change of approach are illustrative: '[T]he Legal Department…has recently expanded its work to include bankruptcy and foreign investment law….The Legal Department addresses these areas of need in close consultation with the legal staffs of other international organizations…in order to arrive at a reasonable division of technical assistance tasks and avoid duplication of work' (IMF Annual Report 1994, p. 183).

Whether these large-scale legal importations following the 1989 political transformations will be more successful (with success itself perhaps differently defined by the law-exporting and the law-importing states) as a result of this competition and coordination is not yet predictable (Kranjc 1993, World Bank 1995). It may be as much a mark of success as of failure that some initial providers of these materials now pay more attention to the difficulties of the transplantation exercise even in such fields, as Company and Capital Market Law, in which transplantation has historically been seen more as a carburetor transplant between automobiles than a kidney transplant between human beings (to the historical view, Klein 1904, p. 10; to the current self-criticism, compare Black and Kraakman 1996 with Black et al. 2000).

3.4 Convergence of Laws As the Outcome of Globalization of Economies

That in 1945 the United States was the only remaining powerful producer, capable supplier of capital, and large internal market posed a challenge to legal theorists speculating on the future shape and content of legal regimes in the postwar world, at least that industrialized portion thereof not within the Socialist camp. The introduction of American versions of major facilitative structures of law, such as antitrust law and capital-market regulation to nations and systems on their way to or hoping to reach similar levels of wealth production (such as the European Economic Community of 1958) fueled the discussion of legal convergence of legal systems (including of the large systems of the Civil Law and the Common Law (Merryman 1978, p.195) and specifically of convergence onto, even the reception of, American law (Wiegand 1991)). Not only substantive law, but changes in the underpinnings of law production in legal education, in the role of the legal profession, and indeed in legal culture itself often were deemed to occur as the almost inevitable byproduct of the unique position of US law and law-related institutions. Because of its economic situation, US law often had to face problems that would in time arise elsewhere because they occurred in the US first, ranging, e.g., from issues of privacy to issues of product liability in an age of mass production. This first-exposure condition made its law a natural object of attention as the underlying economic and social realities began to be experienced elsewhere.

At the same time, however, the imperfect analogy to the Roman-Law reception of medieval times was also noted, and was predicted to set limits on any one-sided convergence of law. Both tendencies were noted by Wiegand (1991, p. 247):

> American law is not superior to European law in the sense that ius commune was to the European law of that time….The lack of th[is] degree of superiority…, however, is compensated for in other areas; in particular by the political and economic dominance of the United States. This dominance was responsible for the dissemination of the new forms of business transactions as well as for the reception of American legal terms and legal thought….One aspect [of the reception of American law] is of particular importance; namely, the fact that…American legal developments have [first] followed the requirements of the post-industrial era and of the service-dominated society.

At present, we can already see the beginnings of a new set of convergence/diffusion phenomena. One is a convergence on a new European-level substance, driven largely by the unification and harmonization imperatives of the European Community (Markesinis 1994). At its extreme, this implies even the partial move of the core Common-Law regime, Great Britain, towards a European-wide and of necessity at least partially Civil-law system. If the well-established Common-Law system as found in Great Britain is experiencing 'Continental drift,' then the second phenomenon also may be on the way to observable status—the establishing of a mixed but largely Civil-Law European Community legal regime that can rival that of the United States in terms of sophistication as well as in power (Markesinis 2000).

On the level of the global economy and the law particularly relevant to its functioning, one type of tension between the leveling effects of product and service (including above all, financial) markets will arise. This tension may be seen as the collision between global and niche markets. As Ginsburg (2000, 840f) puts it

> The single-dimensional shift toward markets and formal rules implicates the issue of legal convergence. There are valid reasons for doubting that the shift toward rule-based law is inevitable, even in an era of global capitalism. Some economies will enjoy economic niches that would be hindered by greater reliance on legal ordering….From this perspective, globalization produces results that are similar to those of modernization theory, but does so as a result of specific political and economic pressures rather than because of a universal cultural shift. In other words, reliance on law reflects local political outcomes….[M]arket solutions and particular policy responses are still being contested, and any legal convergence will remain incomplete as long as this is the case.

Another way to formulate this tension is to focus on the enduring power of political forces at the national level to immunize national markets and economic institutions from the bite of unified formal legal rules. As one writer illustrates this approach: 'Although Japan and the United States of course have differing institutional structures, if there is one place that theory would predict convergence,…[corporation law] might be it. But convergence has not occurred….Th[is] limited convergence of…rules helps elucidate recent claims in the theoretical literature that convergence of rules may not necessarily lead to convergence of corporate structures' (Symposium 2000, 5ff, Coffee 1999).

Seen this way, the convergence of law on a set of rules comprising a mix of relatively uniform (regulatory) and relatively diverse (facilitative) components may still best be explained, and predicted, by the juxtaposition of the original epigrammatic quotations cited at the beginning of this entry.

Machiavelli, Niccolò (1469–1527)

Machiavelli became a political writer because of his failure as a practical politician. For this reason his political thought does not centre on the systematic development of principles of worthy life or norms of a just society. Instead it represents an attempt to describe practical problems, with recourse to historically comparable situations as paradigmatic challenges and to develop general rules for successful political activity from these examples. In *Il Principe* (The Prince) Machiavelli developed these rules principally in the perspective of the political activist, while the *Discorsi* (Discourses on Livy) place more emphasis on the long-term development perspectives of political communities. In this respect two differing perspectives, from theories of action and from theories of structural analysis can be found side by side in Machiavelli's political thought. When Machiavelli addresses potential political activists his considerations are developed for the most part from a perspective of action, whereas when he addresses educated political observers, the emphasis is more on structural aspects. In all his writing he emphasised that his reflections were based on two sources; his own political experiences as well as the 'wisdom of the ancients': the works of the classical writers and historians. The affirmative allusion to classical antiquity identifies Machiavelli as a representative of Humanism; however his judgement of classical knowledge measured against his own experiences goes beyond the conventions of Humanism and classifies Machiavelli as the first modern political thinker in early modern Europe.

1. Biography and Work

Machiavelli was born in the Santa Trinità quarter of Florence on May 3, 1469, as son of a jurist and minor political officer. Little is known of his childhood or the early years of his professional life. The only certainty is that he received a humanist education in accordance with his father's wishes which was to enable him a career in the Florentine administration. In 1498, after the execution of the Dominican monk Girolamo Savonarola, who had tried to reform the republic on the basis of a moralization of the city society orientated by Christian ascetic ideals, he was voted secretary of the second chancery (domestic administration) and later additionally secretary of the council of the Ten (foreign and defence matters). Both posts, which Machiavelli held until his dismissal from office in 1512, allocated him the position of a middle-ranking political officer. However, since the members of the council of the Ten were elected only for short periods his political influence was considerably greater than this position would suggest. He undertook a number of important missions, for example, to the French court, to the Holy Roman emperor Maximilian, to the Roman Curia, and to Cesare Borgia, who had conquered a new duchy in Romagna shortly before. His task on these missions was to explain Florentine politics and also to make enquiries to assess the aims and intentions of the people he visited. Through this role a particularly trusting relationship developed between Machiavelli and Piero Soderini, voted *gonfaloniere a vita* (chief magistrate for life), in 1502, who entrusted Machiavelli repeatedly with the most difficult and confidential tasks.

The most important of these was the project to recapture Pisa, which Florence had lost in 1494. After all attempts to retake the port with the help of mercenary soldiers had failed, Machiavelli was commissioned to establish a Florentine militia, which forced Pisa into a capitulation within 3 years. The ensuing victory celebrations in Florence appeared to represent the climax of Machiavelli's political career. His exceptional position within the political administration of Florence was also expressed in the fact that he tried to develop a more long-term strategy in a series of political memoranda. This strategy was based on a lasting stabilization of the republican system on the inner front, and aimed for the preservation of Florence's political sovereignty on the outer front. Through his notorious emphasis on the exemplary nature of Rome he sought to develop an alternative conception of the republic to Savonarola's Christian moralization program. Here he was not concerned with a political program of action, but with a political ideology from which Florence could gain confidence and courage in difficult and threatening situations.

Due to the energy and decisiveness Machiavelli showed in the tasks allotted to him he advanced rapidly to the *spiritus rector* of the Florentine republic and stood out especially in contrast to the hesitations and procrastinations of other Florentine politicians. He always held a strong aversion to all forms of waiting and delaying, which made him a sharp critic of every policy of neutrality. His singular importance in Florentine politics was also recognized by his contemporaries, seen in the fact that he was the only politician

to be removed from office when the Medici returned to Florence with the support of Spanish troops in November 1512, apart from the chief magistrate Soderini. Shortly afterwards Machiavelli was suspected of taking part in a conspiracy against the Medici. He was thrown into prison and questioned under torture, but there was no proof against him. He was freed in the course of a general amnesty on the occasion of Giovanni de' Medici's election to Pope, on condition that he no longer entered the City of Florence and did not hold any political office.

Machiavelli then began composing political writing on his estate in San Andrea in Percussina. At first this was more as a compensation for his forced political inactivity, but it soon aimed to bring his name into conversation among the then ruling groupings in Florence. He gained the reputation of an experienced and well-versed politician that could be entrusted with practical political tasks once again. The Medici appear to have mistrusted him to the end, however, and he received only a few unimportant missions along with permission to enter Florence again. In the meantime Machiavelli had made himself a name as a writer, with the comedy *Mandragola* (1517) among other writing, and was commissioned to write a history of Florence in 1519, which summarized all the existing annals and chronicles. He completed his *Istorie Fiorentine* in 1525, and it was a masterpiece of political history, scanning from the time of the migration of peoples to the death of Lorenzo de' Medici in 1492. Machiavelli had previously written *Il Principe* and the *Discorsi*, which both remained unpublished until after his death, but which circulated as copies among the political intellectual circles of Florence during his lifetime. In 1520 Machiavelli also wrote the *Dialogo dell' arte della guerra*, a dialogue modeled on a humanistic form on the reform of Italian warfare, as well as the historical novel *Vita di Castruccio Castracani*, in which he describes the conditions of political success using the example of a political adventurer from Lucca. Machiavelli's life took a paradoxical turn; it was only his failure as a political actor that forced him into his existence as a political writer, through which he won success and recognition in his lifetime, and fame and infamy after his death.

Machiavelli himself, however, valued practical politics more highly than political writing, which is the reason why he immediately ran for political office after the Medici were successfully ousted in 1527. For many he appeared by now, however, to be one of the Medici's faithful and he lost the vote for the post he had held until 1512. Machiavelli did not survive this disappointment; he fell ill with acute peritonitis and died a few days later on the June 21, 1527 in Florence. Shortly before his death he is reported to have told friends of a dream he had, in which he saw a crowd of miserable and ragged-looking men, who explained that they were on their way to paradise. Then he saw a group of noble and serious-looking men, among them the great classical philosophers and historians Plato, Plutarch, and Tacitus, who were damned and on their way to hell. Machiavelli is reported to have said to his friends that he would rather discuss politics in hell with the great men of antiquity than die of boredom with the blessed and holy in paradise. 'Machiavelli's dream' is not substantiated and most likely expresses the impression which some of his contemporaries and many of his successors had of him. Yet it does illustrate certain characteristics of Machiavelli's life and thinking—his enjoyment of discussing political problems, his veneration of classical philosophy and historiography, and his contempt for lives given over to Christian contemplation; in fact so well that it has been used and abused in research literature on Machiavelli throughout the years.

2. *Machiavelli as Political Scientist*

What allows us to characterize Machiavelli's political writing and his suggestions for successful politics as scientific, and to understand Machiavelli as the founder of a form of political science not derived from philosophical-theological norms, but based on an independent rationality of political action? Neither the sympathy he held all his life with the republic nor the dry irony of his descriptions, neither the cynicism of some of his advices nor the strict internal worldliness of his ideas are sufficient, but only the specific method with which Machiavelli ordered his material and developed his ideas. It is a process of contrasting two terms or options that are so arranged as to include and sort antithetically all possibilities on one theoretical level. States are drawn up either as republics or autocracies, begins the argumentation of *Il Principe* and the *Discorsi*, and everything that falls between these two variants can be ignored. Among the autocracies, according to the further specification in *Il Principe*, there are hereditary and newly acquired forms. Among the newly acquired forms there are in turn those that have come to their conqueror as a result of his virtue (*virtù*), whilst in the other cases fortunate circumstances (*fortuna*) were of the most importance. And the latter is the very subject of *Il Principe*: the government of newly acquired autocracies gained through fortunate circumstances. The claim to validity of Chaps. 15–19 of *Il Principe*, in which Machiavelli advises the use of pretence and lies, deceit and cruelty, relates to this specific situation, and is in no way to be understood as a general rule of political success, a fact which is often overlooked in the literature on Machiavelli.

The process of antithetical contrast not only represents the material ordering principle in Machiavelli's political thought, but also decides the characteristic style of his thinking and arguments: one must decide on one option or the other, and every attempt to avoid this decision or to leave it open is the beginning of political failure. Thus, Machiavelli turns away from

the characteristic thinking and pattern of argument of Humanism of both–and (*et–et*) and replaces it with an either–or (*vel–vel*), which determines a decision. Although Machiavelli takes at the decision its own value as a decision at various points, *Il Principe* and the *Discorsi* can be read over long stretches as giving advice on making the right decision. To this end he adds comparative methods to the process of antithetical contrast, with which he examines the results and prerequisites of examples from his own time and from classical history. One can therefore describe Machiavelli as the founder of comparative political science. Others before him had argued comparatively, yet always within a given normative frame, whereby the comparison had merely the function of testing out political options as to the realisation of the normative given. Machiavelli on the other hand seeks to work without such moral-philosophical or theological-based guidelines and develops his suggestions for action only out of the comparison, whereby the success of the action or the project provides the scale. What success is, is determined for Machiavelli in view of the prevailing conditions of political action, which are a given factor for the political activists and not optional. He compares, for example, Rome and Sparta, which he recognizes as extremely successful political projects, and which can therefore serve as political models. The more exact comparison shows, however, that Sparta existed longer than Rome, but that the latter had a greater capacity for expansion in the confrontation with outer enemies. Since the Italian states were confronted with massive French and Spanish efforts towards expansion during the early sixteenth century, which they had to tackle on the military front in order to retain their political sovereignty, it was in Machiavelli's view imperative that they take Rome as a model. The recent defeats of Venice, in its fight for the Terraferma were his proof that an oligarchic republic was not a successful model for solving Italy's political problems under the conditions of the time.

The comparison process developed by Machiavelli represents an early variant of the fourfold-point scheme used in modern sociology. Here, Machiavelli uses two contemporary cases, and two from classical antiquity, each chosen according to the model of antithetical contrast and in an attempt to find as paradigmatic a description of the case as possible. Thus, Sparta and Venice are examples of oligarchic republics, Rome and Florence on the other hand represent republics in which the citizens are allowed a broader participation (*governo stretto* vs. *governo largo*). The contrast of the two contemporary and historical examples serves, among other things, to analyze contemporary situations, in which the political process is not complete, against the background of the historical cases which are completed and whose effects and side effects, intended or unintentional, can be fully overviewed. Should the historical cases only differ from the contemporary in the fact of complete and incomplete information, classical antiquity would not be a real comparison, but merely an addition to the present. For Machiavelli, however, classical republics differ from contemporary republics universally through their specific civil-religious foundation. He warned repeatedly of the politically negative effects of a Christianity strongly influenced by contemplation, and saw Christianity as responsible for the fact that there were fewer republics in his time than there were in classical antiquity. Since Christianity, or its prevailing interpretation, extolled the virtues of humble citizens sunk in contemplation rather than those of men of action, it had 'rendered the world weak and a prey to wicked men, who can manage it securely, seeing that the great body of men, in order to go to Paradise, think more of enduring their beatings than in avenging them.' In contrast, he praised the religion of the ancient Romans, which had played an important part in 'commanding the armies, in reuniting the plebs, both in keeping men good, and in making the wicked ashamed.' Machiavelli saw religion as an unavoidable element of people's belief systems, and attempted to explain the differences between classical and renaissance republics in view of this political-cultural dimension. With respect to his own time Machiavelli made several references to the example of Savonarola, who carried out his project of moralizing Florence with the help of sermons and prophecies, with a complementary program of widening political participation to the *petty bourgeoisie*. Machiavelli seems to have developed certain sympathies with this project in hindsight, mentioning Savonarola several times in positive comments. His only criticism is that he was an 'unarmed prophet' who did not have the means to constrain those who did not believe in his sermons and prophecies into obedience at the decisive moment, using armed force. He would have had great sympathy for the appearance of an 'armed prophet' as a political reformer or as a founder of a state, as which he saw Moses for example. Machiavelli blamed in the main the pope and the Roman Curia for the fact that Italy had become a plaything for foreign powers, in the first place through the degeneration of morals spread from papal Rome throughout Italy, and secondly through the Curia's vested interest in a political fragmentation of Italy. Both these ideas were taken up in the Italian *Risorgimento* and made fertile for lay anticlerical politics.

3. *Machiavelli's Republicanism*

However, since Machiavelli rather doubted the possibilities of fundamental political renewal through religious reforms, he placed his hopes in political regeneration of Florence and Italy through the reform of the military, which explains why the subject of war and military organization is present throughout the whole of his writing. At first he was naturally concerned with the reform of Italian military organisation

itself, in the course of which he was in favour of replacing the mercenaries with a militia recruited within the area of rule. He also intended to use the increasing importance of drawn-up infantry on the European battle fields to refer back to the Roman model, in as far as the Romans also owed their military successes more to the infantry than to the cavalry. Aside from this he was interested in the political effect of military reform within the state; the duty of citizens to defend their city and their willingness to involve themselves existentially in political projects. He reserved his harshest criticism for mercenary troops, whom he described as cowards and traitors. Machiavelli's ideas on military reforms played a particular role in Europe after the French Revolution and in postcolonial Africa in the 1960s and 1970s.

Machiavelli's preference for Rome over Sparta, which was based on Rome's greater capacity for military expansion, also meant his taking sides in Florence's inner conflict around its type of constitution and the level of political participation. In *principal* there were two opposing parties, one of which was in favor of limiting access to political power to the rich and noble families, in other words the town patricians, while the other favored a stronger involvement of the middle classes, or the urban *petty bourgeoisie*. Since the uprising of the Florentine wool cloth workers in the late fourteenth century the conflicts in Florence revolved increasingly around this problem, which overshadowed the previous political lines of conflict between single families and their clientele groups. As sharply as Machiavelli rejected the power struggle of the clientele groups and factions, he defended the struggles between the social levels and classes for power and influence as a fountain of youth, which represented an irreplaceable form of revitalization of republican energies. He wrote that those who condemned the conflicts between nobility and the common people and attempted to prevent them through legislation not only limited the capacity for expansion of the republic, but robbed it of its most important source of life. We can see in this an early form of party theory, or rather a theory of the integration of political communities through conflict. Machiavelli saw, however, less value in the possibility of defending certain particular interests than in blocking degeneration and corruption by institutionalizing the inner conflict. Thus, he admits to the middle-classes that they have a greater interest in retaining liberty than the town patricians. However, the liberty to which he refers at this point is not the (liberal) freedom to go about their own interests undisturbed, providing these interests are not in conflict with those of the republic, but the (republican) freedom of political participation and civic engagement. With Polybios and Cicero as his starting point, Machiavelli developed a conception of a hybrid constitution, which was not (as in Montesquieu) oriented at a varying control of power to ensure individual freedom, but at the institutionalization of political conflicts to prevent moral degeneration and party spirit. Machiavelli forms the beginning of the constitutional and party theory of modern republicanism. This aspect of his work, to which Spinoza and Rousseaualready referred, has only been rediscovered and examined in the most recent Machiavelli research, particularly through the work of Gilbert (1965) and Pocock (1975).

4. *Reception*

For a long time the Machiavelli reception was dominated by a concentration on Chaps. 15–19 of *Il Principe*, in which Machiavelli discussed breaking one's word and lying, pretence and treason, violence and cruelty as means of ensuring political rule as to their efficiency, and recommended their purposeful use in rejection of the theological moral-philosophical political theory of the Scholastics and of Humanism. The Machiavelli critique of the Antireformation (Cardinal Pole), the Monarchomachs (Gentillet), and in particular of the Enlightenment (Friedrich II of Prussia) concentrated above all on these passages and thereby brought about the dominant perception of Machiavelli, which is of a theorist of political scrupulousness. The popular image of Machiavelli as 'teacher of evil' and 'spoiler of politics' has been decidedly influenced by this. Aside from this, Machiavelli's writing was received in Italy and Germany, where the nation–states were formed at a later date than in other western countries, as a theory of state-building; Fichte's and Hegel's image of Machiavelli in particular show clear signs of this. Under the influence of Fascism and National Socialism there was further intensive debate on Machiavelli in these countries. He was exemplified and celebrated as a forerunner of fascist politics by several writers while others, for example, König (1941) criticized him as a utopian and romantic, who understood little of real politics and, therefore, chased illusions and so represented the prototype of a fascist intellectual. Thus, the discussion of Machiavelli has always served to survey the various contemporary political problems. Like no other theorist in the history of political thought, he provokes his interpreters to deal with the questions of the present in the light of his own ideas, and to project his ideas onto those of the present. This has often led to a careless handling of the material with regard to its interpretation and analysis, but is on the other hand a precondition that a work should provoke such lively and extreme controversies in research literature as that of Machiavelli.

Macroeconomic Data

Macroeconomic data are aggregate data relating either to sectors of the economy, i.e., specified groups of economic units such as households or financial institutions, or to the economy as a whole, i.e., the entire set of economic units resident in a country. They measure the aggregate values of economic flows or stocks associated with economic activities such as production, consumption, investment, and financing. At the level of the economy as a whole, obvious examples are national income and product, or total exports and imports. At a sector level, household income and consumption, and government income and consumption provide examples. Macroeconomic data also include the aggregate values of stocks of assets such as machinery, structures, and land.

Macroeconomic data are used by businesses, the government, financial markets, the press, and the general public to monitor, and assess, changes taking place within economy. They are also used for purposes of economic analysis and econometric modeling and forecasting. They provide the information needed for purposes macroeconomic policy-making and decision taking by governments and central banks. The collection, processing, and publication of macroeconomic data are usually carried out by national statistical offices and other government agencies. In many countries, the central bank is responsible for the collection and publication of a wide range of macroeconomic data, especially financial statistics and balance of payments statistics, and sometimes also the national accounts.

Many flows such as income and consumption can be defined in different ways so that their values depend on the particular definitions and conventions adopted by those responsible for their collection and publication. As the various economic activities taking place within an economy are interdependent, the associated macroeconomic data are also interdependent. It is therefore desirable that individual macroeconomic variables should be defined and measured consistently with each other within an overall statistical framework that uses the same economic concepts, definitions, and classifications throughout.

Macroeconomic data are inevitably subject to error. Complete information is seldom available on all the units concerned. Most macroeconomic data are not based on censuses or surveys specifically designed for the purpose. Many are essentially estimates derived from data collected for other reasons, such as administrative or tax data. One of the arts of the statisticians responsible is trying to reconcile inconsistencies between data drawn from different sources. The appearance of data from a new source may lead to considerable revisions in previously published statistics.

As one of the main uses of macroeconomic data is to provide up-to-date information for economic forecasting and economic policy-making and decision taking by governments and others, there is considerable pressure from users to obtain the data as quickly as possible. There is a trade-off, however, between timeliness and reliability when the underlying basic data only become available gradually over a period of time. First estimates based on incomplete data can

only be provisional. The earlier they are made and released, the greater the risk that they may have to be substantially revised later when more data become available. Revisions may be acceptable to users as the price to be paid for timely data, but occasionally they may be a major source of embarrassment to the government agencies responsible.

1. The Main Macroeconomic Aggregates

1.1 GDP and Gross Value Added

The objective is to measure the output produced by all the economic units resident in a country. Measuring the output of a single enterprise is straightforward, but aggregating the outputs of different enterprises raises a further complication. From the point of view of the economy as a whole, not all outputs are final because some of the outputs produced by some enterprises may be sold to other enterprises to be used up again as inputs into further production. These products are 'intermediate,' not final. They are not available for consumption by households or governments, for augmenting the capital stock, or for export. In order to measure the contribution of each enterprise to the economy's final output it is necessary to deduct from the value of its own output the value of the intermediate products it consumes. The difference is described as 'gross value added.'

Value added can be measured either before or after deducting the depreciation on the capital goods used in production. If before, it is described as 'gross,' if after, it is 'net.' Gross Domestic Product, or GDP, is defined simply as the sum of the gross values added of all the enterprises resident in an economy. GDP is probably the most important single macroeconomic aggregate, being widely used throughout the world as a key indicator of the level of economic activity. It is measured quarterly as well as annually, its movements being factored into their price and quantity components. The price movements measure inflation while the quantity movements are used to measure rate of real economic growth and cyclical fluctuations in the economy.

1.2 From GDP to National Income

The link between aggregate measures of production and income is established by the fact that the incomes generated by production are all paid out of value added. As operating profits are the residual amount remaining after all the other incomes have been paid, the sum of all the incomes generated by production, including operating profits, must be identical with value added. At the level of the economy, the sum of the incomes generated by production is described as Gross Domestic Income, or GDI, which is equal in value with Gross Domestic Product by definition.

Gross National Income, or GNI, is derived from GDI by adding the incomes received by residents from foreigners and deducting the incomes paid to foreigners. (Unfortunately, GNI has traditionally been described as Gross National Product, or GNP, although it is an income rather than a production concept.) Net National Income is obtained by deducting depreciation from GNI. It is often described simply as National Income.

The numerical identity between GDP and GDI means that they can be estimated from two quite different sets of data, namely income or production data. Because income data are often incomplete and unreliable, most countries place more reliance on GDP measured from the production side using data on inputs and outputs collected in industrial inquiries. There is also a third approach that uses expenditures on final outputs, namely household and government consumption, capital formation, and exports less imports. Estimates from the production, income, and expenditure sides provide checks on each other. In practice, there are usually significant statistical discrepancies between them that may be reduced by adjusting the data, but many countries find it impossible to eliminate statistical discrepancies altogether and are obliged to publish them.

2. From National Income to Economic Accounting

Defining and measuring a few aggregates at the level of the economy as a whole is only one small part of macroeconomic measurement. Macroeconomic analysis and policy making requires sets of data covering many economic variables and activities measured at various levels of aggregation.

The development of comprehensive macroeconomic data systems dates back to the 1930s and 1940s. It was stimulated by two factors, the economic depression and the Second World War. The depression and the switch from peacetime to wartime production both led to more active economic policy making and intervention than previously, but such policies also require more information. The relevant macroeconomic theory and models were also being developed at around the same time.

The macroeconomic data systems came to be known first as national accounts and later as economic accounts. The publication of official estimates of national income aggregates for the USA started in the 1930s, but it was not until the Second World War that proper accounts began to be published. In the UK, the first set of official national accounts was compiled in 1941 by Meade and Stone at the request of Keynes. Towards the end of the war, very close links were established between the experts in the UK and the USA, which led to the development of the international systems described below. The development of

these systems was a collective achievement by a number of economists from Europe and North America, but pride of place is generally given to Richard Stone who was awarded the 1984 Nobel Prize in economics for his work in this field. Stone took the leading role in elaborating the international systems published under the auspices of the Organization for European Economic Cooperation, or OEEC (later the OECD), and the United Nations.

Stone focused on transactions between economic units as the elementary items from which macroeconomic data systems have to be constructed. Transactions can take very many forms. For example, the ownership of some goods or assets may be exchanged between A and B, or some service be provided by A to B, accompanied by a counterpart flow, usually of a financial nature, such as the payment of money by B to A. The objective of economic accounting is to organize, classify, and aggregate the countless transactions taking place within an economy in a way that is informative and useful for purposes of economic analysis and policy making. The challenge that this presents is very different from deciding how to define National Income. Stone observed that transactions could be classified according to the type of economic units involved, the type of economic activity with which the transaction is associated, and the nature of the items exchanged. By cross classifying with respect to these kinds of criteria, quite elaborate data systems can be constructed.

In 1953, the United Nations published its '*System of National Accounts and Supporting Tables*,' or *SNA*, intended for use by all countries in the world except the Soviet Union and other Socialist countries who preferred their own Marxian version referred to later. At the same time, the International Monetary Fund, or IMF, was developing closely related international standards covering Balance of Payments Statistics, Financial Statistics, and Government Statistics. Two major revisions and extensions of the UN *SNA* were published in 1968 and 1993. The revision completed in 1993 was conducted jointly by all the major international economic agencies—UN, IMF, World Bank, the Organization for Economic Cooperation and Development (OECD), and the European Union (EU). The 1993 version of the SNA is the system now used by almost all countries in the world as the norm or standard for their own accounts, including former Socialist countries who abandoned their Marxian system at the time the 1993 *SNA* was being finalized.

3. *The International System of Macroeconomic Accounts, or SNA*

The first paragraph of the 1993 edition of the *SNA* reads as follows: 'The System of National Accounts (*SNA*) consists of coherent, consistent and integrated set of macroeconomic accounts, balance sheets and tables based on a set of internationally agreed concepts, definitions, classifications, and accounting rules. It provides a comprehensive accounting framework within which economic data can be compiled and presented for purposes of economic analysis, decision taking, and policy-making. The accounts themselves present in a condensed way a great mass of detailed information, organized according to economic principles and perceptions, about the working of an economy. They provide a comprehensive and detailed record of the complex economic activities taking place within an economy and of the interactions between different economic agents and groups of agents, that take place on markets and elsewhere.'

3.1 *The Structure of the SNA*

The accounts may be compiled at any level of aggregation. The *SNA* divides the economy into a small number of sectors, such as the household, government, and financial sectors, which may in turn be divided into subsectors. While it is appropriate to describe the accounts for the total economy as 'national accounts' this description is not appropriate for the accounts of individual sectors. For this reason, the general expression 'economic accounts' is preferred.

The economic units resident in the rest of the world can also be viewed as a sector. However, an individual country cannot compile sets of accounts for the rest of the world. Instead, it merely records transactions between resident and nonresident units in a special account, a 'rest of the world account.' This account is essentially the same as a Balance of Payments Account, which can thus be seen to be an integral part of the overall system of economic accounts.

3.2 *The Sequence of Accounts*

Each account in the *SNA* relates to a particular kind of economic activity, such as production or consumption. The entries in the accounts consist of the aggregate values of particular kinds of transactions conducted by the units engaged in those activities. For example, a production account records the purchases of inputs and sales of outputs which producers make as a result of engaging in production. The accounts do not record the activities in a physical or technical sense.

Each account has two columns headed 'uses' and 'resources.' As a general guideline, transactions are recorded under 'resources' if they increase the unit's financial resources, for example sales of outputs, and under 'uses' if they reduce them, for example purchases of inputs. The counterpart changes in money or other financial assets are recorded in the financial account. The production, consumption, and capital accounts record real economic activities in the economy while the financial account deals with the financing of those

activities and also transactions of a purely financial nature.

The purpose of compiling economic accounts is not to have tidy book keeping. By comparing the total values of the 'uses' and 'resources' in an account, the outcome of the associated activity can be evaluated from an economic point of view. The differences between the two totals are described as 'balancing items.' Value added, profits, disposable income, and saving are examples of balancing items that can only be measured within an accounting framework. These balancing items are typically the most interesting and important items within the accounts as they encapsulate a great deal of information about the activities in question. Indeed, the most important single reason for compiling economic accounts is to derive the balancing items. GDP itself is a balancing item equal to the difference between the values of total output and total intermediate inputs in a highly simplified production account for the total economy. GDP is an accounting construct. It is not a flow that can be observed directly.

The accounts following the production account of the *SNA* portray the distribution of the incomes generated by production and their subsequent redistribution by government through taxation and social insurance. They are followed by an account showing expenditures on consumption out of disposable income whose balancing item is saving. The remaining accounts of the *SNA* consist of the capital account and a financial account. Detailed financial accounts that track the flows of funds between different sectors and subsectors are an integral part of the *SNA*, specimen flow of funds accounts being given in the 1993 *SNA*. Finally, the *SNA* also includes balance sheets in which the values of the assets owned by the various sectors are recorded together with their liabilities.

A brief sketch of the *SNA* has been given in the above paragraphs. It is a complex sophisticated system. The *SNA* provides a conceptual framework within which macroeconomic data relating to a very wide range of economic activities can be recorded. It imposes a single set of economic concepts, definitions, classifications, and accounting rules throughout so that all the diverse activities are recorded in a mutually consistent way. Both national and international statistical agencies have long recognized the importance of imposing this kind of discipline so that users have macroeconomic data that are mutually consistent conceptually. It also helps to ensure that they are consistent numerically.

4. Socialist Economic Accounting

National Income has a long history. Income has not always been clearly distinguished from wealth. Income is a flow that can only be measured over a period of time, such as a week, month, or year, whereas wealth refers to the value of a stock of assets that can be measured at a point of time. Attempts to estimate the Nation's Income go back over three centuries to the work of William Petty (1662). However, he was more concerned with measuring the wealth of the nation and taxable capacity than income. The same preoccupation with wealth rather than income is found a century later in Adam Smith's *The Wealth of Nations* (1950).

The extent to which macroeconomic data can be influenced by ideas, concepts, and definitions is vividly illustrated by the distinction that Smith introduced between 'productive' and 'unproductive' labor. Smith argued that only workers who produced goods, as distinct from services, should be regarded as productive because only goods could add to the stock of the nation's productive capital equipment. This distinction was followed by many classical economists in the early nineteenth century, including Karl Marx in *Das Kapital* (1867). One far reaching consequence was that it was built into the Marxian based system of national accounting adopted by the former Soviet Union and subsequently by other centrally planned socialist countries. In the international version of that system developed after the second world war under the auspices of the United Nations it is stated that: 'All fields of productive activity are based on material production, which is primary in comparison with the activities rendering services. The global product and national income are produced in the material sphere … The wealthier a community is, the more material goods it produces … *The non-material sphere creates neither product nor income*' (*Basic Principles of the System of Balances of the National Economy*, United Nations, Statistical Office 1971). This makes strange reading when about two thirds of the GDP of most developed countries consists of the production of services. This system of accounting was not abandoned by the countries concerned until the early 1990s.

5. Household Production and GDP

The treatment of household production in GDP is a contentious, almost a political, issue. As GDP is a measure of the aggregate value added created by production, it might be presumed to be a reasonably objective statistic. However, there are two kinds of production: production whose output is destined for the market and nonmarket production whose output is not. The output from nonmarket production is consumed by the same units that produce it. GDP consists mainly, but not entirely, of the value added created by market production. Its absolute size depends on how much nonmarket production is included, this being very much a matter of convention.

In order for any activity to count as productive in an economic sense, the output to be marketable so that the production can be organized on a market basis. Many of the activities undertaken within households

satisfy this basic criterion but the outputs are not actually offered on the market being retained for consumption within the household. For example, households may grow their own food or other agricultural products. In poor countries, a large part of the total production and consumption not only of food but other basic products may consist of nonmarket production for their own consumption.

GDP covers all market production (even if it is illegal) and the SNA keeps track of all the associated income and consumption flows, which are usually monetary. By convention, it has also been agreed that GDP should include the production of any goods produced for own consumption. These include the produce of gardens and other small plots cultivated by households in developed countries and not only the output of subsistence agriculture.

In most countries, however, most of the production for own consumption within households consists of services such as cooking, cleaning, and childcare. By convention, this service production is excluded from GDP (even though the production of housing services for own consumption by owner-occupiers is included). As most of these household services may be produced by women, this exclusion has been criticized on the grounds that the real contribution of women to the economy's production is thereby grossly underestimated. Using the broad criterion of economic production given above, this criticism is valid, as all the household services concerned can be produced on a market basis by paid servants, nurses, teachers, chauffeurs, hairdressers, etc. Unofficial estimates suggest that the unrecorded production of household service for own consumption could equal a half to two thirds of GDP as conventionally defined. If the definition of GDP were changed to include this production, GDP would rise dramatically.

On the other hand, there are some users and economists who would prefer GDP to move the other way by omitting all production for own consumption completely and confining GDP strictly to output from market activities. One reason is the practical difficulty of estimating the quantity of such output and valuing it in an economically meaningful way. The value of the production of household services is speculative and can vary greatly according to the assumptions made about how to value it. A more fundamental reason is that market and nonmarket productions do not have the same economic significance. When goods or services are produced for the market, there may be disequilibria in the form of excess supply or demand precisely because the suppliers and consumers are different economic units. National accounts were developed to provide aggregate macroeconomic data relating to market activities for purposes of fiscal and monetary policy that are mainly concerned with phenomena such as unemployment or inflation that are symptoms of market disequilibria. Some users would therefore prefer accounts based only on market transactions. To move the other way by including large imputed non-monetary flows attributable to nonmarket production within households would greatly reduce the analytical usefulness and policy relevance of the accounts for most users.

The present concept of GDP is a somewhat uneasy compromise resulting from the desire to have a single multipurpose measure of GDP satisfying the demands of different users. Alternatively, it would be possible to define a hierarchy of different GDP's ranging from a strictly market based concept to one that included every kind of own account production, but the existence of alternative GDP numbers might simply create confusion.

6. *Some Specialized Macroeconomic Data Systems*

There are several specialized macroeconomic data systems that focus on particular sectors or types of economic activity: for example, balance of payments statistics, flow of funds statistics, input-output tables, labor force statistics, and capital stock statistics. Although these systems may have originally developed independently of each other and the *SNA*, a common set of concepts and classifications is needed when data from different systems have to be used together.

6.1 *Labor Force Statistics*

As labor force statistics concern people, it might be presumed that the links with the *SNA* would be tenuous. However, the concept of the labor force, as specified in the international standards published by International Labor Organization, relies directly on the production boundary used in the *SNA*. The main conceptual problem is to determine which members of a household are economically active. This is essentially the same issue as that considered in the previous section, as only those members of a household who are engaged in activity that falls within the production boundary of the *SNA* are treated as being members of the labor force. The size of the labor force, as well as GDP, depends on the conventions adopted with regard to the production boundary. Persons engaged in the production of services for own consumption within the household do not form part of the labor force, whereas those engaged in the own-account production of goods are included. The latter are treated self-employed while the former are not. The concept of employment, which is linked to that of the labor force, clearly refers to persons who receive some kind of remuneration for working in the market sector that generates most of GDP.

6.2 *Balance of Payments Statistics*

Balance of payments statistics record all flows of goods and services, income and capital between an

economy and the rest of the world. International standards for balance of payments statistics are set by the International Monetary Fund, or IMF, in its *Balance of Payments Manual*, the fifth edition of which was produced in 1995. It is intended to be fully consistent with 1993 *SNA*.

The balance of payments is single comprehensive account that records all the transactions between the economic units resident in a country and units resident in the rest of the world. It is essentially the same as the rest of the world account in *SNA*. The balance of payments is divided into four subaccounts. First, a distinction is drawn between current transactions and those relating to assets. This matches the distinction between the current and the accumulation accounts in the *SNA*. The current account of the balance of payments is then subdivided to distinguish trade flows from income flows. The accumulation account is subdivided to distinguish transactions in nonfinancial assets from those in financial assets.

Keeping track of transactions between resident and nonresident units poses special problems. Many of the concepts and definitions in the *SNA* need further precision and refinement in a balance of payments context. Even the concept of residence is becoming increasingly blurred because of increased mobility due to fast air transport and instant international communications through the Internet. The concept of an export or import is also not straightforward when goods are transported through third countries en route to their final destination or are shipped abroad temporarily for processing.

Trade flows may be expected to be among the more reliable items recorded in balance of payments statistics. It is possible to have a check on them because exports from A to B as recorded by A should equal imports by B from A as recorded by B provided they are consistently valued. There are many examples, however, to show that there may be serious inconsistencies between the two sets of data, even for neighboring countries such as the USA and Canada. These difficulties are compounded if there is a lot of smuggling. The difficulties of keeping track of financial transactions can be considerably greater with the emergence of world financial markets on which financial assets are traded continuously and instantaneously as a result of modern communications technology.

As in the *SNA*, the entries in the balance of payments that are usually of the greatest policy interest are balancing items obtained residually, such as the balance on the current account or net lending. In general, however, balancing items are also the most sensitive to error. In principle, the current account balances of all the countries in the world should cancel each other out. One country's deficit is another's surplus. However, when the balance of payments statistics of all the counties in the world are confronted with each other their balances do not cancel and a world current account discrepancy emerges. The IMF has conducted investigations into the factors responsible in order to try to reduce the size of the discrepancy.

Although the concepts and classifications in balance of payments are essentially the same as in the *SNA*, a special manual is needed in the light of the special problems outlined above. It is necessary not only to provide greater precision in certain areas, but also to provide practical operational advice about how best to improve the quality and reliability of the statistics. The IMF has provided technical assistance and training to balance of payments compilers throughout the world over many years.

6.3 Capital Stock and Wealth Data

The aggregate values of a sector's assets and liabilities at the start and end of the accounting period are recorded in the *SNA*'s balance sheets. Total assets less liabilities equal 'net worth,' which is equivalent to 'wealth' in ordinary parlance.

Even though complete information about assets and liabilities is rare at a macroeconomic level, data are often available on holdings of financial assets and on stocks of fixed assets in the form of machinery, equipment, buildings, and other structures. Stocks of fixed assets are often described simply as the 'capital stock.' Estimates of their value are needed for purposes of productivity analysis.

The value of a fixed asset at a point of time is equal to the present, or capitalized, value of the flow of capital services into production that it is capable of providing over the rest of its service life. Capital stock and the flow measures are therefore completely interdependent. Depreciation is measured by the decline, between the start and the end of the accounting period, in the present value of a fixed asset used in production.

Capital stock estimates are usually made using the perpetual inventory method, or PIM, which derives the stock estimate from past data on investment flows, or gross fixed capital formation in *SNA* terminology. If the average life of an asset is estimated to be n years, the investments in the asset over the last n years, revalued at current prices, are cumulated to provide an estimate of the 'gross capital stock.' The cumulative depreciation on each vintage of asset is then deducted to obtain an estimate of the 'net capital stock.' Capital stock estimates derived in this way are available for many countries.

In empirical work on productivity, it is important to note that the input into production is not the capital stock itself but the flow of capital services provided by that stock. Their value is given by depreciation plus the return on the asset. It is possible to estimate volume indexes for flows of capital services for purposes of productivity analysis.

Macrosociology–Microsociology

Macrosociology generally refers to the study of a host of social phenomena covering wide areas over long periods of time. In contrast, microsociology would rather focus on specific phenomena, involving only limited groups of individuals such as family interactions or face-to-face relations. The theories and concepts of macrosociology operate on a systemic level and use aggregated data, whereas those of microsociology are confined to the individual level. This definition reflects a limited aspect of research practice and epistemoligical discussions of sociologists. Hence, it needs to be completed.

Sociologists thus identify two scales of organization—the microscopic and the macroscopic—which they understand to correspond to two types of phenomena and explanation. Recognizing the existence of levels of reality, however, should not lead us to think that there are ontologically distinct entities that correspond to different types of objects. For the time being, no specific dominant point of view has managed to make the basic structures of these two types entirely homogeneous or unifiable (see Wippler and Lindenberg 1987). Our purpose here is to clarify the debate over the links between macroscopic and microscopic, over whether and how it is possible to move from one to the other, and over the idea that the first is founded on the second.

1. Links Between Micro and Macro and the Problem of Explanation

Although the problems raised by the relations between macro- and microsociology are highly relevant today (to judge from the number of studies done on them in recent years) (see for example Collins 1981, Alexander et al. 1987, Huber 1990), few of them are new. They first arose with the institutionalization of sociology as an autonomous scientific discipline positioned at the center of the debates opposing utilitarianism-inspired theorists like Spencer against sociologists who, in search of a foundation for the specificity of the object and the explanations of social phenomena, rejected the hypotheses of classical economy.

Far from being purely rhetorical, these problems determine researchers' choice of instruments, units of observation, and explanatory procedures. A hypothesis tested at the level of the individual may very well prove false at the systemic level; another, verified at the global or context level may prove invalid for the individual case (see Robinson 1950, Goodman 1953, Duncan and Davis 1953, Goodman 1959). The error of inferring the social from the individual corresponds to that of inferring the individual from the social ('contextual fallacy'): though it is sometimes a mistake to deduce (without any supplementary hypothesis) the voting behavior of individuals from information on how ecological units voted, it is just as wrongheaded to affirm, on the basis of a relation of positive dependence between an individual's degree of education and his or her salary, that when the collective level of education rises, the average salary does too.

Let us suppose, as did the founding fathers, that the aim of social sciences consists of explaining the statics and dynamics of social systems (though this definition is neither necessary nor sufficient). Tocqueville (1856) tried to account for political change, mainly the revolutionary one; Durkheim (1893) for the increasing differentiation of functions and the consequences of such differentiation; Weber (1905) for the birth of a new type of socioeconomic organization; Sombart (1906) for the absence of socialism in the USA. Clearly, all these questions pertain to the systemic level. The size of the system may vary, but whatever its components and their number, it constitutes a unit that must not be broken down or dissolved.

We have three competing procedures for conducting an explanation of such phenomena. The first and the most current one is also the least satisfactory. It consists of analyzing the relations between a given social phenomenon and independent social factors; explaining the social by means of the social is the *leitmotiv* of the Durkheimian sociological program. But in order for that first macrological procedure to be legitimate, one's observations must pertain to the same level. We readily affirm that revolution is the result of improvement in economic, political, and social conditions; that an increase in the volume and density of groups or societies leads to the division of labor; that religious ethics facilitates the birth of capitalism; that a high degree of social mobility makes the development of strong left-wing parties less likely.

It seems, however, that this condition of consistency between the content of a sociological proposition and

the unit of observation and analysis is not often met. In most studies conducted by interview or questionnaire, the unit remains the individual, and a hiatus is created between the objective of the theory, which is to formulate macrosociological propositions, and empirical research, which remains focused on explaining individual behavior. This holds true despite the fact that Lazarsfeld and Menzel (1961) drew sociologists' attention to the necessity of consistency. Without consistency, we are caught in an impasse: many hypotheses deduced from macrosociological theories cannot be adequately tested.

The second procedure consists of collecting observations at an infrasystemic level and developing hypotheses on the behavior of such units (individuals, groups, institutions), with the purpose of explaining systemic relations through an appropriate synthesis of these observations. In this case micrological variables positioned in an intermediary position between dependent and independent macroscopic factors are introduced. One affirms that improvement in conditions (macro) generates a level of frustration (micro) such that it increases the probability of protest at the sociopolitical level (macro); that an increase in volume with growing densification aggravates competition between system units confronting each other on the same market, and that this competition is resolved by division of labor; and that social mobility, whether real or perceived as real by individuals, reduces the search for a collective solution by making people believe in the utility of personal effort, thus making the emergence of strong socialist parties less likely.

An explanation operating at this infrasystemic level is sometimes considered more satisfying, stable, and general than one expressed entirely in macroscopic terms. This is Popper's point of view (1934, 1963), as well as Harsany's (1968), Simon's (1977), and Boudon's (1973, 1977). The argument holds that because the behavior and dynamics of a social system are in fact the result of the actions of its components (individuals, subgroups, institutions), it is these components that should be analyzed if we are to better explain and predict systemic characteristics.

To illustrate this case, let us borrow Tocqueville's (1856) explanation of the stagnation of French agriculture at the end of the Old Regime compared to the English one as Boudon (1998) stylized it according to his cognitivist model. Agriculture stagnation is the effect of administrative centralization in France. Both phenomena are macroscopic but their relation has to be explained by bringing to the fore the reasons of classes of persons. More prestigious civil servants' positions in France than in England cause landlords' absenteeism that in turn provokes a low rate of innovation. By buying positions, French landlords think they can increase their power, prestige, and income. They have good reasons to leave their land, rent it, and serve their King. On the other hand, French farmers cultivate the land in a traditional fashion because they do not have the capacity to innovate. In England, the civil servants' positions are less numerous and less rewarding while local political life offers them good social rewards. What Boudon constructs is a social mechanism to explain the relation between the two macroscopic phenomena, i.e., a set of ultimate causes that have the character of being individual decisions we perceive as understandable.

The third approach of conducting an explanation is to analyze the effects due to the nature of the positions and distributions of certain variables on the behavior of the system's component units *without* formulating hypotheses about individuals (see Blau 1977, Blau and Schwartz 1984). Here we are no longer interested, for example, in the influence of religion (or any other variable) on social relations, but rather in the distribution of religious affiliation and the structural parameters of that distribution, understood to determine the dependent variables. It is important to carefully distinguish this macrostructural research, which works not with variables but positions in the social structure, from studies of the first type like Moore's (1966), Lenski's (1966), Skocpol's (1979), and Turner's (1984), in which collective properties and aggregate variables are subjected to classic treatment in terms of factors, relations, correlations, and influences.

Whereas microsociology seeks to explain social relations in terms of psychological traits, or processes such as exchange, communication, competition, and cooperation that shape relations between individuals, structural macrosociology accounts for the relations between the different components of a given society in terms of differentiation and integration. For this last approach, explaining certain aspects of relations between religious or ethnic groups—intermarriage or friendship, for example—means mechanically deducing them from structural properties of the groups—namely, their respective sizes—without having recourse to supplementary hypotheses about individuals, such as how liberal they are.

By way of illustration, let us consider the following example. Suppose we have to study the relation between religion and intermarriage between religious groups, and that we have established a correlation between the two variables, namely that the percentage of Protestants marrying non-Protestants is greater than the percentage of Catholics marrying non-Catholics. How can this be explained? We could develop hypotheses concerning the behavior of Catholics and Protestants: Protestants are less 'practicing,' less sexually inhibited, more tolerant than Catholics, for example. We would then look for indicators of religious practice, tolerance, and so forth, to account for the observed correlation.

Macrosociology proceeds differently. First, it makes no hypotheses about individual behavior. Rather it analyzes the distribution of individuals among the various positions and the effects of those positions on

behavior. Take two groups of different sizes A and B, with A > B. Individuals in group A can come into contact with individuals in group B and their members can intermarry. The first theorem deduced from these hypotheses is that the rate of intergroup association for group B must be greater than that for group A. If A and B are composed respectively of 10,000 and 100 individuals, and if there are 10 mixed marriages (10 pairs of spouses), the respective intermarriage rates are A: 10/10,000 = 1/1,000 and B: 10/100 = 1/10. If A represents the Catholic group and B the Protestant group, the preceding theorem enables us to affirm that B's intermarriage rate is higher than A's—the correlation has been explained in terms of group size.

But no matter how important the analysis of social systems may be, we cannot say that it is the one and only aim of social sciences. Sociological theories also work to explain individual behavior and may study voting behavior, household consumption, and more generally the attitudes and choices of individuals. With the exception of explanations proposed by psychological theories, sociologists explain these behaviors by analyzing characteristics of individuals in their relation to their environment.

It is not hard to show that such problems run through the entire history of sociology; here, however, I will be proceeding logically rather than chronologically. To this effect, I will be proposing a typology whose categories subsume the main sociological theories and bring out relations of inclusion or exclusion concerning models deduced from those theories. I will examine the objectives, problems, and the solutions of macrosociological and microsociological theories, while asking whether they are intractably antinomic or whether there are potential means of passing from one to the other.

2. *Outline of a Typology of Micro- and Macrotheories*

The first definition of micrology and macrology, the simplest but also the least adequate, as indicated above, is etymological: the terms refer to the size of the units of observation used. Micrology is understood to be limited to small units, whereas macrology analyzes groups, collectivities, communities, organizations, institutions, even entire societies. This first, unidimensional definition, is valid for neither sociology nor economics; the observation units used with certain theories do not fall into either of the two categories. The ultimate observation unit in symbolic interactionism or ethnomethodology, for example, is not the individual but the situation in which individuals interact. Nor is size a more relevant criterion, because the unit of observation for certain macrosociological theories, for example, is a limited number of small groups.

Similar definition problems are encountered in economics. The classical distinction between micro- and macroeconomics also refers to several levels. While microeconomics is the study of the behavior of individual decision-makers (households, firms) or, more exactly, choice as limited by different conditions, macroeconomics seeks to analyze the economy as a whole by structuring its hypotheses around aggregate variables (e.g., national income or consumption). But what is true of sociology is also true of economics: it is not so much the unit of observation that matters as the way in which problems are simplified.

The second definition proposed by Cherkaoui (1997) is multidimensional; it has at least three dimensions: (a) the nature of the patterns to be explained; (b) the type of hypotheses—rationalist or a-rationalist—used in conducting the explanation; (c) the unit of observation and analysis used in empirical testing of propositions. These units may be individuals, situations, or structures; the point is that they must be consistent with the hypothesis demonstrated, as discussed above.

The first dimension pertains to the particular problem under study, which may involve either individual behavior regularities or social and group regularities. Voting for a particular political party, consuming a product, adopting a particular attitude, making an economic or social choice are examples of regularities in individual behavior. On the other hand, accounting for the degree of heterogeneity in a given society (the frequency of intermarriage between ethnic or religious groups, for example); for the existence and intensity of cooperation or conflict within an organization; for integration and differentiation; for macroscopic balances andmbalances, involves studying social patterns.

Let us consider the following problem taken from social stratification studies, one of the major fields of macrosociology. When we conduct empirical research on the effects of the father's occupation or the individual's level of education on the social status attained by that individual, we are positioning ourselves at the microsociological level (though we may not be aware of it)—despite the fact that our project is macrosociological. As long as the propositions demonstrated are micrological, we are not violating logical rules; we can legitimately make assertions of the following type: 'When, for individuals, the level of education increases, so does occupational status.' Such affirmations derive from empirical research conducted in accordance with known, standardized rules: construction of a random sample, use of analytical statistical methods in which the individual is the relevant unit. But in proceeding this way, we are working from several implicit hypotheses, the simplest of which affirms that individuals' decisions are entirely independent of each other. Nothing precludes us from applying such simplifications as long as our hypotheses or empirically tested propositions do not go beyond

the microsociological level. But it is clear that (a) individual choices are in fact interdependent; (b) there is not an infinite number of occupational positions; (c) the set of such positions constitutes a structure whose parameters function as constraints on individual choices. Obviously, when I decide to apply for a post in sociology in a given institution, (a) I am competing with other applicants (interdependence of individuals); (b) I know that the number of positions in my discipline for which applicants are competing is limited; (c) the job openings in sociology that applicants are competing to fill are the direct result of what other jobs are available both in other disciplines of other departments of the same institution (they also depend, though indirectly, on the number of places available in other institutions, such as all institutions of higher learning); and (d) when making its decision, the institution that has activated competition for the jobs will take into account the interest that other institutions of the same type may have in sociology.

The second dimension of the definition of micro- and macrosociology proposed here refers to theoretical simplifications and the objectives of such simplifications. I will summarily distinguish between two types of hypothesis about the behavior of units of observation and analysis: a theory requires either rationalist or nonrationalist hypotheses (this last type may be divided into a-rational and nonrational).The rational individual is not necessarily to be reduced to that of *Homo æconomicus*, whose particularity is to maximize the expected value of his utility function—monetary profit, for example. Following Boudon (1996), we can speak of three different types of rationality: expected, cognitive, and axiological.These theoretical simplifications of course only concern individual actors or units, not structures. If we preclude Hegelian-type visions, which reify universals and endow them with intentionality or rationality, it is obvious that under certain conditions, groups, organizations, and institutions may be assimilated to actors.

The third and last dimension is the level of observation and analysis deemed most relevant to a given theory. That level may be individuals, households, organizations, a context-situation, or population distributions. The individual and the county are the units most commonly used in electoral sociology. Whereas for economic and sociological research, the household is considered the most appropriate unit for studying consumption, in the sociology of organizations and microeconomic theory of the firm, the preferred basic unit is the single firm. For some correlation analysis—that between literacy and the proportion of the state budget allocated for education, for example—rates are required. In the example from social stratification research, we saw why observations made at the individual level were not sufficient to give answers to macrosociological questions; they may even be an inappropriate place to look for such answers as demonstrated by Coleman (1990). The empirical tradition founded at the beginning of the 1950s and popularized by Blau and Duncan's *American Occupational Structure* (1967) and Featherman and Hauser's research (1978), among others, does not allow for a move from the micro to the macro.

		level of analysis (D2) & type of Hypothesis (D3)				
		individual		individual-contextal		structure
		R	NR	R	NR	
problem (D1)	IP	1	3	5	7	9
	SP	2	4	6	8	10

Figure 1
Typology of theories: R, rationalist hypothesis; NR, other types of hypothesis; IP, individual patterns; SP, social patterns; D1, D2, D3, 1st, 2nd, 3rd dimensions

With these few taxonomic principles, we can construct the typology of theories (numbers 1–10 correspond to theory types to be identified) as in Fig. 1. This typology is neither exhaustive nor inalterable, and it can be simplified or complexified, namely by specifying hypotheses here designated 'other than rational.' It does, however, enable us to observe (a) the fundamental distinction between macrological and micrological theories; (b) the paradigmatic principles underlying these theories; (c) the relations of opposition, distance, or inclusion that a given theory has with the others. Finally, it identifies 'at a glance' the historical stages of sociological thought.

To each of the 10 'pure' theory types corresponds one or more theories. Type 1 comprises all theories that share the axioms of the market model of pure and perfect competition, some behaviorist theories, and Homans' (1961) and Blau's (1964) theories of social exchange, among others. For Homans, macrosociological structures are no more than repeated individual behaviors: the interaction between individuals is what generates structures; structures do not determine individual behavior. Type 2 is made up of theories in which the market model is applied to particular sociological fields. Coleman (1990, p. 21 et seq.) presents a much-discussed topical example similar in some points to economic markets: the marriage market or, more exactly, the phenomenon described as 'marriage squeeze.' Psychoanalysis is a type 3 theory, though certain variants of it are closer to type 9. Type 4 comprises stochastic models and some theories of collective behavior: stochastic theories, like the econometrician explanation of the income distribution, do not hypothesize about individuals, while collective behavior theories make use of a-rationalist postulates about agents' behavior, such as those implied in notions of 'suggestion' or 'hypnotic effects' as used by Gustave Le Bon (1895).

Type 5 encompasses the models of adaptive behavior particular to certain behaviorist explanations, together with oligopolistic models like Cournot's,

studied in detail by Simon (1982), while type 6 refers to rational choice theory, including actionist theories that are more complex than type 5. It is no longer simple market models but rather rational behavior models that are called upon in the attempt to build bridges between the micro and the macro. Actionists rediscovered the idea dear to Weber and Popper that all social phenomena (macroscopic level), particularly the structure and function of institutions, should be explained and understood as the result of individual actions, not in terms of universals or collective properties. But in affirming this epistemological principle, actionist theorists did not reduce social phenomena to psychological ones, because in their understanding, action can be influenced by institutions, and institutions are to be explained not only by the actions of individual agents but also by those of other institutions. Here we should cite works by Olson (1966), Schelling (1978), Boudon (1973, 1977, 1990), Hechter (1983), and Coleman (1990).

Type 7 encompasses relativist theories such as ethnomethodology, symbolic interactionism, and phenomenological sociology; primary representatives here are Blumer and Garfinkel. For Blumer, social behavior is negotiated case by case, not imposed by a hidden structure. Macrostructure is unreal, and the empirical foundation of a sociological theory can only be individual behavior in real situations. Whereas Homans left macrosociology intact, interpreting it as a series of individual reinforcements, Blumer denied almost all we claim to know of macrosociological structures. For him, the ultimate basic unit of all research is not the individual, but the situation; that is, interaction between individuals. Psychological principles such as reward and punishment are themselves subject to interpretation in terms of situation (this is why we may categorize this approach as microsociology rather than psychology). Type 8 is made up of role, reference group, and frustration theories. All variants of functionalism and social control theories, from Malinowski through Parsons to Bourdieu, are type 9 theories which explain regularities in individual behavior in terms of variables strictly external to individuals such as values and social rules. Type 9 theories, which stand in opposition to type 1 (classical political economy and Spencerian sociology), dominated sociology until the early 1960s. Finally, macrostructural and network theories make up the 10th and last type (see Fararo 1989).

In fact, only type 2, 4, 6, 8, and 9 theories take on the problem of the connection between micro- and macrolevels. The first four of these ask macrosociological or macroeconomic questions, but are based on the individual as unit of observation. The assumption—that hypotheses about such units enable us to get from the micro to the macro—is operative particularly in normative theories, which try to explain individual behavior in terms of social norms. All the other theories do not go beyond a single level—microsociological for types 1, 3, 5, and 7 and macrosociological for type 10.

The macrostructuralist project is limited to certain aspects of social reality. It cannot, any more than any other theory, offer a solution to the problem of the links between the micro and the macro. While the rational choice theory presents an undeniable advantage over other theories, it cannot serve as a universal solution: presenting it as unconditionally valid makes it vulnerable to the same dangers other theories have encountered. As for functionalism, it's error was to yield to the temptation of hegemony; it claimed the title of general theory of social systems, when some of its principles are only valid for particular, tightly circumscribed domains. This means that there is a right way of using functionalism and normative theories, just as there is a wrong way of using such strong, all-encompassing theories. There can be no single solution to the problem of the links between micro- and macrosociology, any more than there can be a single mode for explaining all phenomena (the first of these problems being only an aspect of the second).

Macrostructure in Discourse Comprehension, Psychology of

The availability of a macrostructure representation may influence both the reading process and memory for text content. During reading, the identification of macropropositions provides a context for the interpretation of subordinate content. After reading, the macrostructure representation can guide a systematic search of the reader's memory representation.

Discourse comprehension may be thought of as a process of constructing a memory representation. In the case of text comprehension, a reader is credited with good comprehension to the extent that the reader constructs a coherent representation that is consistent with the message intended by the author. It is particularly critical that the reader accurately represent the text's main ideas and their organization, or macrostructure. This article addresses the processes involved in the construction and use of macrostructure representations as a critical component of discourse comprehension.

1. *Two Levels of Discourse Representation*

A text has both a horizontal organization, or microstructure, and a vertical organization, or macrostructure (Kintsch and van Dijk 1978, van Dijk 1980, van Dijk and Kintsch 1983). A full understanding of a text requires that a reader represent both the microstructure and the macrostructure.

A text's horizontal organization derives from the fact that most sentences can be interpreted in the context of the immediately preceding sentence. A microstructure representation captures these local coherence relations. A formal analysis of a text's microstructure requires that the sentences of the text be analyzed into their underlying ideas, or propositions (see, e.g., *Propositional Representations in Psychology*) and their relations. Propositions are related, for example, if they share referents or if they denote events that are causally related (see, e.g., *Text Comprehension: Models in Psychology*; *Narrative Comprehension, Psychology of*). The resulting analysis of a text's microstructure can be summarized in a network representation with propositions represented as nodes and relations represented as connections between the nodes.

A text's vertical organization derives from the fact that expressed and implied propositions are hierarchically related. The macrostructure represents these hierarchical relationships and thus captures the basis of the global coherence of a text. Formally, a macrostructure representation can be derived from a microstructure representation by the application of three macrorules. One rule deletes micropropositions that are not interpretation conditions of other propositions. A second rule creates new macropropositions by generalization from more specific micropropositions in the microstructure. Finally, a third rule constructs new macropropositions by replacing sequences of micropropositions that denote more complex events. The three macrorules are applied recursively to create new macropropositions that dominate increasingly larger sections of the text. Intuitively, it is useful to think of successively higher levels of a macrostructure as corresponding to increasingly concise summaries of the text.

2. *Constructing a Macrostructure Representation While Reading*

2.1 *Some Cognitive Obstacles to Macroprocessing*

A macrostructure represents the 'gist' of a text so an adequate representation of a text's macrostructure is essential to text comprehension. However, even in circumstances where a text is well written and the reader has the requisite vocabulary and background knowledge to understand it, there are several impediments to processing a text's macrostructure. One is that a written text is an incomplete representation of the author's intended communication. Authors omit from the written text information that they assume their audience can compute from the information provided. Sometimes, they will explicitly state a macroproposition; other times, they will leave it to the reader to infer (generalize or construct) the relevant macroproposition from the more specific information that is explicitly provided.

A second obstacle to macroprocessing is that related macropropositions are often widely separated in a text. This is because the written text is linearly organized whereas the underlying macrostructure is hierarchically organized. In many models of discourse comprehension (e.g., Kintsch and van Dijk 1978; see also *Text Comprehension: Models in Psychology*), this fact creates problems for identifying the relationship between text topics because of readers' memory limitations.

Finally, the identification or construction of a macroproposition can involve the reduction of large amounts of information. For example, a page-long description of a sequence of events might ultimately be summarized by a single macroproposition (e.g., John ate at an Italian restaurant). Again, construction of the appropriate macroproposition may place a heavy burden on the memory abilities of the reader.

2.2 *Monitoring the Macrostructure During Reading*

How do readers cope with the cognitive demands of macroprocessing? There are several empirical demonstrations that readers are sensitive to topic changes and pay more attention to sentences that communicate macropropositions. These important junctures in the underlying macrostructure are signaled in the written text in a variety of redundant ways.

An author can use a variety of explicit signals to alert readers to macrorelevant information (Lorch 1989). Headings, overviews, and other devices emphasize the main topics and their organization within a text and have consistent benefits on reader's memory for a text's macrostructure. In addition, function indicators (e.g., 'It is important to note …'; 'To sum up …') can be used to indicate the relevance of specific statements within a text (van Dijk 1980) with the consequence that readers attend more carefully to the cued information. An author can also be very explicit about a change of topics (e.g., 'In contrast to …'; 'Consider another issue').

The underlying macrostructure is also reflected in the distribution of information within a text. A topic is introduced and elaborated, then a new topic is introduced. The identity of the currently relevant discourse topic is usually reflected in the topic-comment structure of the sentences that elaborate the topic (Kieras 1981). Thus, repeated sentence topics provide a basis for identifying the relevant discourse topic. When a change of topic occurs, several writing conventions aid the process of recognizing the change and identifying the new topic. A change of topic often corresponds with a break in local text coherence which, in turn, is often indicated by paragraph structure. The identification of topic transitions may be further facilitated by the use of marked syntactic

constructions that shift the reader's focus to the new topic. Finally, after a transition has been made, the identification of a new topic is facilitated by the convention that the initial sentence of a new paragraph often corresponds to a macroproposition (Kieras 1981).

2.3 Representing Macropropositions and their Relationships

Although authors occasionally denote the macrorelevance of a statement explicitly, macropropositions are frequently left implicit. In that event, readers are expected to use their prior knowledge and their understanding of information presented in the text to infer relevant macropropositions (see, e.g., *Inferences in Discourse, Psychology of*). Even when a macroproposition is explicitly communicated, readers usually must determine its macrorelevance. Syntactic cues, initial position in a paragraph, and other cues may serve as heuristics in identifying the *possible* macrorelevance of a statement. However, the macrorelevance of a proposition must be *verified* by determining that it occupies a superordinate position with respect to other propositions in the text (i.e., it is elaborated by more specific propositions).

When a macroproposition is identified or inferred, its place in the macrostructure must be determined. This involves not only determining its semantic relationships to subordinate micropropositions, but also determining its relationships to previously identified macropropositions. Again, the author sometimes explicitly communicates these relationships; however, readers are often left to infer how a newly identified macroproposition is related. This involves first identifying potentially related information, then evaluating its relationship to the new macroproposition.

There is very little definitive research on how readers infer implicit macropropositions and how they determine unstated relationships between macropropositions. However, such macroprocessing surely entails interactions between (a) cognitive processes that operate automatically in response to information presented in the text and (b) processing strategies that are invoked by readers to meet their particular reading goals. Successful macroprocessing requires that a reader be able to access relevant background knowledge and information in the text representation. There is substantial empirical evidence of powerful, automatic memory retrieval processes that serve this purpose (Kintsch 1988, Myers and O'Brien 1998; see also *Knowledge Activation in Text Comprehension and Problem Solving, Psychology of*). The involvement of strategic processes is demonstrated by evidence that the reading task modulates readers' macroprocessing: readers are sensitive to macrorelevant information even when the reading task renders such information irrelevant, but they pay even greater attention to the macrostructure when it is relevant to their reading goal (e.g., summarization).

3. Using a Macrostructure Representation

3.1 Influences on Comprehension Processes During Reading

The macrostructure representation a reader constructs during reading has a privileged status with respect to processing of subsequent text. Macropropositions are more accessible than micropropositions so they are particularly likely to serve as the context for the interpretation of new information during reading (McKoon and Ratcliff 1992). This is true in two respects. First, because a recently identified macroproposition is likely to be the most available information when a new sentence is read, it will be the first context consulted as the reader attempts to establish the local coherence of the new information (Kintsch and van Dijk 1978, Kintsch 1998). Second, because macropropositions are typically elaborated in a text, macropropositions should generally be relatively accessible from the text representation even when they were not recently processed. Thus, macropropositions should also be relatively available as a context for establishing global coherence relations (Myers and O'Brien 1998). Indeed, there is substantial empirical evidence that macrorelevant information (e.g., titles) can greatly influence how readers interpret statements and organize their text representations.

3.2 Influences on Memory for Text

A macrostructure representation can also play a prominent role in memory for a text after it has been read. For the same reasons that individual macropropositions tend to be relatively accessible during reading, they are also memorable after reading. As elaborated information, there are many retrieval routes to macropropositions in the text representation (see, e.g., *Memory for Text*). Further, in tasks that emphasize reconstructive processes (e.g., free recall), readers often use their macrostructure representations strategically as a retrieval plan to cue their memories for text content.

4. Future Directions

There are several directions in which future research should develop. First, there is a need for new methods of studying macroprocessing as they occur *on-line* (i.e., during reading). Although there are many empirical studies demonstrating that readers are sensitive to macrorelevant information as they read, very few studies address the nature of the cognitive operations involved in verifying macropropositions, inferring

macropropositions, or determining the relationships among macropropositions. Most on-line methods require great precision in specifying the text conditions eliciting a given process (see, e.g., *Priming, Cognitive Psychology of*). Because macroprocessing often involves the integration of several propositions and depends heavily on a reader's background knowledge, such theoretical precision may not be possible. Thus, methods are required that are sensitive to on-line processes, but which do not require pinpointing a particular text event as *the* stimulus eliciting some process.

In addition to the need for new research methods, theoretical advances are needed in several areas. More detailed models are needed of the cognitive processes that underlie the construction of a macrostructure. The models should identify the text conditions that trigger the processes. More detailed models are also needed of how the availability of a macrostructure representation influences subsequent processing. Models are also needed to explain how the construction of a macrostructure interacts with a reader's knowledge of conventional text structures (e.g., narrative; empirical research report) or what van Dijk and Kintsch (1983) call the superstructure of a text. Finally, theoretical advancement on all fronts depends on the development of ways to model the involvement of readers' background knowledge in all aspects of macroprocessing. Current theory ascribes an extensive role to background knowledge, but promising methods to model its role have only recently begun to take shape (Kintsch 1998; see also *Semantic Processing: Statistical Approaches*).

Mafia

1. The Setting

The term 'mafia' comes originally from Sicily, where it refers to the private use of violence in public domains. Despite its feudal and patrimonial dispositions, mafia is a modern phenomenon. Mafia developed in the slipstream of Italian unification when a modern state structure imposed itself on a predominantly agrarian society still largely feudal in its basic features. In the absence of effective central control over the means of violence, mafia took shape as an *instrumentum regni* of Italian politicians, who chose to rule Sicily through its dominant class of absentee landlords most of whom resided in Palermo, the center of wealth and power of the island.

Mafia presence was particularly strong in and around this city, in the adjacent citrus fruit area of the Conca d'Oro and the vast hinterland of the western interior. This was the area of large cereal-pasture holdings (the so-called *latifondi* or *ex-feudi*), the management of which the absentee owners entrusted to ruthless local, upwardly-mobile leaseholders and overseers who had a reputation for violence. These local bosses and their retainers formed the backbone of the rural mafia, which consisted of loosely-constituted coalitions, called *cosche* or 'families.' Each family or *cosca* controlled its own territory—a village, a town, or an urban neighborhood—and imposed a tribute on all economic transactions. The typical mafioso was a mediator or power-broker, who thrived on the gaps in communication between landlord and peasant, seller and buyer of commodities and services, political candidate and electorate. Ultimately, he held sway over the links between state and local community.

2. Profile

Mafiosi controlled local resources like property, markets, services, and votes. They operated in collusion with members of the elite, most notably urban-based landlords, politicians, government officials, and businessmen. This 'contiguity' involved mutual protection. But the protection which mafiosi offered was some-

times difficult to distinguish from extortion and the boundaries between victim and accomplice were often likewise blurred. In the no-man's-land between public and private domains, mafiosi were left a free hand in the management of local affairs.

Although they exacerbated class tensions between landlords and peasants by their rent-capitalist management of the estates and appropriating land and becoming landowners in their own right, they also controlled these tensions by carving out channels of upward mobility for ambitious and ruthless peasants and shepherds. In Sicily, as probably elsewhere under similar conditions (Brogan 1998, Tilly 1997, 2000, Varese 1994), mafia and politics provided *'carrières ouvertes aux talents'* (Fentress 2000, p. 149). Toward the large mass of landless peasants and shepherds, from whose ranks they usually originated, their attitude involved undisguised disdain and exploitation. When indicted for violent crimes, mafiosi were usually acquitted for lack of evidence because of high-level protection and because no local witness would testify against them. This greatly helped to enhance their power and their reputation as 'men of respect.' Inspired by both fear and admiration, the local population drew up a 'wall of silence' (*omertà*), which ultimately blocked effective prosecution of mafiosi. Until recently, the power of mafiosi, although surrounded and buttressed by silence, was openly displayed. It illustrated the peaceful coexistence between mafia and the State.

Far from being 'a State within a State,' as magistrates and journalists often represented the phenomenon, mafiosi successfully infiltrated public institutions, including political parties, local governments, the judiciary, banks, and legal firms. They did so through their own personal networks of 'friends,' rather than as members of a centralized organization. With the extension of the suffrage, they enlarged their grip on the electorate and controlled more votes. With the extension of postwar government aid to 'develop' the country's southern peripheries, mafiosi swallowed up ever more funds, most notably in the urban construction industry, always capable of placing themselves with cunning and force between State and citizen. Sicilian mafia appears as the violent alternative to civil society. This was the price the Italian State eventually had to pay for the pragmatic accommodation which later became known as 'pollution' of public institutions—the other side of peaceful coexistence.

3. *Representations*

The persistent and popular representation of mafia as 'a State within a State,' as a centralized monolithic organization, is wide of the mark. It makes too much of the organization and too little of it at the same time. Presenting mafia as a single unified structure ignores the organization's fluid character as well as its parasitic relationship to the State. To understand how mafia works is to start the investigation at the local level, because what mafia in Sicily comes down to is local cliques, structured by ties of kinship, marriage, and friendship, that control local resources with violent methods while enjoying a large measure of impunity because of their contiguity with powerful protectors at higher levels of society who need local strongmen as managers of their properties and as canvassers of votes (Blok 2001). The relationships between these 'families' are characterized by conflict and accommodation—strikingly similar to relations between States—rather than being supervised, coordinated, or controlled from the top by a commission of sorts, as current expressions like *Cosa Nostra* ('Our Thing') and 'The Mafia' suggest. In this respect the alliances of mafia families in the United States (largely of Sicilian extraction), from whom the Sicilians adopted this denomination, showed greater stability (Sterling 1990).

The idea that the Sicilian *cosche* operated like sovereignties is neatly illustrated by the failed attempts to coordinate their relations from above. When the so-called 'Commission' of *Cosa Nostra* was put together to contain intramafia violence and to impose a *pax mafiosa*, as happened for the first time in the late 1950s and again on several occasions in the 1970s, it fell apart because representatives of the various factions could not agree about overall policy, or else tried to outmaneuver each other and dominate the Commission. In 1963, what had remained of this board blew up in the notorious Ciaculli affair, which brought an end to the first mafia war and heralded an era of antimafia policy. The second mafia war unfolded around 1980 and ended in the near extermination of one of the warring factions (Sterling 1990, Catanzaro 1998, Stille 1995, Jamieson 2000). These failings alone clearly demonstrate that Sicilian mafia cannot be understood as a single unitary organization. An analysis of these episodes suggests the image of a fluid network that regulates a changing configuration of alliances in and between local 'families.' In all these instances, incipient hierarchy gave way to segmentation.

4. *Transitions*

Since the 1970s, mafia in Sicily gradually lost its role as a pragmatic extension of the State and assumed the character of a hidden power. Mafiosi disappeared as public figures with public identities. Mafia's peaceful coexistence with the State came to an end. Terror replaced accommodation. Like outlaws elsewhere, mafiosi had to hide from the law (if they did not cooperate outright with the judicial authorities), living clandestine lives in modest accommodations. Several factors are responsible for this major transition.

First, beginning in the early 1970s, Sicilian mafiosi moved into the international narcotics trade which produced huge and fast profits but entailed high risks. These ventures, like the building boom in the early 1960s, resulted in internecine struggles between rival factions—between upstarts from the Palermo hinterland, like the Corleonesi led by Luciano Leggio and Salvatore Riina, and the urban establishment in Palermo of which Stefano Bontate was the most striking figure. State interference provoked campaigns of terror against state officials, politicians, magistrates, and policemen. This new development brought mafiosi into open conflict with the Italian State, which could not stand back and accept open warfare on its territory and close its eyes to the massive infiltration of drug money into its economy. Nor could the government ignore the pressure from neighboring States and other countries to take a strong position against the drug traffic and money laundering. The narcotics trade changed the Sicilian and American mafia. Although it became the mafia's most lucrative enterprise, it has also generated more murder, violence, and betrayal than any other criminal activity. As the profits spiraled, so did the need to protect them (Shawcross and Young 1987, p. 307).

The extent to which the tables had been turned on politicians who had either directly or indirectly protected the interests of mafiosi in exchange for electoral support can best be illustrated by the following anecdote. After the first Sicilian politicians and magistrates who tried to withdraw from the mafia or to combat it with determination were assassinated in public places in 1979 and 1980, to be remembered as the first wave of 'excellent cadavers,' Stefano Bontate, the flamboyant mafia leader in Palermo, warned the then prime minister Giulio Andreotti on his visit to the island in February 1980 with the following words: 'We command in Sicily and if you don't want the DC [Christian Democrats] to disappear completely you'll have to do as we say. Otherwise we'll take away not only your votes in Sicily but also votes in Reggio Calabria and the whole of the south of Italy as well. You'll have to make do with the votes in the north where everyone votes Communist' (Jamieson 2000, p. 222).

Yet helped by a new generation of magistrates and special legislation (which included the coinage of the term *associazione mafiosa*), the Italian State, from the early 1980s onwards, started its crackdown on the mafia, which culminated in effective proceedings (the so-called maxi-trials) against hundreds of mafiosi. The prosecution was substantially helped by mafiosi from losing factions who, partly for reasons of revenge and partly in order to survive, repented, turned state's evidence, and helped build a case against their former peers (Stille 1995).

Behind all these changes lurked an even larger transition. This was the demise of communism in Europe, which unintentionally undermined the mafia's *raison d'être*. Since the immediate postwar years, mafiosi had always supported political parties that opposed communist and socialist parties. Faced with the largest communist party in Western Europe, the Italian Christian Democrats could not forgo the support of an informal power that provided huge blocks of votes and thus effectively staved off what was perceived as 'the danger of communism.' With the disintegration of the Soviet Union and the end of the Cold War, the situation radically changed and the shield of protection that kept mafiosi out of prison began to fall apart. The situation resembled the crackdown on the mafia under Fascism. Prefect Mori's large-scale operation in the late 1920s took place after the Sicilian landed classes had obtained more effective and less costly protection of their property from the new government. This turn exposed mafiosi and left them without protection (Duggan 1989).

One cannot help notice another parallel in the different ways the Italian State proceeded against the mafia. In both cases, prosecutors represented the mafia as a corporate organization, as a single, unified, hierarchical organization controlled from the top by one or more super chiefs, who coordinated the relations between local 'families.' As noted above, there is little evidence for this so-called 'monolithic theorem.' Although recurring tendencies toward centralization were not lacking, their very failure shows the strength and structural continuity of local groups tied together by links of kinship, marriage, and friendship. Indeed it has been argued that the absence of a centralized organization at the regional level served the mafia well and helps account for its remarkable longevity in modern society; it reflects the same paucity of communication that made it possible for mafiosi to place themselves at decisive junctions in the relationships between local and national levels (Blok 1974, Catanzaro 1988).

5. *Conclusion*

Today, the term 'mafia' is widely used as a synonym for organized crime. A still larger conflation of the term includes (ironic) references to any coterie wielding illicit power in formal organizations and institutions, including governments, business firms, and universities. To contain the growing inflation of the terminology, one may restrict the use of the term 'mafia' to denote a form of organized crime that includes collusion and contiguity with people representing public institutions. If we agree that mafiosi are agents who operate with violent methods in the border zone of public and private domains to enrich themselves and convert their wealth into honor and social status, there is no need to widen any further the meaning of the term, because the private use of violence in public places has lately expanded on a world scale and has blurred the familiar boundaries

between private and public spheres in Latin America, Eastern Europe, the former Soviet Union, Southeast Asia, and various African countries. All these cases are unique, but one cannot help noticing their family resemblances.

Magic, Anthropology of

Magic is a generic term that refers to different kinds of beliefs and practices related to supernatural forces. Among others, it encompasses such areas as witchcraft, sorcery, and shamanism (see *Witchcraft* and *Shamanism*). In anthropology, the meaning of magic and its different manifestations has been the object of contention and debate for many decades. Accordingly, the aim of this article is to trace the main shifts in the way in which anthropologists have interpreted magic over the years and to suggest reasons for these shifts. It will do so by focusing on the work of key anthropological figures.

1. *The Evolutionists: Magic as a Pseudo-science*

The nineteenth century was the time when anthropology became a recognized academic discipline. It was also the time when the numerous achievements of natural science had captured people's imagination, something partly responsible for the claim that Western societies represented the pinnacle of human endeavor. Faith in both natural science and Western cultural superiority were to bear heavily on the way in which magic was understood by nineteenth-century anthropologists.

For Tylor (1874) the paradigmatic figure of Victorian anthropology, magic was 'one of the most pernicious delusions that ever vexed mankind'; it was also a fundamental characteristic of 'the lowest known stages of civilization.' These claims encapsulate two basic assumptions with which Tylor and his contemporaries were working. First is that natives used magic to achieve certain practical results—control of the natural elements, for example, or restoration of a person's health; second, that all societies follow an evolutionary path with fixed stages of development that represent higher degrees of social and cultural complexity.

On the basis of these assumptions, magic emerged in nineteenth-century anthropology as the negative side of science. Indeed, for Tylor and his contemporaries, it was nothing more than a 'pseudo-science,' a system of thought and practice that attempted to effect changes in the empirical world but was unable to do so. Not that magic as a system of thought was the product of minds radically different from those that invented science. Tylor was clearly against such racist charges. The human mind, he argued, operates everywhere and at all times with the same principles of thought—by associating ideas on the basis of analogy and cause and effect. Yet, despite this fundamental sameness—this 'psychic unity of mankind,' as Tylor would have it—there was still ample room for errors. 'Primitive' people, being at the lowest stage of intellectual development, a stage characterized by simplicity and innocence, were particularly prone to making errors, magic being a paradigmatic example.

To use Tylor's well-known expression, 'primitive' people mistake ideal for a real connections, that is, they treat events that are only accidentally related as if they cause one another. For example, there is nothing in reality that connects the crowing rooster with the rising sun, but because the two events occur regularly and sequentially, 'primitive' people assume that the former causes the latter. Magic is the practical ap-

plication of such misconceptions: the rooster is made to crow so that the sun will rise.

The work of Tylor on magic was further elaborated by Sir James Frazer. To begin with, Frazer (1922/1950) made a distinction between 'sympathetic' and 'contagious' magic. The former was the result of associating ideas on the basis of similarity, the latter on the basis of proximity in space or time. Frazer also took Tylor's evolutionism to its logical extreme. As Tambiah (1990) points out, he arranged 'magic, religion and science in an evolutionary lineal scheme, with the unsupportable suggestion that magic preceded religion in time, and with the inescapable inference … that science must inevitably dissolve religion in our time.'

2. *Twentieth-century Paradigms*

2.1 *Magic as a Source of Hope and Optimism*

By his own admission, Branislaw Malinowski was drawn to anthropology after having read Frazer's work. Yet even though inspired by Frazer, Malinowski was already beginning to question the wisdom of Victorian evolutionism. Moreover, having spent the years of World War I on the Trobriand Islands of the south west Pacific, he developed a difference sense of the place of magic in native life. Indeed, one of Malinowski's aims was to show that belief in magic was not equivalent to irrationalism and mysticism. This marks a fundamental shift in Western perceptions of magic and native life in general and constitutes the basis for all subsequent anthropological studies of magico-religious systems. In more general terms, it marks a shift, at this point still quite subtle, toward a less ethnocentric view of the non-Western world.

In his extended essay *Magic, Science and Religion*, Malinowski (1928/1954) sets out to show that much of what has been written about magic was speculative and had little basis in reality. To this effect, he engages both Tylor and the French philosopher-turned-anthropologist Lévy-Bruhl. The former, Malinowski argues, depicts natives as highly contemplative and rational, much like intellectuals; the latter as being 'hopelessly and completely immersed in a mystical frame of mind' (1928/1954). Malinowski found the natives of the Trobriand Islands to be practical people concerned with such matters as fishing, gardening, building canoes, and tribal festivities. This is not to say that they did not also practice magic; but they did so only when their stock of practical knowledge and experience ran out.

In a celebrated example, Malinowski shows that when fishing in the lagoon, natives do not resort to magical rites; they rely instead on their knowledge and skill. In open-sea fishing, however, which is 'full of danger and uncertainty, there is an extensive magical ritual to secure safety and good results' (1928/1954). This and other similar examples, Malinowski argues, show that natives turn to magic only in situations of emotional stress. As such, magic fulfills an important psychological function; it ritualizes optimism and enhances human confidence and hope.

2.2 *Evans-Pritchard: The Transition to Symbolism*

Even though highly suspicious of evolutionism, Malinowski was never able to transcend the other tenet of Victorian anthropology, namely, that the primary aim of magic was the attainment of practical results. Nor by extension was he able to go beyond the notion that, ultimately, magic was a pseudo-science. The shift from this utilitarian perception to one that views magic as a meaningful and meaning-generating phenomenon came with Evans-Pritchard (1937/1976) in his classic study of Zande witchcraft. Evans-Pritchard was working within the broad sociological problematic developed by Emile Durkheim, which emphasized social stability and treated religion as social institution that contributed to it. In his study of Zande witchcraft, Evans-Pritchard extended the argument to include magical beliefs and practices. At the same time, Evans-Pritchard continued the debate with Lévy-Bruhl that Malinowski began. It is in this confrontation with the French philosopher that he lays the ground for the paradigm that was to dominate subsequent anthropological studies of magico-religious systems and is variously known as the symbolic, interpretive, or cultural approach.

Evans-Pritchard, then, analyzes Zande witchcraft along two axes. The first explores how witchcraft contributes to the cohesion of Zande society—its social function. The other examines when and why the Zande have recourse to it—its cultural function. Witchcraft, Evans-Pritchard points out, embraces a system of values that regulate Zande behavior. No one knows for certain who might be a witch, but spiteful, moody, ill-tempered, bad-mannered, or greedy individuals are prime suspects. Belief in witchcraft acts in a way that encourages more positive dispositions and hence curbs anti-social behavior. To begin with, if the Zande suspect that their neighbors are witches, they are careful not to offend them from fear of being bewitched. Those Zande who are spiteful or jealous, on the other hand, will try to curb their spitefulness. Those of whom they are spiteful may themselves be witches and seek to injure them in return for their spitefulness. In this way, Evans-Pritchard argues, friction and conflict and kept in check and the cohesion of Zande society maintained.

Yet social stability is hardly what the Zande have in mind when they turn to witchcraft. Their purpose, according to Evans-Pritchard, is to explain misfortune, to make events such as the accidental injury of a relative, sickness, even death itself socially meaningful and relevant. Explanations of misfortune through witchcraft set in motion checks and balances that

reproduce social cohesion, but this is only the by-product of a system whose rationale lies elsewhere. Witchcraft is first and foremost an idiom (or a symbol, as we would say today), the language that the Zande use to speak about misfortune so that misfortune is brought into the social domain and can be socially dealt with. Evans-Pritchard does not attempt to explain why the Zande feel the need to turn misfortune into a social issue. He is concerned primarily with explaining that witchcraft, which effects this transformation, has nothing to do with mysticism or, at any rate, does not at all mean that 'primitive' people are unable to perceive how the empirical world operates. Such was the accusation leveled by Lévy-Bruhl whom Evans-Pritchard takes to task.

Witchcraft, Evans-Pritchard points out, does not try to explain how things happen, but rather why they happen. For example, it does not try to explain how old granaries collapse, but rather why they collapse at a certain time and injure certain people. The Zande are well aware that termites eat away the foundations of granaries and that wood decays; they know that it is because of these natural causes that old granaries collapse. What they try to explain through witchcraft accusations is the timing of the event. Why should a particular granary collapse 'at the particular moment when these particular people were sitting beneath it? Through the years it might have collapsed, so why should it fall when certain people sought its kindly shelter?' (1937/1976). When the Zande say that it is witchcraft that caused the granary to collapse, then, it is not because they see a witch push it over; they see termites and rotten wood.

Witchcraft offers an explanation over and above natural causation, one that links the collapse of the granary with the fact that certain people were at that point in time sitting underneath it. We, Evans-Pritchard points out, do not have an explanation for the intersection of the two events; we say that they have independent causes and that their intersection is an accident. The Zande provide the missing link; they say that it is witchcraft.

2.3 Magic as a Symbolic Phenomenon

After Evans-Pritchard's ground-breaking book, the notion that magic is a symbolic phenomenon, something that reflects underlying social and cultural realities rather than an irrational, mystical practice becomes the central argument in most anthropological studies. In what follows, I discuss several well-known works, beginning with Douglas's (1966) famous analysis of pollution and taboo (see *Taboo*).

In this book, Douglas deals with the accusation that 'primitive' people do not make a distinction between the holy and the unclean—an accusation whose implication is that 'primitive' societies have a magical orientation toward the physical world; that people in these societies believe that nature is inhabited by unpredictable and often malevolent supernatural forces; and that contact with unclean things, such as menstrual blood or corpses, brings one perilously close to these forces.

Douglas's response to this accusation is that notions of pollution and taboo are symbolic expressions of conceptual and social disorder, the idiom through which people come to terms with unclassifiable things and intractable social contradictions. Dirt, Douglas points out, is matter out of place, the inevitable outcome of every attempt to classify things and establish a conceptual grip on the world. It is the result of a universal human predicament, the need to transform chaos into a cosmos, that is, a meaningful world. Those things that do not fit our conceptual schemes and hence contradict and undermine them are everywhere designated as dirt; they become dangerous and are either suppressed or avoided. The threat is real enough, since unclassifiable things undermine our ability to construct and lead meaningful lives. At the level of culture, this danger is expressed through beliefs in pollution and defilement and concomitant rules of avoidance.

Contradictions in conceptual schemes are often reproduced in contradictions at the social level. Take, for example, the notion of sexual pollution and the related idea that it is dangerous for men to come into contact with menstrual blood. This notion, Douglas points out, is widespread among New Guinea tribes, but it is particularly pronounced among the Mae Enga. In this tribe men believe that sexual intercourse weakens male strength so that even within marriage it is reduced to the minimum necessary for procreation. This belief may appear as little more than an irrational fear, but as Douglas explains, the taboo reflects conflicts embedded in Enga society. The latter consists of exogamous clans that compete fiercely for prestige and power and are hostile to another. The exogamous clan system, however, forces men to marry outside their own clan, that is, women who come from the enemy's camp. In their pollution beliefs and practices of sexual avoidance, then, the Enga are trying to overcome symbolically a fundamental social contradiction—building marriage and family on enmity.

Less than a decade after Douglas's book, Geertz (1973) wrote a seminal essay that was to consolidate the symbolic approach in the study of magico-religious systems. Geertz's essay is entitled *Religion and as a Cultural System* but the reference to 'religion' should be understood to mean any metaphysical system, including magic. Indeed, Geertz's essay is inspired by, and draws on Evans-Pritchard's discussion of Zande witchcraft. It also draws on Max Weber's religious sociology, but unlike the latter who was working within an evolutionary paradigm and treated magic as historically prior to religion, Geertz does not make a distinction between the two.

Geertz's argument is that 'religion' is a cultural system that helps people maintain faith in the ultimate meaningfulness of life and the world. It does so by accounting for all those anomalies in human experience—paradoxes, puzzles, ambiguities—that threaten to undermine the general order of existence. There are three points, according to Geertz, where chaos, 'a *tumult* of events which lack not just interpretations but *interpretability*' threatens to enter into the world: at the limits of people's ability to explain, to endure suffering, and to make sound moral judgements. Coming up against these limits time and again, Geertz (1973) points out, 'sets ordinary human experience in a permanent context of metaphysical concern and raises the dim, back-of-the-mind suspicions that one may be adrift in an absurd world.' It is at such difficult moments that religion intervenes and affirms the ultimate meaningfulness of the world. It does so not by denying that there is ignorance, suffering, and injustice in the world, but rather by denying that such things are intrinsic to reality—an inescapable fact of the world.

The last work to be examined is Taussig's (1980) book *The Devil and Commodity Fetishism in South America*. This is an interesting and influential book. Although situated within the Marxist problematic, which has been historically unreceptive to the significance of magico-religious systems, the book decisively adopts a symbolic approach. It interprets native beliefs in the devil as a means of making sense of, and resisting symbolically an alien way of life imposed on them from the outside. The book has inspired several anthropologists working in other parts of the world who developed arguments along similar lines.

In rural Colombia, Taussig points out, native people working on sugarcane plantation often enter into a secret contract with the devil. In return for their soul, the devil helps them work faster, increase their production, and hence their wages. Such contracts, however, are said to have several negative consequences. To begin with, it is said that there is no point in investing the extra money in capital goods, such as livestock or land. The money earned with the help of the devil is believed to be inherently barren: the animals will die and the land will become sterile. Moreover, those who enter into such contracts are said to die young and in pain. In short, even though people better their conditions in the short run, the long-term effects of dealing with the devil are destructive. How are these beliefs and practices to be interpreted?

The devil, Taussig argues, signifies the way in which local people are trying to come to terms with the capitalist relations of production imposed on them. It also expresses their evaluation of, and resistance to the new way of life. Having been uprooted from their ancestral homes, the local peasants are now forced into wage labor. Their traditional way of life based on reciprocity and cooperation has been displaced by the capitalist mode of production, exploitation by the landowners, and competition among themselves. It may be the case that they are now financially better off than before, but as the devil stories suggest the quality of their lives has drastically decreased. The devil is an apt symbol for expressing the new order of things.

Magnetoencephalography

Magnetoencephalography or MEG refers to the recording of the rapidly changing magnetic field produced by cerebral activity. From these recordings, one can determine where and when the brain activity in question takes place. MEG has provided important information about sensory as well as higher-level information processing in the brain. MEG is also finding its way to the hospital, to aid in diagnosis and to inform the brain surgeon about the precise location of the functional cortical areas, so that causing damage to important cortical areas can be avoided.

With its total noninvasiveness, simple and quick procedures, good accuracy in locating sources, and millisecond-scale time resolution, MEG is a powerful tool for revealing information-processing sequences and their pathologies of the human brain.

1. Background

The first MEG experiment was performed by David Cohen (1968), who recorded the human alpha rhythm using an induction coil with a million turns of copper

Figure 1
(a) The 306-channel neuromagnetometer at the BioMag Laboratory of the Helsinki University Central Hospital. The superconducting quantum interference device (SQUID) sensors, in a helmet-like array over the head, are immersed in liquid helium at the temperature of 4 K for superconductivity. (b) Cross-section of the sensor array. (c) Signals recorded with the array depicted in (a), when the right median nerve was stimulated at the wrist

wire. Variations in the magnetic flux through the coil induced in it a voltage that could be a detected by computing its correlation with the simultaneous electroencephalography (EEG) alpha rhythm.

Previously, the EEG had been used to record signals close akin those obtained with MEG. However, it was exceedingly difficult to determine which brain structures had given rise to the various EEG signal components. It has been subsequently established that MEG is superior to EEG in determining the location of the underlying brain activity.

The emergence of MEG was made possible by technological advances based on groundbreaking discoveries in physics and technology. Superconductivity, discovered in 1911 (Kamerlingh Onnes, Nobel Prize 1913), was theoretically understood only in the 1950s (Bardeen, Cooper, and Schrieffer, Nobel Prize 1972). This understanding led to the discovery of the Josephson junction (Brian Josephson, Nobel Prize 1973), which made it possible to develop extremely sensitive magnetometers. These magnetometers, based on the superconducting quantum interference device (SQUID), were first developed by Zimmerman and colleagues (Cohen et al. 1970). With the SQUID, the human magnetic alpha rhythm could be detected without correlation or averaging techniques (Cohen 1972); the modulation of this occipitally generated waveform by opening and closing the eyes could be observed in real time.

Initially, building and using SQUIDs was very demanding; only single-channel instruments were available. Sensor arrays were finally developed in the 1980s and early 1990s. At present, the complete magnetic field pattern over the head can be recorded with helmet-shaped magnetometers with up to 306 channels (see Fig. 1).

The 1990s saw an enormous development in various techniques of functional imaging of the human brain. At the same time with the emergence of the large MEG arrays, the so-called functional magnetic resonance imaging (fMRI) was invented. This technique allows the mapping of changes in blood volume and blood oxygenation, indicating areas of enhanced brain activity with millimeter spatial resolution. Being completely harmless to the subject, MEG and fMRI have become very attractive tools for functional imaging of the brain and are increasingly used to complement each other so that both a high spatial and a high temporal resolution can be achieved.

2. *The Genesis of the Neuromagnetic Field*

The magnetic field measured with MEG sensors is produced by electric currents associated with neuronal activity in the brain. When a neuron receives a signal from another neuron at a synapse, an electric current passes through the ion channels that are opened by chemical transmitter molecules. According to the laws of electromagnetism, a magnetic field then encircles the flow of the current. The synaptic currents are

weak, on the order of tens of picoamperes (1 pA = 10^{-12} A). Consequently, the extracerebral magnetic field due to a single postsynaptic potential also is very weak: only on the order of attoteslas (1 aT = 10^{-18} T). Many thousands of these postsynaptic currents have to exist synchronously for the magnetic field to be strong enough to be detected even with the best of the instruments.

It is believed that the magnetic field detectable outside the head is produced by currents initiated at the synapses and guided postsynaptically by the cell structure. Magnetic field lines encircle the flow path of this so-called primary current, extending outside the skull. Because pyramidal cells, which are the largest and most abundant cortical neurons, are predominantly oriented perpendicularly to the cortex, the direction of the primary current also is perpendicular to the cortex. Because MEG detects the tangential component of the primary current only, it is most sensitive to activity in fissural cortex, where the current is oriented parallel to the skull, whereas it does not detect sources that are oriented exactly radially.

Therefore, amplitude comparison between differently oriented sources is possible only if source orientations can be estimated, for example, on the basis of MRI or by simultaneously recorded EEG. It should be noted that the electroencephalogram is produced by precisely the same kinds of mechanisms as the magnetoencephalogram. The main differences between MEG and EEG are (a) that their sensitivity patterns are different, i.e., different cortical locations contribute differently to MEG and EEG signals, and (b) that the sensitivity patterns (the 'lead fields') of EEG electrodes are less accurately known than those of MEG.

The reliable recording of the weak MEG signals requires the use of shielding against external disturbances. For example, variations in the magnetic field of the earth are a million times stronger than the neuromagnetic fields. The recordings are usually performed inside a magnetically shielded room. Noise cancellation is further improved by measuring gradient components of the magnetic field instead of the field itself. In quiet environments, disturbances can be sufficiently dampened by using elaborate compensation methods to permit MEG work even without shielded rooms.

3. *SQUID Magnetometers*

A SQUID magnetometer consists of a superconducting loop of wire (the detector coil) connected inductively to the SQUID loop. The SQUID itself is also a loop made of a superconductor. Its operation is based on allowing a bias current to divide into two alternative paths. When each path includes a weak interruption, the so-called Josephson junction, the voltage over the loop will be a function of the magnetic flux through the loop. The voltage is amplified and from it, the magnetic field strength can be determined.

Magnetoencephalography is limited in spatial resolution in the sense that it is not possible to discern source-current patterns on length scales below 1–2 cm. Nevertheless, one can locate the effective center-of-gravity of the activity with a precision of about 1 mm.

Since the neuromagnetic field outside the head changes slowly as a function of position, near-perfect sampling density can be achieved with a relatively small number of magnetometer channels. Sampling-theoretical calculations (Ahonen et al. 1993) show that most of the field pattern above the head can be obtained with 100–200 channels. All current commercial whole-head devices offer a sufficient number of channels for nearly complete characterization of the neuromagnetic field above the scalp. Therefore, not much will be gained in the future by increasing the number of measurement channels. However, benefits can be expected from efforts to combine MEG with simultaneous EEG recordings and with fMRI and other supplementary information.

4. *Data Analysis*

4.1 *The Forward Problem*

The interpretation of MEG signals requires quantitative understanding of how the electrical currents in the brain produce magnetic fields. This is called the forward problem.

As was pointed out above, neuronal currents are initiated at the synapses and guided postsynaptically by cell structure. The neuronal currents, since ions are moved, change the charge distribution, which, in turn, gives rise to the electric field. The electric field generated in the brain, in its turn, produces passive, so-called volume currents. The volume currents depend on the conductivity structure of the head. The current tends to flow along paths of minimal resistivity. The computation of the complete pattern of electrical currents starting from the active neuronal current (the primary current) requires detailed knowledge of cerebral conductivity and sophisticated finite-element computations. In practice, however, it usually suffices to model the head as a spherically symmetric conductor (consisting of the brain, the skull, and the scalp); then, the extracerebral magnetic field can be easily calculated. In fact, in the spherical model, the complete extracerebral magnetic field can be directly calculated from the primary current; no knowledge about the thickness and conductivity of the skull or the scalp is required.

4.2 *The Inverse Problem*

The benefit from magnetoencephalography is its ability to locate electrical activity in the brain. In the

analysis of neuromagnetic data, it is therefore essential to deal with the inverse problem, i.e., how to determine the internal sources on the basis of measurements performed outside the head. The most common way to tackle this problem is to determine the single source current element (dipole) that most completely explains the MEG pattern.

A current dipole can be thought of as a concentration of primary current to a single point. In MEG applications, a current dipole is used as an equivalent source for unidirectional primary current that may extend over an area of cortex up to several centimeters in diameter. In dipole modeling, the MEG data is interpreted by determining parameters (location, orientation, and amplitude) of a dipole that would best explain the measured signals. This can be done with a computer algorithm that starts from a random dipole position and orientation, and keeps changing these parameters as long as the magnetic field pattern computed from the dipole keeps approaching the experimental one. When no further improvement is obtained, the minimum in the cost function has been reached; a source corresponding to this solution is called the equivalent current dipole (ECD). Dipole fitting is generally done by a computer algorithm that minimizes the sum of squares of the differences of measured signals and those calculated from the dipole. The dipole parameters resulting in minimal discrepancy between measured and calculated signals define the equivalent dipole. The resulting location is near the center of gravity of the underlying activity provided that the active area is small and the primary current, unidirectional.

In cases when a single dipole can not satisfactorily explain the MEG data, one may resort to multidipole modeling. However, the determination of the parameters of several dipoles can be a formidable task as it involves finding a minimum of the sum of squares in a space with the number of dimensions five times the number of dipoles. The algorithm gets easily trapped in a local minimum, which may be far away from the global minimum, corresponding to the actual source locations. In such cases, it may be best to resort to continuous solutions to the inverse problem such as the minimum-norm estimate.

If our prior information of a neural event is limited to knowing that the activity is confined within a specified region of space such as the brain or the cortex, the estimate minimizing the expected error in the inverse-problem solution is the so-called minimum-norm estimate (MNE). This is simply the primary current distribution that has the smallest norm, or overall amplitude, among the current distributions that explain the measurements. MNE was first applied to neuromagnetism by Hämäläinen and Ilmoniemi (1994), who realized that estimates of current distributions could be obtained by suitable linear combinations of magnetometer sensitivity patterns called lead fields. The minimum-norm solution provides a faithful projection of the actual primary current distribution on the lead fields; any improvement in the inverse-problem solution from MNE would require the incorporation of supplementary information about the sources.

When interpreting MEG (or EEG) results, it should be borne in mind that the inverse problem is fundamentally nonunique. Even if the complete electric and magnetic field around the head could be precisely measured, an infinite number of current distributions in the brain could still be constructed that would explain the measured fields. For example, it is always possible that some sources are missed, whatever the measurement set-up. MEG alone is insensitive to radially oriented sources, but even when MEG is complemented with EEG, some sources may remain undetected.

Full utilization of available techniques requires the use of estimation theory to derive optimal solutions to the inverse problem based on all available information, including that provided by MEG and EEG, as well by magnetic resonance imaging (MRI), positron emission tomography (PET), and functional MRI (fMRI). Since MEG is insensitive to the radial component of the primary current, it is essential to perform also EEG measurements in order to get as full a picture of cerebral electrical activity as possible.

If one can assume that the electromagnetically detected electrical activity is limited to areas seen in fMRI or just to the cortex, as revealed by the anatomical MRI, then the inverse solution may be constrained so that no primary current is allowed outside the regions given by these techniques (Ahlfors et al. 1999, Korvenoja et al. 1999). The essential point in fMRI is that it yields the locations of activity while MEG (and/or EEG) gives the temporal sequence and the strength of activation. On the other hand, fMRI can show enhanced activation in regions not visible by MEG or EEG. The time resolution of fMRI, being limited by the dynamics of blood flow and oxygenation, on the order of seconds.

Accordingly, parallel information from these imaging modalities is now being used to constrain the MEG or EEG inverse solutions to limited regions of the cerebrum. This approach provides optimal combined spatial and temporal resolution by exploiting the best aspects of each technology. The combination of the various imaging methods may eliminate the nonuniqueness of the inversion of MEG and EEG data, at least in some applications.

5. *Evoked Magnetic Fields*

MEG signals elicited by sensory stimulation were detected first by Brenner et al. (1975) and Teyler et al. (1975), who were able to record the visually evoked magnetic field. Subsequently, the magnetic field

evoked by auditory (Reite et al. 1978) and other sensory stimuli followed.

Figure 1b shows the kind of evoked-field data that can be obtained with modern MEG systems. In such an arrangement, by presenting stimuli, it is possible to determine the sequence of activation that takes place in the cortex. In addition to somatosensory evoked signals, activity elicited from other modalities can be detected as well. In the visual modality, even face-specific responses, originating from the parietal and temporal lobes, have been reported. Also, MEG has proved to be the best available noninvasive method for revealing the tonotopic organization of the human auditory cortex (Romani et al. 1982). The N1m deflection (peak latency about 100 ms) in the tone-evoked magnetic field, which corresponds to the electrically recorded negative deflection N1 of the event-related potential, was best explained by equivalent current dipoles in tone-frequency-dependent locations of the auditory cortex.

N1m has been reported to show specificity to phonetic features as well. For example, Kuriki and Murase (1989) found that N1m ECDs for speech sounds /ka/ and /a/ differed from one another, with the /ka/ source being located posteriorly to the /a/ source. Interestingly, this difference was obtained in the speech-dominant left hemisphere but not in the right hemisphere, which might indicate that 'the magnetic responses include a component associated with linguistic processing in the auditory cortex.' A further step toward constructing a neuroanatomical phoneme map was taken by Diesch et al. (1996) who reported that neuromagnetic responses to different German vowels had different ECD loci and, further, that the distances between these loci seemed to mirror inter-vowel perceptual distances. This finding supports the idea that the self-organizing neural-network phoneme map of Kohonen may be applicable to model the system of cortical phoneme representation.

MEG has also revealed the functional organization of both primary and secondary somatosensory cortices. The human 'sensory homunculus' of Penfield and Jasper (1954), obtained by stimulating the exposed somatosensory cortex of awake epileptic patients during surgery, was limited to the convexial cortex. MEG, in turn, is at best in studies of fissural cortex. The somatotopic organization of the primary somatosensory cortex was seen with MEG by Okada et al. (1984) and it was further investigated by Hari et al. (1993) and Yang et al. (1993)

Currently there is considerable interest in plastic changes in the functional organization of cortical sensory-receiving areas. Such experience-dependent changes in the somatosensory system were reflected by MEG recordings of Rossini et al. (1994), who first determined ECDs of an early ('N22m') SI response to electrical stimulation of different fingers and thereafter completely anaesthetized four of the fingers. This resulted in the ECD for the unanaesthetized finger shifting in location and becoming stronger. The effect was interpreted by the authors in terms of 'secondary involvement of neighbor neurons within the hand somatic map which usually belong to the anaesthetized fingers,' concluding that 'continuous sensory input from all segments representing a given body district is a prerequisite for normal somatotopic organization' (p. 24).

Kujala et al.'s (2000) MEG recordings from early-blinded subjects showed that their occipital cortex is activated during auditory discrimination. This effect, not found in sighted controls, was elicited by occasional, to-be-detected, changes in the frequency of a repetitive tone.

Menning et al. (2000) demonstrated a training effect in the discrimination of frequency differences in the simple sinusoidal tone. Their standard stimulus was 1000 Hz and deviant stimuli 1005, 1010, and 1050 Hz. The frequency discrimination improved rapidly during the first training week and slowly thereafter. This improvement was associated with enhanced N1m, the magnetically recorded response at about 100 ms from tone onset, as well as in the MMNm response. This enhancement persisted even after training although was somewhat decreased 3 weeks after the training.

MEG is not limited to detecting immediate cortical responses to sensory stimuli—it can also (indirectly) reveal memory traces produced by these stimuli. Previous electrophysiological studies have found the mismatch negativity (MMN), an automatic, attention-independent response to auditory stimulus change, which accurately, albeit indirectly, reflects the properties of stored information, i.e., the neural traces of preceding stimuli (Näätänen 1992). These traces underlying auditory sensory memory can probably be located by determining the sources of the 'mismatch processes,' generating MMN. Several studies using simple tones have indicated that MMNm (the magnetic counterpart of MMN) is generated in supratemporal auditory cortex. This also applies to complex stimuli such as within- and between-category changes in consonant–vowel syllables and to frequency changes in a segment of a complex serial tone pattern.

Using the MMN paradigm, Näätänen et al. (1997) obtained evidence for the existence of phoneme traces in Finnish subjects who were presented with the Finnish vowel /e/ as the standard stimulus and the Finnish vowels /ö/ and /o/ and the Estonian /õ/ as deviants. The stimuli differed from each other only in formant F2 frequency, with F0 and other formants remaining constant. The MMN elicited by the Estonian /õ/ was smaller than that elicited by the Finnish /ö/, even though the acoustical deviation of /õ/ from the standard /e/ was larger than that of /ö/. This phenomenon did not exist in Estonian subjects, who had been exposed to all these vowels in their mother tongue. MEG recordings showed that the

phoneme-related MMN enhancement in the Finnish subjects originated from the left auditory cortex, which was concluded to be the locus of the phoneme traces.

6. Clinical Use of MEG

The noninvasive recording technique of MEG has been used clinically for presurgical mapping, the idea being to locate functional areas, such as the motor cortex or speech areas so that the surgeon may try to avoid harming these (Inoue et al. 1999, Alberstone et al. 2000). Another clinical application is the characterization of epileptic activity (Baumgartner et al. 2000, Minassian et al. 1999), in particular the determination of loci of epileptic activity. This is particularly important when surgery is planned in order to remove the epileptic focus. In children, epileptiform activity has been found to underlie developmental deficits including autism. When characterized with the help of MEG, therapeutic measures can be applied more reliably than without this information.

In addition to clinical applications that benefit the patients themselves, MEG is used in a large variety of studies on different patient groups. For example, Wikström et al. (2000) used MEG to correlate recovery from sensorimotor stroke with the appearance of somatosensory evoked responses in MEG. Pekkonen et al. (1999) studied patients with Alzheimer's disease using MEG and the MMN paradigm, finding impairments in the operation of sensory memory.

7. Conclusion

Magnetoencephalography provides a completely noninvasive tool to probe into the real-time operation of the human brain in experimental conditions that are suitable for studying sensory and cognitive brain functions as well as their disturbances.

In evaluating the future role of MEG in cognitive brain research, it is to be borne in mind that MEG and EEG are the only noninvasive methodologies that provide precise temporal information about the brain activation patterns in its interaction with the environment. Further, of these two methodologies, MEG locates sources considerably more accurately. Of course, this advantage of MEG over EEG only applies to the currents that are visible to MEG, i.e., to those that are not fully radial and not located very deep from the head surface. These limitations, however, should be seen as a strength rather than a weakness of the method, for they could enable one (a) to separately measure a single brain process rather than an amalgamate of multiple temporally overlapping processes which cannot be unequivocally disentangled on the basis of location or orientation, and (b) then, by using this process-specific information, to disambiguate ERP data recorded from the same experimental situation. Therefore, the combined use of the two methodologies is strongly recommended in research aiming at an accurate description of the spatio-temporal activation patterns underlying the brain's cognitive operations. The use of both MEG and EEG, anticipated also in the current developments of the recording systems, will certainly not be made useless or redundant by further developments of EEG signal-analysis techniques which, because of inherent limitations of EEG methodology, cannot challenge the superiority of the combined use. On the contrary, important developments can be made in the field of signal analysis, especially in view of this combined use of the two methodologies, to make their combination especially powerful and an attractive tool of cognitive brain research, which cannot be replaced by any other methodology in the foreseeable future.

Majoritarianism and Majority Rule

This article will use 'majority rule' to denote the voting rule requiring $(n+1)/2$ to carry a decision, and 'majoritarianism' to denote the belief that this rule, and others closely resembling it, are desirable. These ideas may be analyzed by posing four questions:

(a) Is majority rule fair?

(b) Does majority rule efficiently match preferences to outcomes?

(c) Does majority rule comply with basic requirements of formal rationality?

(d) How well do the more complex procedures and electoral systems used in governments match up with majoritarian requirements?

1. *Fairness*

In the long history of human governance, majoritarianism has for the most part been trumped by the rule of minorities. Often, these minorities have been elites based on military prowess, land-ownership, heredity, or priestly knowledge—whether the priests be religious or, for example, socialist. In capitalist and market societies, elites with major ownership stakes and elites constituted by managerial expertise have in many respects held authority denied to popular majorities (Lindblom 1977). In other cases, such as the American Constitution of 1789, *generic* minorities threatened by majorities seeking new uses of governmental power are granted the authority to block action. The US system builds in no bias in favor of a specific minority, and it is indeed prejudicial toward all minorities seeking new uses of government. The favorable bias is specific to defensive minorities seeking to preserve existing policy. The overall historical pattern, we may safely conclude, is that most societies have not been governed in majoritarian fashion.

Majoritarianism arises against this background, in major part, as a demand for political equality. Foremost among the meanings of political equality is the doctrine 'One man [one person], one vote.' This powerful idea links majority rule to the central appeal of popular democracy without specifying exactly the nature of the equality in question. Kenneth May

has conveniently formalized this idea with the criterion of *anonymity*: if a decision process yields the result that X is preferred to Y in a given case, it should again do so for every other case in which the preferences of any two blocks of voters of equal size are transposed (May 1952). Put otherwise, you should always be able to count the votes (and announce a decision) without seeing whose votes they are. Another feature of equality or equity entailed by majority rule concerns the content of the alternatives under consideration. Majority rule is formally neutral in its treatment of alternatives. Whether X or Y is the status quo, for example, makes no difference to the counting of votes. Whether X or Y is pro-labor, respectful of racial minorities, consistent with the tenets of a prevailing ideology, or consistent with the interests of economic elites—none of these or similar considerations about the alternatives in question will matter under majority rule. This additional requirement of 'neutrality' combines with anonymity in 'May's Theorem' to define majority rule as uniquely best among decision rules which respond positively and nonrandomly to voter preferences (May 1952).

The foregoing considerations constitute a strong case for the egalitarian fairness of majoritarianism on an abstractly *a priori* basis. They do not, however, say anything about the fairness of majority rule in specific historical cases where known groups have predictable or announced preferences. Indeed, the neutrality of majority rule toward alternatives implies an embedded incapacity to discriminate in favor of fair, egalitarian, or just policies as against unfair, anti-egalitarian, or unjust ones. Majority rule provides no defense against majorities embracing evil. In racially and religiously divided societies, where strong conflicts predictably divide large groups from small ones, this is a crippling disability which occasions sharp resistance to majority rule. One only needs to think of recent conflict in the Balkans to see this point. The time-honored remedies in cases of this sort are *partition* (to produce more homogeneous, less conflictual, and smaller polities), the protection of *minority rights* against specified forms of majority action within each polity, and, of course, *emigration* opportunities for members of an afflicted minority. The development of civic cultures which surmount and eventually attenuate conflict is probably superior to any of these more mechanical solutions, but requires historical time and good fortune. It is nevertheless worth noting that even some very hierarchical and undemocratic cultures—India, Japan, quite possibly South Africa—have made great strides in this direction (see, in particular, Shapiro 2001).

2. *Preference Efficiency*

Quite apart from considerations of fairness, a case can be made for majority rule based on its efficiency in matching preferences to policy outcomes. Indeed, it can be shown analytically that all other procedures for making collective decisions are inferior to majority rule in their ability to maximize direct fit between preferences and outcomes (See Rae 1969; for a critical evaluation, see Mueller 1989). This applies to other voting rules, rules giving priority to specific types of policy, and all manner of random or arbitrary procedures. Preference-matching efficiency appears most plausible for issues where the determination of basic policy issues and entitlements is concerned. If decisions entail starkly different stakes for different voters ('Shall we destroy the reader's home?') nominal matching of preferences to outcomes is obviously inadequate as a criterion. Where decisions offer gains from trade among the rights so established, market and market-like arrangements appear superior on efficiency criteria. Indeed, as Ronald Coase has shown, trade can turn any well-defined set of initial rights into a Pareto-efficient set of rights on a voluntary basis (Coase 1960). Insofar as such a process of exchange can be embedded in a voting rule, that rule would require unanimity for each change of policy (Wicksell 1896). These market-oriented schemes of course give great leverage to groups and individuals who are privileged by the initial distribution of rights and assets, and are explicitly anti-majoritarian for that reason. It must of course be accepted that neither these market-oriented schemes nor majoritarianism can purport to efficient treatment of preferences which are manipulated, distorted, or subject to intimidation.

3. *Majority Rule and Formal Rationality*

It has been well known since the late eighteenth century that majority rule possesses some quirky features, especially when multiple alternatives are considered in one process. Most famous among these is the 'cycle of voting' identified by the Marquis de Condorcet (1785). In the simplest case, we imagine three voters and three alternatives (Table 1). In sequential application of majority rule, A defeats B on the strength of voters 1 and 2, B beats C via 1 and 3, but then C beats A due to the preferences of voters 2 and 3. This violates the axiom of formal rationality known as transitivity, and opens the possibility that control over agenda sequences is tantamount to control over outcomes. Majority rule is hardly alone in having such quirks. This transitivity requirement, together with others which tap additional aspects of

Table 1
Hypothetical responses of three voters to three alternatives A, B, and C

VOTERS	1	2	3
BEST	A	C	B
	B	A	C
WORST	C	B	A

formal rationality, defines the justly famed Arrow Theorem showing that *all* decision procedures, or 'social welfare functions,' may violate the dictates of formal rationality in one way or another (Arrow 1951).

4. Majoritarianism in Complex Institutions

Far more important than these formal properties for most purposes is the task of realizing majoritarian aims in complex institutions. The American 'electoral college,' for example, contains the very real potential for reversing national majorities—having done so as recently as the fall of 2000. Most single-member electoral systems place an immense premium on spatial distribution of the vote, often giving majority status to parties with well less than majority status in the electorate. Worse yet, where regional parties dominate, as in India, they may fragment outcomes so that nothing close to national majorities are formed. Systems of proportional representation, particularly those based on large districts and exact proportionality, pass the problem of majority formation on to parliaments, and create the opportunity for small parties to exert influence out of all proportion to their size—as with the case of Israel in the 1990s (Taagapera and Shugart 1989). Most, if not all, legislative procedures, entailing many critical veto points, conspicuously violate majority rule. It follows that majoritarianism is less a blueprint than an aspiration.

5. Conclusion

We live in an era when democratic aspirations have very nearly swept the field of direct rivals, particularly among nations that play leading roles in the world economy. Yet in practice, movement toward democratization has been slow, halting, and uncertain in many places. Most of Africa has made little progress, and many key systems from the former Soviet bloc have made minimal progress. Majoritarianism may usefully be seen as one of the key aspirations that should help to shape change and reform in coming decades.

Majorization and Stochastic Orders

1. Introduction

In a specific context, stochastic orders are orderings of 'largeness' on random variables or vectors: that is, a random variable X is stochastically smaller than another random variable Y or a random vector $\mathbf{X} = (X_1,\ldots, X_d)$ is stochastically smaller than another random vector $\mathbf{Y} = (Y_1,\ldots, Y_d)$ if X tends to take smaller values than Y or the component X_i ($i = 1,\ldots, d$) of $\mathbf{X}$ tend to take smaller values than the corresponding component Y_i of $\mathbf{Y}$. In a broad sense, stochastic orders are orderings that apply to the comparison of random variables or vectors, or probability distributions or measures, and there have been many such stochastic orders. Here, a few stochastic orders that may be of greater interest in the social and behavioral sciences are summarized. These include orderings of dispersion and dependence.

Majorization orderings are orderings of divergence of a vector or function from uniformity. They are useful as a means of proving many inequalities. The vector majorization ordering applies to vectors of the same length which have the same sum of components. It has been generalized to orderings of functions on measure spaces, and in this context, there are overlaps with stochastic orders.

Stochastic and majorization orderings are defined in Sects. 2 and 3, starting with the simplest forms.

Comparisons and contrasts of stochastic and majorization orderings are given in Sect. 4 and illustrative examples of these orderings are given in Sect. 5. The few references which are given provide a guide to the research in majorization and stochastic orderings; they include historical perspectives on the orderings—some often cited early references are Hardy–Littlewood–Pólya, Schur, Lorenz, Dalton for majorization and inequalities, and Lehmann for the simplest stochastic order.

For terminology and notation, increasing (decreasing) is used in place of nondecreasing (nonincreasing), $(z)_+$ denotes $\max\{0, z\}$ over reals, $\stackrel{d}{=}$ denotes random quantities that are equal in distribution, $F^{-1}(v) = \inf\{x: F(x) \geqslant v\}$ is the functional inverse of a univariate cumulative distribution function F, and $X \sim F$ denotes a random variable X having the distribution F.

2. Stochastic Orders

A stochastic order in general means a partial ordering or preordering (the latter need not be reflexive) that compares random variables or vectors, or probability distributions or measures. A stochastic order in a specific sense means the simplest ordering of largeness of random variables; for clarity of terminology, this is referred to as the *stochastic largeness order* (it is called the *usual stochastic order* in Shaked and Shanthikumar 1994). Many stochastic orders generalize this stochastic largeness order in some way. Some main references for this section are Stoyan (1983), Mosler and Scarsini (1993a, 1993b), Shaked and Shanthikumar (1994).

The definitions of the stochastic largeness orders are given next.

Definition 1 (*Stochastic largeness order for random variables.*) *Let X, Y be random variables with respective distribution functions F, G. X is stochastically smaller than Y, written $X \prec^{st} Y$ or $F \prec^{st} G$, if one of the following equivalent conditions hold.*

(a) $\Pr(X > u) \leqslant \Pr(Y > u)$ *for all* $-\infty < u < \infty$, *or* $\Pr(X \leqslant u) \geqslant \Pr(Y \leqslant u)$ *for all* $-\infty < u < \infty$.

(b) $E[\psi(X)] \leqslant E[\psi(Y)]$ *for all increasing functions* ψ *for which the expectations exist.*

(c) *There exist random variables* $\hat{X}$, $\hat{Y}$ *on the same probability space such that* $\hat{X} \stackrel{d}{=} X$, $\hat{Y} \stackrel{d}{=} Y$, *and* $\Pr(\hat{X} \leqslant \hat{Y}) = 1$.

(d) *There exists a monotone kernel* $K: \mathscr{R} \times \mathscr{R} \to [0, 1]$ (*that is*, $K(t, \cdot)$ *is a distribution function for all* $t \in \mathscr{R}$ *and* $K(t, u) = 0$ for $u \leqslant t$) *such that* $G(u) = \int_{-\infty}^{\infty} K(t,u)\,\mathrm{d}F(t)$.

(e) $F^{-1}(v) \leqslant G^{-1}(v)$ *where* F^{-1}, G^{-1} *are the inverse cumulative distribution functions.*

Definition 2 (*Stochastic largeness order in a partially ordered space.*) *Let P_1, P_2 be probability measures on a partially ordered Polish space* $(\mathscr{X}, \mathscr{A})$ [*usually Euclidean space*] *with measure* ν [*usually Lebesgue or counting measure*]. *Let* $\prec$ *be the partial order on* $\mathscr{X}$; *for d-dimensional Euclidean space, the usual partial order is given by* $\mathbf{x} \prec \mathbf{y}$ *if* $x_i \leqslant y_i$, $i = 1,\ldots, d$. P_1 *is stochastically smaller than* P_2, *written* $P_1 \prec^{st} P_2$, *if one of the following equivalent conditions hold.*

(a) $P_1(A) \leqslant P_2(A)$ *for all upper sets* A [*i.e., sets for which* $\mathbf{x} \in A$ *and* $\mathbf{x} \prec \mathbf{y}$ *imply* $\mathbf{y} \in A$].

(b) $\int \psi\,\mathrm{d}P_1 \leqslant \int \psi\,\mathrm{d}P_2$ *for all increasing functions* ψ *for which the expectations exist.*

(c) *There exists random quantities* X_1, X_2 *with values in* $(\mathscr{X}, \mathscr{A})$ *such that* $X_1 \sim P_1$, $X_2 \sim P_2$ *and* $X_1 \prec X_2$ *almost surely.*

(d) *There exists a Markov kernel* $M: \mathscr{X} \times \mathscr{A} \to [0, 1]$ *such that* $M(\mathbf{t}, \cdot)$ *is a measure with support on* $\{\mathbf{z}: \mathbf{t} \prec \mathbf{z}\}$ *and* $P_2(A) = \int M(\mathbf{t}, A) P_1(\mathrm{d}\mathbf{t})$ *for all* $A \in \mathscr{A}$.

Many general stochastic orders take the form of (b) with other classes of functions ψ; for example, convex functions, increasing convex functions, increasing concave functions. Generalizations of the form of (b) are also known as *dilation orderings*. The class of increasing concave functions leads to *second-order dominance*. The class of convex functions leads to a *dispersion ordering* of random variables with the same mean (see Sect. 4), one of many dispersion orderings that have been proposed.

Generalizations for random variables include the hazard rate order, reverse hazard rate order, likelihood ratio order. These are useful for proving results that are intuitively plausible with a stochastic largeness order; sometimes the result will not hold or may be much more difficult to prove with $\prec^{st}$.

Definition 3 (*Some additional univariate stochastic orders.*) *Let X, Y be two random variables with respective cumulative distributions functions F, G and densities f, g.*

(a) *G is larger than F in the likelihood ratio order, denoted by* $F \prec^{LR} G$ or $X \prec^{LR} Y$, *if* $f(x)g(y) \geqslant f(y)g(x)$ *for all* $-\infty < x < y < \infty$.

(b) *G is larger than F in the hazard rate order, denoted by* $F \prec^{HR} G$ *or* $X \prec^{HR} Y$, *if* $f(x)/[1-F(x)] \geqslant g(x)\,[1-G(x)]$ *for all* $-\infty < x < \infty$.

(c) *G is larger than F in the reverse hazard rate order, denoted by* $F \prec^{RHR} G$ *or* $X \prec^{RHR} Y$, *if* $f(x)/F(x) \leqslant g(x)/G(x)$ *for all* $-\infty < x < \infty$.
